Berek & Novak’s Gynecology

Fourteenth Edition
To Deborah, who sustains me.
Contents

Dedication ................................................................. v
Foreword ................................................................. xi
Preface ................................................................. xii

Section I  
Principles of Practice

Chapter 1  
Initial Assessment and Communication  
Jonathan S. Berek  
Paula J. Adams Hillard ........................................ 3

Chapter 2  
Principles of Patient Care  
Joanna M. Cain ..................................................... 27

Chapter 3  
Quality Assessment, Performance Improvement, and Patient Safety  
Joseph C. Gambone  
Robert C. Reiter  
Paul A. Gluck ....................................................... 39

Chapter 4  
Epidemiology for the Gynecologist  
Daniel W. Cramer  
Karen Loeb Lifford .................................................. 55

Section II  
Basic Principles

Chapter 5  
Anatomy and Embryology  
Jean R. Anderson  
Rene Genadry ....................................................... 75

Chapter 6  
Molecular Biology and Genetics  
Oliver Dorigo  
Otoniel Martínez-Maza  
Jonathan S. Berek .............................................. 129

Chapter 7  
Reproductive Physiology  
David L. Olive  
Steven F. Palter .................................................... 161
Section III
Preventive and Primary Care

Chapter 8
Preventive Health Care and Screening
Paula J. Adams Hillard ......................................................... 187

Chapter 9
Primary Care in Gynecology
Dayton W. Daberkow II
Thomas E. Nolan. .............................................................. 211

Chapter 10
Family Planning
Phillip G. Stubblefield
Sacheen Carr-Ellis
Nathalie Kapp. ................................................................. 247

Chapter 11
Sexuality, Sexual Dysfunction, and Sexual Assault
David A. Baram
Rosemary Basson ............................................................ 313

Chapter 12
Common Psychiatric Problems
Nada Logan Stotland ......................................................... 351

Chapter 13
Complementary Therapy
Tracy W. Gaudet ............................................................... 385

Section IV
General Gynecology

Chapter 14
Benign Diseases of the Female Reproductive Tract
Paula J. Adams Hillard ......................................................... 431

Chapter 15
Pelvic Pain and Dysmenorrhea
Andrea J. Rapkin
Candace N. Howe ........................................................... 505

Chapter 16
Genitourinary Infections and Sexually Transmitted Diseases
David E. Soper ................................................................. 541

Chapter 17
Intraepithelial Disease of the Cervix, Vagina, and Vulva
Ilana B. Addis
Kenneth D. Hatch
Jonathan S. Berek .......................................................... 561
## Contents

### Chapter 18
**Early Pregnancy Loss and Ectopic Pregnancy**  
*Thomas G. Stovall* .......................... 601

### Chapter 19
**Benign Breast Disease**  
*Baiba J. Grube*  
*Armando E. Giuliano* ......................... 637

### Section V
**Operative Gynecology**

#### Chapter 20
**Preoperative Evaluation and Postoperative Management**  
*Daniel L. Clarke-Pearson*  
*Paula S. Lee*  
*Monique A. Spillman*  
*Christopher V. Lutman* ..................... 671

#### Chapter 21
**Gynecologic Endoscopy**  
*Malcolm G. Munro*  
*Andrew I. Brill*  
*William H. Parker* ......................... 749

#### Chapter 22
**Hysterectomy**  
*Thomas G. Stovall* ......................... 805

### Section VI
**Urogynecology and Pelvic Reconstructive Surgery**

#### Chapter 23
**Lower Urinary Tract Disorders**  
*Ingrid Nygaard*  
*Shawn A. Menefee*  
*L. Lewis Wall* ................................ 849

#### Chapter 24
**Pelvic Organ Prolapse**  
*Holly E. Richter*  
*R. Edward Varner* ......................... 897

#### Chapter 25
**Anorectal Dysfunction**  
*Robert E. Gutman*  
*Geoffrey W. Cundiff* ....................... 935

### Section VII
**Reproductive Endocrinology**

#### Chapter 26
**Puberty**  
*Robert W. Rebar* ......................... 991
Chapter 27
Amenorrhea
Wendy J. Schillings
Howard D. McClamrock .............................................. 1035

Chapter 28
Endocrine Disorders
Ivan Huang
Mark Gibson
C. Matthew Peterson .................................................. 1069

Chapter 29
Endometriosis
Thomas M. D’Hooghe
Joseph A. Hill III ......................................................... 1137

Chapter 30
Infertility
Richard O. Burney
Daniel J. Schust
Mylene W. M. Yao ...................................................... 1185

Chapter 31
Recurrent Pregnancy Loss
Laura Fox-Lee
Daniel J. Schust ............................................................. 1277

Chapter 32
Menopause
Jan L. Shifren
Isaac Schiff ................................................................. 1323

Section VIII
Gynecologic Oncology

Chapter 33
Uterine Cancer
John R. Lurain .............................................................. 1343

Chapter 34
Cervical and Vaginal Cancer
Michael A. Bidus
John C. Elkas .............................................................. 1403

Chapter 35
Ovarian and Fallopian Tube Cancer
Jonathan S. Berek
Sathima Natarajan ...................................................... 1457
Contents

Chapter 36
Vulvar Cancer
Christine H. Holschneider
Jonathan S. Berek ....................................................... 1549

Chapter 37
Gestational Trophoblastic Disease
Ross S. Berkowitz
Donald P. Goldstein ...................................................... 1581

Chapter 38
Breast Cancer
Kristine E. Calhoun
Armando E. Giuliano ...................................................... 1605

Index ................................................................. 1633
The perennial standard in the field, *Textbook of Gynecology*, edited by Emil Novak of Johns Hopkins University School of Medicine and Hospital, was first published in 1941. The present 14th edition of that landmark text has been given a new title, *Berek and Novak’s Gynecology*, honoring both the late Dr. Novak and the significant contribution made to the work by Dr. Jonathan S. Berek who, in sustaining and, where necessary, even reinventing the work in its last several editions, has thereby succeeded in maintaining its vitality and its relevance for new generations of physicians. Thus, the book has retained its prominence as one of the important textbooks in the discipline.

For the present edition, Dr. Berek has again assembled an impressive array of contributors—clinicians and researchers, leaders in their respective fields—who bring insightful knowledge and valuable perspectives to their areas of expertise. The result is a comprehensive treatment of current practice—but with an eye toward future developments—in the science of gynecology and its related subspecialties. Innovative developments in research and clinical practice are treated in detail. Commensurate with the expansion of the subspecialty in gynecology, a new section with chapters on pelvic reconstruction and urogynecology has been added. Another feature of note is that this new edition has been published in a striking new format, with full-color, substantially improved illustrations and graphics that enhance the readability and accessibility of the material.

Practitioners of the medical specialty of gynecology, both clinicians and researchers, are wholly dedicated to the care and well-being of women. As both a teaching tool and reference, this new edition of *Berek and Novak’s Gynecology* will prove an invaluable asset to them as they ply their important work.

*Isaac Schiff, MD*
Joe Vincent Meigs Professor of Gynecology
Harvard Medical School
Chief, Vincent Obstetrics and Gynecology Service
Massachusetts General Hospital
Boston, Massachusetts
The 1st edition of Novak’s Textbook of Gynecology appeared in 1941, written by the distinguished Dr. Emil Novak of Johns Hopkins. The book became a successful and important international reference for the practice of gynecology. When I undertook the extensive expansion and reorganization for the 12th edition in 1995, it was a great honor to be invited to become the editor, and it is my privilege to continue in this role for the 14th edition, which bears the title Berek & Novak’s Gynecology.

The book retains the format of the prior two editions, enhanced by full color illustrations and photographic reproductions. As with the previous editions, the goal is to provide a comprehensive summary of the specialty of gynecology. All chapters have been thoroughly revised to provide timely information and references. Special attention has been paid to the illustrations and photographs to make them more accessible and informative. A new section on “Urogynecology and Pelvic Reconstructive Surgery,” with chapters devoted to urogynecology, prolapse and colorectal problems, has been added to address the new subspecialty and our expanded role as gynecologists in this essential area of care. The increasing use of nontraditional medicine in gynecology inspired the inclusion of a chapter on Complementary Medicine.

This textbook, originated by the faculty of the Johns Hopkins University School of Medicine, continues to reflect the contributions of that great institution. After the 5th edition and subsequent death of Dr. Novak in 1957, many physicians from Johns Hopkins, and subsequently some members of the Vanderbilt faculty, helped carry the torch—Dr. Edmund R. Novak through the 9th edition in 1979; Drs. Howard W. Jones, Jr. and Georgeanna Seegar Jones through the 10th edition in 1981; and Drs. Howard W. Jones, III, Lonnie S. Burnett, and Anne Colston Wentz through the 11th edition in 1988. These editors, assisted by many contributors from the faculty at Johns Hopkins, especially Drs. J. Donald Woodruff and Conrad G. Julian, helped define the specialty of gynecology during the latter half of the 20th century. These physicians shaped the practice of gynecology as we know it today—its surgical and medical therapies, reproductive endocrinology, assisted reproductive technologies, gynecologic oncology, urogynecology, and infectious diseases. As a graduate of Johns Hopkins University School of Medicine, I am proud to contribute to that rich tradition.

Berek & Novak’s Gynecology, 14th edition, is presented in eight sections. The first, “Principles of Practice,” includes the initial assessment of the gynecologic patient, the history and physical examination, and communication skills. This section addresses ethical principles of patient care, quality assessment and improvement, and the epidemiology of gynecologic conditions. The second section, “Basic Principles,” summarizes the scientific basis for the specialty—anatomy and embryology, molecular biology and genetics, and reproductive physiology. The third section, “Preventive and Primary Care,” emphasizes the importance of primary health care for women, which has evolved to address preventive care, screening, family planning, sexuality, and common psychiatric problems. The fourth section, “General Gynecology,” reviews benign diseases of the female reproductive tract, the evaluation of pelvic infections, pain, intraepithelial diseases, the management of early pregnancy loss and ectopic pregnancy, and the evaluation of benign breast disease. The fifth section, “Operative General Gynecology” covers perioperative care, and the operative management of benign gynecologic conditions using endoscopy and hysterectomy. The sixth section is new—“Urogynecology and Pelvic Reconstructive Surgery.” The seventh section, “Reproductive Endocrinology,” summarizes the major disorders affecting the
growth, development, and function of women from puberty through menopause. The eighth section, “Gynecologic Oncology,” covers malignant diseases of the female reproductive tract and breast cancer.

I acknowledge the many individuals who contributed to this book. I am grateful to Rebecca Rinehart for her superb editorial assistance and to Tim Hengst, an outstanding medical illustrator, for the excellent illustrations, anatomic drawings and thematic designs. I appreciate the many people at Lippincott Williams & Wilkins who have helped me, especially Charley Mitchell, with whom I have worked for nearly two decades, and consider the best editor in medical book publishing. I extend my gratitude to Anne Sydor, Nicole Dernoski, Sonya Seigafuse, Nicole Walz, and Tracey Becker for their dedication and commitment during the editorial process to enthusiastically and skillfully produce the manuscript. I acknowledge the outstanding work of Barbara Stabb who so diligently and expertly worked closely with me to do the final page layout and formatting of this book that makes its first appearance in full color. I acknowledge the efforts of my mentors and colleagues—Dean Sherman Mellinkoff, Drs. J. Donald Woodruff, Kenneth J. Ryan, Isaac Schiff, J. George Moore, William J. Dignam, Gautam Chaudhuri, and Neville F. Hacker. Each of these physicians and scholars provided me with guidance and encouragement. My special thanks to Nicole Kidman, the chair of the advisory board for the UCLA Women’s Reproductive Cancer Program—whose support and friendship helped stimulate this project.

The publication of this book coincides with a major change in my medical career, which took me along the east coast from Brown to Johns Hopkins and then to Harvard, before providing a lengthy and rewarding sojourn at UCLA. After more than 26 years at UCLA, I moved to Stanford University School of Medicine to become the Professor and Chair of the Department of Obstetrics and Gynecology. I welcome the opportunity there to participate in teaching the specialty of gynecology, researching the related sciences, and delivering patient care while learning from my new colleagues.

I look forward to the continued positive impact of the specialty on women’s health throughout the world. It is my fervent hope that this work will benefit all women and reduce the numbers of those who are afflicted with diseases of the female reproductive tract. To that end, this book is offered as a resource to assist and encourage all who study the specialty of gynecology.

SECTION

PRINCIPLES OF PRACTICE
1

Initial Assessment and Communication

Jonathan S. Berek
Paula J. Adams Hillard

• We are all products of our environment, our background, and our culture. The importance of ascertaining the patient’s general, social, and familial situation cannot be overemphasized. The physician should avoid being judgmental, particularly with respect to questions about sexual practices and sexual orientation.

• Good communication is essential to patient assessment and treatment. The foundation of communication is based on key skills: empathy, attentive listening, expert knowledge, and rapport. These skills can be learned and refined.

• The Hippocratic Oath demands that physicians be circumspect with all patient-related information. For physician–patient communication to be effective, the patient must feel that she is able to discuss her problems fully.

• Different styles of communication may affect the physician’s ability to perceive the patient’s status and to achieve the goal of optimal assessment and successful treatment. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest response.

• Some patients lack accurate information about their illness. Lack of full understanding of an illness can produce dissatisfaction with medical care, increased anxiety, distress, coping difficulties, unsuccessful treatment, and poor treatment response.

• After a dialogue has been established, the patient assessment proceeds with obtaining a complete history and performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details.

• At the completion of the physical examination, the patient should be informed of the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately; this discussion should take place after the examination with the patient clothed.
The practice of gynecology requires many skills. In addition to medical knowledge, the gynecologist should develop interpersonal and communication skills that promote patient–physician interaction and trust. The assessment must be of the “whole patient,” not only of her general medical status. It should include any apparent medical condition as well as the psychological, social, and family aspects of her situation. To view the patient in the appropriate context, environmental and cultural issues that affect the patient must be taken into account. This approach is of value in routine assessments, providing opportunities for preventive care and counseling on an ongoing basis, as well as in the assessment of medical conditions.

Variables that Affect Patient Status

Many external variables exert an influence on the patient and on the care she receives. Some of these factors include the patient’s “significant others”—her family, friends, and personal and intimate relationships (Table 1.1). These external variables also include psychological, genetic, biologic, social, and economic issues. Factors that affect a patient’s perception of disease and pain and the means by which she has been taught to cope with illness include her education, attitudes, understanding of human reproduction and sexuality, family history of disease, and, in some cases, need for attention (1–3). Cultural factors, socioeconomic status, religion, ethnicity, and sexual orientation are important considerations in understanding the patient’s response to her care.

We are all products of our environment, our background, and our culture. The importance of ascertaining the patient’s general, social, and familial situation cannot be overemphasized (4). The context of the family can and should be ascertained directly. The family history should include a careful analysis of those who have had significant illnesses, such as cancer. The patient’s understanding of key events in the family medical history and

Communication

Good communication is essential to patient assessment and treatment. The patient–physician relationship is based on communication conducted in an open, honest, and careful manner that allows the patient’s situation and problems to be accurately understood and effective solutions developed collaboratively. Good communication requires patience, dedication, and practice, and involves both listening and communicating verbally and nonverbally.

The foundation of communication is based on key skills: empathy, attentive listening, expert knowledge, and rapport. These skills can be learned and refined (4–6). Once the initial relationship with the patient is established, the physician must vigilantly pursue interviewing techniques that create opportunities to foster an understanding of the patient’s concerns (7). Trust is the fundamental element that encourages the patient to communicate her feelings, concerns, and thoughts openly, without withholding information (8).

Although there are many styles of interacting with patients, and each physician must develop and determine the best way that he or she can relate to patients, physicians must convey that they are able and willing to listen and that they receive the information with utmost confidentiality (1). The Hippocratic Oath demands that physicians be circumspect with all patient-related information. The Health Insurance Portability and Accountability Act (HIPAA), which took effect in 2003, established national standards that were intended to protect the privacy of personal health information. Most physicians agree that there must be room for professional judgment to prevent such laws from becoming a bureaucratic impediment to patient care (9).

Communication Skills

It is essential for the physician to communicate with a patient in a manner that allows her to continue to seek appropriate medical attention. Not only the words used, but also the patterns of speech, the manner in which the words are delivered, even body language and eye contact are important aspects of the patient–physician interaction. The traditional role of the physician has been paternalistic, with the physician being expected to deliver direct commands or “orders” and specific guidance on all matters (4). Patients are now appropriately demanding more balanced communication with their physicians, and although they do not in most cases command an understanding of medicine, they do expect to be treated with appropriate deference, respect for their intellect, and a manner more equal in stature with the physician (10). As a result of electronic access to medical information, patients sometimes have more specific medical knowledge of a given medical problem than the physician does. When this is the case, the physician must avoid feeling defensive. The patient often lacks a broader knowledge of the context of the problem, awareness of the variable reliability of different electronic sources of information, an ability to assess a given study or journal report in an historical context or in comparison with other studies on the topic, knowledge of the interactions of drugs, an ability to have an intellectual distance from the topic that allows objectivity, and experience in the practice of the art and science of medicine. The physician possesses these skills and knowledge, whereas the patient has an intense personal interest in her specific medical condition. A collaborative relationship that allows patients greater involvement in the relationship potentially can lead to better health outcomes (1,11,12).
The pattern of the physician's speech can influence interactions with the patient. Some important components of effective communication between patients and physicians are presented in Table 1.2. There is evidence that not only can scientifically derived and empirically validated interview skills be taught and learned, but also that these skills can result in improved outcomes (6). A list of such skills is found in Table 1.3.

For physician–patient communication to be effective, the patient must feel that she is able to discuss her problems fully. Time constraints imposed by the pressures of office scheduling to meet economic realities make this difficult; both the physician and the patient frequently need to reevaluate their priorities. If the patient perceives that she participates in decision making and that she is given as much information as possible, she will respond to the mutually derived treatment plan with lower levels of anxiety and depression, embracing it as a collaborative plan of action. She should be able to propose alternatives or modifications to the physician’s recommendations that reflect her own beliefs and attitudes. There is ample evidence that patient communication, understanding, and treatment outcomes are improved when discussions with physicians are more dialogue than lecture. In addition, when patients feel they have some room for negotiation, they tend to retain more information regarding health-care recommendations (13). The concept of collaborative planning between patients and physicians has been embraced as a more effective alliance than the previous model in which physicians issued orders (13). The patient thus becomes more vested, determining health-care choices. For example, decisions about the risks and benefits of menopausal hormone therapy must be discussed in the context of an individual’s health and family history as well as her personal beliefs and goals. Whether the benefits outweigh the potential risks ultimately is determined by the woman, who decides whether to use such therapy. Whereas most women prefer shared decision making in the face of uncertainty, with an evidence-based discussion of her risks and benefits, others want a more directive approach (14). The physician’s challenge is to be able to personalize the interaction and communication.

---

There is evidence that when patients are heard and understood, when they become more vocal and inquisitive, their health improves (7). Participation facilitates investment and empowerment. Good communication is essential to the maintenance of a relationship between the patient and physician that fosters ongoing care. Health maintenance, therefore, can be linked directly to the influence of positive interactions between the physician and patient. Women who are comfortable with their physician may be more likely to raise issues or concerns or convey information about potential health risks and may be more receptive to the physician’s recommendations. This degree of rapport may promote the effectiveness of health interventions, including behavior modification. It also helps ensure that patients return for regular care because they feel the physician is genuinely interested in their welfare.

When patients are ill, they feel vulnerable, physically and psychologically exposed, and powerless. The physician, by virtue of his or her knowledge and status, has power that can be intimidating. It is essential that the physician be aware of this disparity so the “balance of power” does not shift too far away from the patient. Shifting it back from the physician to the patient may help improve outcomes (1,11,12). Physicians’ behaviors can suggest that they are not respectful of the patient. Such actions as failing to maintain scheduled appointment times, routinely holding substantive discussions with the patient undressed, or speaking to her from a standing position while she is lying down or in the lithotomy position can emphasize the imbalance of power in the relationship.

In assessing the effects of the patient–physician interaction on the outcome of chronic illness, three characteristics associated with better health care outcomes have been identified (12):

1. Empathetic physician and a high level of patient involvement in the interview
2. Expression of emotion by both patient and physician
3. Provision of information by the physician in response to the patient’s inquiries

Among patients with diabetes, these characteristics resulted in improved diastolic blood pressure and reduction of hemoglobin A1c. The best responses were achieved when an empathetic physician provided as much information and clarification as possible, responded to the patients’ questions openly and honestly, and expressed a full range of emotions, including humor. Responses improved when the relationship was not dominated by the physician (12).

In studies of gender and language, men tend to talk more than women, successfully interrupt women, and control the topics of the conversation (15). As a result, male physicians may tend to take control, and the imbalance of power may be magnified in the field of obstetrics and gynecology, in which all the patients are women. Male physicians may be more assertive than female physicians are. Men’s speech tends to be characterized by interruptions, command, and lectures, and women’s speech is characterized by silence, questions, and proposals (16,17). Some patients may simply feel more reticent in the presence of a male physician, whereas others may be more forthcoming with a male than a female physician (18). Women’s preference for a male or female physician may be based on sex as well as experience, competency, communication styles, and other skills (19,20). Although these generalizations clearly do not apply to all physicians, they can raise awareness about the various styles of communication and how they shape the physician–patient relationship (21,22). These patterns indicate the need for all physicians, regardless of their sex, to be attentive to their style of speech because it may affect their ability to elicit open and free responses from their patients (21,23).
their feelings and to have them validated and shared in an attempt to gain understanding of their concerns (13,15,16).

Different styles of communication may affect the physician’s ability to perceive the patient’s status and to achieve the goal of optimal assessment and successful treatment. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest response.

**Style**

The art of communication and persuasion is based on mutual respect and development of the patient’s understanding of the circumstances of her health (7). Insight is best achieved when the patient is encouraged to question her physician and when she is not pressured to make decisions (1,13). Patients who feel “backed into a corner” have the lowest compliance with recommended treatments (11).

Following are techniques to help achieve rapport with patients:

1. **Use positive language** (e.g., agreement, approval, and humor).
2. **Build a partnership** (e.g., acknowledgment of understanding, asking for opinions, paraphrasing, and interpreting the patient’s words).
3. **Ask rephrased questions.**
4. **Give complete responses to the patient’s questions.**

The manner in which a physician guides a discussion with a patient will determine the patient’s level of understanding and her ability to successfully complete therapy. The term *compliance* has long been used in medicine; it suggests that the patient will follow the physician’s recommendations or “orders.” The term has been criticized as being overly paternalistic; an alternative term, *adherence* to therapy, has been proposed (24,25). This term still carries the connotation that the therapy will be dictated by the physician. A more collaborative approach is suggested by the phrase *successful use* of therapy, which can be credited mutually to the physician and the patient. With this phrase, however, the ultimate success of the therapy appropriately accrues to the patient (26). If a directive is given to take a prescribed medication without a discussion of the rationale for its use, patients may not comply, particularly if the instructions are confusing or difficult to follow (13). Difficulties in compliance may be dictated by practical considerations: Nearly everyone finds a qid regimen more difficult than daily use. A major factor in successful compliance is simplicity of the regimen (27). Practical factors that affect successful use include financial considerations, insurance coverage, and even literacy (28). A discussion and understanding of the rationale for therapy along with the potential benefits and risks are necessary components of successful use; however, it may not be sufficient in the face of practical barriers. The specifics of when and how to take medication, including what to do when medication is missed, also have an impact on successful use.

The *style of the presentation of information is key to its effectiveness.* As noted, the physician should establish a balance of power in the relationship, including conducting serious discussions about diagnosis and management strategies when the patient is fully clothed and face-to-face with the physician in a private room. Body language is also important in interactions with patients. The physician should avoid an overly casual manner, which can communicate a lack of caring or compassion. The patient should be viewed directly and spoken to with eye contact so that the physician is not perceived as “looking off into the distance” (7).
Laughter and Humor

Humor is an essential component that promotes open communication. It can be either appropriate or inappropriate. Appropriate humor allows the patient to diffuse anxiety and understand that (even in difficult situations) laughter can be healthy (29). Inappropriate humor would horrify, disgust, or offend a patient or generally make her uncomfortable or seem disrespectful. Laughter can be used as an appropriate means of relaxing the patient and making her feel better.

Laughter is a “metaphor for the full range of the positive emotions” (29). It is the response of human beings to incongruities and one of the highest manifestations of the cerebral process. It helps to facilitate the full range of positive emotions—love, hope, faith, the will to live, festivity, purpose, and determination (29). Laughter is a physiologic response, a release that helps us all feel better and allows us to accommodate the collision of logic and absurdity. Illness, or the prospect of illness, heightens our awareness of the incongruity between our existence and our ability to control the events that shape our lives and our outcomes. We use laughter to combat stress, and stress reduction is an essential mechanism used to cope with illness.

Strategies for Improving Communication

All physicians should appreciate the importance of the art of communication during the medical interview. It is essential that interactions with patients are professional, honorable, and honest. Issues that have been reported to be important to physicians regarding patient–physician interactions are presented in Table 1.4. Similarly, patients have

suggested the importance of many of these same issues in facilitating participatory decision making (30).

Following are some general guidelines that can help to improve communication:

1. **Listen more and talk less.**
2. **Encourage the pursuit of topics introduced by and important to patients.**
3. **Minimize controlling speech habits such as interrupting, issuing commands, and lecturing.**
4. **Seek out questions and provide full and understandable answers.**
5. **Become aware of any discomfort that arises in an interview, recognize when it originates in an attempt by the physician to take control, and redirect that attempt.**
6. **Assure patients that they have the opportunity to discuss their problem fully.**
7. **Recognize when patients may be seeking empathy and validation of their feelings rather than a solution. Sometimes all that is necessary is to be there as a compassionate human being.**

In conducting interviews, it is important for the physician to understand the patient’s concerns. Given the realities of today’s busy office schedules, an additional visit may be required to discuss some issues fully. In studies of interviewing techniques it has been shown that although clinicians employ many divergent styles, the successful ones tend to look for “windows of opportunity” (i.e., careful, attentive listening with replies or questions at opportune times) (7). This skill of communication is particularly effective in exploring psychological and social issues during brief interviews. The chief skill essential to allowing the physician to perceive problems is the ability to listen attentively.

An interview that permits maximum transmission of information to the physician is best achieved by the following approach (7):

1. **Begin the interview with an open-ended question.**
2. **As the patient begins to speak, pay attention not only to her answers but also to her emotions and general body language.**
3. **Extend a second question or comment, encouraging the patient to talk.**
4. **Allow the patient to respond without interrupting, perhaps by employing silence, nods, or small facilitative comments, encouraging the patient to talk while the physician is listening.**
5. **Summarize and express empathy and understanding at the completion of the interview.**

Attentiveness, rapport, and collaboration characterize good medical interviewing techniques. Open-ended questions (“How are you doing?” “How are things at home?” “How does that make you feel?”) generally are desirable, particularly when they are coupled with good listening skills (31).
Premature closure of an interview and inability to get complete information to the patient may occur for several reasons (7). It may arise from a lack of recognition of the patient’s particular concern, from not providing appropriate opportunity for discussion, from the physician becoming uncomfortable in sharing the patient’s emotion, or perhaps from the physician’s lack of confidence that he or she can deal with the patient’s concern. One of the principal factors undermining the success of the interview is lack of time. This is a realistic concern as perceived by physicians, but skilled physicians can facilitate considerable interaction even in a short time by encouraging open communication (32).

Some patients lack accurate information about their illness. Lack of full understanding of an illness can produce dissatisfaction with medical care, increased anxiety, distress, coping difficulties, unsuccessful treatment, and poor treatment response (33–35). As patients increasingly request more information about their illnesses and more involvement in decisions about their treatment, and as physicians attempt to provide more open negotiation, communication problems become more significant. Although patients vary in their intellectual capacity, medical sophistication, levels of denial and anxiety, and their own communication skills, poor patient understanding stems as well from poor physician communication techniques, lack of consultation time, and in some cases, the withholding of information considered detrimental to patient welfare (33).

If clinical findings or confirmatory testing strongly suggest a serious condition (e.g., malignancy), the gravity and urgency of this situation must be conveyed in a manner that does not unduly alarm or frighten the individual. Honest answers should be provided to any specific questions the patient may want to discuss (34,35).

Allowing time for questions is important, and scheduling a follow-up visit to discuss treatment options after the patient has had an opportunity to consider the options and recommendations often is valuable (34,35). The patient should be encouraged to bring a partner or family member with her to provide moral support, to serve as another listener to hear and understand the discussion, and to assist with questions. The patient should also be encouraged to write down any questions or concerns she may have and bring them with her to a subsequent visit; important issues may not come to mind easily during an office visit. If the patient desires a second opinion or if a second opinion is mandated by her insurance carrier, it should always be facilitated. Physicians should not feel threatened by patient attempts to gain information and knowledge.

Valuable information can be provided by interviews with ancillary support staff and by providing pamphlets and other materials produced for patient education. Some studies have demonstrated that the use of pamphlets is highly effective in promoting an understanding of the condition and treatment options. Others have shown that the use of audiotapes and videotapes has a positive impact on knowledge and can decrease anxiety (33).

There are numerous medicine Web sites that can be accessed electronically, although the accuracy of the information is variable and must be carefully reviewed by physicians before recommending to patients. Physicians should be familiar with Internet sources of accurate information and be prepared to provide the addresses of these sites if the patient expresses interest (36).

The relationship between the patient and her physician, as with all aspects of social interchange, is subject to constant change. The state of our health is dynamic. Many of us are fortunate to be in a good state of health for much of our lives, but some are not so fortunate. Open communication between patient and physician can help achieve maximum effectiveness in diagnosis, treatment, and compliance for all patients.
History and Physical Examination

After a dialogue has been established, the patient assessment proceeds with obtaining a complete history and performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details. During the history and physical examination, risk factors that may require special attention should be identified. These factors should be reviewed with the patient in developing a plan for her future care (see Chapter 8).

Depending on the setting—ambulatory care/office, inpatient hospitalization, or outpatient surgical center—record keeping is typically facilitated by written forms, which provide prompts for important elements of the medical, family, and social history. Increasingly electronic medical records are being developed. However, one challenge is that paper and electronic records to not always “mesh,” and both paper and electronic records are periodically unavailable. Efforts to develop patient-held medical records have not yet been widely adopted. Self-completed forms may encourage a collaborative approach to preventive care (37).

History

After the chief complaint and characteristics of the present illness have been ascertained, the medical history of the patient should be obtained. It should include her complete medical and surgical history, her reproductive history (including menstrual and obstetric history), and a thorough family and social history.

A technique for obtaining information about the present illness is presented in Table 1.5. The physician should consider what other members of the health-care team might be helpful in completing the evaluation and providing care. Individuals who interact with the patient in the office—from the receptionists to medical assistants, nurses, advance practice nurses (nurse practitioners or nurse-midwives)—can all contribute to the patient’s care and may provide additional information or insight or be appropriate clinicians for providing follow-up. The role that each of these individuals plays in a given office or health-care setting may not be apparent to the patient; care should be taken with introductions, and it may be necessary to discuss the roles and functions of each individual. In some cases, referral to a nutritionist, physical or occupational therapist, social worker, psychologist, psychiatrist, or sex counselor would be helpful. Referral to or consultations with these clinicians as well as with physicians in other specialty areas should be addressed as needed. The nature of the relationship between the obstetrician/gynecologist and the patient should be clarified. Some women have a primary clinician whom they rely on for primary care. Other women, particularly healthy women of reproductive age, consider their obstetrician-gynecologist their primary clinician. The
SECTION 1  Principles of Practice

Table 1.5 Technique of Taking the History of the Present Illness

1. The technique used in taking the history of the present illness varies with the patient, the patient's problem, and the physician. Allow the patient to talk about her chief symptom. Although this symptom may or may not represent the real problem (depending on subsequent evaluation), it is usually uppermost in the patient's mind and most often constitutes the basis for the visit to the physician.

During the phase of the interview, establish the temporal relation of the chief symptom to the total duration of the illness. Questions such as, “Then up to the time of this symptom, you felt perfectly well?” may elicit other symptoms that may antedate the chief one by days, months, or years. In this manner, the patient may recall the date of the first appearance of illness.

Encourage the patient to talk freely and spontaneously about her illness from the established date of onset. Do not interrupt the patient's account, except for minor promptings such as, “When did it begin?” and “How did it begin?” which will help in developing chronologic order in the patient's story.

After the patient has furnished her spontaneous account (and before the next phase of the interview), it is useful to employ questions such as, “What other problems have you noticed since you became ill?” The response to this question may reveal other symptoms not yet brought forth in the interview.

Thus, in the first phase of the interview, the physician obtains an account of the symptoms as the patient experiences them, without any bias being introduced by the examiner's direct questions. Information about the importance of the symptoms to the patient and the patient's emotional reaction to her symptoms are also revealed.

2. Because all available data regarding the symptoms are usually not elicited by the aforementioned techniques, the initial phase of the interview should be followed by a series of direct and detailed questions concerning the symptoms described by the patient. Place each symptom in its proper chronologic order and then evaluate each in accordance with the directions for analyzing a symptom.

In asking direct questions about the details of a symptom, take care not to suggest the nature of the answer. This particularly refers to questions that may be answered "yes" or "no." If a leading question should be submitted to the patient, the answer must be assessed with great care. Subject the patient to repeated cross-examination until you are completely satisfied that the answer is not given just to oblige you.

Finally, before dismissing the symptom under study, inquire about other symptoms that might reasonably be expected under the clinical circumstances of the case. Symptoms specifically sought but denied are known as negative symptoms. These negative symptoms may confirm or rule out diagnostic possibilities suggested by the positive symptoms.

3. The data secured by the techniques described in the first two phases of the interview should now suggest several diagnostic possibilities. Test these possibilities further by inquiring about other symptoms or events that may form part of the natural history of the suspected disease or group of diseases.

4. These techniques may still fail to reveal all symptoms of importance to the present illness, especially if they are remote in time and seemingly unrelated to the present problem. The review of systems may then be of considerable help in bringing forth these data. A positive response from the patient on any item in any of the systems should lead immediately to further detailed questioning.

5. Throughout that part of the interview concerning the present illness, consider the following factors:

a. The probable cause of each symptom or illness, such as emotional stress, infection, neoplasm. Do not disregard the patient's statements of causative factors. Consider each statement carefully, and use it as a basis for further investigation. When the symptoms point to a specific infection, direct inquiry to water, milk, and foods eaten; exposure to communicable diseases, animals, or pets; sources of sexually transmitted disease; or residence or travel in the tropics or other regions where infections are known to exist. In each of the above instances, ascertain, if possible, the date of exposure, incubation period, and symptoms of invasion (prodromal symptoms).

b. The severity of the patient's illness, as judged either by the presence of systemic symptoms, such as weakness, fatigue, loss of weight, or by a change in personal habits. The latter includes changes in sleep, eating, fluid intake, bowel movements, social activities, exercise, or work. Note the dates the patient discontinued her work or took to bed. Is she continuously confined to bed?

c. Determine the patient's psychological reaction to her illness (anxiety, depression, irritability, fear) by observing how she relates her story as well as her nonverbal behavior. The response to a question such as, “Have you any particular theories about or fear of what may be the matter with you?” may yield important clues relative to the patient's understanding and feeling about her illness. The reply may help in the management of the patient's problem and allow the physician to give advice according to the patient's understanding of her ailment.

individual physician’s comfort with this role should be discussed and clarified at the initial visit and revisited periodically as required in the course of care. These issues are covered in Section III, Preventative and Primary Care (see Chapters 8 through 13). Laboratory testing for routine care and high-risk factors are presented in Chapter 8.

**Physical Examination**

A thorough general physical examination typically is performed at the time of the initial visit, on a yearly basis, and as needed throughout the course of treatment (Table 1.6). The extent of the physical examination is often dictated by the patient’s primary concerns and symptoms. For example, for healthy teens without symptoms who are requesting oral contraceptives before the initiation of intercourse, a gynecologic exam is not necessarily required. Some aspects of the examination—such as assessment of vital signs in addition to measurement of height, weight, and blood pressure and calculation of a body mass index—are performed routinely during most office visits. Typically, examination of the breast, abdomen, and a complete examination of the pelvis are considered to be the essential parts of the gynecologic examination.

**Abdominal Examination**

With the patient in the supine position, an attempt should be made to have her relax as much as possible. Her head should be leaned back and supported gently by a pillow so that she does not tense her abdominal muscles.

The abdomen should be inspected for signs of an intra-abdominal mass, organomegaly, or distention that would, for example, suggest ascites or intestinal obstruction. Auscultation of bowel sounds, if deemed necessary to ascertain the nature of the bowel sounds, should precede palpation. The frequency of intestinal sounds and their quality should be noted. In a patient with intestinal obstruction, “rushes,” as well as the occasional high-pitched sound, can be heard. Bowel sounds associated with an ileus may occur less frequently but at the same pitch as normal bowel sounds.

The abdomen is palpated to evaluate the size and configuration of the liver, spleen, and other abdominal contents. Evidence of fullness or mass effect should be noted. This is particularly important in evaluating patients who may have a pelvic mass and in determining the extent of omental involvement, for example, with metastatic ovarian cancer. A fullness in the upper abdomen could be consistent with an “omenta cake.” All four quadrants should be carefully palpated for any evidence of mass, firmness, irregularity, or distention. A systematic approach should be used (e.g., clockwise, starting in the right upper quadrant). Percussion should be used to measure the dimensions of the liver. The patient should be asked to inhale and exhale during palpation of the edge of the liver.

**Pelvic Examination**

The pelvic examination usually is performed with the patient in the dorsal lithotomy position (Fig. 1.1). The patient’s feet should rest comfortably in stirrups with the edge of the buttocks at the lower end of the table so that the vulva can be readily inspected and the speculum can be inserted in the vagina without obstruction from the table. Raising the head of the examination table, if possible, may facilitate relaxation. Drapes should be placed to provide a measure of cover for the patient’s legs but should be depressed over the abdomen to allow observation of the patient’s expression and to facilitate communication.

Before each step of the examination, the patient should be informed of what she will feel next: “First you’ll feel me touch your inner thighs; next I’ll touch the area around the outside of your vagina.” The vulva and perineal area should then be carefully inspected. Evidence of any lesions, erythema, pigmentation, masses, or irregularity should be noted. The skin quality should be noted as well as any signs of trauma, such as excoriations or
Table 1.6 Method of the Female Pelvic Examination

The patient is instructed to empty her bladder. She is placed in the lithotomy position (Fig. 1.1) and draped properly. The examiner’s right or left hand is gloved, depending on his or her preference. The pelvic area is illuminated well, and the examiner faces the patient. The following order of procedure is suggested for the pelvic examination:

A. External genitalia

1. Inspect the mons pubis, labia majora, labia minora, perineal body, and anal region for characteristics of the skin, distribution of the hair, contour, and swelling. Palpate any abnormality.

2. Separate the labia majora with the index and middle fingers of the gloved hand and inspect the epidermal and mucosal characteristics and anatomic configuration of the following structures in the order indicated below:

   a. Labia minora
   b. Clitoris
   c. Urethral orifice
   d. Vaginal outlet (introitus)
   e. Hymen
   f. Perineal body
   g. Anus

3. If disease of the Skene glands is suspected, palpate the gland for abnormal excretions by milking the undersurface of the urethra through the anterior vaginal wall. Examine the expressed excretions by microscopy and cultures.

   If there is a history of labial swelling, palpate for a diseased Bartholin gland with the thumb on the posterior part of the labia majora and the index finger in the vaginal orifice. In addition, sebaceous cysts, if present, can be felt in the labia minora.

B. Introitus

With the labia still separated by the middle and index fingers, instruct the patient to bear down. Note the presence of the anterior wall of the vagina when a cystocele is present or bulging of the posterior wall when a rectocele or enterocele is present. Bulging of both may accompany a complete prolapse of the uterus.

The supporting structure of the pelvic outlet is evaluated further when the bimanual pelvic examination is done.

C. Vagina and cervix

Inspection of the vagina and cervix using a speculum should always precede palpation.

The instrument should be warmed with tap water—not lubricated—if vaginal or cervical smears are to be obtained for the test or if cultures are to be performed.

Select the proper size of speculum (Fig. 1.2), warmed and lubricated (unless contraindicated). Introduce the instrument into the vaginal orifice with the blades oblique, closed, and pressed against the perineum. Carry the speculum along the posterior vaginal wall, and after it is fully inserted, rotate the blades into a horizontal position and open them. Maneuver the speculum until the cervix is exposed between the blades. Gently rotate the speculum around its long axis until all surfaces of the vagina and cervix are visualized.

1. Inspect the vagina for the following:

   a. The presence of blood
   b. Discharge. This should be studied to detect trichomoniasis, monilia, and clue cells and to obtain cultures, primarily for gonococci and chlamydia.
   c. Mucosal characteristics (i.e., color, lesions, superficial vascularity, and edema)

      The lesion may be:

      1. Inflammatory—redness, swelling, exudates, ulcers, vesicles
      2. Neoplastic
      3. Vascular

2. Inspect the cervix for the same factors listed above for the vagina. Note the following comments relative to the inspection of the cervix:

   a. Unusual bleeding from the cervical canal, except during menstruation, merits an evaluation for cervical or uterine neoplasia.

   b. Inflammatory lesions are characterized by a mucopurulent discharge from the os and redness, swelling, and superficial ulcerations of the surface.

   c. Polyps may arise either from the surface of the cervix projecting into the vagina or from the cervical canal. Polyps may be inflammatory or neoplastic.

   d. Carcinoma of the cervix may not dramatically change the appearance of the cervix or may appear as lesions similar in appearance to an inflammation. Therefore, a biopsy should be performed if there is suspicion of neoplasia.

D. Bimanual palpation

The pelvic organs can be outlined by bimanual palpation; the examiner places one hand on the lower abdominal wall and the finger(s) (one or two) (see Fig. 1.3) of the other hand in the vagina (or vagina and rectum in the rectovaginal examination) (see Fig. 1.4). Either the right or left hand may be used for vaginal palpation. The number of fingers inserted into the vagina should be based on what can comfortably be accommodated, the size and pliability of the vagina, and the weight of the patient. For example, adolescent, slender, and older patients might be best examined with a single finger technique.

1. Introduce the well-lubricated index finger and, in some patients, both the index and the middle finger into the vagina at its posterior aspect near the perineum. Test the strength of the perineum by pressing downward on the perineum and asking the patient to bear down. This procedure may disclose a previously concealed cystocele or rectocele and descensus of the uterus.

   Advance the fingers along the posterior wall until the cervix is encountered. Note any abnormalities of structure or tenderness in the vagina or cervix.

2. Press the abdominal hand, which is resting on the infraumbilical area, very gently downward, sweeping the pelvic structures toward the palpating vaginal fingers.

   Coordinate the activity of the two hands to evaluate the body of the uterus for:

   a. Position

   b. Architecture, size, shape, symmetry, tumor

   c. Consistency

   d. Tenderness

   e. Mobility

   Tumors, if found, are evaluated for location, architecture, consistency, tenderness, mobility, and number.

3. Continue the bimanual palpation, and evaluate the cervix for position, architecture, consistency, and tenderness, especially on mobility of the cervix. Rebound tenderness should be noted at this time. The intravaginal fingers should then explore the anterior, posterior, and lateral fornices.

4. Place the “vaginal” finger(s) in the right lateral fornix and the “abdominal” hand on the right lower quadrant.

   Manipulate the abdominal hand gently downward toward the vaginal fingers to outline the adnexa.

   A normal tube is not palpable. A normal ovary (about $4 \times 2 \times 3 \text{ cm}$ in size, sensitive, firm, and freely movable) is often not palpable. If an adnexal mass is found, evaluate its location relative to the uterus and cervix, architecture, consistency, tenderness, and mobility.

5. Palpate the left adnexal region, repeating the technique described previously, but place the vaginal fingers in the left fornix and the abdominal hand on the left lower quadrant.
SECTION I  Principles of Practice

Table 1.6  Continued

6. Follow the bimanual examination with a rectovaginal–abdominal examination.
   Insert the index finger into the vagina and the middle finger into the rectum very gently. Place the other hand on the
   infraumbilical region. The use of this technique makes possible higher exploration of the pelvis because the cul-de-sac
   does not limit the depth of the examining finger.

7. In patients who have an intact hymen, examine the pelvic organs by the rectal-abdominal technique.

E. Rectal examination

1. Inspect the perianal and anal area, the pilonidal (sacroccocygeal) region, and the perineum for the following aspects:
   a. Color of the region (note that the perianal skin is more pigmented than the surrounding skin of the buttocks and is
      frequently thrown into radiating folds)
   b. Lesions
      1. The perianal and perineal regions are common sites for itching. Pruritus ani is usually indicated by thickening,
         excoriations, and eczema of the perianal region and adjacent areas.
      2. The anal opening often is the site of fissures, fistulae, and external hemorrhoids.
      3. The pilonidal area may present a dimple, a sinus, or an inflamed pilonidal cyst.

2. Instruct the patient to ‘strain down’ and note whether this technique brings into view previously concealed internal
   hemorrhoids, polyps, or a prolapsed rectal mucosa.

3. Palpate the pilonidal area, the ischiorectal fossa, the perineum, and the perianal region before inserting the gloved
   finger into the anal canal.
   Note the presence of any concealed induration or tenderness in any of these areas.

4. Palpate the anal canal and rectum with a well-lubricated, gloved index finger. Lay the pulp of the index finger
   against the anal orifice and instruct the subject to strain downward. Concomitant with the patient’s downward
   straining (which tends to relax the external sphincter muscle), exert upward pressure until the sphincter is felt to
   yield. Then, with a slight rotary movement, insinuate the finger past the anal canal into the rectum. Examine the anal
   canal systematically before exploring the rectum.

5. Evaluate the anal canal
   a. Tonus of the external sphincter muscle and the anorectal ring at the anorectal junction
   b. Tenderness (usually caused by a tight sphincter, anal fissure, or painful hemorrhoids)
   c. Tumor or irregularities, especially at the pectinate line
   d. Superior aspect: Reach as far as you can. Mild straining by the patient may cause some lesions, which are out of
      reach of the finger, to descend sufficiently low to be detected by palpation.
   e. Test for occult blood: Examine the finger after it is withdrawn for evidence of gross blood, pus, or other
      alterations in color or consistency. Smear the stool to test for occult blood (guaiac).

6. Evaluate the rectum
   a. Anterior wall
      1. Cervix: size, shape, symmetry, consistency, and tenderness, especially on manipulation
      2. Uterine or adnexal masses
      3. Rectouterine fossa for tenderness or implants
         In patients with an intact hymen, the examination of the anterior wall of the rectum is the usual method of
         examining the pelvic organs.
   b. Right lateral wall, left lateral wall, posterior wall, superior aspect; test for occult blood

ecchymosis. The presence of any visible lesions should be quantitated and carefully
described with regard to their full appearance and characteristics on palpation (i.e., mobi-
licity, tenderness, consistency). A drawing of the location of skin lesions is helpful.
Ulcerative or purulent lesions of the vulva should be evaluated and cultured as outlined in
subsequent chapters, and biopsy should be performed on any lesions.

After thorough visualization and palpation of the external genitalia, including the mons pubis
and the perianal area, a speculum is inserted in the vagina. In a normal adult who is sexually
active, a Pederson speculum is typically used. The types of specula that are used in gynecol-
ogy are presented in Fig. 1.2. In general, the smallest speculum necessary to produce
adequate visualization should be used. The larger Graves speculum may be required in

Figure 1.1  The lithotomy position for the pelvic examination.

Figure 1.2  Vaginal specula: 1, Graves extra long; 2, Graves regular; 3, Pederson
extra long; 4, Pederson regular; 5, Huffman "virginal"; 6, pediatric regular; and
7, pediatric narrow.
women who have lax vaginal walls, are pregnant, or will be undergoing cervical or endome-
trial biopsies or procedures. In some women, a longer speculum (either Pederson or Graves)
may facilitate visualization of the cervix in a manner that is less uncomfortable to the patient.
If any speculum other than the typically sized specula is used, the patient should be informed
so that she can remind the clinician before her next examination. The speculum should be
warmed before it is inserted into the vagina; a heating pad or speculum warmer can be placed
under the supply of specula. **If lubrication is required, warm water generally is sufficient.**
The patient should be asked to relax the muscles of her distal vagina before the insertion of
the speculum to facilitate the placement and to avoid startling her by this portion of the exam-
ination. After insertion, the cervix and all aspects of the vagina should be carefully inspected.
Particular attention should also be paid to the vaginal fornices because lesions (e.g., warts)
may be present in those areas and are not readily visualized.

The appropriate technique for cervical cytology testing is presented in Chapter 17. **Biopsy
should be performed on any obvious lesions on the cervix or in the vagina.** An endome-
trial biopsy usually is performed with a flexible cannula or a Novak curette (see Chapter
14). Any purulence in the vagina or cervix should be cultured (see Chapter 16). **Testing for
sexually transmitted diseases should be performed routinely in adolescents and young
adults as recommended by the Centers for Disease Control and Prevention.**

After the speculum is removed and the pelvis palpated, lubrication is applied to the exam-
ination glove, and **one or two (the second and/or first) fingers are inserted gently into
the vagina.** In general, in right-handed physicians, the right hand is inserted into the
vagina and the left hand is used on the abdomen to provide counterpressure as the pelvic
viscera are moved (Fig. 1.3). In patients with pelvic pain, a stepwise “functional pelvic

---

**Figure 1.3** The bimanual examination.
exam” involves the sequential palpation of anatomic structures, including the pelvic floor, bladder, rectum, cervix, and cul-de-sac. These areas are assessed for tenderness and a specific source of pain. The vagina, its fornices, and the cervix are palpated carefully for any masses or irregularities. One or two fingers are placed gently into the posterior fornix so the uterus can be moved. With the abdominal hand in place, the uterus can usually be palpated just above the surface pubis. In this manner, the size, shape, mobility, contour, consistency, and position of the uterus are determined. The patient is asked to provide feedback about any areas of tenderness, and her facial expressions are observed during the examination.

The adnexa are then palpated gently on both sides, paying particular attention to any enlargements. Again, the size, shape, mobility, and consistency of any adnexal structures should be carefully noted.

A digital rectal examination is suggested periodically in women 40 years of age and older (see American College of Obstetricians and Gynecologists guidelines, Chapter 8) and may be helpful in premenopausal women in whom there is any difficulty ascertaining the adnexal structures (Fig. 1.4). Rectovaginal examination should also be performed in these women to exclude the possibility of concurrent rectal disease (38). Stool testing for occult blood has been found to reduce colon cancer mortality for individuals older than age 50 (39). During rectal examination, the quality of the sphincter muscles, support of the pelvis, and evidence of masses such as hemorrhoids or lesions intrinsic to the rectum should be noted. Nodularity and tenderness within the rectovaginal septum suggests endometriosis; nodularity may also suggest the spread of an intra-abdominal malignancy such as ovarian cancer.

Figure 1.4 The rectovaginal examination.
At the completion of the physical examination, the patient should be informed of the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately; this discussion should take place after the examination with the patient clothed. A plan to evaluate the findings should be outlined briefly and in clear, understandable language. The implications and timing of any proposed procedure (e.g., biopsy) should be discussed, and the patient should be informed when the results of any tests will be available.

**Pediatric Patients**

A careful examination is indicated when a child presents with genital symptoms such as itching, discharge, burning with urination, or bleeding. The examiner should be familiar with the normal appearance of the prepubertal genitalia. The normal unestrogenized hymenal ring and vestibule can appear mildly erythematous. The technique of examination is different from that used for examining an adult and may need to be tailored to the individual child based on her age, size, and comfort with the examiner.

A speculum examination should not be performed in a prepubertal child in the office. A young child can usually be examined best in a “frog leg” position on the examining table. Some very young girls (toddlers or infants) do best when held in their mother’s arms. Sometimes, the mother can be positioned, clothed, on the examining table (feet in stirrups, head of table elevated) with the child on her lap, the child’s legs straddling her mother’s legs. The knee–chest position may also be helpful for the examination (40). The child who is relaxed and warned about touching will usually tolerate the examination satisfactorily. An otoscope can be used to examine the distal vagina if indicated.

Some children who have been abused, who have had particularly traumatic previous examinations, or who are unable to allow an examination may need to be examined under anesthesia, although a gentle office examination should almost always be attempted first. If the child has had bleeding and no obvious cause of bleeding is visible externally or within the distal vagina, an examination under anesthesia is indicated to visualize the vagina and cervix completely. A hysteroscope, cytoscope, or other endoscopic instrument can be used to provide magnification and light source for this examination, which should be performed with anesthesia.

**Adolescent Patients**

A pelvic examination may be less revealing in an adolescent than in an older woman, particularly if it is the patient’s first examination or if it takes place on an emergency basis. An adolescent who presents with excessive bleeding should have a pelvic examination if she has had intercourse, if the results of a pregnancy test are positive, if she has abdominal pain, if she is markedly anemic, or if she is bleeding heavily enough to compromise hemodynamic stability. The pelvic examination occasionally may be deferred in young teenagers who have a classic history of irregular cycles soon after menarche, who have normal hematocrit levels, who deny sexual activity, and who will reliably return for follow-up. A pelvic examination may be deferred in adolescents who present to the office requesting oral contraceptives before the initiation of intercourse, or at the patient’s request, even if she has had intercourse. Newer testing methods using DNA amplification techniques allow noninvasive urine testing for gonorrhea and chlamydia (41).

Other diagnostic techniques (such as pelvic ultrasound) can substitute for or supplement an inadequate examination. However, an examination is usually required when there is a question of pelvic pain, genital anomaly, pregnancy-related condition, or possibility of pelvic infection. The keys to a successful examination in an adolescent lie in earning the patient’s trust, explaining the components of her examination, performing only the essential components, and using a very careful and gentle technique. It is helpful
to ascertain whether the patient has had a previous pelvic examination, how she perceived the experience, and what she has heard about a pelvic examination from her mother or friends.

Before a first pelvic examination is performed, a brief explanation of the planned examination (which may or may not need to include a speculum), instruction in relaxation techniques, and the use of lidocaine jelly as a lubricant can be helpful. The patient should be encouraged to participate in the examination by voluntary relaxation of the introital muscles or by using a mirror if she wishes. If significant trauma is suspected or the patient finds the examination too painful and is truly unable to cooperate, an examination under anesthesia may occasionally be necessary. The risks of general anesthesia must be weighed against the value of information that would be obtained by the examination.

Confidentiality is an important issue in adolescent health care. A number of medical organizations, including the American Medical Association, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecologists, have endorsed adolescents’ rights to confidential medical care. Particularly with regard to issues as sensitive as sexual activity, it is critical that the adolescent be interviewed alone, without a parent in the room. The patient should be asked if she has engaged in sexual intercourse, if she used any method of contraception, and if she feels there is any possibility of pregnancy.

Follow-up

Arrangements should be made for the ongoing care of patients, regardless of their health status. Patients with no evidence of disease should be counseled regarding health behaviors and the need for routine care. For those with signs and symptoms of a medical disorder, further assessments and a treatment plan should be discussed. The physician must determine whether he or she is equipped to treat a particular problem or whether the patient should be directed to another health professional, either in obstetrics and gynecology or another specialty, and how that care should be coordinated. If the physician believes it is necessary to refer the patient elsewhere for care, the patient should be reassured that this measure is being undertaken in her best interests and that continuity of care will be ensured.

Summary

The management of patients’ gynecologic symptoms, as well as abnormal findings and signs detected during examination, requires the full use of a physician’s skills and knowledge. Physicians are challenged to practice the art of medicine in a manner that leads to effective alliances with their patients. The value of skilled medical history-taking cannot be overemphasized. Physicians should listen carefully to what patients are saying about the nature and severity of their symptoms. They also should listen to what patients may not be expressing: their fears, anxieties, and personal experiences that lead them to react in a certain manner when faced with what is often, to them, a crisis (such as the diagnosis of an abnormality on examination, laboratory testing, or pelvic imaging).

Physicians should supplement their formal education and clinical experience by constantly striving for new information. To meet the challenges posed by the complexities of patient care, physicians must learn to practice evidence-based medicine, based on the very latest data of highest quality. Computers have made the world of information management accessible to both physicians and patients. Physicians need to search the medical literature to acquire knowledge that can be applied, using the art of medicine, to patient care to maintain health, alleviate suffering, and manage and cure disease.
### References

The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege.

Exceptions from the Healthcare Insurance Portability and Accountability Act (HIPAA) requirement to obtain patient authorization to share health information include areas such as patient treatment, payment, operations (quality improvement, quality assurance, education), disclosure to public health officials and health oversight agencies, and legal requirements.

Informed consent is a process whereby the physician educates the patient about the medical condition, explores her values, and informs her about the risks and benefits of treatment and reasonable medical alternatives.

The concept of autonomy should not allow a patient’s wishes to take precedence over good medical judgment.

For children, parents are the surrogate decision makers, except in circumstances in which the decision is life threatening and might not be the choice a child would make later, when adult beliefs and values are formed.

Research on the outcomes of care provided by gynecologists or affected adversely by the current system for financing health care (financial aspects, quality-of-life measures, survival, morbidity, and mortality) will allow the discipline to have a voice in determining choices for women’s health care.

The practice of gynecology, as with all branches of medicine, is based on ethical principles that guide patient care. These principles and concepts create a framework for ethical decision making that applies to all aspects of practice:

- **Autonomy**: a person’s right to self-rule, to establish personal norms of conduct, and to choose a course of action based on a set of personal values and principles derived from them

- **Beneficence**: the obligation to promote the well-being of others
Confidentiality: a person’s right to decide how and to whom personal medical information will be communicated

Covenant: a binding agreement between two or more parties for the performance of some action

Fiduciary Relationship: a relationship founded on faith and trust

Informed Consent: the patient’s acceptance of a medical intervention after adequate disclosure of the nature of the procedure, its risks and benefits, and alternatives

Justice: the right of individuals to claim what is due them based on certain personal properties or characteristics

Maleficence: the act of committing harm (Nonmaleficence obliges one to avoid doing harm)

Patient and Physician

Health care providers fulfill a basic need—to preserve and advance the health of human beings. Despite the challenges imposed by the commercial aspects of the current medical environment, for most physicians, the practice of medicine remains very much a "calling," a giving of oneself to the greater good. Although much of medicine is contractual in nature, it cannot be understood in only those terms: "The kind of minimalism that a contractualist understanding of the professional relationship encourages produces a professional too grudging, too calculating, too lacking in spontaneity, too quickly exhausted to go the second mile with his patients along the road of their distress” (1). There is a relationship between physician and patient that extends beyond a contract and assumes the elements of a fiduciary relationship—a covenant between parties. The physician, having knowledge about the elements of health care, assumes a trust relationship with the patient whereby her interests are held paramount. Both the patient and the physician have rights and responsibilities in this relationship, and both are rewarded when those rights and responsibilities are upheld. Confidentiality and informed consent are two expressions of that trust or covenantal relationship.

Confidentiality

The patient seeking assistance from a health professional has the right to be assured that the information exchanged during that interaction is private. Privacy is essential to the trust relationship between doctor and patient. Discussions are privileged information. The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege. Privileged information belongs to the patient except when it impinges on the legal and ethical rights of institutions and society at large, regardless of the setting. In a court situation, for example, physicians cannot reveal information about their patients unless the patient waives that privilege. If privilege is waived, the physician may not withhold such testimony.

The privilege of privacy must be maintained even when it does not seem intrinsically obvious. A patient’s family, friend, or spiritual guide, for example, has no right to medical information regarding the patient unless the patient specifically approves it, except if the patient is unable to provide that guidance because of their medical circumstance. In that circumstance, health providers must exercise their judgment based on their assessment of
the involvement of that particular person with the patient’s health. This may seem obvious but often can be overlooked, such as when a health care giver receives a call from a concerned relative inquiring about the status of a patient. The response may be a natural attempt to reassure and inform a caring individual about the patient’s status. However, for her own reasons, the patient may not want certain individuals informed of her medical condition. Thus, confidentiality has been breached. It is wise to ask patients about who may be involved in decision making and who may be informed about their status. If a health care giver is unclear of the patient’s wishes regarding the person requesting information, the reply should indicate that the patient’s permission is necessary before discussing her status. Finally, when trying to contact patients for follow-up of medical findings, it is never appropriate to reveal the reason to an individual other than the patient.

**Record Keeping**

Health care professionals are part of a record-keeping organization. Those records are used for multiple purposes in medicine and are a valuable tool in patient care. Unfortunately, there is an increasing tendency for ancillary organizations to collect, maintain, and disclose information about individuals with whom they have no direct connection (2). Given the present lack of universal and nondiscriminatory access to health insurance in the United States, physicians must be aware of this practice and its ramifications. Patients sign a document, often without understanding its meaning, upon registering with a health care institution or insurance plan. That document waives the patient’s privilege to suppress access and gives insurers, and often other health care providers who request it, access to the medical record. The consequences of such disclosure for patients can be significant in terms of insurance coverage and potential job discrimination (3). This concern must be weighed against the need for all health care providers involved with an individual to be informed about past or present diseases or activities that may interfere with or complicate management. The use of illegal drugs, a positive human immunodeficiency virus (HIV) test result, and even a history of cancer or psychiatric illness are all exceptionally important to health care providers in evaluating individual patients. When revealed to outside institutions, however, these factors may affect the patient’s ability to obtain medical care, insurance, or even credit. **Everything that is written in a patient’s record should be important to the medical care of that patient, and extrinsic information should be avoided.** Furthermore, it is appropriate for physicians to discuss with patients the nature of medical records and their release to other parties so that patients can make an informed choice about such release.

The Healthcare Insurance Portability and Accountability Act (HIPAA), instituted in April 2003, has imposed additional requirements for access to patient records for clinical research as well as guidelines for protecting electronic medical records. Although the intent of the act was laudable, the extent to which privacy will be improved is unknown, and the potential harm to the public from failure to do critical database research because of its costly requirements may be greater than any benefit. The considerable confusion and misunderstanding of the rules associated with the act also can potentially harm patients. The exceptions from the requirement to obtain patient authorization to share health information include areas such as patient treatment, payment, operations (quality improvement, quality assurance, and education), disclosure to public health officials and health oversight agencies, and legal requirements (4). One widely misunderstood feature of the act was whether protected health information could be sent via fax or e-mail or mail to other treating physicians (which is allowed) (5). It is important that researchers understand the influence of these rules in all settings; preplanning for clinical database research when the patient first enters the office or institution will make this critical research possible (6). **The security of medical records, therefore, is a concern not just for individual patients and physicians but also for health systems and researchers.**
Legal Issues

The privilege of patients to keep their records or medical information private can be superseded by the needs of society, but only in rare circumstances. The classic legal decision quoted for the needs of others superseding individual patient rights is that of *Tarasoff v. Regents of the University of California* (7). That decision establishes that the special relationship between a patient and doctor may support affirmative duties for the benefit of third persons. It requires disclosure if “necessary to avert danger to others” but still in a fashion “that would preserve the privacy of the patient to the fullest extent compatible with the prevention of the threatened danger.” This principle also is compatible with the various codes of ethics that allow physicians to reveal information to protect the welfare of the individual or the community. In other words, “the protective privilege ends where the public peril begins” (7).

Legislation can also override individual privilege. The most frequent example is the recording of births and deaths, which is the responsibility of physicians. Various diseases are required to be reported depending on state law (e.g., HIV status may or may not be reportable in individual states, whereas acquired immunodeficiency syndrome [AIDS] is reportable in all states). Reporting injuries caused by lethal weapons, rapes, and battering (e.g., elder and child abuse) is mandatory in some states and not others. The regulations for the reporting of these conditions are codified by law and can be obtained from the state health department. These laws are designed to protect the individual’s privacy as much as possible while still serving the public interest. Particularly in the realm of abuse, physicians have a complex ethical role regardless of the law. Victims of abuse, for example, must feel supported and assured that the violent act they have survived will not make a difference in how they are treated as people. Their sense of vulnerability and their actual vulnerability may be so great that reporting an incident may increase their risk for medical harm. Despite the laws, physicians also have an ethical responsibility protect the patient’s best interest, and weighing that ethical responsibility can be difficult.

Informed Consent

Informed consent is a process that involves an exchange of information directed toward reaching mutual understanding and informed decision making. Ideally, informed consent should be the practical manifestation of respect for patient preferences (autonomy) (8,9). Unfortunately, an act of informed consent is often misunderstood as procurement of a signature on a document. Furthermore, the intent of the individual involved in the consent process often is the protection of the physicians from liability. Nothing could be further from either the legal or ethical meaning of this concept.

Informed consent is a conversation between physician and patient that teaches the patient about the medical condition, explores her values, and informs her about the reasonable medical alternatives. Informed consent is an interactive discussion in which one participant has greater knowledge about medical information and the other participant has greater knowledge about that individual’s value system and circumstances affected by the information. This process does not require an arduous lecture on the medical condition or extensive examination of the patient’s psyche. It does require adjustment of the information to the educational level of the patient and respectful elicitation of concerns and questions. It also requires acknowledgment of the various fears and concerns of both parties. Fear that the information may frighten patients, fear of hearing the information by the patient, lack of ability to comprehend technical information, and inability to express that lack are among the many barriers facing physicians and patients engaging in this conversation. Communication skills are part of the art of medicine, and observation of good role models, practice, and positive motivation can help to instill this ability in physicians (10).
Autonomy

Informed consent arises from the concept of autonomy. Pellegrino (11) defines an autonomous person as “one who, in his thoughts, work, and actions, is able to follow those norms he chooses as his own without external constraints or coercion by others.” This definition contains the essence of what health care providers must consider as informed consent. The choice to receive or refuse medical care must be in concert with the patient’s values and freely chosen, and the options must be considered in light of the patient’s values.

Autonomy is not respect for a patient’s wishes against good medical judgment. Consider the example of a patient with inoperable, advanced-stage cervical cancer who demands surgery and refuses radiation therapy. The physician’s ethical obligation is to seek the best for the patient’s survival (beneficence) and avoid the harm (nonmaleficence) of surgery, even though that is what the patient wishes. Although physicians are not obligated to offer treatment that is of no benefit, the patient does have the right to refuse treatment if it does not fit into her values. Thus, this patient could refuse treatment for her cervical cancer, but she does not have the right to be given any treatment she wishes.

Surrogate Decision Makers

If the ability to make choices is diminished by extreme youth, mental processing difficulties, extreme medical illness, or loss of awareness, surrogate decision making may be required. In all circumstances, the surrogate must make every attempt to act as the patient would have acted (12). The hierarchy of surrogate decision makers is specified by statutory law in each state and differs slightly from state to state. For adults, the first surrogate decision maker is a court-appointed guardian if one exists and second is a durable power of attorney, followed by relatives by degree of presumed familiarity (e.g., spouse, adult children, parents).

For children, parents are the surrogate decision makers, except in circumstances in which the decision is life threatening and might not be the choice a child would make later, when adult beliefs and values are formed. The classic example of this is the Jehovah’s Witness parents who refuse life-saving transfusions for their child (13). Although this case is the extreme, it illustrates that the basic principle outlined for surrogate decision making should also apply to parents. Bias that influences decision making (in protection of parental social status, income, or systems of beliefs) needs to be considered by physicians because the potential conflict may lead parents to decisions that are not in the best interest of the child. If there is a conflicting bias that does not allow decisions to be made in the best interest of the child or that involves a medical threat to a child, legal action to establish guardianship (normally through a child protective agency by the courts) may be necessary. This action can destroy not only the patient (child)–physician relationship but also the parent–physician relationship. It also may affect the long-term health and well-being of the child, who must return to the care of the parents. Such decisions should be made only after all attempts to educate, clarify, and find alternatives have been exhausted.

The legal age at which adolescents may make their own decisions regarding their health care varies by state (14). However, there is a growing trend to increase the participation of adolescents who are capable of decision making in decisions about their health care. Because minors often have developed a value system and the capacity to make informed choices, their ability to be involved in decisions should be assessed individually rather than relying solely on the age criteria of the law and their parents’ views.

A unique area for consideration of informed consent is in the international context, either providing care or conducting clinical research in foreign settings or caring for individuals from other countries who have widely differing viewpoints regarding individual informed consent. For example, if the prevailing standard for decision making by a woman is that her closest male relative makes it for her, how is that standard accommodated
within our present autonomy-based system? In international research, these issues have presented major concerns when women were assigned to placebo or treatment groups and consent was accepted from male relatives (15). Furthermore, the coercive effect of access to health care through clinical trials when no other access to health care is available creates real questions about the validity and freedom of choice for participants in these studies (16). Guidelines for limiting coercion and ensuring the ability to choose participation in research are being developed for international research. When caring for patients from certain cultures and foreign countries in daily practice, however, it is important to recognize that these issues exist in a microcosm. Ensuring that the patient can make the choice herself (or freely chooses to have a relative make it for her) remains an important element of informed consent between individual physicians and patients.

Beneficence and Nonmaleficence

The principles of beneficence and nonmaleficence are the basis of medical care—the “to do good and no harm” of Hippocrates. However, these issues are often clouded by other decision makers, consultants, family members, and sometimes financial constraints or conflicts of interests. Of all the principles of good medical care, benefit is the one that continually must be reassessed. Simple questions often have no answers. What is the medical indication? How does the proposed therapy address this issue? How much will this treatment benefit the patient? How much will it extend the patient’s life? Furthermore, when confronted with multiple medical problems and consultants, physicians should ask how much treatment will be of benefit given all the patient’s problems (e.g., failing kidneys, progressive cardiomyopathy, HIV-positive status, and respiratory failure) rather than unnecessarily attempting intubation and respiratory support to treat the immediate problem.

The benefit or futility of the treatment, along with quality-of-life considerations, should be considered in all aspects of patient care. It is best to weigh all of the relevant issues in a systematic fashion. Some systematic approaches depend on a sequential gathering of all the pertinent information in four domains: medical indications (benefit and harm), patient preferences (autonomy), quality of life, and contextual issues (justice) (8). Other approaches identify decision makers, followed by facts, and then ethical principles. It is important for physicians to select an ethical model of analysis with which to practice so that, when faced with troubling and complex decisions, a system is available to help clarify the issues.

Medical Futility

The essence of good medical care is to attempt to be as clear as possible about the outcomes of the proposed interventions. If the proposed intervention (e.g., continued respiratory support or initiating support) has a very low or highly unlikely chance of success, intervention might be considered futile. Physicians have no obligation to continue or initiate therapies of no benefit (17). The decision to withdraw or withhold care, however, is one that must be accompanied by an effort to ensure that the patient or her surrogate decision maker is educated about the decision and agrees with it. Other issues, such as family concerns, can and should modify decisions if the overall well-being of the patient and of the family is best served. For example, waiting (within reason) to withdraw life support may be appropriate to allow a family to reach consensus or a distant family member to see the patient for a last time.

Quality of Life

Quality of life is a much used, often unclear term. In the care of patients, quality of life is the effect of therapy on the patient’s experience of living based on her perspective. It is perilous and wholly speculative to assume that physicians know what quality of life represents for a particular patient judging from a personal reaction. It is instructive, however, to attempt to guess what it means and then seek the patient’s perspective. The
results may be surprising. For example, when offered a new drug for ovarian cancer, a patient might prefer to decline the treatment because the side effects may not be acceptable even when there may be a reasonable chance that her life may be slightly prolonged. In some instances, the physician may not believe that further treatment is justified but the patient finds joy and fulfillment in preserving her existence as long as possible.

Controversy exists regarding whether currently available quality-of-life measurement systems will provide information to help patients make decisions (18). Information from quality-of-life studies might be judged by criteria that include whether the measured aspects of the patient’s life were based on the patient’s views or the physician’s clinical experience (19). Informing patients of the experiences of others who have had alternative treatments may help in their decision making, but it is never a substitute for the individual patient’s decisions.

Professional Relations

Conflict of Interest

All professionals have multiple interests that affect their decisions. Contractual and covenantal relationships between physician and patient are intertwined and complicated by health care payers and colleagues, which create considerable pressure. The conflict with financial considerations directly influences how patients’ lives are affected, often without their consent. Rennie (20) described that pressure eloquently: “Instead of receiving more respect (for more responsibility), physicians feel they are being increasingly questioned, challenged, and sued. Looking after a patient seems less and less a compact between two people and more a match in which increasing numbers of spectators claim the right to interfere and referee.” An honest response to this environment is for the physician to attempt to protect his or her efforts by assuming that the physician–patient relationship is contractual, and only contractual, in nature. This allocation of responsibility and authority for the contract precludes the need for the covenant between the physician and patient. For example, a preexisting contract, insurance, relationship with a particular hospital system, or managed-care plan may discourage referral to a more knowledgeable specialist, removing the physician’s responsibility. Thus, the contract seems to establish the extent of the physician–patient relationship. All health care providers must decide whether they will practice within a covenantal or contractual relationship and whether the relationship they develop remains true to this decision. In either setting, a reasonable perception of that relationship is “one that allows clients as much freedom as possible to determine how their lives are affected as is reasonably warranted on the basis of their ability to make decisions” (21).

Health Care Payers

An insurance coverage plan may demand that physicians assume the role of gatekeeper and administrator. Patients can be penalized for a lack of knowledge about their future desires or needs and the lack of alternatives to address the changes in those needs. Patients are equally penalized when they develop costly medical conditions that would not be covered if they moved from plan to plan. These situations often place the physician in the position of being the arbiter of patients’ coverage rather than acting as an advocate and adviser. It is an untenable position for physicians because they often cannot change the conditions or structure of the plan but are made to be the administrators of it.

In an effort to improve physician compliance with and interest in decreasing costs, intense financial conflicts of interest can be brought to bear on physicians by health care plans or health care systems. If a physician’s profile on costs or referral is too high, he or she might be excluded from the plan, thus decreasing his or her ability to earn a living or to provide care to certain patients with whom a relationship has developed. Conversely, a physician may receive a greater salary or bonus if the plan makes more money. The
ability to earn a living and to see patients in the future is dependent on maintaining relationships with various plans and other physicians. These are compelling loyalties and conflicts that cannot be ignored (22–24).

These conflicts are substantially different from those of fee-for-service plans, although the ultimate effect on the patient can be the same. In fee-for-service plans, financial gain may result in failure to refer a patient, or referral is restricted to those cases in which the financial gain is derived by return referral of other patients (25). Patients who have poor insurance coverage may be referred differentially. Patients may be unaware of these underlying conflicts of interest, a situation that elevates conflict of interest to an ethical problem. A patient has a right to know what her plan covers, to whom she is being referred and why, and the credentials of those to whom she is referred. The reality is that health care providers make many decisions under the pressure of multiple conflicts of interest. Physicians are potentially caught between self-interest and professional integrity. Whether it is blatant lying about indications for a procedure to receive reimbursement or a more subtle persuasion to sign up patients for a certain protocol because of points earned for a study group, the outcome for individuals’ and society’s relationship with health care providers is damaged by failure to recognize and specifically address conflicts of interest that impede decision making (26). Focusing clearly on the priority of the patient’s best interest and responsibly rejecting choices that compromise the patient’s needs are ethical requirements.

Institutions, third-party payers, and legislatures have avoided accountability for revealing conflicts of interest to those to whom they offer services. The restrictions of health care plans are never placed in a position as equally prominent as the coverage. The coverage choices can be quite arbitrary, and there is rarely an easily accessible and usable system for challenging them. Whole health systems or options may or may not be covered, but their presence or absence is obscured in the information given to patients. The social and financial conflicts of interest of these payers can directly affect the setting and nature of the relationship between physician and patient. To deal with ambiguous and sometimes capricious decision making, revelation of the conflicts of interest and accountability for choices should be demanded by physicians and patients (27).

Legal Problems

Abuses of the system (e.g., referral for financial gain) have led to proposals and legislation, often referred to as Stark I and II, affecting physicians’ ability to send patients to local laboratories and facilities in which they have a potential for financial gain. Although there have been clearly documented abuses, the same legislation would affect rural clinics and laboratories in which the sole source of financial support is rural physicians. States vary on the statutory legislation regarding this issue. Regardless of the laws, however, it is ethically required that financial conflicts of interest are revealed to patients (28–31).

Another abuse of the physician–patient relationship caused by financial conflicts of interest is fraudulent Medicare and Medicaid billings. This activity resulted in the Fraud and Abuse Act of 1987 (42. U.S.C. at 1320a–7b), which prohibits any individual or entity making false claims or soliciting or receiving any remuneration in cash or any kind, directly or indirectly, overtly or covertly, to induce a referral. Indictments under these laws are felonies, with steep fines, jail sentences, and loss of the license to practice medicine. Physicians should be aware of the legal ramifications of their referral and billing practices (26,32).

Harassment

The goal of medicine is excellence in the care of patients and, often, research and education that will advance the practice of medicine. Thus, everyone involved in the process should be able to pursue the common goal on equal footing and without
CHAPTER 2 Principles of Patient Care

harassment that interferes with employees’ or colleagues’ ability to work or be equally promoted in that environment. Every office and institution must have written policies on discrimination and sexual harassment that detail inappropriate behavior and state specific steps to be taken to correct an inappropriate situation. The legal sanction for this right is encoded in both statutory law through the Civil Rights Act of 1964 [42 U.S.C.A. at 2000e–2000e–17 (West 1981 and Supp. 1988)] and reinforced with judicial action (case or precedent law) by state and U.S. Supreme Court decisions. In particular, charges of sexual harassment can be raised as a result of unwelcome sexual conduct or a hostile workplace (such as areas of medicine that have been known for antifeminist attitudes in the past). As stated in one legal case, “a female does not assume the risk of harassment by voluntarily entering an abusive, antifemale environment” (Barbetta v. Chemlawn Service Co., 669 F, Supp. 569, WDNY, 1989). The environment must change; it is not acceptable to expect men or women to adapt because “they knew what it would be like.” The tension in the legal debate regarding harassment (sexual, racial, disability) always hinges on the weight of protection of free speech and the right of the individual to equality and a nonhostile work environment.

Stress Management

There is little doubt that the day-to-day stress of practicing medicine is significant. Besides the acknowledged stress of the time pressures and responsibility of medicine, the current health care environment has had a detrimental effect on physicians’ job security, with concurrent health risks (33). Stress takes a toll not only on cardiac function (34) but also on the practice of medicine and life outside of medicine (35).

Responding to stress through drug or alcohol abuse increases overall health and marital problems and decreases effectiveness in practice. In a long-term prospective study of medical students, individuals with high-risk (e.g., volatile, argumentative, aggressive) temperaments have been shown to have a high rate of premature death (particularly before 55 years of age) (36). Adequate sleep, reasonable working hours, exercise, and nutritional balance are directly related to decreases in psychological distress (37). Simple relaxation training has been shown to decrease gastroesophageal reflux in response to stress (38).

The pace that physicians maintain has a seductive quality that can easily mask the need for stress reduction by means of good health practices, exercise, and relaxation training. The answer to increased stress is not to work harder and extract the time to work harder from the relaxing and enjoyable pursuits that exist outside medicine. The outcome of that strategy (in terms of optimal psychological and physical functioning) is in neither the physician’s nor the patient’s best interest. Both the welfare of the patient and the welfare of the physician are enhanced by a planned strategy of good health practices and relaxation. Furthermore, such a strategy is important to all members of the health care team. By providing such leadership, physicians can contribute to a better work and health care environment for everyone.

Society and Medicine

Justice

Some of the ethical and legal problems in the practice of gynecology relate to the fair and equitable distribution of burdens and benefits. How benefits are distributed is a matter of great debate. There are various methods of proposed distribution:

- Equal shares (everyone has the same number of health care dollars per year)
- Need (only those people who need health care get the dollars)
- Queuing (the first in line for a transplant gets it)
• Merit (those with more serious illnesses receive special benefits)
• Contribution (those who have paid more into their health care fund get more health care)

Each of these principles could be appropriate as a measure of just allocation of health care dollars, but each will affect individual patients in different ways. Only recently has just distribution become a major issue in health care. The principles of justice apply only when the resource is desired or beneficial and to some extent scarce (39).

The traditional approach to medicine has been for practitioners to accept the intense focus on the individual patient. However, the current changes in medicine will alter the focus from the patient to a population (40)—“in the emerging medicine, the presenting patient, more than ever before, will be a representative of a class, and the science that makes possible the care of the patient will refer prominently to the population from which that patient comes.” Physicians are increasingly bound by accumulating outcomes data (population statistics) to modify the treatment of an individual in view of the larger population statistics. If, for example, the outcome of liver transplantation is only 20% successful in a patient with a certain set of medical problems, that transplant may instead be offered to someone who has an 85% chance of success. Theoretically, the former individual might have a successful transplant and the procedure might fail in the latter, but population statistics have been used to allocate this scarce resource. The benefit has been measured by statistics that predict success, not by other forms of justice allocation by need, queuing, merit, or contribution. This approach represents a major change in the traditional dedication of health care to the benefits of individual patients. With scarce resources, the overall benefits for all patients are considered in conjunction with the individual benefits for one patient.

There has always been an inequity in the distribution of health care access and resources. This inequity has not been seen by many health care providers who do not care for those patients who are unable to gain access, such as those who lack transportation or live in rural areas or where limits are imposed by lack of health care providers, time, and financial resources. Social discrimination sometimes leads to inequity of distribution of health care. Minorities are less likely to see private physicians or specialists, regardless of their income or source of health care funding (41–43). Thus, health care is rationed by default.

Health care providers must shift the paradigm from the absolute “do everything possible for this patient” to the proportionate “do everything reasonable for all patients” (8). To reform the health care system requires not just judicial, legislative, or business mandates but also attention to the other social components that can pose obstacles to efforts to expand health care beyond a focus on individual patients.

Health Care Reform

The tension between understanding health as an inherently individual matter (in which the receipt of health care is critical to individual well-being) and as a communal resource (in which distribution of well-being throughout society is the goal) underpins much of the political and social debate surrounding health care reform (44). The questions of health care reform are twofold: 1) What is the proper balance between individual and collective good? and 2) Who will pay for basic health care? Because much of health care reform requires balancing competing goals, legislation to achieve reform should specifically address how this balance can be achieved. The role of government should be as follows:

• Regulating access of individuals to health care
• Regulating potential harms to the public health (e.g., smoking, pollution, drug use)
• Promoting health practices of benefit to large populations (e.g., immunization, fluoridation of water)
In the present health system structure in the United States, health care payers, not individual providers, often make decisions regarding both the amount and distribution of resources. The health insurance industry determines what are “reasonable and customary” charges and what will be covered. The government decides (often with intense special-interest pressure) what Medicare and Medicaid will cover (45–47). These decisions directly affect patient care. For that reason, health care providers cannot ethically remain silent when the health and well-being of their individual patients and their communities are adversely affected by health care reform decisions.

The significant growth of uninsured individuals and uncompensated care in the United States reflects a threat to the health of women that should be of concern to all. The United States “is one of the few industrialized nations in the world that does not guarantee access to health care for its population” (48). The direct health consequences for women are significant and contribute to death and disability in our population. The burden of the shifted costs is falling more heavily on certain institutions, and the private community is providing less care for this population. The “implicit assumption of the United States health care system is that poor, uninsured persons who become ill can obtain free or discounted care” (49). There is, in fact, no more margin of funds that can be shifted to cover the cost of this care. The choice to provide access only to those who can afford it through wealth or through insurance coverage as our means of health care allocation is antithetical to the professional oaths and ethical standards of medicine. Health care providers should assess proposed reforms—or lack of action toward reform—in light of the needs of their community and their individual patients. Criteria should be established for judging proposals for health care reform, and physicians should add their voice to the debate on access (50–52).

Research on the outcomes of care provided by gynecologists or affected adversely by the current system for financing health care (financial aspects, quality-of-life measures, survival, morbidity, and mortality) will allow the discipline to have a voice in determining choices for women’s health care.

SECTION I  Principles of Practice

The emphasis on health care quality has been stimulated by the need to control costs.

The principles of quality assessment in health care have evolved from traditional retrospective review.

Newer methods to assess and improve the delivery of health care services involve prospective measurement of the processes of care to improve health outcomes.

The discovery of the extent of preventable medical error has led to an emphasis on improving patient safety.

Disclosure of medical error is now recommended by professional societies and mandated by accrediting agencies.

The need to maintain or increase the quality and safety of health care while controlling costs is stimulating a great deal of interest and activity in quality assessment and performance improvement. Several reports from the Institute of Medicine (IOM), on medical error (1) and on health care quality (2), have generated considerable public interest and concern about the overall quality of health care in the United States and the high estimated number of preventable deaths caused by medical errors. Although some of the conclusions of these reports have been questioned, the findings raise fundamental and disturbing questions about health care quality and safety in the United States.

Health Care Costs

The annual per capita expenditure for health care (in constant dollars) in the United States has risen steadily from about $950 in 1970 to more than $6,000 in 2004 (averaging about
12% increases per year). Although efforts in the 1990s to “manage” care and its costs were reasonably successful in slowing increases in annual health care premiums, they have recently been returning to double digits (Table 3.1). According to a Kaiser Foundation survey, the cost of health insurance increased by 59% during the 5-year period from 2000 to 2005, whereas workers wages increased by only 12%. Currently, annual United States per capita expenditure for health care delivery is estimated to exceed $6,500. The “political” failure and public distrust of 1990s-style managed care has resulted in predictions of its demise despite well-documented economic success (3). Before the mid-1990s, much of the increase in health care costs had been shifted from individuals to state and federal governments and to employers. More recently, however, employers have been setting limits on their contributions to health care benefits and shifting more of the increased costs to their employees. Some employers have even discontinued benefits. Currently, the United States spends more on health care (approaching 16% of gross domestic product) than on education and defense combined.

Despite this enormous outlay of resources, there is concern about the overall quality of health care (2,4). The health status of U.S. residents (in terms of life expectancy, neonatal mortality, and rates of illness and disability) is poorer than that of people living in most European and Scandinavian countries, the United Kingdom, Japan, and Canada, although these countries spend far less per capita on health care. Quality improvement programs in other industries have shown that management methods can both increase quality and reduce costs. Because of concerns about quality, cost, and safety, patients, as well as private and public third-party payers, are demanding ongoing quality assessment and performance improvement programs in health care delivery systems.

### Traditional Quality Assessment

Until recently, the medical profession has focused its efforts largely on assessing and improving the quality of health services through internal, self-imposed, retrospective peer review. Examples of such mechanisms are morbidity and mortality (M&M) review conferences, medical society-sponsored and state-legislated peer-review programs, surgical case reviews (tissue committees), and the specialty board-certification processes. These programs review adverse occurrences retrospectively (e.g., assessment of medical and surgical complications and review of misdiagnoses). Although useful as part of the peer-review process, these “quality assurance” or QA programs are not aimed at prevention of errors and are not designed to assess and improve the effectiveness of health care services and procedures (5).
The differences between traditional QA programs and newer performance improvement and quality management programs, such as continuous quality improvement (CQI) or total quality management (TQM), are presented in Figure 3.1. Quality Assessment programs are designed to identify and eliminate the small percentage of substandard care represented on the left side of the normal curve (the “bad apple” approach). Most “standard” care occurs in the middle of the curve, however, and is the focus of newer programs like CQI.

Such programs are designed to study prospectively the processes of care based on need and to improve outcomes by the reduction of unintended variation (6). The right side of the curve represents state-of-the-art practice usually performed under protocols at universities and other large centers of excellence that are monitored by institutional review boards and national research groups such as the National Cancer Institute and the Gynecologic Oncology Group. As more emphasis is placed on quality management programs in health care, innovations should come from both traditional research and performance improvement efforts.

Quality management programs such as CQI, TQM, and performance improvement each have three essential elements (7):

1. To understand customers (patients, payers, and other clients) and to link that knowledge to the activities of the organization

2. To mold the culture (beliefs and performance characteristics) of the organization through the deeds of leaders; to foster pride, enjoyment, collaboration, and scientific thinking
3. To increase knowledge (of how to improve performance) continuously and to control variation (unintended and wasteful differences in performance) by scientific methods

Health care professionals often do not like to refer to health care services as products and to patients as customers or consumers. The older, paternalistic attitude (i.e., patients passively agreeing to health care procedures that were determined largely by health care providers) is being replaced by a more egalitarian view of patients as intelligent and informed consumers who should participate in their care (8). The consumerism movement in health care is predicated on the belief that health care services should conform to acceptable standards of quality, efficiency, and safety (9). This newer attitude may lead to improved communication and shared decision making (between patient and provider) and should alter the wasteful practice of “defensive medicine,” which has been shown to increase health care costs significantly (10,11).

### Principles of Quality Assessment

**Quality means different things in different situations.** The concept of quality in products (e.g., consumer goods and state-of-the-art machinery) is different than that of complex services (e.g., health care delivery to people). However, many of the principles of quality assessment and improvement that have been shown to improve the quality of consumer goods and services can also be applied to the evaluation and improvement of health services. There are certain principles of quality assessment that should be considered when attempting to measure and improve health care quality.

### Efficacy, Effectiveness, and Efficiency

*Efficacy* and *effectiveness* are similar terms that are often used interchangeably to describe evaluations of outcomes of health care services and procedures. As defined by the IOM, *efficacy* refers to what an intervention or procedure can accomplish under ideal conditions and when applied to appropriate patients (12). *Effectiveness* refers to the actual performance in customary practice of an intervention or procedure. An example of this difference is the theoretical success rate (efficacy) of oral contraception used for 1 year (99% successful at preventing pregnancy) versus the actual or use-rate effectiveness, usually reported to be 93% to 97%. Most health care decisions have been based on efficacy rates obtained from controlled clinical trials rather than the actual effectiveness of such decisions. One of the major challenges for quality assessment and management programs is to develop and use measurements that reflect the actual, or real-life, success rates of treatment options so that evidence-based decision making can replace authority-based decision making. Also, strategies need to be developed to improve patient compliance rates to increase the likelihood that the actual effectiveness is as close as possible to theoretical efficacy (13).

*Efficiency* describes the relative “waste” or resource use (complications and costs) of alternative effective interventions. To realize meaningful improvements in health services, health professionals and organizations must develop more efficient interventions (e.g., medical therapy or expectant management versus surgical treatment for abnormal bleeding) when appropriate. The goal of health care quality improvement is optimal value.

*Value* is defined as quality divided by the cost, or as the quotient of outcomes (benefits) divided by resources used:

$$\text{Value} = \frac{\text{outcomes}}{\text{resource use}}.$$

### Optimal versus Maximal Care

The assessment of the quality of health care depends on whether the goal of the system is to provide maximally effective or optimally effective care (14). Figure 3.2 shows a theoretical representation of the difference between maximally effective health care (Point B),
in which every conceivable intervention is offered regardless of cost to those who can afford it, and optimally effective health care (Point A), in which resources are used in a manner that will provide the most good for as many people as possible. Maximized health care emphasizes individual intervention, whereas optimized care emphasizes public health care and prevention. When optimal health care becomes the goal of a health care system, conflicting individual and societal needs must be resolved.

Assessing Outcomes

A widely accepted system for assessing the quality of health care is based on the measurement of indicators of structure, process, and outcome (15). Structure includes the resources, equipment, and people who provide health care. Process is the method by which a procedure or course of action is executed. Outcome includes the complications, adverse events, and short-term results of interventions, as well as the patient’s health status and health-related quality of life after treatment, which reflects the effectiveness of the intervention.

Evaluation of health care structure involves the assessment of the stable and tangible resources needed to provide care, such as safe and adequately sized operating rooms and properly functioning equipment. Other examples of structural elements include the aspects of the medical staff’s qualifications, such as school accreditation, licensure, continuing

---

**Figure 3.2** The “optimal” versus the “maximal” benefits and costs of medical treatments. On the top panel, the benefits to health and the costs of care are plotted. On the bottom panel, the cost is subtracted from the benefits, illustrating that after a certain point, additions of care may detract from the benefits. (From Donabedian A. The quality of care: how can it be assessed. JAMA 1988;260:1743–1748, with permission.)
medical education credits, and specialty board certification. Although these elements form the foundation of a health care organization or system, there is a weak correlation between structural assessment and other measures of the quality of care, such as clinical outcomes (16). Therefore, many health-services researchers believe that organizations need to measure clinical outcomes directly (including not only death and short-term morbidity but also disability and health-related quality-of-life issues) if they hope to improve both the effectiveness and efficiency of health care delivery. Their research also emphasizes measurement of clinical or health outcomes that are defined as those that patients can experience and value without the interpretation of a health care provider. Examples of clinical or health outcomes and their corresponding intermediate or surrogate end points are presented in Table 3.2. Ultimately, longevity and quality-of-life factors may be the only relevant outcomes of health care.

Quality-of-Life Measurement

In the past, traditional quality-assessment programs have tended to focus on the assessment of short-term risks and the confirmation of pathologic diagnoses. This effort has usually been limited to quantification of mortality and major morbidity—such as infection, blood transfusion, and the need to re-operate—that occurred while the patient was hospitalized and was verified by tissue diagnosis. Most standardized lists of clinical QA indicators are from the medical model of outcomes assessment. Although the importance of these kinds of indicators seems obvious, these indicators may have little or no relevance to the more fundamental question of actual effectiveness of a procedure in terms of preserving or enhancing quality of life. For example, if a patient with pelvic pain undergoes a hysterectomy for leiomyomata, experiences no short-term complications, and has a diagnosis that is confirmed histologically, the procedure may be considered successful from the standpoint of surgical risk management, short-term outcome, and histologic verification. However, if the patient continues to experience pain and has no improvement in the quality of her life, the surgery has been, in reality, unsuccessful. Short-term risk indicators often have little or no bearing on whether the procedure actually works.

Behavioral Model of Health Outcomes

Efforts to measure the success or the effectiveness of health care procedures in the United States are based on the traditional medical model in which a patient is evaluated for a symptom, diagnosed as having a condition, and treated for that diagnosis. A procedure is usually considered successful if the diagnosis is confirmed.

Medicine has traditionally relied on short-term risk indicators and histologic confirmation because these measurements seem more objective and quantifiable. Death and infection rates, blood loss, and rates of histologic verification can all be measured and expressed numerically. Crucial to the application of a more predictive behavioral model in clinical outcomes research are several statistically valid and reliable methods to measure health-related quality of life. Many measures have been developed and validated, but few are used in clinical practice (17).

**Table 3.2 Clinical and Health Outcomes and Their Corresponding Intermediate or Surrogate Endpoints: Some Examples**
Using the behavioral model of effectiveness, the concept of quality-adjusted life-years (QALY) has been proposed to measure the benefit, in both quantity and quality of life, of a health care procedure (18). The number of QALYs is determined by combining the extra years of life that a procedure offers with a validated measure of eight categories of disability and four measures of distress. The use of this methodology allows standardized comparison of the cost of entirely different health care procedures. Despite its inadequacies, the medical model has been the standard, but now the behavioral model of outcomes is being incorporated increasingly into health care evaluation and research (19).

Scales of health-related quality-of-life issues, called the SF-36 and the SF-12 (short form 36 and short form 12) based on the health-status tool derived from the RAND Medical Outcomes Survey, have been developed (20).

Performance Improvement

Most methods for the assessment of the quality of health care and the delivery of health services have been based on the premise that quality is the sole responsibility of the health care practitioner. Because the practitioner’s technical skills, knowledge, and interpersonal interactions are the basis for quality of patient care and its delivery, many regulatory agencies (e.g., the Joint Commission on the Accreditation of Health Care Organizations [JCAHO]) and hospitals have created traditional QA models that focus mostly on the practitioner. However, many interacting forces determine quality of care, and the practitioner clearly does not deliver care in isolation. The delivery of health care requires the integration and management of many processes. The practitioner’s ability to deliver care is influenced by the environment, the ability and skill of support staff, policies and procedures, facilities, governing processes, methods of work, and equipment and materials available, as well as innumerable patient variables, such as severity of illness, concurrent illness (comorbidity), and social support. Historically, QA efforts attempted to monitor these processes to document bad outcomes. However, this approach has not proved to be adequate in improving the quality of care (21). Regulatory agencies and hospitals are now focusing on the overall performance of health care organizations in terms of clinical or health outcomes.

Performance improvements in health care have been based on knowledge that physicians and other health care professionals acquired in medical and other professional schools. Improvements have been brought about by clinicians applying knowledge developed by discipline-specific experts (22). The recent national emphasis on health care reform is an indication that the past rate of improvements is not sufficient to meet the financial needs and expectations of society. Performance improvements in efficiency must be made at a faster pace because consumers are seeking greater value for and access to health care services. A theoretical basis for organizational change that promotes continuous improvement includes knowledge of a system, knowledge of variation, and the theory of knowledge (23, 24).

Knowledge of a System

The first component of continuous performance improvement is knowledge of a system. A system is defined as a network of interdependent components that work together to accomplish its aim. A system does not exist without an aim and is capable only of improving if there is a connection between the aim, the means of production, and the means of improving. An open system is one that permits continued access from outside the system. Because health care organizations are accountable to patients and to the community as a whole, they are considered open systems. The aim of an organization involves the integration of the knowledge of the social needs and the needs of patients.
Knowledge of a system includes three components:

1. **Customer knowledge**, derived by identifying the organization’s customers and by understanding the measures they use to judge quality

2. **How the organization provides its services**, which involves knowledge of processes or steps taken to deliver the service

3. **How the organization improves**, which involves knowledge of the aim and identification of areas for improvement that are likely to have the greatest impact

Understanding the interrelationships between the aim, the customers, the primary areas for improvement, and the specific processes that can be improved is known as **systems thinking**. When a health care organization is focused on providing as many services as possible without consideration for the needs of the community and their customers, it will eventually fail to deliver quality services. **Proper perspective for customer needs and preferences gained through a process called strategic planning may even lead to a competitive advantage for a health care organization** (25).

### Knowledge of Variation

Another element of continuous improvement is **knowledge of variation**. Variation is present in every aspect of our lives. Variation is inherent to everyone’s behavior, learning styles, and ways of performing a task. Although the presence of variation, or uniqueness, can be considered a kind of quality, most services are judged on the basis of predictability and a low level of variation. When a service is thought to be of high quality, we expect it to be exactly the same each time, and if there is to be any variation, it must be an improvement.

To improve health products and services continually, it is necessary to know the customers, their needs, and how they judge the quality of health services. The processes by which health services are delivered must be understood and unintended variations reduced. If an organization is to improve and be innovative, it must plan changes that are based on knowledge of what can be better. Two types of variation found in production processes are those that occur by chance (common cause) and those due to assignable causes (special causes) (26). The ability to differentiate between these two types of variation is essential to making improvements in health care.

Clinicians regularly make decisions in their practices based on variation. For example, a physician making frequent rounds may note a change in a patient’s temperature and may decide to treat or to observe the patient based on the temperature change and on experience (i.e., judgment). If the temperature variation is seen as special cause (i.e., infection), a decision may be made to prescribe an antibiotic. However, if the change or variation is interpreted as common-cause variation in temperature due to short-term, normal changes or chance, it may be ignored. If this happens often, the physician may alter the frequency of observation, thereby making an improvement to the monitoring process. Frequently, however, common-cause variation is not recognized in health care, and the variation is acted on prematurely, resulting in the overuse of resources and a lower quality of care (7). If the approach is to measure and change, too many costly changes might be made.

**Learning how to respond appropriately to variation in health care processes is a major challenge.** Understanding and controlling variation in health care services should be the main emphasis of quality management. The notion of controlling variation, however, causes concern and skepticism in many health care professionals. Physicians who fear any effort to control variation are worried about the loss of options and about restrictions on their judgment. As Berwick points out (7), however, “The (problem) is not considered, intentional variation, but rather unintended or misinterpreted variation in the work of
Variation in Utilization

One of the earliest and most compelling influences on modern health care quality assessment in the United States was a series of investigations that demonstrated a wide variation in the use of health care procedures (27). Although previous investigations had documented a twofold to fourfold difference in the rates of selected procedures both within the United States and between the United States and other industrialized countries, these variations usually were disregarded as secondary to population differences. However, a small-area analysis documented similar or even greater magnitudes of variation within small (25 to 50 miles) geographic regions that could not be explained by differences in patient characteristics or appropriate differences in standards of care (28).

Variations in utilization have now been analyzed for virtually all major surgical procedures, including hysterectomy and cesarean delivery (29,30). Also, variation in the performance of medical procedures, such as those used in the management of acute myocardial infarction and sepsis, has been identified (31). On the basis of these analyses, significant variation has been documented in utilization and in important outcomes such as complications, cost, and derived benefit (32). This type of analysis does not usually allow accurate assessment of which rate of utilization or outcome is appropriate. However, it can help to focus attention on the quality of health services and the complexities of using statistically valid methods to measure health care quality.

Variation in utilization of health care services can be categorized as follows:

1. Necessary and intended variation because of well-recognized patient differences, such as severity of illness, comorbidity, and legitimate patient preferences
2. Acceptable but reducible variation because of uncertainty and lack of accurate information about outcomes
3. Unacceptable variation because of nonclinical factors, such as habitual differences in practice style, which are not grounded in knowledge or reason

Most of the differences in utilization rates of many health care procedures result from the last two categories.

Variation in Women’s Health Care

Overall, the rate of inpatient surgery for women age 15 to 44 years is more than 3 times that of males, excluding vaginal deliveries. The most commonly performed major surgical procedure in the United States is cesarean delivery, with about one million procedures (one quarter of all births) performed annually in the United States. Rates of cesarean delivery vary by region, state, and small geographic areas. Overall, the rate of cesarean deliveries is 12% to 40%, and the national mean is about 23%. Comparative rates for the United Kingdom are 6% to 12%.

Hysterectomy is also a common inpatient surgical procedure in the United States. The total annual incidence of hysterectomy for all ages, all indications, and all institutions (federal and nonfederal) in the United States exceeds 500,000. Hysterectomy rates in the southern and western United States are 50% to 75% higher than those in the Midwest and New England. A twofold to fivefold variation in utilization rates has been documented within states and small geographic areas within the United States (29). National rates in the United States are twice those in the United Kingdom and more than three times the rates in Sweden and Norway (33).
Hysterectomy utilization in the United States varies by both provider and patient characteristics. Studies of utilization patterns have demonstrated that older physicians are more likely than younger physicians to recommend hysterectomy and that (when controlled for age) sex does not appear to influence hysterectomy decision making (34). With respect to patient variables, although hysterectomy utilization is similar among African-American women and white women (35,36), low income and low educational level are risk factors for hysterectomy (37). By 65 years of age, the prevalence of hysterectomy is 40% for women with a high school education and 20% for women with a college education.

Short-term outcomes of hysterectomy vary significantly by race. African-American women have a substantially higher relative risk (RR) for morbidity and in-hospital mortality (RR = 3.1) compared with age- and condition-matched white women (38). The reasons for this variation are not known. Quality management techniques are being applied to research in an attempt to eliminate these wasteful variations.

The Theory of Knowledge

The final component of knowledge for improvement is the theory of knowledge. The theory of knowledge refers to the need for the application of a scientific method for improving performance. One model for testing small-scale change is called the Plan, Do, Study, Act (PDSA) method (24). Unlike the ideal scientific method recommended for clinical trials, the PDSA method does not include a control group. Although randomized controlled trials have been considered to be the best way to determine the value of health care interventions, they have two distinct disadvantages: they are expensive, and they tend to define the efficacy of an intervention such as a drug or a surgical procedure. Because efficacy is the way an intervention works under ideal conditions, compared with effectiveness, which is the way an intervention works in everyday practice, health services researchers now recognize that it may not be possible to generalize about an intervention’s effectiveness based on its efficacy as measured in a randomized trial. Also, it is too expensive to perform randomized trials in all situations in which the effectiveness of health care services needs to be improved.

This continuous improvement model has found application in health care performance improvement (24). The PDSA cycle has been further modified as FOCUS-PDCA: Find a process, Organize a team, Clarify the process, Understand the variation, and Select an improvement (FOCUS). In this model, the P represents the need to plan an improvement by first identifying a change that might lead to improvement and then testing the change on a small scale. During this phase, who will do what, when the change will occur, and how the change will be communicated to those who will be affected are detailed. The D stands for doing or implementing the plan (change to the process) and collecting the data. The C stands for checking the data to determine whether the change to the process represents an improvement, and the A stands for acting or incorporating the change into the process if it is found to be an improvement. A new cycle with another change is started if an improvement was not recognized.

Health care organizations are seeking efficient ways to optimize their delivery of health care and to improve services. The notion that high-quality health care automatically means high cost is no longer accepted without question. At a time when many businesses have transformed themselves by using newer methods of quality management, enabling them to deliver high-quality goods and services at reasonable costs, health care professionals and organizations are beginning to test these improvement methods in medical and surgical practice.

Newer Methods for Improving Performance

Health services researchers and clinicians are beginning to develop and validate newer methods for the measurement and improvement of health care quality. For example, there is a need to make valid comparisons of quality between divergent populations and to
correlate clinical performance with measurable processes of care. The goal of a new branch of investigation called clinical evaluative or outcomes sciences is to obtain valid measures of relevant outcomes that are correlated with measurable processes of care so that changes in process can be identified and initiated, thereby improving outcomes. This discipline incorporates methodologies from divergent areas such as epidemiology, clinical research, management, engineering, economics, and behavioral sciences.

Statistical adjustments are used to allow clinically dissimilar populations, such as high-risk and low-risk patients and those with complicated and uncomplicated conditions, to be compared. This procedure is called case-mix adjustment and controls for severity of illness and comorbidity (39,40). Outcomes that are assessed include traditional (medical model) measures, such as complications and adverse occurrences, as well as newer, well-validated measures of satisfaction, health, and functional status.

Concurrently, the processes of care are assessed. This assessment includes measurement of resources used during an episode of care (e.g., supplies, medications, specialized personnel) and practice parameters (e.g., physician orders and nursing practices).

Measurement of the processes and outcomes of health care can be prohibitively expensive if this measurement is not integrated into the daily clinical care. For this reason, another goal of clinical quality outcomes research is to develop and incorporate methods of quality assessment into routine practice. This mechanism could be accomplished, for example, by using the SF-36 as a standard nursing intake form at the time of admission.

Analytic methods in clinical outcomes science rely heavily on multivariate statistics and iterative outcomes databases to provide valid correlations between measurable (and changeable) processes and outcomes. However, the mere identification of process changes that would improve outcomes does not ensure that they will, in fact, be used. For this reason, process and outcomes data must be linked to methods that will allow this information to be incorporated into clinical and operational decision making if they are to change behavior and improve outcomes. These analyses must be readily available both geographically and temporally at the point of care (the place and time that the decision is made) if they are to improve outcomes.

One approach to QA, performance improvement, and medical decision making that has been recommended (the PREPARED system) uses a checklist to analyze the value of a health care procedure before it is performed (9,41). The purpose is to review sequentially the critical data categories of information, each represented by a letter in the word PREPARED, that should be used to determine the most appropriate course of action or choice (42):

- **Procedure**: the course of action being considered
- **Reason**: the indication or rationale
- **Expectation**: the chances of benefit and failure
- **Preferences**: patient-centered priorities (utilities) affecting choice
- **Alternatives**: other reasonable options
- **Risks**: the potential for harm from procedures
- **Expenses**: all direct and indirect costs
- **Decision**: fully informed collaborative choice

Standardized procedural analysis using this sequenced checklist has been shown to improve health care decision making by increasing patient satisfaction and self-efficacy, thereby facilitating patient choice. It has the potential to improve the assessment of the quality and appropriateness of both provider and patient decision making.
Outcomes Research and Evidence-Based Clinical Guidelines

In the past, clinical practice guidelines or parameters have been largely derived by expert opinion and consensus. A major goal of clinical outcomes science is to allow for the development of guidelines based on actual measured outcomes that could self-adjust based on performance and newer methods of diagnosis and treatment. **One such process for incorporating outcomes data into clinical practice is the critical pathway–case management method** (43). In this method, consensus practice parameters for a given condition (e.g., management of preterm labor) are initially developed by a multidisciplinary team consisting of all professional, allied, and support services involved in the care of the target population. **This list of parameters is called a critical path or clinical map.** The critical path details all laboratory, dietary, consultative, medical, teaching, and nursing activities that are thought to be necessary to obtain specific clinical outcomes. Outcomes of care, as well as variations from the “path,” are monitored and collected continuously.

Positive and negative outcomes are analyzed and correlated with variances from the critical pathway. These data are then returned to the multidisciplinary team, which recommends changes in the entire path based on the outcomes and variance analyses.

In one pilot study of a critical pathway method for cesarean delivery, length of stay and cost were reduced by 13% and 14%, respectively. Additionally, five of seven measurements of satisfaction, including quality of care, were improved, and health status was unchanged (43). A relatively new federal government agency, the Agency for Healthcare Research and Quality (AHRQ), formerly known as the Agency for Health Care Policy and Research (AHCPR), is responsible for funding developmental efforts, collecting information about clinical care guidelines, and disseminating information. AHRQ has provided a comprehensive repository of available evidence-based clinical guidelines through an outstanding searchable Web site (www.guidelines.gov).

Patient Safety and Medical Error

The term “patient safety” was first used by the American Society of Anesthesiologists in 1984 to refer to the avoidance of medical error. Patient safety has been identified by the IOM as one of the most important dimensions of health care QA and performance improvement. **According to a recent report from the IOM, it is estimated that between 44,000 and 98,000 preventable deaths may be due to medical error** (1). Although there continues to be controversy about the validity of methods used in these analyses, critics admit that even if the actual number of preventable deaths from error is much smaller than estimated, efforts should be made to eliminate as many as possible.

Patient safety has its roots in traditional risk management (RM) but there are important conceptual differences between the two (Fig. 3.3). **Risk management is retrospective and is focused on individual outliers. It is also outcomes oriented and addresses significant adverse (sentinel) events.** The goals of RM include sanctions for substandard providers with far less attention to finding systems-oriented improvements that could prevent recurrent medical errors. Patient safety initiatives are prospective, interdisciplinary, and focused on health care process in addition to outcomes. They are designed to be nonpunitive and to recognize that most adverse outcomes result from systems deficiencies and not individual error. Therefore, system changes in the overall process of delivery of care are necessary to prevent future problems. For example, when the wrong extremity is removed during a therapeutic amputation, RM efforts usually focus on legal liability issues, holding surgeons and operating room personnel accountable. Ideally, a patient safety initiative would study the entire process of care using a root-cause analysis approach (Fig. 3.4). All of the members of the health care team, from admission to discharge, would be involved to identify and implement preventive measures. This “going beyond blame” approach was a significant recommendation in the IOM report, and it is the approach that is commonly used in other industries, such as aviation safety (1). Process changes and improvements include such practices as having the
Patient and surgeon sign the correct extremity using indelible ink at the time of admission and sharing the responsibility during the process so that several individuals (operating room personnel, anesthesia personnel, and members of the surgical team) would verify that the correct extremity is prepared and eventually removed. This team accountability approach is now being applied in all specialties, including obstetrics and gynecology.

JCAHO has been active and influential in the evolution of patient safety activities. Starting with an initial requirement that all significant (sentinel) events be reported, it now requires that root-cause analyses be used to investigate incidents, identify contributing factors, and improve the process of care (44). Starting with all JCAHO surveys performed after June 2001, the Joint Commission requires documented evidence that a healthcare organization being reviewed has invested in a “top-down” commitment to patient safety improvement.

Figure 3.3  A conceptual evolution of the characteristics of risk management (RM), quality assurance (QA), continuous quality improvement (CQI), and patient safety.

Figure 3.4  Root-cause(s) analysis: getting to the single or multiple causes of adverse outcomes.
Business and government are also interested in promoting patient safety activities. A business committee called the Leapfrog Group, representing the National Business Roundtable and corporations such as General Electric, General Motors, and Verizon, have announced that they will give purchasing preference to health care organizations that have at least the following three patient safety programs that have been shown to improve performance: (a) 24-hour, 7-days-per-week in-house coverage by intensive-care specialists; (b) computerized physician-order (CPOE) systems; and (c) referral to “centers of excellence” with documented best outcomes for high-risk procedures, such as cardiovascular and transplant surgeries. Properly designed computer systems, such as CPOE, can improve physician workflow and decrease serious medical errors by more than 50% and reduce adverse drug events by nearly 85%.

Leaders in health care assessment and performance improvement have recommended five principles to help make health systems safer:

1. Leadership in the organization should commit to patient safety to provide the necessary personnel and financial resources.

2. System design should recognize human limitations. The noted health care improvement researcher, David Eddy, has stated that “the complexity of modern medicine exceeds the limitations of the unaided human mind.” The one-person (“captain-of-the-ship”) accountability of the past may actually lead to more errors in the current health care system.

3. Working and training in teams can help deliver safer care and more dependable accountability.

4. Training should emphasize the need to anticipate the unexpected.

5. The organization should foster a learning environment for continual improvement of patient safety.

Disclosure and Reporting of Medical Error

The official position of the National Patient Safety Foundation (NPSF) concerning the disclosure of medical errors when health care injury occurs is that the patient and the family or representative are entitled to a prompt explanation of how the injury occurred and its short- and long-term consequences. Patients should be informed that the factors involved in the injury will be investigated so that steps may be taken to reduce the likelihood of similar injury to other patients (www.NPSF.org). During the process of informing patients and their families about medical error, it is very important to listen to how they feel about what has happened, explain the events further when asked, and to empathize with the feelings that are expressed (45). Recent evidence suggests that proper disclosure of unintentional medical error may actually decrease lawsuits (46).

There is a growing consensus that there will need to be a nonpunitive reporting system to identify not only medical errors but also “near misses” and other hazards so that they may be corrected before the patient is harmed. The aviation industry is a prime example of how measures can be taken to improve safety. Operations are simplified and standardized. Crew resource management empowers the most appropriate individual to correct a problem, even if that person is not the pilot. Simulators and team training are widely employed. The industry has a system, the airline safety reporting system, for reporting actual incidents and near misses. Furthermore, this system is confidential and
CHAPTER 3 Quality Assessment, Performance Improvement, and Patient Safety

separated from the Federal Aviation Agency (their main regulatory body) by the National Aviation and Space Agency.

AHRQ has stated that recognition and reporting of medical errors is an important component of quality assessment to improve patient safety. Currently AHRQ publishes case studies of medical error (including ob-gyn examples) on the World Wide Web at www.webmm.ahrq.gov.

Summary

Quality assessment and performance improvement activities are becoming increasingly important components of health care delivery. Although retrospective peer review and other QA efforts are still necessary, newer, prospectively focused methods to improve performance are being introduced. In the past, managing the cost of health care has been a major rationale for quality assessment and performance improvement programs. Recently, however, concerns about patient safety and deficiencies in quality have been prompted by several IOM reports (1,2). The complexity of modern health care delivery now requires a multidisciplinary team approach to quality management and error reduction. To improve health care quality and safety significantly, health care professionals need to move away from an atmosphere of blame and individual accountability to a more effective systems approach. This process should include appropriate disclosure and analysis of medical error that is focused on measurable performance improvement.

Epidemiology for the Gynecologist

Daniel W. Cramer
Karen Loeb Lifford

• Epidemiology is the study of the occurrence of health events in human populations.

• Incidence is the rate of occurrence of new cases over a specified time, whereas prevalence is the existing number of cases at a point in time.

• Epidemiologic studies can be descriptive, including case series and cross-sectional studies, or analytic, including cohort studies, case-control studies, and clinical trials. Analytic studies provide a higher level of evidence because they test a hypothesis about and measure an association between exposure and outcome.

• Cohort studies measure the occurrence of a particular outcome among those who did or did not have a particular exposure (or treatment). Attributable risk is the difference between the occurrence measure in exposed versus unexposed, whereas the relative risk is the ratio between the two.

• A case-control study assesses exposures among individuals with or without a particular disease or outcome of interest. The measure of the association is the exposure odds ratio, which approximates the relative risk.

• Judging the scientific validity of an epidemiologic study requires addressing whether chance, bias, or confounding could have accounted for the findings.

• Misclassification, as may occur from differential recall of the exposure, and selection bias may especially affect case-control studies, whereas confounding can occur in all types of analytic studies.

• A clinical trial is a prospective cohort study to evaluate treatment for disease in humans with the key feature of randomization of the treatment assignment to minimize bias and confounding.

• Dose response, consistency, and biologic credibility are three factors often used in judging whether an association between exposure and outcome represents cause and effect.
• A meta-analysis is a formal method for assessing consistency and pooling results from several independent studies examining the same exposure (or treatment) and outcome and is a key tool of evidence-based medicine.

• Reproductive epidemiology may include the domain of studies that address how reproductive events may affect common diseases in women and how common exposures may affect reproductive diseases.

Epidemiology is the study of the occurrence of health events in human populations. Studies typically thought of as epidemiologic in nature are those investigating how disease or death rates vary by age or nationality or how risk for a disease changes after a specific exposure. Epidemiologic concepts are much broader, however, and enter into the interpretation of almost all studies performed in humans. To critically read the gynecologic literature and practice evidence-based medicine today, physicians must have an increasingly sophisticated knowledge of epidemiologic concepts. In this context, it is important to be aware of the types of epidemiologic studies, their strengths and limits, and criteria for judging their validity. An understanding of the impact of common exposures on gynecologic diseases as well as the impact of gynecologic conditions on common diseases provides perspective on the scope of epidemiology in gynecology. Readers are urged to consult other resources for additional information, especially regarding some of the methodological aspects (1–8).

Gynecologic diseases have always been a major focus for epidemiologic research. Involvement of gynecologists in the design and interpretation of such studies can help ensure that the physiologic and clinical relevance of various associations are adequately discussed. Even if the gynecologist does not actually perform epidemiologic research, an understanding of epidemiologic principles allows for a more critical reading of the medical literature and sharpens the practice of preventive medicine in gynecology.

Study Designs

Epidemiologic studies may be broadly categorized as either descriptive, examining the distribution and frequency of disease, or analytic, examining the relationship between exposure and disease. The methodology of a study can affect the strength of the evidence it provides. Thus the U.S. Preventive Task Force created a framework by which the quality of evidence can be assessed (Table 4.1) (7).

Descriptive Studies

The two principal types of descriptive studies are case series and cross-sectional studies.

Case Reports or Series

Design

In a case report or case series, the characteristics of individuals who have a particular disease are described. Through the description of individual cases, hypotheses

</table>
about exposures and disease are developed that can then be further explored in analytic studies. For example, a link between oral contraceptives and thromboembolism was first suggested by case reports (2,3) and later confirmed in a case-control study (4). Occasionally, when case series describe the co-occurrence of rare exposures and rare diseases, they are compelling enough on their own to suggest a cause-and-effect relationship. Links between thalidomide and fetal limb reduction (5), the Dalkon shield intrauterine device and septic abortion (6), and sequential oral contraceptives and premenopausal endometrial cancer (8) emerged through case series that were persuasive enough to initiate public health action without the performance of formal epidemiologic studies. In general, however, just because members of a case series share a particular characteristic, one cannot assume that there is a cause-and-effect relationship. The quality of the information provided by a case report or series is evaluated by scrutinizing the details of the case selection. Investigators should strive to be sure that clear criteria exist for the definition of disease or study variables and that identification of cases was complete.

**Incident cases, which are new cases identified after the study’s start, are more likely to provide accurate information about factors related to the development of the condition under study.** When case series extend over a long period, changes in the diagnosis or treatment of the condition may confuse objectives. The quality of the information (record-based or personal contact with the patient) and interobserver or reviewer reliability also needs to be assessed. Because a case series has no comparison group, statistical tests of association between the exposure and illness cannot be performed. However, careful assembly of a case series is the first step in performing a case-control study, which is the logical extension of a case series.

**Yield**

A case series does not usually yield any formal epidemiologic measures other than estimates of the frequency, or prevalence, of a particular characteristic among members of the case series. This is often referred to as the incidence of a particular characteristic among cases, but prevalence is usually the more appropriate term.

**Cross-Sectional Studies**

**Design**

Cross-sectional studies are larger in scope than case series and generally do not focus on a particular disease. Individuals are surveyed to provide a “snapshot” of health events in the population at a particular time. The U.S. Census Bureau counts the population by categories of age, sex, and ethnicity. The U.S. National Center for Health Statistics compiles a wide variety of data on the health of the population, such as occurrence of hospitalization for various conditions. State health departments are required to count the number of births and deaths annually in their population, and some maintain registries to count the number of individuals who have cancer.

**Yield**

*Incidence* is the rate of occurrence of new cases of diseases or conditions over a specific time. Cross-sectional studies often yield incidence rates in which births, new disease cases, or deaths are counted annually for a specified census region and divided by the population size to yield events per population per year. The rate is usually multiplied by a base (1,000, 10,000, or 100,000) to give numbers that can more easily be tabulated. Incidence is an important concept in epidemiology and is often used to calculate other measures of disease frequency, such as prevalence and lifetime risk.
**SECTION I  Principles of Practice**

**Age-specific incidence** refers to the number of new events occurring in 5- or 10-year age groups per year. Because of marked differences by age for most illnesses, age-specific incidence rates are the best way to describe event occurrence in a population. If the incidence rate is not specified with regard to age, it is described as “crude” or unadjusted.

**Prevalence** is the existing number of cases at a specific point in time. Prevalence is another measure frequently developed from cross-sectional studies. For example, in 1988, the Family Growth Survey Branch of the National Center for Health Statistics interviewed a sample of married couples and found the prevalence of infertility among married women younger than 45 years of age in the United States to be about 8.0% (9). The National Health and Nutrition Examination Survey (NHANES) is a series of population-based surveys designed to collect information on the health and nutrition of the U.S. population. From this study we have learned that the seroprevalence of herpes simplex virus-2 in the United States is increasing, from 16.7% in NHANES-II (midpoint 1978) to 21.7% in NHANES-III (midpoint 1991) (10). Because prevalence measures disease status in a population rather than events occurring over time, prevalence is a proportion, not a rate.

Although cross-sectional studies are primarily descriptive, they may contribute information on the cause of a disease by showing how that disease varies by age, sex, race, or geography. In ecologic studies, disease rates in various populations are correlated with other population characteristics (e.g., endometrial cancer rates worldwide are positively correlated with per capita fat consumption and negatively correlated with cereal and grain consumption) (11). Such observations are valuable in suggesting topics for analytic studies or supporting the consistency of an association.

**Analytic Studies**

The purpose of an analytic epidemiologic study is to test a hypothesis about and to measure an association between exposure (or treatment) and disease occurrence (or prevention) (Fig. 4.1). Analytic studies may be subdivided into experimental studies and nonexperimental, or observational, studies.

In experimental studies, such as clinical trials, the investigator assigns exposure; thus these studies cannot involve exposures known, or strongly suspected, to be harmful. The goal of an experimental study is to confirm that the observed outcome is due to the assigned exposure. Thus features these studies should include are randomization (in which participants are randomly assigned to exposures), measures to ensure unbiased assessment of outcome, and analysis of all participants based on assigned exposure (an “intention to treat” analysis). Many exposures may not be amenable to an experimental design, either because the exposure is rare or suspected to have harmful effects. Observational analytic studies include cohort and case-control studies and take advantage of “natural experiments” in which exposure is not assigned by the investigator; rather, individuals do or do not have a particular disease and have or have not had an exposure of potential interest.

**Observational Studies**

**Cohort Studies**

**Design** A cohort is a group of people who have some factor in common. In the context of a survival analysis, the cohort begins with a population that is 100% well (or alive) at a particular time and is followed over time to calculate the percentage of the
cohort still well (or alive) at later times. Survival analysis describes mortality after disease (i.e., cancer patients who died within 5 years) but can be adapted to other events (e.g., the percentage of women who continue to menstruate after 50 years of age or the percentage of infertile women who conceive after therapy).

Other types of cohorts are defined by subsets of a population who are, have been, or may in the future be exposed to factors hypothesized to influence the occurrence of a given disease. The exposed and nonexposed subjects are observed long enough to generate person-years as the denominator for incidence or mortality rates in exposed and nonexposed subsets (Fig. 4.2).

Cohort studies are also called follow-up or longitudinal studies. Cohort studies may be prospective, meaning that the exposure is identified before outcome, or retrospective, in which the exposure and outcome have already occurred when the study is begun. For example, studies of radiation and subsequent cancer are often based on records of patients who received radiation therapy many years previously. Medical records and death certificates are used to determine whether a second cancer occurred after the radiation therapy.

Cohort studies may yield two measures of an association between exposure and illness. These measures are attributable risk and relative risk.

- **Attributable risk** is the difference between the occurrence measure in the exposed and the unexposed cohort. The null value is zero, indicating no association between exposure and disease; a positive number indicates how many cases
SECTION I  Principles of Practice

- Relative risk divides occurrence in the exposed cohort by occurrence in the nonexposed cohort. The null value for the relative risk is 1. A value greater than 1 indicates that exposure may increase risk for the disease (i.e., a relative risk of 1.5 indicates that exposed individuals had 1.5 times, or 50% greater, the risk for disease as unexposed individuals). A value less than 1 indicates that exposure may decrease risk for disease (i.e., a relative risk of 0.5 indicates that the rate in exposed individuals was half that of the rate in the nonexposed individuals).

Strengths and Weaknesses  The ability to obtain both attributable and relative risks is a strength of cohort studies. In addition, cohort studies are less susceptible to selection and recall bias. Misclassification of exposure and confounding variables can occur, however. Disadvantages of a cohort study generally include higher cost and longer time for completion. Cohort studies are most useful for examining the occurrence of common diseases after a rare exposure. For rare exposures, an investigator may use the general population as the unexposed group. In this type of study, the observed number of cases in the exposed cohort is divided by the number of cases expected if general population rates had prevailed in the exposed cohort. This comparison is called the standardized morbidity or mortality ratio (SMR) and is equivalent to relative risk.
CHAPTER 4 Epidemiology for the Gynecologist

Case-Control Studies

Design A case-control study starts with the identification of individuals with a disease or outcome of interest and a suitable control population without the disease or outcome of interest. The controls must be a representative sample of the population from which the cases arose. The relationship of a particular attribute or exposure to the disease is studied by comparing how the cases and controls differed in that exposure. Because the history of exposure before disease is assessed after the disease has occurred, case-control studies are often described as retrospective.

Yield The yield of a case-control study is the exposure odds ratio (or simply odds ratio). It is the ratio of exposed cases to unexposed cases divided by the ratio of exposed to unexposed controls (Fig. 4.3). If an entire population could be characterized by its exposure and disease status, the exposure odds ratio would be identical to the relative risk obtainable from a cohort study of the same population. Although it is not feasible to survey the entire population, as long as the sampling of cases or controls from the population was not influenced by their exposure status, the exposure odds ratio will approximate the relative risk. Attributable risk is not directly obtainable in a case-control study. Thus, case-control studies provide only relative measures of risk; they do not give us information about the absolute impact of the exposure.

Strengths and Weaknesses The advantages of case-control studies are that they are generally lower in cost and easier to conduct than other analytic studies. Case-control studies are most feasible for examining the association between a relatively common exposure and a relatively rare disease. Disadvantages include greater potential for selection bias, information bias, and confounding variables.

Experimental Studies Because an investigator must assign exposures according to a strict protocol, human experimental studies are limited to the study of measures that will prevent disease or the consequences of disease. Examples of experimental studies are clinical trials and field and community intervention trials.

To improve the availability of information from clinical trials of treatment for serious or life-threatening diseases and conditions, federal law now requires that pharmaceutical companies make this information accessible to patients and members of the public (12).
As a result of this legislation, the Clinical Trials Data Bank became available to the public in February 2000 on the Internet at http://clinicaltrials.gov (13).

**Clinical Trials**

The clinical trial is a prospective cohort study to evaluate treatments for disease in humans. Randomization of the treatment assignment is the cornerstone of a good clinical trial because it minimizes bias, which can result from confounding variables or preferential assignment of treatment based on patient characteristics. Evidence must be provided that factors that might influence outcome, such as stage of disease, were similar in patients assigned to the study protocol compared with patients assigned to placebo or traditional treatment. A published report of a clinical trial should include a table showing a comparison of the treatment groups with respect to potential confounders to demonstrate the groups did not differ in any important ways before the experimental intervention. Criteria for successful treatment must be clearly defined. Blinding the subject and clinician to the treatment modality may help ensure unbiased assessment of the outcome. A properly designed clinical trial will have a sufficient number of subjects enrolled to ensure that a “negative” study is powerful enough to rule out a treatment effect.

**Yield**

Clinical trials provide information about both relative and absolute risks. In addition to considering statistical significance, the reader must assess the size of the effect and whether it has clinical significance. Confidence intervals provide information about both the size and significance, and thus provide more information than p values alone. An additional consideration when interpreting study results is that absolute changes in risk are more relevant to patient care than relative changes in risk. The number needed to treat (NNT), provides a measure of the absolute risk. It is the average number of patients that a doctor would need to treat to have one additional event occur.

**Field and Community Intervention Trials**

Field and community intervention trials evaluate population measures that may prevent disease, such as vaccines, dietary interventions, or screening procedures. In a field trial, the intervention is applied to individuals. In a community intervention trial, the intervention (e.g., water fluoridation) is applied on a communitywide basis rather than to individuals. Both types of studies include subjects who do not yet have disease and may require large numbers of participants, especially for studies of screening procedures to prevent cancer. In the latter context, issues related to the validity of screening tests (i.e., sensitivity, specificity, and predictive value) are quite important (Table 4.2).

---

**Understanding the Results of Analytic Studies**

To judge the scientific validity of the results of an analytic study, one needs to consider other possible explanations for the reported association, including chance, bias (a systematic error in the way the study was conducted), and confounding.

**Chance**

*Statistical inference* is the application of statistical methods to quantify how likely it is that the study result is due to chance and to give the reader some idea of the range in which the “true” statistical measure calculated (e.g., mean, proportion, and relative risk) is expected to occur.

- **Statistical significance** is determined by application of a statistical method to test the null hypothesis (i.e., the hypothesis that two or more factors are not associated). The degree of conflict between the test result and the result predicted by the null hypothesis is indicated by the *p value*. Typically, *p* ≤ 0.05 is used to determine statistical significance and indicates a 5% chance of incorrectly rejecting the null hypothesis.
The confidence interval (CI) is a component of statistical inference in which an interval is provided to give the reader some idea of the range in which the true statistical measure (e.g., mean, proportion, and relative risk) is expected to occur. A 95% CI implies that if a study were to be repeated many times within the same population, the measures assessed would be expected to fall in this interval 95% of the time. Confidence intervals of 95% for an odds ratio or relative risk that includes the null value of 1 would not be statistically significant.

Bias

Bias is a systematic error in the design, conduct, or analysis of a study. Such errors result in a mistaken conclusion and can take various forms. It is important for the investigator to anticipate the types of bias that might occur in a study and correct them during the design of the study, because it may be difficult or impossible to correct for them in the analysis.

- **Information bias** occurs when subjects are classified incorrectly with respect to exposure or disease. This may occur if records are incomplete or if the criteria for exposure or outcome were poorly defined, leading to misclassification.

- **Recall bias** is a specific type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures. For example, in a study of antenatal medication exposure and birth defects, a mother with an infant born with a birth defect may be more likely to report exposures than a woman with a healthy infant. In addition to adequate criteria and complete records, information bias may be reduced by making interviewers unaware of the status of the subjects or the purpose of the study whenever possible.

- **Selection bias** may occur when correlates of the exposure or outcome influence sampling from the larger population of potentially eligible subjects. An example of selection bias that may arise in a hospital-based case-control study occurs when the combination of the disease under study and a particular exposure is more likely to lead to hospital admission (14). Using incident cases from more than one hospital, obtaining high participation rates, and attempting to describe
nonparticipants are several ways to reduce or at least evaluate the potential for selection bias.

**Confounding**

- A **confounder** is an extraneous variable that accounts for the apparent effect of the study variable or masks the true association.
- When a factor differs between cases and controls or cohort members and is associated with both the study exposure and the study outcome, a distortion of the true association between the exposure and the disease may be produced.

Age, race, and socioeconomic status are likely confounders; results must be adjusted for these variables by using statistical techniques such as stratification or multivariate analysis. Stratification involves examining the association of interest only within groups that are similar with respect to a potential confounder. Multivariate analysis is a statistical technique commonly used in epidemiologic studies that controls a number of confounders simultaneously. After an analysis to control for confounding variables, the investigator presents the adjusted odds ratio or relative risk that presumably reflects an association free of confounding.

### Assessing Causality

In addition to an unbiased design, there are a number of factors that, when present, strengthen the likelihood that the factors being studied are causally related rather than just associated.

- **Dose response** means that a change in the amount, intensity, or duration of an exposure is associated with either a consistent increase or decrease in risk for a specified disease or outcome. Trend tests are used to determine whether a dose response exists.
- **Consistency** between findings in different populations, at different times, and by different methods or investigators is an important criterion used to judge whether there is likely to be a causal relationship. A formal method for studying consistency and pooling results from different studies is meta-analysis. **Meta-analysis** is the process of combining results from several independent studies examining the same exposure (or treatment) and same outcome to conduct a more powerful test of the null hypothesis. A meta-analysis is conducted by assembling measures of the association from different studies, such as relative risks, weighting them by the variance of the measure, and taking an overall average. In the weighting process, the studies with the largest sample size contribute the greatest information. A properly performed meta-analysis also has a qualitative component that establishes criteria for acceptance of a study (e.g., only randomized studies might be chosen for a meta-analysis of the effect of a particular treatment on a particular disease).
- **Biologic credibility** means that an association is plausible, taking into consideration all aspects of what is known about the natural history or demographics of a disease or what has been observed in relevant experimental models. Whereas an imaginative epidemiologist can find an explanation for any single association, a key issue is whether a model can be proposed accounting for a variety of exposures as well as experimental data and cross-sectional observations.

### Reproductive Epidemiology

Although there is no standard definition of what constitutes “reproductive epidemiology,” theoretically it could include the domain of epidemiologic studies addressing reproductive (or gynecologic) events that affect common diseases in women and common exposures that affect reproductive or gynecologic diseases.
Reproductive Events

Age at menarche, characteristics of menstrual cycles, number of pregnancies, contraceptives or hormones used, and age at menopause are important events that may have broad impact on many diseases, including endometriosis (15), fibroids (16), heart disease (17), osteoporosis (18), and cancers of the breast, endometrium, or ovary (19–21). Gynecologists should maintain careful records of reproductive landmarks, both for their potential usefulness in advising patients and for their relevance to clinical research.

Contraception and Sterilization

Barrier Contraception

Barrier contraception includes spermicides, vaginal barriers (cervical caps, diaphragms, and female condoms), and male condoms. In general, a protective effect of barrier contraception against pelvic inflammatory disease (PID) (22), tubal infertility (23), ectopic pregnancy (24), and cervical cancer (25) has been consistently observed. However, spermicides appear not to protect against HIV transmission (26), and use of synthetic condoms is recommended. Women using the diaphragm are at an increased risk of symptomatic urinary tract infection (27).

Intrauterine Devices

Current or past use of an intrauterine device has been linked with risk for PID (28), ectopic pregnancy (29), and tubal infertility (30). It is likely that these risks could be reduced by restricting IUD use to women at low risk for genital infections (e.g., women in mutually monogamous relationships). In addition to providing effective long-term contraception, the IUD has been shown to have noncontraceptive benefits. A recent comprehensive review of the association between copper-bearing IUDs and risk of and endometrial cancer provides good evidence for this protective effect, with the risk in IUD users reduced by approximately 50% (31). There is some evidence that IUD use may also reduce the risk for ovarian cancer, perhaps through an immune-mediated mechanism that might also pertain to the association with endometrial cancer. Levonorgestrel-containing IUDs have been shown to be effective for the treatment of idiopathic menorrhagia (32).

Oral Contraceptives

Early epidemiologic research on oral contraceptives (OCs) focused on adverse events, including thromboembolism (particularly with high-dose formulations) (33), hypertension (34), myocardial infarction (especially in women older than 40 years of age who also smoked) (35), and liver adenomas (36). Protective effects of OCs have more recently been appreciated, including lower risk for benign breast disease (37), ovarian cysts (38), ovarian cancer (39), and PID (40). Controversy exists concerning the relationship between OC use and cervical and breast cancer. The results of a large observational study suggested that women who were currently taking oral contraceptives and as well as those who had stopped within 10 years had a small but significant increase in the risk of breast cancer that declined with time since last use (41). The possible increased risk of developing breast cancer at an early age associated with past OC use may be more than offset by a decreased risk for developing breast cancer at an older age (42). There is a modest but fairly consistent association between OC use and cervical cancer (43) that may relate to an interaction with human papillomavirus (HPV) infection (44).

Long-Acting Progestin Contraceptives

Long-term use of depot medroxyprogesterone acetate (DMPA), a progestin hormonal contraceptive, can result in significant bone loss, which may not be entirely reversible (45,46). Although FDA labeling recommends the use of DMPA for more than 2 years only
under circumstances when other methods are inadequate (47); the World Health Organization Statement on Hormonal Contraception and Bone Health recommends no restriction on duration of use among women aged 18–45 years old, given the insufficient data on DMPA use and risk of fracture in menopause (48).

**Sterilization**

Concerns that sterilization might induce early menopause (49) have not been proved. An unexpected effect of female sterilization may be protection from ovarian cancer (50). This protection may derive from interruption of the utero-ovarian circulation or from closure of the female tract, which would prevent substances in the vagina or uterus from reaching the ovaries. Alternatively, it has been speculated that tubal ligation may predispose women to the formation of antibodies that protect against the development of ovarian cancer (51).

**Hormone Replacement Therapy**

Early studies of menopausal hormones identified increased risk of endometrial cancer associated with unopposed estrogen use (52). This association has likely been obviated by the use of combined estrogen–progesterone regimens (53). Although observational studies suggested protective effects on heart disease (54), osteoporosis (55), and even Alzheimer’s disease (56), recent clinical trials have questioned some of these benefits. The Heart and Estrogen/progestin Replacement Study (HERS), a randomized controlled trial of hormone therapy (HT) in more than 2,700 women with documented coronary heart disease, found no benefit of HT for secondary prevention of coronary heart disease (CHD) (57,58). The Women’s Health Initiative (WHI) is a national study that included a randomized controlled trial of HT for prevention of disease in postmenopausal women. In the combined estrogen–progestin portion of the study, which included approximately 16,000 women without preexisting CHD, a 29% increased risk of primary CHD events (95% CI 1.02–1.63) was found (59). Although benefits were seen for the prevention of colon cancer (Hazard Ratio [HR] = 0.63; 95% CI 0.43–0.92) and hip fracture (HR = 0.66; 95% CI 0.45–0.98), the risk of breast cancer was increased (HR = 1.26; 95% CI 1.00–1.59) and total morality in the HT group was higher (HR = 1.15; 95% CI 1.05–1.28). Thus, HT is recommended only for the treatment of menopausal symptoms, not for the primary prevention of other diseases (60) (see Chapter 32).

The reason for the discrepancy between the randomized controlled trials of estrogen for primary and secondary disease prevention and the observational studies has been the subject of discussion among epidemiologists (61). Selection bias due to the health-user effect has been suggested as the reason for this difference (62). However, a biologically plausible reason for this discrepancy is that the populations studied were substantially different; in observational studies, most women started HT at the time of menopause, whereas many women in randomized studies started HT remote from the time of menopause (63).

The association between menopausal hormones and breast cancer also continues to be debated. A recent meta-analysis of studies of menopausal hormone use and breast cancer provided reassurance that the effect of such agents on breast cancer risk is modest (64). In the WHI, women taking combined estrogen and progestin HT had an increased risk of breast cancer compared with placebo (HR = 1.26; 95% CI 1.00–1.59); however, no increased risk was seen in the estrogen alone HT component of the study (HR = 0.77; 95% CI 0.59–1.01) (65) (see Chapter 32). Thus, progestin use is likely to play an important role in whether an HT regimen increases the risk of breast cancer.

**Sexually Transmitted Disease**

Worldwide, sexually transmitted diseases are possibly the most important preventable cause of morbidity in women. This morbidity includes not only PID from gonorrhea and chlamydia but also chronic disease from syphilis and genitally transmitted viruses, including hepatitis, HPV, and HIV. Based on epidemiologic data, the most consistent risk factor for chlamydia infection is age; thus the Centers for Disease Control and Prevention recommends...
annual screening for all sexually active women younger than the age of 25 (66). Epidemiologic data have also been used to recommend strategies for the evaluation of Pap test results showing atypical cells of undetermined significance (ASCUS) based on the presence of high-risk HPV subtypes (67). The importance of public health measures to prevent the spread of sexually transmitted diseases, especially the use of barrier contraception, cannot be overemphasized; the morbidity from these infections may carry over to the offspring of those infected.

### Lifestyle

An appreciation of lifestyle factors that increase or decrease risk for disease allows the physician to suggest important changes in behavior that can prevent disease and improve patients’ health. Assessment and evaluation of some of the following factors should be a part of the annual history and physical examination.

#### Smoking, Alcohol, and Caffeine

About 20% of women in the United States smoke tobacco, consume two or more cups of coffee per day, or have four or more alcoholic drinks per week. As a result, these behaviors are significant to reproductive epidemiology. Adverse effects of smoking on the lungs and heart are well known; however, it is less widely appreciated that smoking may be linked to tubal infertility (68), ectopic pregnancy (69), cervical cancer (70), and early menopause (71). In moderation, alcohol use is associated with decreased risk of cardiovascular disease (72), which is offset by an increased risk for breast cancer (73). Alcohol use has been associated with an increased risk of endometriosis and fibroids (74,75). It is possible that these effects are mediated by the ability of alcohol to retard the metabolism of estrogen, thereby leading to higher circulating levels of estrogen (76). Alternatively, some investigators have attributed the adverse effects of alcohol to folate deficiency and suggested that they could be countered with folate supplementation (77). Coffee consumption is the major source of caffeine in the diet and is another very common exposure that has been extensively investigated with regard to gynecologic problems. The effects of caffeine on delayed conception and spontaneous abortion have been of particular interest. In one study, women consuming more than five cups of coffee per day (equivalent to more than 500 mg of caffeine) were 1.45 times more likely to need more than 9 months to conceive compared with women who did not regularly consume caffeine (78). Regarding spontaneous abortion, a high-profile article suggested that caffeine intake above the level of 500 mg may increase the risk for abortion of a karyotypically normal fetus (79), whereas another review concluded that the evidence was equivocal given potential biases related to recall and selection as well as confounding variables (80).

#### Exercise and Nutrition

Exercise and nutrition have broad implications to women’s health, and gynecologic problems can occur at either extreme. The lean athlete in training who becomes amenorrheic may lose bone mass because of a lack of estrogen, as might the patient with anorexia (23). In obese women, menstrual difficulties may occur that are related to higher estrogen levels, which may, in the longer term, be associated with a higher risk for endometrial cancer (81) and postmenopausal breast cancer (82). Indeed, there is almost no aspect of gynecologic or obstetric care that is not affected by obesity (83).

#### Talc

Use of talc in genital hygiene is an exposure emphasized as a potential risk factor for ovarian cancer (84). Because genital talc use has no benefit other than aesthetic purposes, this practice should be discouraged.

### Illnesses and Mortality Statistics

Many gynecologists are primary care providers for women, and they may increasingly assume this role in the future. It is important, therefore, for gynecologists to be aware of the major causes of mortality in women.
Table 4.3 shows the 10 leading causes of death in 2002 for women in the United States by age from the National Center for Health Statistics data (85). Heart disease remains the major cause of death in women overall, but there is considerable age variation. Accidents and homicides, and suicides are most important at ages younger than 40 years, and cancer is most important at ages 40 to 79 years.

HIV, human immunodeficiency virus.
CHAPTER 4  Epidemiology for the Gynecologist

Table 4.4 shows the incidence of gynecologic cancers over a 5-year period from 1997 to 2001 by various ages (86). Figure 4.4 illustrates the age-specific incidence of genital malignancies in all women in the United States (87). The incidence of invasive cervical cancer remains fairly steady across all ages, whereas ovarian and endometrial cancer increase markedly during the perimenopausal years and predominate after 50 years of age. The sharp increase in endometrial and ovarian cancer rates around the time of menopause may reflect anovulatory cycles associated with unopposed estrogen and increased levels of gonadotropins. Although ovarian cancer appears to rank second to endometrial cancer in terms of incidence, mortality from ovarian cancer currently exceeds the combined mortality of endometrial and cervical cancer (88).

SECTION II

BASIC PRINCIPLES
Although the basic facts of anatomy do not change, our understanding of specific anatomic relationships and the development of new clinical and surgical correlations continue to evolve.

There is significant variation in the branching pattern of pelvic blood vessels between individuals, and patterns of blood flow may be asymmetric from side to side in the same individual. The pelvic surgeon should be prepared for deviations from “textbook” vascular patterns.

An understanding of the development of pelvic floor disorders and their safe and effective management requires a comprehensive understanding of the interrelationships between the bony pelvis and its ligaments, pelvic muscles and fasciae, nerves and blood vessels, and pelvic viscera.

About 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system with special implications in pelvic surgery.

About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures, most commonly abdominal hysterectomy; risk is increased with distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids.

An understanding of the anatomy of the female pelvis is fundamental to the knowledge base of a practicing gynecologist. Although the basic facts of anatomy and their relevance to gynecologic practice do not change with time, our understanding of specific anatomic relationships and the development of new clinical and surgical correlations continue to evolve.

The anatomy of the fundamental supporting structures of the pelvis and the genital, urinary, and gastrointestinal viscera are presented in this chapter. Because significant variation has developed in the names of many common anatomic structures, the terms used here reflect
current standard nomenclature according to the *Nomina Anatomica* (1); however, other 
commonly accepted terms are included in parentheses.

**Pelvic Structure**

**Bony Pelvis**
The skeleton of the pelvis is formed by the sacrum and coccyx and the paired hip bones 
(coxal, innominate), which fuse anteriorly to form the symphysis pubis. Figure 5.1 illustrates 
the bony pelvis as well as its ligaments and foramina.

**Sacrum and Coccyx**
The sacrum and coccyx are an extension of the vertebral column resulting from the five 
fused sacral vertebrae and the four fused coccygeal vertebrae. They are joined by a 
symphyseal articulation (sacroccocygeal joint), which allows some movement.

The essential features of the sacrum and coccyx are as follows:

1. **Sacral promontory**—the most prominent and anterior projection of the sacrum, 
   this is an important landmark for insertion of a laparoscope. It is located at the 
   level of bifurcation of the common iliac arteries.

2. **Four paired anterior and posterior sacral foramina**—exit sites for the ante-
   rior and posterior rami of the corresponding sacral nerves; anterior foramina are 
   also traversed by the lateral sacral vessels.

**Figure 5.1** The female pelvis. The pelvic bones (the innominate bone, sacrum, and 
coccyx) and their joints, ligaments, and foramina.
3. Sacral hiatus—results from incomplete fusion of the posterior lamina of the fifth sacral vertebra, offering access to the sacral canal, which is clinically important for caudal anesthesia.

Laterally, the alae (“wings”) of the sacrum offer auricular surfaces that articulate with the hipbones to form synovial sacroiliac joints.

Os Coxae

The paired *os coxae*, or hip bones, have three components: the ilium, the ischium, and the pubis. These components meet to form the acetabulum, a cup-shaped cavity that accommodates the femoral head.

Ilium

1. Iliac crest—provides attachments to the iliac fascia, abdominal muscles, and fascia lata.

2. Anterior superior and inferior spine—superior spine provides the point of fixation of the inguinal ligament.

3. Posterior superior and inferior spine—superior spine is the point of attachment for the sacrotuberous ligament and the posterior sacral iliac ligament.

4. Arcuate line—marks the pelvic brim and lies between the first two segments of the sacrum.

5. Iliopectineal eminence (linea terminalis)—the line of junction of the ilium and the pubis.

6. Iliac fossa—the smooth anterior concavity of the ilium, covered by the iliacus muscle.

Ischium

1. Ischial spine—delineates the greater and lesser sciatic notch above and below it. It is the point of fixation for the sacrospinous ligament; the ischial spine represents an important landmark in the performance of pudendal nerve block and sacrospinous ligament vaginal suspension; vaginal palpation during labor allows detection of progressive fetal descent.

2. Ischial ramus—joins that of the pubic rami to encircle the obturator foramen; provides the attachment for the inferior fascia of the urogenital diaphragm and the perineal musculofascial attachments.

3. Ischial tuberosity—the rounded bony prominence upon which the body rests in the sitting position.

Pubis

1. Body—formed by the midline fusion of the superior and inferior pubic rami.

2. Symphysis pubis—a fibrocartilaginous symphyseal joint where the bodies of the pubis meet in the midline; allows for some resilience and flexibility, which is critical during parturition.
3. **Superior and inferior pubic rami**—join the ischial rami to encircle the obturator foramen; provide the origin for the muscles of the thigh and leg; provide the attachment for the inferior layer of the urogenital diaphragm.

4. **Pubic tubercle**—a lateral projection from the superior pubic ramus, to which the inguinal ligament, rectus abdominis, and pyramidalis attach.

---

**Clinical Considerations**

Recent studies using magnetic resonance imaging (MRI) or computed tomography (CT) pelvimetry have found an association between the architecture of the bony pelvis, specifically a wider transverse inlet (distance between the most superior aspects of the iliopectineal line) (2,3) and a shorter obstetric conjugate (shortest distance between the sacral promontory and the pubic symphysis), and the occurrence of pelvic floor disorders (3). It is speculated that women with these characteristics may be more likely to suffer neuromuscular and connective tissue injuries during labor and delivery, predisposing them to the development of pelvic neuropathy or pelvic organ prolapse or both. There may be a potential role for imaging of the bony pelvis to identify those women most likely to benefit from cesarean delivery for the prevention of pelvic floor disorders.

---

**Pelvic Bone Articulations**

The pelvic bones are joined by four articulations:

1. **Two cartilaginous symphyseal joints**—the sacrococcygeal joint and the *symphysis pubis*—these joints are surrounded by strong ligaments anteriorly and posteriorly, which are responsive to the effect of relaxin and facilitate parturition.

2. **Two synovial joints**—sacroiliac joints—these joints are stabilized by the sacroiliac ligaments, the iliolumbar ligament, the lateral lumbosacral ligament, the sacrotuberous ligament, and the sacrospinous ligament.

The pelvis is divided into the *greater and lesser pelvis* by an oblique plane passing through the sacral promontory, the *linea terminalis* (arcuate line of the ilium), the pectineal line of the pubis, the pubic crest, and the upper margin of the symphysis pubis. This plane lies at the level of the superior pelvic aperture (*pelvic inlet*) or pelvic brim. The inferior pelvic aperture or *pelvic outlet* is irregularly bound by the tip of the coccyx, the symphysis pubis, and the ischial tuberosities. The dimensions of the superior and inferior pelvic apertures have important obstetric implications.

---

**Ligaments**

Four ligaments—inguinal, Cooper’s, sacrospinous, and sacrotuberous—of the bony pelvis are of special importance to the gynecologic surgeon.

**Inguinal Ligament**

The inguinal ligament is important surgically in the repair of inguinal hernia. The inguinal ligament:

1. Is formed by the lower border of the aponeurosis of the external oblique muscle folded back upon itself.

2. Is fused laterally to the iliacus fascia and inferiorly to the fascia lata.

3. Flattens medially into the lacunar ligament, which forms the medial border of the femoral ring.
Cooper’s Ligament

Cooper’s ligament is used frequently in bladder suspension procedures. Cooper’s ligament:

1. Is a strong ridge of fibrous tissue extending along the pectineal line—also known as the pectineal ligament.

2. Merges laterally with the iliopectineal ligament and medially with the lacunar ligament.

Sacrosinous Ligament

The sacrosinous ligament is often used for vaginal suspension. This ligament offers the advantage of a vaginal surgical route. The sacrosinous ligament:

1. Extends from the ischial spine to the lateral aspect of the sacrum.

2. Is separated from the rectovaginal space by the rectal pillars.

3. Lies anterior to the pudendal nerve and the internal pudendal vessels at its attachment to the ischial spine.

The inferior gluteal artery, with extensive collateral circulation, is found between the sacrosinous and sacrotuberous ligaments and may be injured during sacrosinous suspension (4) (Fig. 5.2). Injury to the inferior gluteal artery, as well as to the pudendal nerve and internal pudendal vessels, during sacrosinous ligament suspension may be minimized by

Figure 5.2  Tone drawing of left hemipelvis with sacrosinous ligament reflected. a. = artery; Inf. = inferior; lig. = ligament; n. = nerve; Sacros. = sacrosinous; Sacrotub. = sacrotuberous. (Redrawn from Thompson JR, Gibbs JS, Genadry R, et al. Anatomy of pelvic arteries adjacent to the sacrosinous ligament: importance of the coccygeal branch of the inferior gluteal artery. Obstet Gynecol 1999;94(6):973–977, with permission.)
careful and controlled retraction and suture placement at least two fingerbreadths medial to the ischial spine.

Sacrotuberous Ligament
The sacrotuberous ligament is sometimes used as a point of fixation for vaginal vault suspension. The sacrotuberous ligament:

1. Extends from the ischial tuberosity to the lateral aspect of the sacrum.
2. Merges medially with the sacrospinous ligament.
3. Lies posterior to the pudendal nerve and the internal pudendal vessels.

Foramina
The bony pelvis and its ligaments delineate three important foramina that allow the passage of the various muscles, nerves, and vessels to the lower extremity.

Greater Sciatic Foramen
The greater sciatic foramen transmits the following structures: the piriformis muscle, the superior gluteal nerves and vessels, the sciatic nerve along with the nerves of the quadratus femoris, the inferior gluteal nerves and vessels, the posterior cutaneous nerve of the thigh, the nerves of the obturator internus, and the internal pudendal nerves and vessels.

Lesser Sciatic Foramen
The lesser sciatic foramen transmits the tendon of the obturator internus to its insertion on the greater trochanter of the femur. The nerve of the obturator internus and the pudendal vessels and nerves reenter the pelvis through it.

Obturator Foramen
The obturator foramen transmits the obturator nerves and vessels. The obturator neurovascular bundle can be potentially injured during transobturator tape placement, a procedure for treatment of urinary incontinence. Injury can be prevented by careful identification of anatomic landmarks and placement away from the obturator foramen.

Muscles
The muscles of the pelvis include those of the lateral wall and those of the pelvic floor (Fig. 5.3; Table 5.1).

Lateral Wall
The muscles of the lateral pelvic wall pass into the gluteal region to assist in thigh rotation and adduction. They include the piriformis, the obturator internus, and the iliopsoas.

Pelvic Floor
Pelvic Diaphragm
The pelvic diaphragm is a funnel-shaped fibromuscular partition that forms the primary supporting structure for the pelvic contents (Fig. 5.4). It is composed of the
Figure 5.3  The pelvic diaphragm. A: A view into the pelvic floor that illustrates the muscles of the pelvic diaphragm and their attachments to the bony pelvis. B: A view from outside the pelvic diaphragm illustrating the divisions of the levator ani muscles (superficial plane removed on the right). C: A lateral, sagittal view of the pelvic diaphragm and superior fascia of the urogenital diaphragm. The muscles include the deep transverse perineal and sphincter urethrae.
The levator ani muscles are composed of the pubococcygeus (including the pubovaginalis, pubourethralis, puborectalis, and the iliococcygeus). It is a broad, curved sheet of muscle stretching from the pubis anteriorly and the coccyx posteriorly, and from one side of the pelvis to the other. It is perforated by the urethra, vagina, and anal canal. Its origin is from the tendinous arch extending from the body of the pubis to the ischial spine. It is inserted into the central tendon of the perineum, the wall of the anal canal, the anococcygeal ligament, the coccyx, and the vaginal wall.

The levator ani assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents. It supports the vagina, facilitates defecation, and aids in maintaining fecal continence. During parturition, the levator ani supports the fetal head while the cervix dilates. The levator ani is innervated by S3 to S4, the inferior rectal nerve.

Urogenital Diaphragm

The muscles of the urogenital diaphragm reinforce the pelvic diaphragm anteriorly and are intimately related to the vagina and the urethra. They are enclosed between the inferior and superior fascia of the urogenital diaphragm. The muscles include the deep transverse perineal and sphincter urethrae (Table 5.1).
Blood Vessels

The pelvic blood vessels supply genital structures as well as the following:

- Urinary and gastrointestinal tracts
- Muscles of the abdominal wall, pelvic floor and perineum, buttocks, and upper thighs
• Fasciae, other connective tissue, and bones
• Skin and other superficial structures.

Classically, vessels supplying organs are known as **visceral vessels** and those supplying supporting structures are called **parietal vessels**.

### Major Blood Vessels

The course of the major vessels supplying the pelvis is illustrated in Figure 5.5; their origin, course, branches, and venous drainage are presented in Table 5.2. In general, the venous system draining the pelvis closely follows the arterial supply and is named accordingly. Not infrequently, a vein draining a particular area may form a plexus with multiple channels. Venous systems, which are paired, mirror each other in their drainage patterns, with the notable exception of the ovarian veins. Unusual features of venous drainage are also listed in Table 5.2.

### General Principles

“Control blood supply” and “maintain meticulous hemostasis” are two of the most common exhortations to young surgeons. In developing familiarity with the pattern of blood flow in the pelvis, several unique characteristics of this vasculature should be understood because of their potential implications to surgical practice:

1. **The pelvic vessels play an important role in pelvic support.** They provide condensations of endopelvic fascia that act to reinforce the normal position of pelvic organs (5).

2. **There is significant anatomic variation between individuals in the branching pattern of the internal iliac vessels.** There is no constant order in which branches divide from the parent vessel; some branches may arise as common

| **Inferior mesenteric artery (IMA)** | Unpaired left-sided retroperitoneal artery arising from the aorta 2–5 cm proximal to its bifurcation | IMA and its branches pass over the left psoas muscle and common iliac vessels; IMA courses anterior to the ureter and ovarian vessels above the pelvic brim | 1. *Left colic*—originates above pelvic brim; supplies left transverse colon, splenic flexure, descending colon  
2. *Sigmoid*—several branches; supply sigmoid colon  
3. *Superior rectal (hemorrhoidal)*—divides into two terminal branches to supply rectum | Inferior mesenteric vein empties into the splenic vein |
| **Common iliac artery**       | Terminal division of the aorta at fourth lumbar vertebra               | Oblique and lateral course, about 5 cm in length           | 1. *External iliac*  
2. *Internal iliac* | Lie posterior and slightly medial to arteries; drain into inferior vena cava |
| **External iliac femoral artery** | Lateral bifurcation of common iliac, begins opposite the lumbosacral joint | Along the medial border of the psoas muscle and lateral pelvic side wall; becomes femoral artery after passing under the inguinal ligament to supply lower extremity | 1. *Superficial epigastric*—supplies skin and subcutaneous tissue of lower anterior abdominal wall  
2. *External pudendal*—supplies skin and subcutaneous tissue of mons pubis and anterior vulva  
3. *Superficial circumflex iliac*—supplies skin/subcutaneous tissues of the flank  
4. *Inferior epigastric*—supplies musculofascial layer of lower anterior abdominal wall  
5. *Deep circumflex iliac*—supplies musculofascial layer of lower abdominal wall | Lie posterior and then medial to the artery as it enters the anterior thigh; drain into common iliac veins |
| **Internal iliac (hypogastric) artery** | Medial bifurcation of common iliac artery, begins opposite the lumbosacral joint; is major blood supply to the pelvis | Descends sharply into the pelvis; divides into an anterior and posterior division 3–4 cm after origin | 1. *Iliolumbar*—anastomoses with lumbar and deep circumflex iliac arteries; helps supply lower abdominal wall, iliac fossa  
2. *Lateral sacral*—supplies contents of sacral canal, piriiformis muscle | Deep to arteries, from complex plexus; drain into common iliac veins |
3. **Superior gluteal**—supplies gluteal muscles  

**Anterior division:**  
1. **Obturator**—supplies iliac fossa, posterior pubis, obturator internus muscle  
2. **Internal pudendal**  
3. **Umbilical**—remnant of fetal umbilical artery; after giving off branches, as the medial umbilical ligament  
4. **Superior, middle, inferior vesical**—supply bladder and one or more branches to the ureter  
5. **Middle rectal (hemorrhoidal)**—supplies rectum, branches to midvagina  
6. **Uterine**—supplies uterine corpus and cervix, with branches to upper vagina, tube, round ligament, and ovary  
7. **Vaginal**—supplies vagina  
8. **Inferior gluteal**—supplies gluteal muscles, muscles of posterior thigh

trunks or may spring from other branches rather than from the internal iliac. Occasionally, a branch may arise from another vessel entirely (e.g., the obturator artery may arise from the external iliac or inferior epigastric artery). This variation may also be found in the branches of other major vessels; the ovarian arteries have been reported to arise from the renal arteries or as a common trunk from the front of the aorta on occasion. The inferior gluteal artery may originate from the posterior or the anterior branch of the internal iliac (hypogastric) artery (2). Patterns of blood flow may be asymmetric from side to side, and structures supplied by anastomoses of different vessels may show variation from person to person in proportion of vascular support provided by the vessels involved. The pelvic surgeon must be prepared for deviations from “textbook” vascular patterns.

3. The pelvic vasculature is a high-volume, high-flow system with enormous expansive capabilities throughout reproductive life. Blood flow through the uterine arteries increases to about 500 mL/min in late pregnancy. In nonpregnant women, certain conditions, such as uterine fibroids or malignant neoplasms, may be associated with neovascularization and hypertrophy of existing vessels and a corresponding increase in pelvic blood flow. Understanding of the volume and flow characteristics of the pelvic vasculature in different clinical situations will enable the surgeon to anticipate problems and take appropriate preoperative and intraoperative measures (including blood and blood product availability) to prevent or manage hemorrhage.

4. The pelvic vasculature is supplied with an extensive network of collateral connections (Fig. 5.6) that provides a rich anastomotic communication between different major vessel systems. This degree of redundancy is important to ensure adequate supply of oxygen and nutrients in the event of major trauma or other vascular compromise. Hypogastric artery ligation continues to be used as a strategy for management of massive pelvic hemorrhage when other measures have failed. Bilateral hypogastric artery ligation, particularly when combined with ovarian artery ligation, dramatically reduces pulse pressure in the pelvis, converting flow characteristics from that of an arterial system to a venous system and allowing use of collateral channels of circulation to continue blood supply to pelvic structures. The significance of collateral blood flow is demonstrated by reports of successful pregnancies occurring after bilateral ligation of both hypogastric and ovarian arteries (6). Table 5.3 lists the collateral channels of circulation in the pelvis.

Special Vascular Considerations

To avoid injury to vascular structures and resultant hemorrhage while inserting a trocar into the anterior abdominal wall during laparoscopy, the surgeon should keep in mind certain anatomic relationships. The inferior epigastric artery is a branch of the external iliac artery, arising from the parent vessel at the medial border of the inguinal ligament and coursing cephalad lateral to and posterior to the rectus sheath at the level of the arcuate line. It lies about 1.5 cm lateral to the medial umbilical fold, which marks the site of the obliterated umbilical artery. The aortic bifurcation occurs at the level of L4 to L5, just above the sacral promontory. Palpation of the sacral promontory to guide trocar insertion allows the surgeon to avoid the major vascular structures in this area (see Fig. 21.4 in Chapter 21).

Lymphatics

The pelvic lymph nodes are generally arranged in groups or chains and follow the course of the larger pelvic vessels, for which they are usually named. Smaller nodes that lie close to the visceral structures are usually named for those organs. Lymph nodes in the pelvis receive afferent lymphatic vessels from pelvic and perineal visceral and parietal structures and send efferent lymphatics to more proximal nodal groups. The number of lymph nodes and their exact location is variable; however, certain nodes tend to be relatively constant:
1. Obturator node in the obturator foramen, close to the obturator vessels and nerve

2. Nodes at the junction of the internal and external iliac veins

3. Ureteral node in the broad ligament near the cervix, where the uterine artery crosses over the ureter

4. The Cloquet or Rosenmüller node—the highest of the deep inguinal nodes that lies within the opening of the femoral canal
Figure 5.7 illustrates the pelvic lymphatic system. Table 5.4 outlines the major lymphatic chains of relevance to the pelvis and their primary afferent connections from major pelvic and perineal structures. There are extensive interconnections between lymph vessels and nodes; more than one lymphatic pathway is usually available for drainage of each pelvic site. Bilateral and crossed extension of lymphatic flow may occur, and entire groups of nodes may be bypassed to reach more proximal chains.

The natural history of most genital tract malignancies directly reflects the lymphatic drainage of those structures, although the various interconnections, different lymphatic paths, and individual variability make the spread of malignancy somewhat unpredictable. Regional lymph node metastasis is one of the most important factors in formulation of treatment plans for gynecologic malignancies and prediction of eventual outcome.

**Nerves**

The pelvis is innervated by both the autonomic and somatic nervous systems. The autonomic nerves include both sympathetic (adrenergic) and parasympathetic (cholinergic) fibers and provide the primary innervation for genital, urinary, and gastrointestinal visceral structures and blood vessels.

**Somatic Innervation**

The *lumbosacral plexus* (Fig. 5.8) and its branches provide motor and sensory somatic innervation to the lower abdominal wall, the pelvic and urogenital diaphragms, the perineum, and the hip and lower extremity. The nerves originating from the muscles, the lumbosacral trunk, the anterior divisions of the upper four sacral nerves (*sacral plexus*), and the anterior division of the coccygeal nerve and fibers from the fourth and fifth sacral nerves (*coccygeal plexus*) are found on the anterior surface of the piriformis muscle and...
lateral to the coccyx, respectively, deep in the posterior pelvis. In Table 5.5 each major branch is listed by spinal segment and structures innervated. In addition to these branches, the lumbosacral plexus includes nerves that innervate muscles of the lateral pelvic wall (obturator internus, piriformis), posterior hip muscles, and the pelvic diaphragm. A visceral component, the pelvic splanchnic nerve, also is included.

Nerves supplying the cutaneous aspects of the anterior, medial, and lateral lower extremities, as well as the deep muscles of the anterior thigh, primarily leave the pelvis by passing beneath the inguinal ligament. Nerves supporting the posterior cutaneous and deep structures of the hip, thigh, and leg lie deep in the pelvis and should not be vulnerable to injury during pelvic surgery. The obturator nerve travels along the lateral pelvic wall to pass

Figure 5.7 The lymphatic drainage of the female pelvis. The vulva and lower vagina drain to the superficial and deep inguinal nodes, sometimes directly to the iliac nodes (along the dorsal vein of the clitoris) and to the other side. The cervix and upper vagina drain laterally to the parametrial, obturator, and external iliac nodes and posteriorly along the uterosacral ligaments to the sacral nodes. Drainage from these primary lymph node groups is upward along the infundibulopelvic ligament, similar to drainage of the ovary and fallopian tubes to the paraaortic nodes. The lower uterine body drains in the same manner as the cervix. Rarely, drainage occurs along the round ligament to the inguinal nodes.

through the obturator foramen into the upper thigh, and it may be encountered in more radical dissections involving the lateral pelvic wall and in paravaginal repairs.

The pudendal nerve crosses over the piriformis to travel with the internal pudendal vessels into the ischiorectal fossa, where it divides into its three terminal branches to provide the primary innervation to the perineum. Other nerves contribute to the cutaneous innervation of the perineum:

1. The anterior labial nerve branches of the ilioinguinal nerve—these nerves emerge from within the inguinal canal and through the superficial inguinal ring to the mons and upper labia majora.

2. The genital branch of the genitofemoral nerve—this branch enters the inguinal canal with the round ligament and passes through the superficial inguinal ring to the anterior vulva.

3. The perineal branches of the posterior femoral cutaneous nerve—after leaving the pelvis through the greater sciatic foramen, these branches run in front of the ischial tuberosity to the lateral perineum and labia majora.

4. Perforating cutaneous branches of the second and third sacral nerves—these branches perforate the sacrotuberous ligament to supply the buttocks and contiguous perineum.
5. The anococcygeal nerves—these nerves arise from S4 to S5 and also perforate the sacrotuberous ligament to supply the skin overlying the coccyx.

Autonomic Innervation

Functionally, the innervation of the pelvic viscera may be divided into an efferent component and an afferent, or sensory, component. In reality, however, afferent and efferent fibers are closely associated in a complex interlacing network and cannot be separated anatomically.

Efferent Innervation

Efferent fibers of the autonomic nervous system, unlike motor fibers in the somatic system, involve one synapse outside the central nervous system, with two neurons required to carry each impulse. In the sympathetic (thoracolumbar) division, this synapse is generally at some distance from the organ being innervated; conversely, the synapse is on or near the organ of innervation in the parasympathetic (craniosacral) division.

Axons from preganglionic neurons emerge from the spinal cord to make contact with peripheral neurons arranged in aggregates known as autonomic ganglia. Some of these ganglia, along with interconnecting nerve fibers, form a pair of longitudinal cords called the sympathetic trunks. Located lateral to the spinal column from the base of the cranium to the coccyx, the sympathetic trunks lie along the medial border of the psoas muscle from T12 to the sacral prominence and then pass behind the common iliac vessels to continue into the pelvis on the anterior surface of the sacrum. On the anterolateral surface of the aorta, the aortic plexus forms a lacy network of nerve fibers with interspersed ganglia. Rami arising from or traversing the sympathetic trunks join this plexus and its subsidiaries.

The ovaries and part of the fallopian tubes and broad ligament are innervated by the ovarian plexus, a network of nerve fibers accompanying the ovarian vessels and derived from the aortic and renal plexuses. The inferior mesenteric plexus is a subsidiary of the celiac plexus and aortic plexus and is located along the inferior mesenteric artery and its branches, providing innervation to the left colon, sigmoid, and rectum.

The superior hypogastric plexus (presacral nerve) (Fig. 5.9) is the continuation of the aortic plexus beneath the peritoneum in front of the terminal aorta, the fifth lumbar vertebra, and the sacral promontory, medial to the ureters. Embedded in loose areolar tissue, the plexus overlies the middle sacral vessels and is usually composed of two or three incompletely fused trunks. It contains preganglionic fibers from lumbar nerves, postganglionic fibers from higher sympathetic ganglia and from the sacral sympathetic trunks, and visceral afferent fibers. Just below the sacral promontory, the superior hypogastric plexus divides into two loosely arranged nerve trunks, the hypogastric nerves. These nerves course inferiorly and laterally to connect with the inferior hypogastric plexuses (pelvic plexuses) (Fig. 5.9), which are a dense network of nerves and ganglia that lie along the lateral pelvic sidewall overlying branches of the internal iliac vessels.

The inferior hypogastric plexus includes efferent sympathetic fibers, afferent (sensory) fibers, and parasympathetic fibers arising from the pelvic splanchnic nerves (S2 to S4, nervi erigentes).

This paired plexus is the final common pathway of the pelvic visceral nervous system and is divided into three portions, representing distribution of innervation to the viscera:

1. Vesical plexus
   - Innervation: bladder and urethra
   - Course: along vesical vessels
2. Middle rectal plexus (hemorrhoidal)
   - Innervation: rectum
   - Course: along middle rectal vessels

3. Uterovaginal plexus (Frankenhäuser ganglion)
   - Innervation: uterus, vagina, clitoris, vestibular bulbs
   - Course: along uterine vessels and through cardinal and uterosacral ligaments; sympathetic and sensory fibers derive from T10, L1; parasympathetic fibers derive from S2 to S4.

**Afferent Innervation**

Afferent fibers from the pelvic viscera and blood vessels traverse the same pathways to provide sensory input to the central nervous system. They are also involved in reflex arcs needed for bladder, bowel, and genital tract function. The afferent fibers reach the central nervous system to have their first synapse within posterior spinal nerve ganglia.

Presacral neurectomy, in which a segment of the superior hypogastric plexus is divided and resected in order to interrupt sensory fibers from the uterus and cervix, has been associated with relief of dysmenorrhea secondary to endometriosis in about 50% to 75% of cases in which it has been used (7,8).
travel with the ovarian plexus; thus, pain originating from the ovary or tube is not relieved by resection of the presacral nerve. Because this plexus also contains efferent sympathetic and parasympathetic nerve fibers intermixed with afferent fibers, disturbance in bowel or bladder function may result. An alternative surgical procedure advocated in recent years is resection of a portion of the uterosacral ligaments; because they contain numerous nerve fibers with more specific innervation to the uterus, it is postulated that bladder and rectal function is less vulnerable to compromise.

An anesthetic block of the pudendal nerve is performed most often for pain relief with uncomplicated vaginal deliveries but may also provide useful anesthesia for minor perineal surgical procedures. This nerve block may be accomplished transvaginally or through the perineum. A needle is inserted toward the ischial spine with the tip directed slightly posteriorly and through the sacrospinous ligament. As anesthetic agent is injected, frequent aspiration is required to avoid injection into the pudendal vessels, which travel with the nerve.

### Pelvic Viscera

#### Embryonic Development

The female urinary and genital tracts are closely related, not only anatomically but also embryologically. Both are derived largely from primitive mesoderm and endoderm, and there is evidence that the embryologic urinary system has an important inductive influence on the developing genital system. **About 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system** (9).

Developmental defects may play a significant role in the differential diagnosis of certain clinical signs and symptoms and have special implications in pelvic surgery (9–13). Thus it is important for gynecologists to have a basic understanding of embryology.

Following is a presentation of the urinary system, internal reproductive organs, and external genitalia in order of their initial appearance, although much of this development occurs concurrently. The development of each of these three regions proceeds synchronously at an early embryologic age (Table 5.6).

#### Urinary System

**Kidneys, Renal Collecting System, Ureters**

The kidneys, renal collecting system, and ureters derive from the longitudinal mass of mesoderm (known as the nephrogenic cord) found on each side of the primitive aorta. This process gives rise to three successive sets of increasingly advanced urinary structures, each developing more caudal to its predecessor.

The **pronephros**, or “first kidney,” is rudimentary and nonfunctional; it is succeeded by the “middle kidney,” or **mesonephros**, which is believed to function briefly before regressing. Although the **mesonephros** is transitory as an excretory organ, its duct, the **mesonephric (wolffian) duct**, is of singular importance for the following reasons:

1. It grows caudally in the developing embryo to open, for the first time, an excretory channel into the primitive cloaca and the “outside world.”

2. It serves as the starting point for development of the metanephros, which becomes the definitive kidney.
3. It ultimately differentiates into the sexual duct system in the male.

4. Although regressing in female fetuses, there is evidence that the mesonephric duct may have an inductive role in development of the paramesonephric or müllerian duct (10).

Development of the metanephros is initiated by the ureteric buds, which sprout from the distal mesonephric ducts; these buds extend cranially and penetrate the portion of the nephrogenic cord known as the metanephric blastema. The ureteric buds begin to branch sequentially, with each growing tip covered by metanephric blastema. The metanephric blastema ultimately form the renal functional units (the nephrons), whereas the ureteric buds become the collecting duct system of the kidneys (collecting tubules, minor and major calyces, renal pelvis) and the ureters. Although these primitive tissues differentiate along separate paths, they are interdependent on inductive influences from each other—neither can develop alone.

The kidneys initially lie in the pelvis but subsequently ascend to their permanent location, rotating almost 90 degrees in the process as the more caudal part of the embryo in effect grows away from them. Their blood supply, which first arises as branches of the middle sacral and common iliac arteries, comes from progressively higher branches of the aorta until the definitive renal arteries form; previous vessels then regress.

### Bladder and Urethra

The cloaca forms as the result of dilation of the opening to the fetal exterior. The cloaca is partitioned by the mesenchymal urorectal septum into an anterior urogenital sinus and a posterior rectum. The bladder and urethra form from the most superior portion of the urogenital sinus, with surrounding mesenchyme contributing to their muscular and serosal layers. The remaining inferior urogenital sinus is known as the phallic or definitive urogenital sinus. Concurrently, the distal mesonephric ducts and attached ureteric
buds are incorporated into the posterior bladder wall in the area that will become the bladder trigone. As a result of the absorption process, the mesonephric duct ultimately opens independently into the urogenital sinus below the bladder neck.

The allantois, which is a vestigial diverticulum of the hindgut that extends into the umbilicus and is continuous with the bladder, loses its lumen and becomes the fibrous band known as the urachus or median umbilical ligament. In rare instances, the urachal lumen remains partially patent, with formation of urachal cysts, or completely patent, with the formation of a urinary fistula to the umbilicus.

Genital System

Although genetic sex is determined at fertilization, the early genital system is indistinguishable between the two sexes in the embryonic stage. This is known as the “indifferent stage” of genital development, during which both male and female fetuses have gonads with prominent cortical and medullary regions, dual sets of genital ducts, and external genitalia that appear similar. Clinically, sex is not apparent until about the twelfth week of embryonic life and depends on the elaboration of testis-determining factor and, subsequently, androgens by the male gonad. Female development has been called the “basic developmental path of the human embryo,” requiring not estrogen but the absence of testosterone.

Internal Reproductive Organs

The primordial germ cells migrate from the yolk sac through the mesentery of the hindgut to the posterior body wall mesenchyme at about the tenth thoracic level, which is the initial site of the future ovary (Figs. 5.10 and 5.11). Once the germ cells reach this area, they induce proliferation of cells in the adjacent mesonephros and celomic epithelium to form a pair of genital ridges medial to the mesonephros. The development of the gonad is absolutely dependent on this proliferation because these cells form a supporting aggregate of cells (the primitive sex cords) that invest the germ cells and without which the gonad would degenerate.

Müllerian Ducts

The paramesonephric or müllerian ducts form lateral to the mesonephric ducts; they grow caudally and then medially to fuse in the midline. They contact the urogenital sinus in the region of the posterior urethra at a slight thickening known as the sinus tubercle. Subsequent sexual development is controlled by the presence or absence of testis-determining factor, encoded on the Y chromosome and elaborated by the somatic sex cord cells. Testis-determining factor causes the degeneration of the gonadal cortex and differentiation of the medullary region of the gonad into Leydig cells and the cortical sex cords break up into isolated cell clusters (the primordial follicles).

The Sertoli cells secrete a glycoprotein known as anti-müllerian hormone (AMH), which causes regression of the paramesonephric duct system in the male embryo and is the likely signal for differentiation of Leydig cells from the surrounding mesenchyme. The Leydig cells produce testosterone and, with the converting enzyme 5α-reductase, dihydrotestosterone. Testosterone is responsible for evolution of the mesonephric duct system into the vas deferens, epididymis, ejaculatory ducts, and seminal vesicle. At puberty, testosterone leads to spermatogenesis and changes in primary and secondary sex characteristics. Dihydrotestosterone triggers the development of the male external genitalia and the prostate and bulbourethral glands. In the absence of testis-determining factor, the medulla regresses, and the cortical sex cords break up into isolated cell clusters (the primordial follicles).

The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes, at which point development is arrested until puberty. In the absence of AMH, the mesonephric duct system degenerates, although in at least one fourth of adult women (11), remnants may be found in the mesovarium (epoophoron, paroophoron) or along the lateral wall of the uterus or vagina (Gartner duct cyst).
Figure 5.10  The comparative changes of the female and male during early embryonic development.
The paramesonephric duct system subsequently develops. The inferior fused portion becomes the uterovaginal canal, which later becomes the epithelium and glands of the uterus and the upper vagina. The endometrial stroma and myometrium differentiate from surrounding mesenchyme. The cranial unfused portions of the paramesonephric ducts open into the celomic (future peritoneal) cavity and become the fallopian tubes.

The fusion of the paramesonephric ducts brings together two folds of peritoneum, which become the broad ligament and divide the pelvic cavity into a posterior rectouterine and anterior vesicouterine pouch or cul-de-sac. Between the leaves of the broad ligament, mesenchyme proliferates and differentiates into loose areolar connective tissue and smooth muscle.

**Vagina** The vagina forms in the third month of embryonic life. While the uterovaginal canal is forming, the endodermal tissue of the sinusal tubercle begins to proliferate, forming a pair of sinovaginal bulbs, which become the inferior 20% of the vagina. The most inferior portion of the uterovaginal canal becomes occluded by a solid core of tissue (the vaginal plate), the origin of which is unclear. Over the subsequent 2 months, this tissue elongates and canalizes by a process of central desquamation, and the peripheral cells become the vaginal epithelium. The fibromuscular wall of the vagina originates from the mesoderm of the uterovaginal canal.

**Accessory Genital Glands** The female accessory genital glands develop as outgrowths from the urethra (paraurethral or Skene) and the definitive urogenital sinus (greater vestibular or Bartholin). Although the ovaries first develop in the thoracic region, they ultimately arrive in the pelvis by a complicated process of descent. This descent by differential growth is under the control of a ligamentous cord called the gubernaculum, which is attached to the ovary superiorly and to the fascia in the region of the future labia majora inferiorly. The gubernaculum becomes attached to the paramesonephric ducts at their point of superior fusion so that it becomes divided into two separate structures. As the ovary and its mesentery (the mesovarium) are brought into the superior portion of the broad ligament,
the more proximal part of the gubernaculum becomes the *ovarian ligament*, and the distal gubernaculum becomes the *round ligament*.

**External Genitalia**

Early in the fifth week of embryonic life, folds of tissue form on each side of the cloaca and meet anteriorly in the midline to form the *genital tubercle* (Fig. 5.12). With the division of the cloaca by the urorectal septum and consequent formation of the perineum, these
Cloacal folds are known anteriorly as the urogenital folds and posteriorly as the anal folds. The genital tubercle begins to enlarge. In the female embryo, its growth gradually slows to become the clitoris, and the urogenital folds form the labia minora. In the male embryo, the genital tubercle continues to grow to form the penis, and the urogenital folds are believed to fuse to enclose the penile urethra. Lateral to the urogenital folds, another pair of swellings develops, known in the indifferent stage as labioscrotal swellings. In the absence of androgens, they remain largely unfused to become the labia majora. The definitive urogenital sinus gives rise to the vaginal vestibule, into which open the urethra, vagina, and greater vestibular glands.

Clinical Correlations

Developmental abnormalities of the urinary and genital systems can be explained and understood by a consideration of female and male embryologic development. Because of the intertwined development of these two systems, it is easy to understand how abnormalities in one may be associated with abnormalities in the other (12).

Urinary System

Urinary-tract anomalies arise from defects in the ureteric bud, the metanephric blastema, or their inductive interaction with each other.

Renal Agenesis

Renal agenesis occurs when one or both ureteric buds fail to form or degenerate, and the metanephric blastema is therefore not induced to differentiate into nephrons. Bilateral renal agenesis is incompatible with postnatal survival, but infants with only one kidney usually survive, and the single kidney undergoes compensatory hypertrophy. Unilateral renal agenesis is often associated with absence or abnormality of fallopian tubes, uterus, or vagina—the paramesonephric duct derivatives.

Abnormalities of Renal Position

Abnormalities of renal position result from disturbance in the normal ascent of the kidneys. A malrotated pelvic kidney is the most common result; a horseshoe kidney, in which the kidneys are fused across the midline, occurs in about 1 in 600 individuals and also has a final position lower than usual because its normal ascent is prevented by the root of the inferior mesenteric artery.

Duplication of the Upper Ureter and Renal Pelvis

Duplication of the upper ureter and renal pelvis are relatively common and result from premature bifurcation of the ureteric bud. If two ureteric buds develop, there will be complete duplication of the collecting system. In this situation, one ureteric bud will open normally into the posterior bladder wall, and the second bud will be carried more distally within the mesonephric duct to form an ectopic ureteral orifice into the urethra, vagina, or vaginal vestibule; incontinence is the primary presenting symptom. Most of the aforementioned urinary abnormalities remain asymptomatic unless obstruction or infection supervenes. In that case, anomalous embryologic development must be included in the differential diagnosis.

Genital System

Because the early development of the genital system is similar in both sexes, congenital defects in sexual development, usually arising from a variety of chromosomal abnormalities, tend to present clinically with ambiguous external genitalia. These conditions are known as intersex conditions or hermaphroditism and are classified according to the histologic appearance of the gonads (see Chapter 24).

True Hermaphroditism

Individuals with true hermaphroditism have both ovarian and testicular tissue, most commonly as composite ovotestes but occasionally with an ovary on one side and a testis on the other. In the latter case, a fallopian tube and single uterine horn may develop on the side with the ovary because of the absence of local AMH. True hermaphroditism is an extremely rare condition associated with chromosomal mosaicism, mutation, or abnormal cleavage involving the X and Y chromosomes.
Pseudohermaphroditism In individuals with pseudohermaphroditism, the genetic sex indicates one sex, whereas the external genitalia has characteristics of the other sex. Males with pseudohermaphroditism are genetic males with feminized external genitalia, most commonly manifesting as hypospadias (urethral opening on the ventral surface of the penis) or incomplete fusion of the urogenital or labioscrotal folds. Females with pseudohermaphroditism are genetic females with virilized external genitalia, including clitoral hypertrophy and some degree of fusion of the urogenital or labioscrotal folds. Both types of pseudohermaphroditism are caused either by abnormal levels of sex hormones or abnormalities in the sex hormone receptors.

Another major category of genital tract abnormalities involves various types of uterovaginal malformations (Fig. 5.13), which occur in 0.16% of women (13). These malformations are believed to result from one or more of the following situations:
1. Improper fusion of the paramesonephric ducts
2. Incomplete development of one paramesonephric duct
3. Failure of part of the paramesonephric duct on one or both sides to develop
4. Absent or incomplete canalization of the vaginal plate

Genital Structures

Vagina

A sagittal section of the female pelvis is presented in Fig. 5.14.

The vagina is a hollow fibromuscular tube extending from the vulvar vestibule to the uterus. In the dorsal lithotomy position, the vagina is directed posteriorly toward the sacrum, but its axis is almost horizontal in the upright position. It is attached at its upper end to the uterus just above the cervix. The spaces between the cervix and vagina are known as the anterior, posterior, and lateral vaginal fornices. Because the vagina is attached at a higher point posteriorly than anteriorly, the posterior vaginal wall is about 3 cm longer than the anterior wall.

![Figure 5.14 The pelvic viscera. A sagittal section of the female pelvis with the pelvic viscera and their relationships.](image-url)
The posterior vaginal fornix is separated from the posterior cul-de-sac and peritoneal cavity by the vaginal wall and peritoneum. This proximity is clinically useful, both diagnostically and therapeutically. Culdocentesis, a technique in which a needle is inserted just posterior to the cervix through the vaginal wall into the peritoneal cavity, has been used to evaluate intraperitoneal hemorrhage (e.g., ruptured ectopic pregnancy, hemorrhagic corpus luteum, other intraabdominal bleeding), pus (e.g., pelvic inflammatory disease, ruptured intraabdominal abscess), or other intraabdominal fluid (e.g., ascites). Incision into the peritoneal cavity from this location in the vagina, known as a posterior colpotomy, can be used as an adjunct to laparoscopic excision of adnexal masses, with removal of the mass intact through the posterior vagina.

The vagina is attached to the lateral pelvic wall with endopelvic fascial connections to the arcus tendineus (white line), which extends from the pubic bone to the ischial spine. This connection converts the vaginal lumen into a transverse slit with the anterior and posterior walls in apposition; the lateral space where the two walls meet is the vaginal sulcus. Lateral detachments of the vagina are recognized in some cystocele formation.

The opening of the vagina may be covered by a membrane or surrounded by a fold of connective tissue called the hymen. This tissue is usually replaced by irregular tissue tags later in life as sexual activity and childbirth occur. The lower vagina is somewhat constricted as it passes through the urogenital hiatus in the pelvic diaphragm; the upper vagina is more spacious. However, the entire vagina is characterized by its distensibility, which is most evident during childbirth.

The vagina is closely applied anteriorly to the urethra, bladder neck and trigonal region, and posterior bladder; posteriorly, the vagina lies in association with the perineal body, anal canal, lower rectum, and posterior cul-de-sac. It is separated from both the lower urinary and gastrointestinal tracts by their investing layers of fibromuscular elements known as the endopelvic fascia.

The vagina is composed of three layers:

1. **Mucosa**—nonkeratinized stratified squamous epithelium, without glands. Vaginal lubrication occurs primarily by transudation, with contributions from cervical and Bartholin gland secretions. The mucosa has a characteristic pattern of transverse ridges and furrows, known as rugae. It is hormonally sensitive, responding to stimulation by estrogen with proliferation and maturation. The mucosa is colonized by mixed bacterial flora with lactobacillus predominant; normal pH is 3.5 to 4.5.

2. **Muscularis**—connective tissue and smooth muscle, loosely arranged in inner circular and outer longitudinal layers.

3. **Adventitia**—endopelvic fascia, adherent to the underlying muscularis.

**Blood Supply**  The blood supply of the vagina includes the vaginal artery and branches from the uterine, middle rectal, and internal pudendal arteries.

**Innervation**  The innervation of the vagina is as follows: the upper vagina—uterovaginal plexus; the distal vagina—pudendal nerve.

---

**Uterus**  The uterus is a fibromuscular organ usually divided into a lower cervix and an upper corpus or uterine body (Fig. 5.15).
Cervix

The portion of cervix exposed to the vagina is the exocervix or portio vaginalis. It has a convex round surface with a circular or slitlike opening (the external os) into the endocervical canal. The endocervical canal is about 2 to 3 cm in length and opens proximally into the endometrial cavity at the internal os.

The cervical mucosa generally contains both stratified squamous epithelium, characteristic of the exocervix, and mucus-secreting columnar epithelium, characteristic of the endocervical canal. However, the intersection where these two epithelia meet—the squamocolumnar junction—is geographically variable and dependent on hormonal stimulation. It is this dynamic interface, the transformation zone, that is most vulnerable to the development of squamous neoplasia.

In early childhood, during pregnancy, or with oral contraceptive use, columnar epithelium may extend from the endocervical canal onto the exocervix, a condition known as eversion or ectopy. After menopause, the transformation zone usually recedes entirely into the endocervical canal.

Production of cervical mucus is under hormonal influence. It varies from profuse, clear, and thin mucus around the time of ovulation to scant and thick mucus in the postovulatory phase of the cycle. Deep in the mucosa and submucosa, the cervix is composed of fibrous connective tissue and a small amount of smooth muscle in a circular arrangement.

Corpus

The body of the uterus varies in size and shape, depending on hormonal and childbearing status. At birth, the cervix and corpus are about equal in size; in adult women, the corpus has grown to 2 to 3 times the size of the cervix. The position of the uterus in relation to other pelvic structures is also variable and is generally described in terms of positioning—anterior, midposition, or posterior; flexion; and version. Flexion is the angle between the long axis of the uterine corpus and the cervix, whereas version is the angle
of the junction of the uterus with the upper vagina. Occasionally, abnormal positioning may occur secondary to associated pelvic pathology, such as endometriosis or adhesions.

The uterine corpus is divided into several different regions. The area where the endocervical canal opens into the endometrial cavity is known as the isthmus or lower uterine segment. On each side of the upper uterine body, a funnel-shaped area receives the insertion of the fallopian tubes and is called the uterine cornu; the uterus above this area is the fundus.

The endometrial cavity is triangular in shape and represents the mucosal surface of the uterine corpus. The epithelium is columnar and gland forming with a specialized stroma. It undergoes cyclic structural and functional change during the reproductive years, with regular shedding of the superficial endometrium and regeneration from the basal layer.

The muscular layer of the uterus, the myometrium, consists of interlacing smooth muscle fibers and ranges in thickness from 1.5 to 2.5 cm. Some outer fibers are continuous with those of the tube and round ligament.

Peritoneum covers most of the corpus of the uterus and the posterior cervix and is known as the serosa. Laterally, the broad ligament, a double layer of peritoneum covering the neurovascular supply to the uterus, inserts into the cervix and corpus. Anteriorly, the bladder lies over the isthmic and cervical region of the uterus.

**Blood Supply** The blood supply to the uterus is the uterine artery, which anastomoses with the ovarian and vaginal arteries.

**Innervation** The nerve supply to the uterus is the uterovaginal plexus.

**Fallopian Tubes**

The fallopian tubes and ovaries collectively are referred to as the adnexa. The fallopian tubes are paired hollow structures representing the proximal unfused ends of the müllerian duct. They vary in length from 7 to 12 cm, and their function includes ovum pickup, provision of physical environment for conception, and transport and nourishment of the fertilized ovum.

The tubes are divided into several regions:

1. **Interstitial**—narrowest portion of the tube, lies within the uterine wall and forms the tubal ostia at the endometrial cavity.
2. **Isthmus**—narrow segment closest to the uterine wall.
3. **Ampulla**—larger diameter segment lateral to the isthmus.
4. **Fimbria (infundibulum)**—funnel-shaped abdominal ostia of the tubes, opening into the peritoneal cavity; this opening is fringed with numerous fingerlike projections that provide a wide surface for ovum pickup. The fimbria ovarica is a connection between the end of the tube and ovary, bringing the two closer.

The tubal mucosa is ciliated columnar epithelium, which becomes progressively more architecturally complex as the fimbriated end is approached. The muscularis consists of an inner circular and outer longitudinal layer of smooth muscle. The tube is covered by peritoneum and, through its mesentery (mesosalpinx), which is situated dorsal to the round ligament, is connected to the upper margin of the broad ligament.

**Blood Supply** The vascular supply to the fallopian tubes is the uterine and ovarian arteries.
Innervation  The innervation to the fallopian tubes is the uterovaginal plexus and the ovarian plexus.

Ovaries

The ovaries are paired gonadal structures that lie suspended between the pelvic wall and the uterus by the infundibulopelvic ligament laterally and the uteroovarian ligament medially. Inferiorly, the hilar surface of each ovary is attached to the broad ligament by its mesentery (mesovarium), which is dorsal to the mesosalpinx and fallopian tube. Primary neurovascular structures reach the ovary through the infundibulopelvic ligament and enter through the mesovarium. The normal ovary varies in size, with measurements up to \(5 \times 3 \times 3\) cm. Variation in dimension results from endogenous hormonal production, which varies with age and with each menstrual cycle. Exogenous substances, including oral contraceptives, gonadotropin-releasing hormone agonists, or ovulation-inducing medication, may either stimulate or suppress ovarian activity and, therefore, affect size.

Each ovary consists of a cortex and medulla and is covered by a single layer of flattened cuboidal to low columnar epithelium that is continuous with the peritoneum at the mesovarium. The cortex is composed of a specialized stroma and follicles in various stages of development or attrition. The medulla occupies a small portion of the ovary in its hilar region and is composed primarily of fibromuscular tissue and blood vessels.

Blood Supply  The blood supply to the ovary is the ovarian artery, which anastomoses with the uterine artery.

Innervation  The innervation to the ovary is the ovarian plexus and the uterovaginal plexus.

Urinary Tract

Ureters

The ureters are the urinary conduit leading from the kidney to the bladder; it measures about 25 cm in length and is totally retroperitoneal in location.

The lower half of each ureter traverses the pelvis after crossing the common iliac vessels at their bifurcation, just medial to the ovarian vessels. It descends into the pelvis adherent to the peritoneum of the lateral pelvic wall and the medial leaf of the broad ligament and enters the bladder base anterior to the upper vagina, traveling obliquely through the bladder wall to terminate in the bladder trigone.

The ureteral mucosa is a transitional epithelium. The muscularis consists of an inner longitudinal and outer circular layer of smooth muscle. A protective connective tissue sheath, which is adherent to the peritoneum, encloses the ureter.

Blood Supply  The blood supply is variable, with contributions from the renal, ovarian, common iliac, internal iliac, uterine, and vesical arteries.

Innervation  The innervation is through the ovarian plexus and the vesical plexus.

Bladder and Urethra

Bladder

The bladder is a hollow organ, spherically shaped when full, that stores urine. Its size varies with urine volume, normally reaching a maximum volume of at least 300 mL. The bladder is often divided into two areas, which are of physiologic significance:
1. The **base of the bladder** consists of the urinary trigone posteriorly and a thickened area of detrusor anteriorly. The three corners of the trigone are formed by the two ureteral orifices and the opening of the urethra into the bladder. The bladder base receives α-adrenergic sympathetic innervation and is the area responsible for maintaining continence.

2. The **dome of the bladder** is the remaining bladder area above the bladder base. It has parasympathetic innervation and is responsible for micturition.

The bladder is positioned posterior to the pubis and lower abdominal wall and anterior to the cervix, upper vagina, and part of the cardinal ligament. Laterally, it is bounded by the pelvic diaphragm and obturator internus muscle.

The bladder mucosa is transitional cell epithelium and the muscle wall (detrusor). Rather than being arranged in layers, it is composed of intermeshing muscle fibers.

**Blood Supply**  The blood supply to the bladder is from the superior, middle, and inferior vesical arteries, with contribution from the uterine and vaginal vessels.

**Innervation**  The innervation to the bladder is from the vesical plexus, with contribution from the uterovaginal plexus.

**Urethra**

The vesical neck is the region of the bladder that receives and incorporates the urethral lumen. The female urethra is about 3 to 4 cm in length and extends from the bladder to the vestibule, traveling just anterior to the vagina.

The urethra is lined by nonkeratinized squamous epithelium that is responsive to estrogen stimulation. Within the submucosa on the dorsal surface of the urethra are the paraurethral or Skene glands, which empty through ducts into the urethral lumen. Distally, these glands empty into the vestibule on either side of the external urethral orifice. Chronic infection of Skene glands, with obstruction of their ducts and cystic dilation, is believed to be an inciting factor in the development of suburethral diverticula.

The urethra contains an inner longitudinal layer of smooth muscle and outer, circularly oriented smooth muscle fibers. The inferior fascia of the urogenital diaphragm or perineal membrane begins at the junction of the middle and distal thirds of the urethra. Proximal to the middle and distal parts of the urethra, voluntary muscle fibers derived from the urogenital diaphragm intermix with the outer layer of smooth muscle, increasing urethral resistance and contributing to continence. At the level of the urogenital diaphragm, the skeletal muscle fibers leave the wall of the urethra to form the sphincter urethrae and deep transverse perineal muscles.

**Blood Supply**  The vascular supply to the urethra is from the vesical and vaginal arteries and the internal pudendal branches.

**Innervation**  The innervation to the urethra is from the vesical plexus and the pudendal nerve.

**The lower urinary and genital tracts are intimately connected anatomically and functionally.** In the midline, the bladder and proximal urethra can be dissected easily from the underlying lower uterine segment, cervix, and vagina through a loose avascular plane. The distal urethra is essentially inseparable from the vagina. Of surgical significance is the location of the bladder trigone immediately over the middle third of the vagina. Unrecognized injury to the bladder during pelvic surgery may result in development of a vesicovaginal fistula.
Fortunately, dissection to the level of the trigone is rarely required, and damage to this critical area is unusual. If dissection is carried too far laterally away from the midline, attachments between the bladder and cervix or vagina become much more dense and vascularized, resulting in increased blood loss and technical difficulty.

**Lower Gastrointestinal Tract**

**Sigmoid Colon**

The sigmoid colon begins its characteristic S-shaped curve as it enters the pelvis at the left pelvic brim (Fig. 5.16). The columnar mucosa and richly vascularized submucosa are surrounded by an inner circular layer of smooth muscle and three overlying longitudinal bands of muscle called tenia coli. A mesentery of varying length attaches the sigmoid to the posterior abdominal wall.

*Blood Supply*  The blood supply to the sigmoid colon is from the sigmoid arteries.

*Innervation*  The nerves to the sigmoid colon are derived from the inferior mesenteric plexus.

**Rectum**

The sigmoid colon loses its mesentery in the midsacral region and becomes the rectum about 15 to 20 cm above the anal opening. The rectum follows the curve of the lower sacrum and coccyx and becomes entirely retroperitoneal at the level of the rectouterine pouch or posterior cul-de-sac. It continues along the pelvic curve just posterior to the

---

*Figure 5.16*  The rectosigmoid colon, its vascular supply, and muscular support.

(Coronal view: peritoneum removed on right.)
vagina until the level of the anal hiatus of the pelvic diaphragm, at which point it takes a sharp 90-degree turn posteriorly and becomes the anal canal, separated from the vagina by the perineal body.

The rectal mucosa is lined by a columnar epithelium and characterized by three transverse folds that contain mucosa, submucosa, and the inner circular layer of smooth muscle. The tenia of the sigmoid wall broaden and fuse over the rectum to form a continuous longitudinal external layer of smooth muscle to the level of the anal canal.

**Anal Canal**

The anal canal begins at the level of the sharp turn in the direction of the distal colon and is 2 to 3 cm in length. At the anorectal junction, the mucosa changes to stratified squamous epithelium (the pectinate line), which continues until the termination of the anus at the anal verge, where there is a transition to perianal skin with typical skin appendages. It is surrounded by a thickened ring of circular muscle fibers that is a continuation of the circular muscle of the rectum, the internal anal sphincter. Its lower part is surrounded by bundles of striated muscle fibers, the external anal sphincter (14).

Fecal continence is primarily provided by the puborectalis muscle and the internal and external anal sphincters. The puborectalis surrounds the anal hiatus in the pelvic diaphragm and interdigitates posterior to the rectum to form a rectal sling. The external anal sphincter surrounds the terminal anal canal below the level of the levator ani.

The anatomic proximity of the lower gastrointestinal tract to the lower genital tract is particularly important during surgery of the vulva and vagina. Lack of attention to this proximity during repair of vaginal lacerations or episiotomies can lead to damage of the rectum and resulting fistula formation or injury to the external anal sphincter resulting in fecal incontinence. Because of the avascular nature of the rectovaginal space, it is relatively easy to dissect the rectum from the vagina in the midline, which is routinely done in the repair of rectoceles.

**Blood Supply**

The vascular supply to the rectum and anal canal is from the superior, middle, and inferior rectal arteries. The venous drainage is a complex submucosal plexus of vessels that, under conditions of increased intraabdominal pressure (pregnancy, pelvic mass, ascites), may dilate and become symptomatic with rectal bleeding or pain as hemorrhoids.

**Innervation**

The nerve supply to the anal canal is from the middle rectal plexus, the inferior mesenteric plexus, and the pudendal nerve.

**The Genital Tract and Its Relations**

The genital tract is situated at the bottom of the intraabdominal cavity and is related to the intraperitoneal cavity and its contents, the retroperitoneal spaces, and the pelvic floor. Its access through the abdominal wall or the perineum requires a thorough knowledge of the anatomy of these areas and their relationships.

**The Abdominal Wall**

The anterior abdominal wall is bound superiorly by the xiphoid process and the costal cartilage of the seventh to tenth ribs and inferiorly by the iliac crest, anterosuperior iliac spine, inguinal ligament, and pubic bone. It consists of skin, muscle, fascia, and nerves and vessels.
The lower abdominal skin may exhibit striae, or “stretch marks,” and increased pigmentation in the midline in parous women. The subcutaneous tissue contains a variable amount of fat.

Five muscles and their aponeuroses contribute to the structure and strength of the anterolateral abdominal wall (Fig. 5.17; Table 5.7).

**Superficial Fascia**

The superficial fascia consists of two layers:

1. **Camper fascia**—the most superficial layer, which contains a variable amount of fat and is continuous with the superficial fatty layer of the perineum

2. **Scarpa fascia**—a deeper membranous layer continuous in the perineum with Colles fascia (superficial perineal fascia) and with the deep fascia of the thigh (fascia lata).

**Rectus Sheath**

The aponeuroses of the external and internal oblique and the transversus abdominis combine to form a sheath for the rectus abdominis and pyramidalis, fusing mediadly...
in the midline at the linea alba and laterally at the semilunar line (Fig. 5.18). Above the arcuate line, the aponeurosis of the internal oblique muscle splits into anterior and posterior lamella (Fig. 5.18A). Below this line, all three layers are anterior to the body of the rectus muscle (Fig. 5.18B). The rectus is then covered posteriorly by the transversalis fascia, providing access to the muscle for the inferior epigastric vessels.

**Transversalis Fascia and Endopelvic Fascia**

The transversalis fascia is a firm membranous sheet on the internal surface of the transversus abdominis muscle that extends beyond the muscle and forms a fascia lining the entire abdominopelvic cavity. Like the peritoneum, it is divided into a parietal and a visceral component. It is continuous from side to side across the linea alba and covers the posterior aspect of the rectus abdominis muscle below the arcuate line. Superiorly, it becomes the inferior fascia of the diaphragm. Inferiorly, it is attached to the iliac crest, covers the iliac fascia and the obturator internus fascia, and extends downward and medially to form the superior fascia of the pelvic diaphragm.

Characteristically, the transversalis fascia continues along blood vessels and other structures leaving and entering the abdominopelvic cavity and contributes to the formation of the visceral (endopelvic) pelvic fascia (15). The pelvic fascia invests the pelvic organs and

---

**Table 5.7 Muscles Contributing to the Structure and Strength of the Anterolateral Abdominal Wall**

| Muscle            | Origin                                                                 | Insertion                                                                 | Action                                                                 |
|-------------------|                                                                      |                                                                          |                                                                        |
| **External oblique** | Fleshy digitations from the outer surfaces of ribs 5–12 | Fibers radiate inferiorly, anteriorly, and medially, in most cases ending in the aponeurosis of the external muscle and inserting into the anterior half of the iliac crest, the pubic tubercle, and the linea alba. The superficial inguinal ring is located above and lateral to the pubic tubercle at the end of a triangular cleft in the external oblique muscle, bordered by strong fibrous bands that transmit the round ligament. | Compresses and supports abdominal viscera; flexes and rotates vertebral column |
| **Internal oblique** | Posterior layer of the thoracolumbar fascia, the anterior two thirds of the iliac crest, and the lateral two thirds of the inguinal ligament | Inferior border of ribs 10–12. The superior fibers of the aponeurosis split to enclose the rectus abdominis muscle and join at the linea alba above the arcuate line. The most inferior fibers join with those of the transverse abdominis muscle to insert into the pubic crest and pecten pubis via the conjoint tendon. | Compresses and supports abdominal viscera |
| **Transversus abdominus** | Inner aspect of the inferior six costal cartilages, the thoracolumbar fascia, the iliac crest, and the lateral one third of the inguinal ligament | Linea alba with the aponeurosis of the internal oblique, the pubic crest and the pecten pubis through the conjoint tendon | Compresses and supports abdominal viscera |
| **Rectus abdominis** | Superior pubic ramus and the ligaments of the symphysis pubis | Anterior surface of the xiphoid process and the cartilage of ribs 5–7 | Tenses anterior abdominal wall and flexes trunk |
| **Pyramidalis** | Small triangular muscle contained within the rectus sheath, anterior to the lower part of the rectus muscle | On the linea alba, easily recognizable shape, used to locate the midline, particularly in a patient with previous abdominal surgery and scarring of the abdominal wall | Tenses the linea alba, insignificant in terms of function, and is frequently absent |
attaches them to the pelvic sidewalls, thereby playing a critical role in pelvic support. In the inguinal region, the fascial relationships result in the development of the inguinal canal, through which the round ligament exits into the perineum. The fascia is separated from the peritoneum by a layer of preperitoneal fat. Areas of fascial weaknesses or congenital or posttraumatic and surgical injuries result in herniation of the underlying structures through a defective abdominal wall. The incisions least likely to result in damage to the integrity and innervation of the abdominal wall muscles include a midline incision through the linea alba and a transverse incision through the recti muscle fibers that respects the integrity of its innervation (16).

Figure 5.18  A transverse section of the rectus abdominis. The aponeurosis of the external and internal oblique and the transversus abdominis from the rectus abdominis. A: Above the arcuate line. B: Below the arcuate line.

The tissues of the abdominal wall are innervated by the continuation of the inferior intercostal nerves T4 to T11 and the subcostal nerve T12. The inferior part of the abdominal wall is supplied by the first lumbar nerve through the iliohypogastric and the ilioinguinal nerves. The primary blood supply to the anterior lateral abdominal wall includes the following:

1. The inferior epigastric and deep circumflex iliac arteries, branches of the external iliac artery

2. The superior epigastric artery, a terminal branch of the internal thoracic artery
The inferior epigastric artery runs superiorly in the transverse fascia to reach the arcuate line, where it enters the rectus sheath. It is vulnerable to damage by abdominal incisions in which the rectus muscle is completely or partially transected or by excessive lateral traction on the rectus. The deep circumflex artery runs on the deep aspect of the anterior abdominal wall parallel to the inguinal ligament and along the iliac crest between the transverse abdominis muscle and the internal oblique muscle. The superior epigastric vessels enter the rectus sheath superiorly just below the seventh costal cartilage.

The venous system drains into the saphenous vein, and the lymphatics drain to the axillary chain above the umbilicus and to the inguinal nodes below it. The subcutaneous tissues drain to the lumbar chain.

Perineum

The perineum is situated at the lower end of the trunk between the buttocks. Its bony boundaries include the lower margin of the pubic symphysis anteriorly, the tip of the coccyx posteriorly, and the ischial tuberosities laterally. These landmarks correspond to the boundaries of the pelvic outlet. The diamond shape of the perineum is customarily divided by an imaginary line joining the ischial tuberosities immediately in front of the anus, at the level of the perineal body, into an anterior urogenital and a posterior anal triangle (Fig. 5.19).

Urogenital Triangle

The urogenital triangle includes the external genital structures and the urethral opening (Fig. 5.19). These external structures cover the superficial and deep perineal compartments (Figs. 5.20 and 5.21) and are known as the vulva.
SECTION II  Basic Principles

Figure 5.20  Superficial perineal compartment.

Figure 5.21  Deep perineal compartment.
**Vulva**

**Mons Pubis**
The mons pubis is a triangular eminence in front of the pubic bones that consists of adipose tissue covered by hair-bearing skin up to its junction with the abdominal wall.

**Labia Majora**
The labia majora are a pair of fibroadipose folds of skin that extend from the mons pubis downward and backward to meet in the midline in front of the anus at the posterior fourchette. They include the terminal extension of the round ligament and occasionally a peritoneal diverticulum, the canal of Nuck. They are covered by skin with scattered hairs laterally and are rich in sebaceous, apocrine, and eccrine glands.

**Labia Minora**
The labia minora lie between the labia majora, with which they merge posteriorly, and are separated into two folds as they approach the clitoris anteriorly. The anterior folds unite to form the prepuce or hood of the clitoris. The posterior folds form the frenulum of the clitoris as they attach to its inferior surface. The labia minora are covered by hairless skin overlying a fibroelastic stroma rich in neural and vascular elements. The area between the posterior labia minora forms the vestibule of the vagina.

**Clitoris**
The clitoris is an erectile organ that is 2 to 3 cm in length. It consists of two crura and two corpora cavernosa and is covered by a sensitive rounded tubercle (the glans).

**Vaginal Orifice**
The vaginal orifice is surrounded by the hymen, a variable crescentic mucous membrane that is replaced by rounded caruncles after its rupture. The opening of the duct of the greater vestibular (Bartholin) glands is located on each side of the vestibule. Numerous lesser vestibular glands are also scattered posteriorly and between the urethral and vaginal orifices.

**Urethral Orifice**
The urethral orifice is immediately anterior to the vaginal orifice about 2 to 3 cm beneath the clitoris. The Skene (paraurethral) gland duct presents an opening on its posterior surface.

**Superficial Perineal Compartment**
The superficial perineal compartment lies between the superficial perineal fascia and the inferior fascia of the urogenital diaphragm (perineal membrane) (Fig. 5.20). The superficial perineal fascia has a superficial and deep component. The superficial layer is relatively thin and fatty and is continuous superiorly with the superficial fatty layer of the lower abdominal wall (Camper fascia). It continues laterally as the fatty layer of the thighs. The deep layer of the superficial perineal (Colles) fascia is continuous superiorly with the deep layer of the superficial abdominal fascia (Scarpa fascia), which attaches firmly to the ischiopubic rami and ischial tuberosities. The superficial perineal compartment is continuous superiorly with the superficial fascial spaces of the anterior abdominal wall, allowing spread of blood or infection along that route. Such spread is limited laterally by the ischiopubic rami, anteriorly by the transverse ligament of
the perineum, and posteriorly by the superficial transverse perineal muscle. The superficial perineal compartment includes the following.

**Erectile Bodies**

The vestibular bulbs are 3-cm, highly vascular structures surrounding the vestibule and located under the bulbocavernosus muscle. The body of the clitoris is attached by two crura to the internal aspect of the ischiopubic rami. They are covered by the ischiocavernosus muscle.

**Muscles**

The muscles of the vulva are the ischiocavernosus, the bulbocavernosus, and superficial transverse perineal. They are included in the superficial perineal as follows:

**Ischiocavernosus**
- Origin—ischial tuberosity
- Insertion—ischiopubic bone
- Action—compresses the crura and lowers the clitoris

**Bulbocavernosus**
- Origin—perineal body
- Insertion—posterior aspect of the clitoris; some fibers pass above the dorsal vein of the clitoris in a slinglike fashion
- Action—compresses the vestibular bulb and dorsal vein of the clitoris

**Superficial Transverse Perineal**
- Origin—ischial tuberosity
- Insertion—central perineal tendon
- Action—fixes the perineal body

**Vestibular Glands**

The vestibular glands are situated on either side of the vestibule under the posterior end of the vestibular bulb. They drain between the hymen and the labia minora. Their mucous secretion helps maintain adequate lubrication. Infection in these glands can result in an abscess.

**Deep Perineal Compartment**

The deep perineal compartment is a fascial space bound inferiorly by the perineal membrane and superiorly by a deep fascial layer that separates the urogenital diaphragm from the anterior recess of the ischiorectal fossa (Fig. 5.21). It is stretched across the anterior half of the pelvic outlet between the ischiopubic rami. The deep compartment may be directly continuous with the pelvic cavity superiorly (17). Indeed, the posterior pubourethral ligaments, functioning as winglike elevations of the fascia ascending from the pelvic floor to the posterior aspect of the symphysis pubis, provide a point of fixation to the urethra and support the concept of the continuity of the deep perineal compartment with the pelvic cavity.

The anterior pubourethral ligaments represent a similar elevation of the inferior fascia of the urogenital diaphragm and are joined by the intermediate pubourethral ligament, with the junction between the two fascial structures arcing under the pubic symphysis (18). The urogenital diaphragm includes the sphincter urethrae (urogenital sphincter) and the deep transverse perineal (transversus vaginae) muscle.
The sphincter urethrae (Fig. 5.22) is a continuous muscle fanning out as it develops proximally and distally, including the following:

1. The **external urethral sphincter**, which surrounds the middle third of the urethra

2. The **compressor urethrae**, arcing across the ventral side of the urethra

3. The **urethrovaginal sphincter**, which surrounds the ventral aspect of the urethra and terminates in the lateral vaginal wall

The deep transverse perineal muscle originates at the internal aspect of the ischial bone, parallels the muscle compressor urethrae, and attaches to the lateral vaginal wall along the perineal membrane.

The urinary and genital tracts have a common reliance on several interdependent structures for support. **The cardinal and uterosacral ligaments are condensations of endopelvic fascia** that support the cervix and upper vagina over the levator plate. Laterally, endopelvic fascial condensations attach the midvagina to the pelvic walls at the arcus tendineus fascia pelvis anteriorly and the arcus tendineus levator ani posteriorly. The distal anterior vagina and urethra are anchored to the urogenital diaphragm, and the distal posterior vagina to the perineal body.

Anteriorly, the pubourethral ligaments and pubovesical fascia and ligaments provide fixation and stabilization for the urethra and bladder. Posteriorly, they rely on the vagina and lower uterus for support. Partial resection or relaxation of the uterosacral ligaments often leads to relaxation of the genitourinary complex, resulting in the formation of a cystocele. Various types and degrees of genital tract prolapse or relaxation are almost always associated with similar findings in the bladder, urethra, or both.
**Blood Supply**  The blood supply to the vulva is as follows:

1. External pudendal artery (from femoral artery), internal pudendal artery
2. Venous drainage—internal pudendal veins

The blood supply to the superficial and deep perineal compartments is as follows:

1. Internal pudendal artery, dorsal artery of the clitoris
2. Venous drainage—internal pudendal veins, which are richly anastomotic
3. Lymphatic drainage—internal iliac chain

**Innervation** The innervation to the vulva is from branches of the following nerves:

1. Ilioinguinal nerve
2. Genitofemoral nerve (genital branch)
3. Lateral femoral cutaneous nerve of the thigh (perineal branch)
4. Perineal nerve (branch of pudendal)

Superficial and deep perineal compartments are innervated by the perineal nerve.

---

**Perineal Body**

The perineal body or central perineal tendon is critical to the posterior support of the lower aspect of the anterior vaginal wall. It is a triangle-shaped structure separating the distal portion of the anal and vaginal canals that is formed by the convergence of the tendinous attachments of the bulbocavernosus, the external anal sphincter, and the superficial transverse perinei muscle. Its superior border represents the point of insertion of the rectovaginal (Denonvilliers) fascia, which extends to the underside of the peritoneum covering the cul-de-sac of Douglas, separating the anorectal from the urogenital compartment [19]. The perineal body also plays an important anchoring role in the musculofascial support of the pelvic floor. It represents the central connection between the two layers of support of the pelvic floor—the pelvic and urogenital diaphragm. It also provides a posterior connection to the anococcygeal raphe. Thus, it is central to the definition of the bilevel support of the floor of the pelvis.

---

**Anal Triangle**

The anal triangle includes the lower end of the anal canal. The external anal sphincter surrounds the anal triangle, and the ischiorectal fossa is on each side. Posteriorly, the anococcygeal body lies between the anus and the tip of the coccyx and consists of thick fibromuscular tissue (of levator ani and external anal sphincter origin) giving support to the lower part of the rectum and the anal canal.

The external anal sphincter forms a thick band of muscular fibers arranged in three layers running from the perineal body to the anococcygeal ligament. The subcutaneous fibers are thin and surround the anus and, without bony attachment, decussate in front of it. The superficial fibers sweep forward from the anococcygeal ligament, and the tip of the coccyx around the anus inserts into the perineal body. The deep fibers arise from the perineal body to encircle the lower half of the anal canal to form a true sphincter muscle, which fuses with the puborectalis portion of the levator ani.
The ischiorectal fossa is mainly occupied by fat and separates the ischium laterally from the median structures of the anal triangle. It is a fascia-lined space located between the perineal skin inferiorly and the pelvic diaphragm superiorly; it communicates with the contralateral ischiorectal fossa over the anococcygeal ligament. Superiorly, its apex is at the origin of the levator ani muscle from the obturator fascia. It is bound medi ally by the levator ani and the external sphincter with their fascial covering, laterally by the obturator internus muscle with its fascia, posteriorly by the sacrotuberous ligament and the lower border of the gluteus maximus muscle, and anteriorly by the base of the urogenital diaphragm. It is widest and deepest posteriorly and weakest medially.

An ischiorectal abscess should be drained without delay, or it will extend into the anal canal. The cavity is filled with fat that cushions the anal canal and is traversed by many fibrous bands, vessels, and nerves, including the pudendal and the inferior rectal nerves. The perforating branch of S2 and S3 and the perineal branch of S4 also run through this space.

The pudendal (Alcock) canal is a tunnel formed by a splitting of the inferior portion of the obturator fascia running anteromedially from the ischial spine to the posterior edge of the urogenital diaphragm. It contains the pudendal artery, vein, and nerve in their traverse from the pelvic cavity to the perineum.

**Blood Supply** The blood supply to the anal triangle is from the inferior rectal (hemorrhoidal) artery and vein.

**Innervation** The innervation to the anal triangle is from the perineal branch of the fourth sacral nerve and the inferior rectal (hemorrhoidal) nerve.

---

**Retroperitoneum and Retroperitoneal Spaces**

The subperitoneal area of the true pelvis is partitioned into potential spaces by the various organs and their respective fascial coverings and by the selective thickenings of the endopelvic fascia into ligaments and septa (Fig. 5.23). It is imperative that surgeons operating in the pelvis be familiar with these spaces, as discussed below.

**Prevesical Space**

The prevesical (Retzius) space is a fat-filled potential space bound anteriorly by the pubic bone, covered by the transversalis fascia, and extending to the umbilicus between the medial umbilical ligaments (obliterated umbilical arteries); posteriorly, the space extends to the anterior wall of the bladder. It is separated from the paravesical space by the ascending bladder septum (bladder pillars).

Upon entering the prevesical space, the pubourethral ligaments may be seen inserting the posterior aspect of the symphysis pubis as a thickened prolongation of the arcus tendineus fascia. With combined abdominal and vaginal bladder neck suspensory procedures, the point of entry is usually the Retzius space between the arcus tendineus and the pubourethral ligaments.

**Paravesical Space**

The paravesical spaces are fat filled and limited by the fascia of the obturator internus muscle and the pelvic diaphragm laterally, the bladder pillar medially, the endopelvic fascia inferiorly, and the lateral umbilical ligament superiorly.

**Vesicovaginal Space**

The vesicovaginal space is separated from the Retzius space by the endopelvic fascia. This space is limited anteriorly by the bladder wall (from the proximal urethra to the upper vagina), posteriorly by the anterior vaginal wall, and laterally by the bladder septa (selective thickenings of the endopelvic fascia inserting laterally into the arcus tendineus). A tear in these fascial investments and thickenings medially, transversely, or laterally allows herniation and development of a cystocele.
SECTION II Basic Principles

Rectovaginal Space

The rectovaginal space extends between the vagina and the rectum from the superior border of the perineal body to the underside of the rectouterine Douglas pouch. It is bound anteriorly by the rectovaginal septum (firmly adherent to the posterior aspect of the vagina), posteriorly by the anterior rectal wall, and laterally by the descending rectal septa separating the rectovaginal space from the pararectal space on each side. The rectovaginal septum represents a firm membranous transverse septum dividing the pelvis into rectal and urogenital compartments, allowing the independent function of the vagina and rectum and providing support for the rectum. It is fixed laterally to the pelvic sidewall by rectovaginal fascia (part of the endopelvic fascia) along a line extending from the posterior fourchette to the arcus tendineus fasciae pelvis, midway between the pubis and the ischial spine (20). An anterior rectocele often results from a defective septum or an avulsion of the septum from the perineal body. Reconstruction of the perineum is critical for the restoration of this important compartmental separation as well as for the support of the anterior vaginal wall (21). Lateral detachment of the rectovaginal fascia from the pelvic sidewall may constitute a “pararectal” defect analogous to anterior paravaginal defects.

Pararectal Space

The pararectal space is bound laterally by the levator ani, medially by the rectal pillars, and posteriorly above the ischial spine by the anterolateral aspect of the sacrum. It is separated from the retrorectal space by the posterior extension of the descending rectal septa.
Retrorectal Space
The retrorectal space is limited by the rectum anteriorly and the anterior aspect of the sacrum posteriorly. It communicates with the pararectal spaces laterally above the uterosacral ligaments and extends superiorly into the presacral space.

Presacral Space
The presacral space is the superior extension of the retrorectal space and is limited by the deep parietal peritoneum anteriorly and the anterior aspect of the sacrum posteriorly. It harbors the middle sacral vessels and the hypogastric plexi between the bifurcation of the aorta invested by loose areolar tissue. Presacral neurectomy requires familiarity with and working knowledge of this space.

Peritoneal Cavity
The female pelvic organs lie at the bottom of the abdominopelvic cavity covered superiorly and posteriorly by the small and large bowel. Anteriorly, the uterine wall is in contact with the posterosuperior aspect of the bladder. The uterus is held in position by the following structures:

1. The round ligaments coursing inferolaterally toward the internal inguinal ring
2. The uterosacral ligaments, which provide support to the cervix and upper vagina and interdigitate with fibers from the cardinal ligament near the cervix
3. The cardinal ligaments, which provide support to the cervix and upper vagina and contribute to the support of the bladder

Anteriorly, the uterus is separated from the bladder by the vesicouterine pouch and from the rectum posteriorly by the rectouterine pouch or Douglas cul-de-sac. Laterally, the bilateral broad ligaments carry the neurovascular pedicles and their respective fascial coverings, attaching the uterus to the lateral pelvic sidewall.

The broad ligament is in contact inferiorly with the paravesical space, the obturator fossa, and the pelvic extension of the iliac fossa, to which it provides a peritoneal covering, and with the uterosacral ligament. Superiorly, it extends into the infundibulopelvic ligament.

Ureter
In its pelvic path, in the retroperitoneum, several relationships are of significance and identify areas of greatest vulnerability to injury of the ureter (Fig. 5.24):

1. The ovarian vessels cross over the ureter as it approaches the pelvic brim and lie in proximity just lateral to the ureter as it enters the pelvis.
2. As the ureter descends into the pelvis, it runs within the broad ligament just lateral to the uterosacral ligament, separating the uterosacral ligament from the mesosalpinx, mesovarium, and ovarian fossa.
3. At about the level of the ischial spine, the ureter crosses under the uterine artery in its course through the cardinal ligament; the ureter divides this area into the suprareuterine parametrium surrounding the uterine vessels and the infraureteric paracervix molded around the vaginal vessels and extending posteriorly into the uterosacral ligament. In this location, the ureter lies 2 to 3 cm lateral to the cervix and in proximity to the insertion of the uterosacral ligament at the cervix. This proximity warrants caution when using the uterosacral ligament for vaginal vault suspension.
4. The ureter then turns medially to cross the anterior upper vagina as it traverses the bladder wall.

About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures, most commonly abdominal hysterectomy (23). Distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids, may increase susceptibility to injury by displacement or alteration of usual anatomy. Careful identification of the course of the ureter before securing the infundibulopelvic ligament and uterine artery is the best protection against ureteric injury during hysterectomy or adnexectomy. Even with severe intraperitoneal disease, however, the ureter can always be identified using a retroperitoneal approach and noting fundamental landmarks and relationships.

Pelvic Floor

The pelvic floor includes all of the structures closing the pelvic outlet from the skin inferiorly to the peritoneum superiorly. It is commonly divided by the pelvic diaphragm into a pelvic and a perineal portion (24). The pelvic diaphragm is spread transversely in a hammocklike fashion across the true pelvis, with a central hiatus for the urethra, vagina, and rectum. Anatomically and physiologically, the pelvic diaphragm can be divided into two components—the internal and external components.

The external component originates from the arcus tendineus, extending from the pubic bone to the ischial spine. It gives rise to fibers of differing directions, including the pubococcygeus, the iliococcygeus, and the coccygeus.

The internal component originates from the pubic bone above and medial to the origins of the pubococcygeus and is smaller but thicker and stronger (24). Its fibers run in a sagittal direction and are divided into the following two portions:
1. *Pubovaginalis* fibers run in a perpendicular direction to the urethra, crossing the lateral vaginal wall at the junction of its lower one third and upper two thirds to insert into the perineal body. The intervening anterior interlevator space is covered by the urogenital diaphragm.

2. *Puborectalis* superior fibers sling around the rectum to the symphysis pubis; its inferior fibers insert into the lateral rectal wall between the internal and external sphincter.

The pelvic diaphragm is covered superiorly by fascia, which includes a parietal and a visceral component and is a continuation of the transversalis fascia (Fig. 5.25). The parietal fascia has areas of thickening (ligaments, septae) that provide reinforcement and fixation for the pelvic floor. The visceral (endopelvic) fascia extends medially to invest the pelvic viscera, resulting in a fascial covering to the bladder, vagina, uterus, and rectum. It becomes attenuated where the peritoneal covering is well defined and continues laterally with the pelvic cellular tissue and neurovascular pedicles.

Musculofascial elements (the hypogastric sheath) extend along the vessels originating from the internal iliac artery. Following these vessels to their respective organs, the hypogastric sheath extends perivascular investments that contribute to the formation of the endopelvic fascia so critical for the support of the pelvic organs.

Thus, the parietal fascia anchors the visceral fascia, which defines the relationship of the various viscera and provides them with significant fixation (uterosacral and cardinal ligaments), septation (vesicovaginal and rectovaginal), and definition of pelvic spaces (prevesical, vesicovaginal, rectovaginal, paravesical, pararectal, and retrorectal).

![Figure 5.25](image.png) The fascial components of the pelvic diaphragm.
For its support, the pelvic floor relies on the complementary role of the pelvic diaphragm and its fascia resting on the perineal fibromuscular complex. It is composed of the perineal membrane (urogenital diaphragm) anteriorly, and the perineal body joined to the anococcygeal raphe by the external anal sphincter posteriorly. This double-layered arrangement, when intact, provides optimal support for the pelvic organs and counterbalances the forces pushing them downward with gravity and with any increase in intraabdominal pressure (Fig. 5.26). Dynamic imaging techniques, such as MRI, CT, and ultrasonography, are increasingly used to provide additional information in the evaluation of pelvic floor problems by visualizing anatomic landmarks during different functional phases.

**Summary**

New surgical approaches are being developed to solve old problems and often require surgeons to revisit familiar anatomy from an unfamiliar perspective (e.g., through a laparoscope) or with a different understanding of complex anatomic relationships. Anatomic alterations secondary to disease, congenital variation, or intraoperative complications may make even familiar surgical territory suddenly seem foreign. All of these situations require surgeons to be perpetual students of anatomy, regardless of their breadth or depth of experience.

Several strategies for continuing education in anatomy are suggested:

1. Review relevant anatomy before each surgical procedure.
2. Study the gynecologic literature on an ongoing basis—numerous publications have documented the evolution of newer concepts regarding anatomic issues such as pelvic support.
3. Operate with more experienced pelvic surgeons, particularly when incorporating new surgical procedures into practice.

4. Periodically dissect fresh or fixed cadaveric specimens; this practice can generally be arranged through local or regional anatomy boards or medical schools or by special arrangement at the time of autopsy.

5. Take advantage of newer computer-generated 3D pelvic models and virtual reality interactive anatomic and surgical simulators, when available, to better understand functional anatomy and to help plan complicated surgical procedures (25,26).

References

• The regulation and maintenance of normal tissue requires a balance between cell proliferation and programmed cell death, or apoptosis.

• The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms. Disruption of these autocrine and paracrine intraovarian pathways may be the basis of polycystic ovarian disease, disorders of ovulation, and ovarian neoplastic disease.

• Among the genes that participate in control of cell growth and function, proto-oncogenes and tumor suppressor genes are particularly important.

• Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are protein kinases that convert an extracellular signal into an intracellular signal. Many of the proteins that participate in the intracellular signal transduction system are encoded by proto-oncogenes that are divided into subgroups based on their cellular location or enzymatic function.

• Oncogenes comprise a family of genes that result from gain of function mutations of their normal counterparts, proto-oncogenes. The normal function of proto-oncogenes is to stimulate proliferation in a controlled context. Activation of oncogenes can lead to stimulation of cell proliferation and development of a malignant phenotype.

• Tumor suppressor genes are involved in the development of most cancers and are usually inactivated in a two-step process in which both copies of the tumor suppressor gene are mutated or inactivated by epigenetic mechanisms like methylation. The most commonly mutated tumor suppressor gene in human cancers is p53.

• T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses. T cells can be distinguished from other types of lymphocytes by their cell surface phenotype, based on the
pattern of expression of various molecules, as well as by differences in their biologic functions.

- There are two major subsets of mature T cells that are phenotypically and functionally distinct: T helper/inducer cells, which express the CD4 cell surface marker, and the T suppressor/cytotoxic cells, which express the CD8 marker. TH1 and TH2 are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: Clones of TH1 produce IL-2 and IFN-γ, whereas TH2 clones produce IL-4, IL-5, IL-6, and IL-10.

Recent advances in molecular biology and genetics have led to improved understanding of basic biologic concepts and disease development. The knowledge acquired with the completion of the human genome project, the development of novel diagnostic modalities like microarray technology for the analysis of DNA and proteins, as well as the emergence of treatment strategies that target specific disease mechanisms, all have an increasing impact on the specialty of obstetrics and gynecology.

Normal cells are characterized by discrete metabolic, biochemical, and physiologic mechanisms. Specific cell types differ with respect to their mainly genetically determined responses to external influences (Fig. 6.1). In general, an external stimulus is converted to an intracellular signal, for example, via a cell membrane receptor. The intracellular signal is transferred to the nucleus and generates certain genetic responses that lead to changes in cellular function, differentiation, and proliferation. Although specific cell types and tissues exhibit unique functions and responses, many basic aspects of cell biology and genetics are common to all eukaryotic cells.

**Cell Cycle**

**Normal Cell Cycle**

Adult eukaryotic cells possess a well-balanced system of continuous production of DNA (transcription) and proteins (translation). Proteins are constantly degraded and replaced depending on the specific cellular requirements. Cells proceed through a sequence of phases called the cell cycle, during which the DNA is distributed to two daughter cells (*mitosis*) and subsequently duplicated (*synthesis phase*). This process is controlled at key checkpoints that monitor the status of a cell, for example, the amount of DNA present. The cell cycle is regulated by a small number of heterodimeric protein...
Kinases that consist of a regulatory subunit (cyclin) and a catalytic subunit (cyclin-dependent kinase). Association of a cyclin with a cyclin-dependent kinase (CdkC) determines which proteins will be phosphorylated at a specific point during the cell cycle.

The cell cycle is divided into four major phases: M phase (mitosis), G\(_1\) phase (period between mitosis and initiation of DNA replication), S phase (DNA synthesis), and G\(_2\) phase (period between completion of DNA synthesis and mitosis) (Fig. 6.2). Postmitotic cells can “exit” the cell cycle into the so-called G\(_0\) phase and remain for days, weeks, or even a lifetime without further proliferation. The duration of the cell cycle may be highly variable, although most human cells complete the cell cycle within approximately 24 hours. During a typical cell cycle, mitosis lasts about 30 to 60 minutes, the G\(_1\) phase 7 to 10 hours, S phase 10 hours, and G\(_2\) phase 5 hours. With respect to the cell cycle, there are three subpopulations of cells:

1. **Terminally differentiated cells** cannot reenter the cell cycle.
2. **Quiescent (G\(_0\)) cells** can enter the cell cycle if appropriately stimulated.
3. **Dividing cells** are currently in the cell cycle.

Red blood cells, striated muscle cells, uterine smooth muscle cells, and nerve cells are terminally differentiated. Other cells, such as fibroblasts, exit from the G\(_1\) phase into the G\(_0\) phase and are considered to be out of the cell cycle. These cells enter the cell cycle following exposure to specific stimuli, such as growth factors and steroid hormones. Dividing cells are found in the gastrointestinal tract, the skin, and the cervix.
**SECTION II  Basic Principles**

**G₁ Phase**

In response to specific external stimuli, cells enter the cell cycle by moving from the G₀ phase into the G₁ phase. The processes during G₁ phase lead to the synthesis of enzymes and regulatory proteins necessary for DNA synthesis during S phase, and are mainly regulated by G₁ cyclin-dependent kinase–cyclin complexes (G₁ CdkC). Complexes of G₁ CdkC induce degradation of the S phase inhibitors in late G₁. Release of the S phase CdkC complex subsequently stimulates entry into the S phase. **Variations in the duration of the G₁ phase of the cell cycle, ranging from less than 8 hours to longer than 100 hours, account for the different generation times exhibited by different types of cells.**

**S Phase**

The nuclear DNA content of the cell is duplicated during the S phase of the cell cycle. The S phase CdkC complex activates proteins of the DNA prereplication complexes that assemble on DNA replication origins during G₁. The prereplication complex activates initiation of DNA replication and inhibits the assembly of new prereplication complexes. This inhibition ascertains that each chromosome is replicated only once during S phase.

**G₂ Phase**

RNA and protein synthesis occurs during the G₂ phase of the cell cycle. The burst of biosynthetic activity provides the substrates and enzymes to meet the metabolic requirements of the two daughter cells. Another important event that occurs during the G₂ phase of the cell cycle is repair of errors of DNA replication that may have occurred during the S phase. Failure to detect and correct these genetic errors can result in a broad spectrum of adverse consequences for the organism as well as the individual cell (1). Defects in the DNA repair mechanism have been associated with an increased incidence of cancer (2). Mitotic CdkC complexes are synthesized during the S and G₂ phase, but are inactive until DNA synthesis is completed.

**M Phase**

Nuclear–chromosomal division occurs during mitosis or M phase. During this phase, the cellular DNA is equally distributed to each of the daughter cells. Mitosis provides a diploid (2n) DNA complement to each somatic daughter cell. Following mitosis, eukaryotic mammalian cells contain diploid DNA reflecting a karyotype that includes 44 somatic chromosomes and a XX or XY sex chromosome complement. Exceptions to the diploid cellular content include hepatocytes (4n) and the functional syncytium of the placenta.

**Mitosis is divided into prophase, metaphase, anaphase, and telophase.** Mitotic CdkC complexes induce chromosome condensation during the prophase, assembly of the mitotic spindle apparatus, and alignment of the chromosomes during the metaphase. Activation of the anaphase promoting complex (APC) leads to inactivation of the protein complexes that connect sister chromatids during metaphase, permitting the onset of anaphase. During anaphase, sister chromatides segregate to opposite spindle poles. The nuclear envelope breaks down into multiple small vesicles early in mitosis and reforms around the segregated chromosomes as they decondense during telophase. Cytokinesis is the process of division of the cytoplasm that segregates the endoplasmatic reticulum and the Golgi apparatus during mitosis. After completion of mitosis, cells enter the G₁ phase and either re-enter the cell cycle or remain in G₀.

**Ploidy**

After meiosis, germ cells contain a haploid (1n) genetic complement. After fertilization, a 46,XX or 46,XY diploid DNA complement is restored. Restoration of the normal cellular DNA content is crucial to normal function. Abnormalities of cellular DNA content cause distinct phenotypic abnormalities as exemplified by hydatidiform molar pregnancy (see Chapter 37). With complete hydatidiform mole, an oocyte without any nuclear genetic material (e.g., an empty ovum) is fertilized by one sperm.
The haploid genetic content of the fertilized ovum is then duplicated and the diploid cellular DNA content is restored, resulting in a homozygous 46,XX gamete. Less often, a complete hydatidiform mole results from the fertilization of an empty ovum by two sperm, resulting in a heterozygous 46,XX or 46,XY gamete. In complete molar pregnancies, the nuclear DNA is usually paternally derived, embryonic structures do not develop, and trophoblast hyperplasia occurs. Rarely, complete moles are biparental. This karyotype seems to be found in patients with recurrent hydatidiform moles and is associated with a higher risk of persistent trophoblastic disease.

A partial hydatiform mole follows the fertilization of a haploid ovum by two sperm, resulting in a 69,XXX, 69,XXY, or 69,XYY karyotype. A partial mole contains paternal and maternal DNA, and both embryonic and placental development occur. Both the 69,YYY karyotype and the 46,YY karyotype are incompatible with embryonic and placental development. These observations demonstrate the importance of maternal genetic material, in particular the X chromosome, in normal embryonic and placental development.

In addition to total cellular DNA content, the chromosome number is an important determinant of cellular function. Abnormalities of chromosome number, which are often the result of nondisjunction during meiosis, result in well-characterized clinical syndromes such as trisomy 21 (Down syndrome), trisomy 18, and trisomy 13.

Cell Division Cycle among the factors that regulate the cell cycle checkpoints, proteins encoded by the cdc2 family of genes and the cyclin proteins appear to play particularly important roles (8,9). Growth factor–stimulated mammalian cells express early-response or delayed-response genes depending on the chronological sequence of the appearance of specific RNAs. The early- and delayed-response genes act as nuclear transcription factors and stimulate the expression of a cascade of other genes. Early-response genes like c-Jun and c-Fos enhance the transcription of delayed-response genes like E2Fs. E2F transcription factors are required for the expression of various cell cycle genes and are functionally regulated by the retinoblastoma (Rb) protein. Binding of Rb to E2F converts E2F from a transcriptional activator to a repressor of transcription. Phosphorylation of Rb inhibits its repressing function and therefore permits E2F-mediated activation of genes required for entry into the S phase. Cdk4-cyclin D, Cdk6-cyclin D, and Cdk2-cyclin E complexes cause phosphorylation of Rb, which remains phosphorylated throughout the S, G2, and M phases of the cell cycle. After completion of mitosis, a decline of the level of Cdk-cyclins leads to dephosphorylation of Rb by phosphatases and, consequently, an inhibition of E2F in the early G1 phase.

As cells approach the G1/S phase transition, synthesis of cyclin A is initiated. The Cdk2-cyclin A complex can trigger initiation of DNA synthesis by supporting the prereplication complex. The p34cdc2 protein and specific cyclins form a complex heterodimer referred to as mitosis-promoting factor (MPF), which catalyzes protein phosphorylation and drives the cell into mitosis. Cdk1 assembles with cyclin A and cyclin B in G2 phase and promotes the activity of the mitosis-promoting factor (MPF). Mitosis is initiated by activation of
The **cdc gene at the G₂/M checkpoint** (10,11). Once the G₂/M checkpoint has been passed, the cell undergoes mitosis. In the presence of abnormally replicated chromosomes, progression past the G₂/M checkpoint does not occur.

**The p53 tumor suppressor gene participates in cell cycle control.** Cells exposed to radiation therapy exhibit an S-phase arrest that is accompanied by increased expression of p53. This delay permits the repair of radiation-induced DNA damage. With mutations of p53, the S-phase arrest that normally follows radiation therapy does not occur (12,13). The wild type p53 gene can be inactivated by the human papillomavirus E6 protein, preventing S-phase arrest in response to DNA damage (14).

---

**Apoptosis**

The regulation and maintenance of normal tissue requires a balance between cell proliferation and programmed cell death, or *apoptosis*. When proliferation exceeds programmed cell death, the result is hyperplasia. When programmed cell death exceeds proliferation, the result is atrophy. Programmed cell death is a crucial concomitant of normal embryologic development. This mechanism accounts for deletion of the interdigital webs (15), palatal fusion (16), and development of the intestinal mucosa (17). Programmed cell death is also an important phenomenon in normal physiology (18). The reduction in the number of endometrial cells following alterations in steroid hormone levels during the menstrual cycle is, in part, a consequence of programmed cell death (19,20). In response to androgens, granulosa cells undergo programmed cell death (e.g., follicular atresia) (21).

Programmed cell death, or apoptosis, is an energy-dependent, active process that is initiated by the expression of specific genes. This process is distinct from cell necrosis, although both mechanisms result in a reduction in total cell number. In programmed cell death, cells shrink and undergo phagocytosis. Apoptosis is an energy-dependent process that results from the expression of specific genes. Conversely, groups of cells expand and lyse when undergoing cell necrosis. The process is energy-independent and results from noxious stimuli. Programmed cell death is triggered by a variety of factors, including intracellular signals and exogenous stimuli such as radiation exposure, chemotherapy, and hormones. Cells undergoing programmed cell death may be identified on the basis of histologic, biochemical, and molecular biologic changes. Histologically, apoptotic cells exhibit cellular condensation and fragmentation of the nucleus. Biochemical correlates of impending programmed cell death include an increase in transglutaminase expression and fluxes in intracellular calcium concentration (22).

Programmed cell death has recently emerged as an important factor in the growth of neoplasms. Historically, neoplastic growth has been characterized by uncontrolled cellular proliferation that resulted in a progressive increase in tumor burden. It is now recognized that the increase in tumor burden associated with progressive disease reflects an imbalance between cell proliferation and cell death. Cancer cells not only fail to respond to the normal signals to stop proliferating, but they may also fail to recognize the physiologic signals that trigger programmed cell death.

---

**Modulation of Cell Growth and Function**

The normal cell exhibits an orchestrated response to the changing extracellular environment. The three groups of substances that signal these extracellular changes are steroid hormones, growth factors, and cytokines. The capability to respond to these stimuli requires a cell surface recognition system, intracellular signal transduction, and nuclear responses for the expression of specific genes in a coordinated fashion. Among the genes that participate in control of cell growth and function, proto-oncogenes and tumor
**Suppressor Genes** are particularly important. More than 100 proto-oncogene products that contribute to growth regulation have been identified (23) (Table 6.1). As a group, proto-oncogenes exert positive effects upon cellular proliferation. In contrast, tumor suppressor genes exert inhibitory regulatory effects on cellular proliferation (Table 6.2).

### Steroid Hormones

Steroid hormones play a crucial role in reproductive biology as well as in general physiology. Among the various functions, steroid hormones influence pregnancy, cardiovascular function, bone metabolism, and an individual’s sense of general well-being. The action of steroid hormones is mediated via extracellular signals to the nucleus to affect a physiologic response.

Estrogens exert a variety of effects on growth and development of different tissues. The effects of estrogens are mediated via estrogen receptors (ER), intracellular proteins that function as ligand-activated transcription factors and belong to the nuclear receptor superfamily (24). Two mammalian ERs have been identified, denoted ERα and ERβ. The structure of both receptors is similar and consists of six domains named A through F from the N- to C-terminus, encoded by 8 to 9 exons (25).

</table>
Domains A and B are located at the N-terminus and contain an agonist-independent transcriptional activation domain (Activation Function 1, or AF-1). The C domain is a highly conserved central DNA-binding domain composed of two zinc fingers through which ER interacts with the major groove and the phosphate backbone of the DNA helix. The C-terminus of the protein contains domains E and F and functions as ligand-binding domain (LBD–domain E) and Activation Function 2 (AF-2–domain F) (Fig. 6.3).

Activation of transcription via the estrogen receptor is a multistep process. The initial step requires activation of the ER via various mechanisms (Fig. 6.4). For example, estrogens such as 17β-estradiol can diffuse into the cell and bind to the LBD of the ER. Upon ligand binding, the ER undergoes conformational changes followed by a dissociation of various bound proteins, mainly heat shock proteins 90 and 70 (hsp90 and hsp70). Activation of the ER also requires phosphorylation by several protein kinases, including casein kinase II.
protein kinase A, and components of the Ras/MAP kinase pathway (26). Four phosphorylation sites of the ER are clustered in the NH\textsubscript{2} terminus with the AF-1 region. The activated ER elicits a number of different genomic as well as nongenomic effects on intracellular signaling pathways. The classical steroid signaling pathway involves binding of the activated estrogen receptor to an estrogen responsive element (ERE) on the genome as homodimers and subsequent stimulation of transcription (27). The minimal consensus sequence for the ERE is a 13 bp palindromic inverted repeat (IR) and is defined as 5'-GGTCAnnnTGACC-3'. Genes that are regulated by activated ERs include early gene responses such as \textit{c-myc}, \textit{c-fos}, and \textit{d-jun}, as well as genes encoding for growth factors such as insulin-like growth factor (IGF) or epidermal growth factor to their membrane receptor can cause activation of protein kinases like PKA, which subsequently activates ER by phosphorylation.

The activated ER elicits a number of different genomic as well as nongenomic effects on intracellular signaling pathways. The classical steroid signaling pathway involves binding of the activated estrogen receptor to an estrogen responsive element (ERE) on the genome as homodimers and subsequent stimulation of transcription (27). The minimal consensus sequence for the ERE is a 13 bp palindromic inverted repeat (IR) and is defined as 5'-GGTCAnnnTGACC-3'. Genes that are regulated by activated ERs include early gene responses such as \textit{c-myc}, \textit{c-fos}, and \textit{d-jun}, as well as genes encoding for growth factors such as insulin-like growth factor (IGF-1 and IGF-2), epidermal growth factor (EGF), transforming growth factor-\textalpha, and colony-stimulating factor (CSF-1).

In addition to the described genomic effects of estrogens, there is growing evidence for nongenomic effects of estrogens on intracellular signal transduction pathways. These effects include, for example, rapid activation of the adenylate cyclase, which results in...
cyclic adenosine monophosphate (cAMP)–dependent activation of protein kinase A (PKA) (28). Estrogens can also stimulate the mitogen-activated protein kinase (MAPK) pathways and rapidly activate the Erk1/Erk2 proteins.

Various ligands with different affinities to the ER have been developed and are called selective estrogen receptor modulators (SERMs). Tamoxifen, for example, is a mixed agonist/antagonist for ERα but it is a pure antagonist for ERβ. The ERβ receptor is ubiquitously expressed in hormone-responsive tissues, whereas the expression of ERα fluctuates in response to the hormonal milieu. The cellular and tissue effects of an estrogenic compound appear to reflect a dynamic interplay between the actions of these estrogen receptor isoforms. These observations underscore the complexity of estrogen interactions with both normal and neoplastic tissue. Mutations of hormone receptors and their functional consequences illustrate their important contributions to normal physiology. For example, absence of ERα in a male human has been reported (29). The clinical sequelae attributed to this mutation include incomplete epiphyseal closure, increased bone turnover, tall stature, and impaired glucose tolerance. The androgen insensitivity syndrome is caused by mutations of the androgen receptor (30). Mutations of the receptors for growth hormone and thyroid-stimulating hormone result in a spectrum of phenotypic alterations. Mutations of hormone receptors may also contribute to the progression of neoplastic disease and resistance to hormone therapy (31,32).

Growth Factors

Growth factors are polypeptides that are produced by a variety of cell types and exhibit a wide range of overlapping biochemical actions. Growth factors bind to high-affinity cell membrane receptors and trigger complex positive and negative signaling pathways that regulate cell proliferation and differentiation (33). In general, growth factors exert positive or negative effects upon the cell cycle by influencing gene expression related to events that occur at the G1/S cell cycle boundary (34).

Because of their short half-life in the extracellular space, growth factors generally act over limited distances through autocrine or paracrine mechanisms. In the autocrine loop, the growth factor acts on the cell that produced it. The paracrine mechanism of growth control involves the effect of growth factors on another cell in proximity. Growth factors that play an important role in female reproductive physiology are listed in Table 6.3. The biologic response of a cell to a specific growth factor depends on a variety of factors, including the cell type, the cellular microenvironment, and the cell cycle status.

The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms (35–41). The growth and differentiation of ovarian cells are particularly influenced by the insulinlike growth factors (IGF) (Fig. 6.5). Insulinlike growth factors amplify the actions of gonadotropin hormones on autocrine and paracrine growth factors found in the ovary. The IGF-1 acts on granulosa cells to cause an increase in cAMP, progesterone, oxytocin, proteoglycans, and inhibitin. On theca cells, IGF-1 causes an increase in androgen production. Theca cells produce tumor necrosis factor-α (TNF-α) and EGF, which are regulated by follicle-stimulating hormone (FSH). Epidermal growth factor acts on granulosa cells to stimulate mitogenesis. Follicular fluid contains IGF-1, IGF-2, TNF-α, TNF-β, and EGF. Disruption of these autocrine and paracrine intraovarian pathways may be the basis of polycystic ovarian disease, disorders of ovulation, and ovarian neoplastic disease.

Transforming growth factor (TGF)-β activates intracytoplasmic serine threonine kinases and inhibits cells in the late G1 phase of the cell cycle (41). It appears to play an important role in embryonic remodeling, Müllerian-inhibiting substance (MIS), which is responsible for regression of the müllerian duct, is structurally and functionally related to TGF-β (42). Transforming growth factor α is an EGF homologue that binds to the EGF
receptor and acts as an autocrine factor in normal cells. As with EGF, TGF-α promotes entry of G₀ cells into the G₁ phase of the cell cycle. The role of growth factors in endometrial growth and function has been the subject of several reviews (36–41). Similar to the ovary, autocrine, paracrine, and endocrine mechanisms of control also occur in endometrial tissue.

**Intracellular Signal Transduction**

Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are **protein kinases** that convert an extracellular signal into an intracellular signal. The interaction between growth factor ligand and its receptor results in receptor dimerization, autophosphorylation, and tyrosine kinase activation. Activated receptors in turn phosphorylate substrates in the cytoplasm and trigger the intracellular signal transduction system (Fig. 6.6). The intracellular signal transduction system relies on serine threonine kinases, src-related kinases, and G proteins. Intracellular signals activate nuclear factors that regulate gene expression. Many of the proteins that participate in the intracellular signal transduction system are encoded by **proto-oncogenes** that are divided into subgroups based on their cellular location or enzymatic function (43,44) (Fig. 6.7).

The **raf** and **mos** proto-oncogenes encode proteins with serine threonine kinase activity. These kinases integrate signals originating at the cell membrane with those that are forwarded to the nucleus (45,46). Protein kinase C (PKC) is an important component of a second messenger system that exhibits serine threonine kinase activity. This enzyme...
plays a central role in phosphorylation, which is a general mechanism for activating and deactivating proteins. It also plays an important role in cell metabolism and division (47).

The Scr family of tyrosine kinases is related to PKC and includes protein products encoded by the scr, yes, fgr, hck, lyn, fyn, lck, alt, and fps/fes proto-oncogenes. These proteins bind to the inner cell membrane surface.

The G proteins are guanyl nucleotide-binding proteins. The heterotrimeric or large G proteins link receptor activation with effector proteins such as adenyl cyclase, which activates the cAMP-dependent, kinase-signaling cascade (48). The monomeric or small G proteins, encoded by the ras proto-oncogene family, are designated p21 and are particularly important regulators of mitogenic signals. The p21 Ras protein exhibits guanyl triphosphate (GTP) binding and GTPase activity. Hydrolysis of GTP to guanyl diphosphate (GDP) terminates p21 Ras activity. The p21 Ras protein influences the production of deoxyguanosine (dG) and inositol phosphate (IP) 3, arachidonic acid production, and IP turnover.

The phosphoinositide 3 (PI3) kinase can be activated by various growth factors like platelet-derived growth factor (PDGF) or IGF results. Activation of PI3-kinase results in an increase of intracellular, membrane-bound lipids, phosphatidylinositol-(3,4)-diphosphate (PIP2), and phosphatidylinositol-(3,4,5)-triphosphate (PIP3). The Akt protein is subsequently

---

**Figure 6.5** The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms.
phosphorylated by PIP3-dependent kinases (PDK) for full activation. Activated Akt is released from the membrane and elicits downstream effects that lead to an increase in cell proliferation, prevention of apoptosis, invasiveness, drug resistance, and neoangiogenesis (49). The PTEN (phosphatase and chicken tensin homologue deleted on chromosome 10) protein is an important factor in the phosphoinositide 3 (PI3)–kinase pathway, because it counteracts the activation of Akt by dephosphorylating PIP3. Cells with mutated tumor
suppressor gene PTEN and lack of functional PTEN expression display an increased proliferation rate and decreased apoptosis, therefore possibly supporting the development of a malignant phenotype. PTEN is frequently mutated in endometrioid adenocarcinoma. Furthermore, lack of functional PTEN expression has been described in endometriosis.

Gene Expression

Regulation of genetic transcription and replication is crucial to the normal function of the daughter cells as well as the tissues and ultimately the organism. Transmission of external signals to the nucleus by way of the intracellular signal transduction cascade culminates in the transcription and translation of specific genes that ultimately affect the structure, function, and proliferation of the cell.

The human genome project has resulted in the determination of the sequence of DNA of the entire human genome. With the completion of this project, it appears that the human genetic complement consists of approximately 30,000 genes. Sequencing the human genome is a major scientific achievement that opens the door for more detailed studies of structural and functional genomics. Structural genomics involves the study of three-dimensional structures of proteins based on their amino acid sequences. Functional genomics provides a way to correlate structure and function. Proteomics involves the identification and cataloging of all proteins used by a cell, and cytomics involves the study of cellular dynamics, including intracellular system regulation and response to external stimuli. Each of these areas of investigation requires an understanding of basic genetic alterations.

Cancer Genetics

Cancer is a genetic disease that results from a series of mutations in various cancer genes. Uncontrolled cell growth occurs because of accumulation of somatic mutations or the inheritance of one or more mutations through the germline followed by
additional somatic mutations. The mutation in genes that are directly involved in normal cellular growth and proliferation can lead to the development of uncontrolled growth, invasion, and metastasis.

According to the Knudson hypothesis, which was first described in children with hereditary retinoblastoma, two hits or mutations within the genome of a cell are required for a malignant phenotype to develop (50). In hereditary cancers, the first hit is present in the genome of every cell. Only one additional hit is necessary, therefore, to disrupt the correct function of the second cancer gene allele. In contrast, sporadic cancers develop in cells without hereditary mutations in the cancer predisposing alleles. In this case, both hits must occur in a single somatic cell to disrupt both cancer gene alleles (Fig 6.8).

Most adult solid tumors require 5 to 10 rate-limiting mutations to acquire the malignant phenotype. Among these mutations, some are responsible for causing the cancer phenotype, whereas others might be considered bystander mutations, as with, for example, the amplification of genes that are adjacent to an oncogene. The most compelling evidence for the mutagenic tumor development process is that the age-specific incidence rates for most human epithelial tumors increase at roughly the fourth to eighth power of elapsed time.

**Gatekeepers and Caretakers**

Cancer susceptibility genes are divided into “gatekeepers” and “caretakers” (51). Gatekeeper genes control cellular proliferation and are divided into oncogenes and tumor suppressor genes. In general, oncogenes stimulate cell growth and proliferation, and tumor suppressor genes reduce the rate of cell proliferation or induce apoptosis. Gatekeepers prevent the development of tumors by inhibiting growth or promoting cell death. Examples of gatekeeper genes include the tumor suppressor genes p53 and the retinoblastoma gene.

Caretaker genes preserve the integrity of the genome and are involved in DNA repair (stability genes). The inactivation of caretakers increases the likelihood of persistent mutations in
gatekeeper genes and other cancer-related genes. The DNA mismatch repair genes MLH1, MSH2, and MSH6 are examples of a caretaker gene.

**Hereditary Cancer**

Most cancers are caused by spontaneous somatic mutations. However, a small percentage of cancers arise on a heritable genomic background. About 12% of all ovarian cancers and about 5% of endometrial cancers are considered to be hereditary (52,53). Germline mutations in general require additional mutations at one or more loci for tumorigenesis to occur. These mutations occur via different mechanisms, for example, via environmental factors such as ionizing radiation or mutations of stability genes. Characteristics of hereditary cancers include diagnosis at a relatively early age and a family history of cancer, usually of a specific cancer syndrome, in two or more relatives. Hereditary cancer syndromes associated with gynecologic tumors are summarized in Table 6.4.

Various cancer-causing genetic and epigenetic mechanisms have been described. On the genomic level, gain of function gene mutations can lead to a conversion of proto-oncogenes into oncogenes, and loss of function gene mutations can inactivate tumor-suppressor genes. Epigenetic changes include DNA methylation, which can cause inactivation of tumor suppressor gene expression by preventing the correct function of the associated promoter sequence. Collectively, these genetic and epigenetic changes are responsible for the development of cancer characterized by the ability of cells to invade and metastasize, grow independently of growth factor support, and escape from antitumor immune responses.

Oncogenes

Oncogenes comprise a family of genes that result from gain of function mutations of their normal counterparts, proto-oncogenes. The normal function of proto-oncogenes is to stimulate proliferation in a controlled context. Activation of oncogenes can lead to stimulation of cell proliferation and development of a malignant phenotype. Oncogenes were initially discovered through retroviral tumorigenesis. Viral infection of mammalian cells can result in integration of the viral sequences into the proto-oncogene sequence of the host cell. The integrated viral promoter activates transcription from the surrounding DNA sequences, including the proto-oncogene. Enhanced transcription of the proto-oncogene sequences results in the overexpression of growth factors, growth factor receptors, and signal transduction proteins that result in stimulation of cell proliferation. One of the most important group of viral oncogenes is the family of ras genes, which include c-H(Harvey)-ras, c-K(Kirsten)-ras, and N(Neuroblastoma)-ras.

Tumor Suppressor Genes

Tumor suppressor genes are involved in the development of most cancers and are usually inactivated in a two-step process in which both copies of the tumor suppressor gene are mutated or inactivated by epigenetic mechanisms like methylation (54). The most commonly mutated tumor suppressor gene in human cancers is p53 (55). The p53 protein regulates transcription of other genes involved in cell cycle arrest such as p21. Upregulation of p53 expression is induced by DNA damage and contributes to cell cycle arrest, allowing DNA repair to occur. p53 also plays an important role in the initiation of apoptosis. Interestingly, the most common mechanism of inactivation of p53 differs from the classic two-hit model. In most cases, missense mutations that change a single amino acid in the DNA binding domain of p53 results in overexpression of nonfunctional p53 protein in the nucleus of the cell.

The identification of tumor-suppressor genes has been facilitated by positional cloning strategies. The main approaches are cytogenetic studies to identify chromosomal alterations in tumor specimens, DNA linkage techniques to localize genes involved in inherited predisposition to cancer, and examination for loss of heterozygosity or allele among studies in sporadic tumors. Comparative genomic in situ hybridization (CGH) allows fluorescence identification of chromosome gain and loss in human cancers within a similar experiment.

Stability Genes

The third class of cancer genes is “stability genes,” which promote tumorigenesis in a way different from tumor suppressor genes or amplified oncogenes. The function of stability genes is mainly the preservation of the correct DNA sequence during DNA replication (caretaker function) (56). Mistakes that are made during normal DNA replication or induced by exposure to mutagens can be repaired by a variety of mechanisms that involve mismatch repair genes, nuclear-type excision repair genes, and base excision repair genes. The inactivation of stability genes leads to a higher mutation rate in potentially all genes. However, only mutations in oncogenes and tumor-suppressor genes influence cell proliferation and confer a selective growth advantage to the mutant cell. Similar to tumor-suppressor genes, both alleles of stability genes must be activated to cause loss of function.

Genetic Aberrations

Gene replication, transcription, and translation are imperfect processes, and the fidelity is less than 100%. Genetic errors may result in abnormal structure and function of genes and proteins. Genomic alterations such as gene amplification, point mutations, and deletions or rearrangements have been identified in premalignant, malignant, and benign neoplasms of the female genital tract (57) (Fig. 6.9).
**SECTION II  Basic Principles**

**Amplification**

Amplification refers to an increase in the copy number of a gene. Amplification results in enhanced gene expression by increasing the amount of template DNA that is available for transcription. Proto-oncogene amplification is a relatively common event in malignancies of the female genital tract. The HER2/Neu proto-oncogene, also known as c-erbB-2 and HER2, encodes a 185 kDa transmembrane glycoprotein with intrinsic tyrosine kinase activity. It belongs to a family of transmembrane receptor genes that includes the epidermal growth factor receptors (erbB-1), erbB-3, and erbB-4. HER2/Neu interacts with a variety of different cellular proteins that in general increase cell proliferation. Overexpression of HER2/neu has been demonstrated in about 30% of breast cancers, 20% of advanced ovarian cancers, and as many as 50% of endometrial cancers (58). High tissue expression of HER2/neu is correlated with a decreased overall survival particularly in patients with endometrial cancer.

**Point Mutations**

Point mutations of a gene may remain without any consequence for the expression and function of the protein (gene polymorphism). However, point mutations can alter a codon sequence and subsequently disrupt the normal function of a gene product. The ras gene family is an example of oncogene-encoded proteins that disrupt the intracellular signal transduction system following point mutations. Transforming Ras proteins contain point mutations in critical codons (i.e., codons 11, 12, 59, 61) with decrease of GTPase activity and subsequent expression of constitutively active Ras. Point mutations of the p53 gene are the most common genetic mutations described in solid tumors. These mutations
occur at preferential “hot spots” that coincide with the most highly conserved regions of the gene. The \( p53 \) tumor suppressor gene encodes for a phosphoprotein that is generally detectable in the nucleus of normal cells. When DNA damage occurs, \( p53 \) can arrest cell cycle progression to allow the DNA to be repaired or undergo apoptosis. The lack of function of normal \( p53 \) within a cancer cell results in a loss of control of cell proliferation with inefficient DNA repair and genetic instability. Mutations of the \( p53 \) gene occur in approximately 50% of advanced ovarian cancers and 30% to 40% of endometrial cancers but are uncommon in cervical cancer.

Point mutations in the \( BRCA1 \) and \( BRCA2 \) genes can alter the activity of these genes and predispose to the development of breast and ovarian cancer (59). The frequency of \( BRCA1 \) and \( BRCA2 \) mutations in the general population in the United States is estimated at 1:250. Specific founder mutations have been reported for various ethnic groups. For example, two \( BRCA1 \) mutations (185delAG and 5382insC) and one \( BRCA2 \) mutation (6174delT) are found in 2.5% of Ashkenazi Jews of Central and Eastern European descent. Additional founder mutations have been described in other ethnic groups, including from the Netherlands (\( BRCA1 \) 2804delAA and several large deletion mutations), Iceland (\( BRCA2 \), 995del5), and Sweden (\( BRCA1 \), 3171ins5).

The \( BRCA \) proteins are involved in DNA repair. If DNA is damaged, for example, by ionizing radiation or chemotherapy, the \( BRCA2 \) protein binds to the \( RAD51 \) protein, which is central for the repair of double-stranded breaks via homologous recombination. \( BRCA2 \) regulates the availability and activity of \( RAD51 \) in this key reaction. Phosphorylation of the \( BRCA2/RAD51 \) complex allows \( RAD51 \) to bind to the site of DNA damage and, in conjunction with several other proteins, mediates repair of DNA by homologous recombination. \( BRCA1 \) functions within a complex network of protein–protein interactions mediating DNA repair by homologous recombination and regulating transcription via the \( BRCA1 \) associated surveillance complex (BASC).

**Deletions and Rearrangements**

Deletions and rearrangements reflect gross changes in the DNA template that may result in the synthesis of a markedly altered protein product. Somatic mutations may involve chromosomal translocations that result in chimeric transcripts with juxtaposition of one gene to the regulatory region of another gene. This mutation type is most commonly reported in leukemias, lymphomas, and mesenchymal tumors. The Philadelphia chromosome in chronic myeloid leukemia, for example, is the result of a reciprocal translocation between one chromosome 9 and one chromosome 22. The DNA sequence removed from chromosome 9 contains the proto-oncogene \( c-ABL \) and inserts into the \( BCR \) gene sequence on chromosome 22 (Philadelphia chromosome). The resulting chimeric \( BCR-ABL \) gene product functions as a constitutively active tyrosine kinase and stimulates cellular proliferation by such mechanisms as an increase of growth factors.

**Immunology**

The immune system plays an essential part in host defense mechanisms, in particular in response to infections and neoplastic transformation. Our increased understanding of immune system regulation has provided opportunities for the development of novel immunotherapeutic and immunodiagnostic approaches.

**Immunologic Mechanisms**

The human immune system has the potential to respond to abnormal or tumor cells in various ways. Some of these immune responses occur in an innate or antigen-nonspecific manner, whereas others are adaptive or antigen specific. Adaptive
responses are specific to a given antigen. The establishment of a memory response allows
a more rapid and vigorous response to the same antigen in future encounters. Various
innate and adaptive immune mechanisms are involved in responses to tumors, including
cytotoxicity directed to tumor cells mediated by cytotoxic T cells, natural killer (NK) cells,
macrophages, and antibody-dependent cytotoxicity mediated by complementation activa-
tion (60).

**Adaptive or specific immune responses include humoral and cellular responses.**

**Humoral immune responses refer to the production of antibodies.** Antibodies are
bifunctional molecules composed of specific antigen-binding sites for interaction with
foreign antigens. They are associated with a constant region that directs the biologic
activities of the antibody, such as binding to phagocytic cells or activation of comple-
ment. **Cellular immune responses are antigen-specific immune responses mediated
directly by activated immune cells rather than by the production of antibodies.**
The distinction between humoral and cellular responses is historical and originates
from the experimental observation that humoral immune function can be transferred by
serum, whereas cellular immune function requires the transfer of cells. Most immune
responses include both humoral and cellular components. Several types of cells, includ-
ing cells from both the myeloid and lymphoid lineages, make up the immune system.
Specific humoral and cellular immune responses to foreign antigens involve the coor-
dinated action of populations of lymphocytes operating in concert with each other
and with phagocytic cells (macrophages). These cellular interactions include both
direct cognate interactions involving cell-to-cell contact and cellular interactions
involving the secretion of and response to cytokines or lymphokines. Lymphoid cells
are found in lymphoid tissues, such as lymph nodes or spleen, or in the peripheral circu-
ation. The cells that make up the immune system originate from stem cells in the
bone marrow.

### B Cells, Hormonal Immunity, and Monoclonal Antibodies

**B lymphocytes synthesize and secrete antibodies.** Mature, antigen-responsive B cells
develop from pre-B cells (committed B-cell progenitors) and differentiate to become
plasma cells, which produce large quantities of antibodies. Pre-B cells originate from bone
marrow stem cells in adults after rearrangement of immunoglobulin genes from their
germ-cell configuration. Mature B cells express cell surface immunoglobulin molecules
that function as receptors for antigen.

**Upon interaction with antigen, mature B cells respond to become antibody-producing
cells.** The process also requires the presence of appropriate cell–cell stimulatory signals
and cytokines. Monoclonal antibodies are directed against a specific antigenic determi-
nant. In contrast, polyclonal antibodies detect multiple epitopes that might be presented by
just one or a panel of proteins. The in vitro production of monoclonal antibodies,
pioneered by Kohler and Milstein in the 1970s, has become an invaluable diagnostic and
therapeutic tool, particularly for the management of malignancies (61). The tumor antigen
CA125, for example, was detected in a screen of antibodies generated against ovarian
cancer cell lines. A radioimmunoassay is widely used to measure CA125 in the serum of
patients with ovarian cancer and guide treatment decisions. Therapeutic approaches have
utilized immunotoxin-conjugated monoclonal antibodies directed to human ovarian
adenocarcinoma antigens. These antibodies induce tumor cell killing and can prolong
survival in mice implanted with a human ovarian cancer cell line. However, many obsta-
cles limit the clinical use of monoclonal antibodies, including tumor cell antigenic hetero-
genity, modulation of tumor-associated antigens, and cross-reactivity of normal host and
tumor-associated antigens. No unique tumor-specific antigens have been identified. All
tumor antigens have to be considered as tumor-related antigens because they are expressed
on the malignant as well as the nonmalignant tissues. Because most monoclonal antibod-
ies are murine, the host’s immune system can recognize and respond to these foreign
mouse proteins. The use of the genetically engineered monoclonal antibodies composed of
human-constant regions with specific antigen-reactive murine variable regions should result in reduced antigenicity to the host.

**T Lymphocytes and Cellular Immunity**

T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses. T-cell precursors originate in bone marrow and move to the thymus, where they mature into functional T cells. During their thymic maturation, T cells learn to recognize antigen in the context of the major histocompatibility complex (MHC) type of the individual person. Self-responding T cells also are removed during development in the thymus.

T cells can be distinguished from other types of lymphocytes by their cell surface phenotype, based on the pattern of expression of various molecules, as well as by differences in their biologic functions. All mature T cells express certain cell surface molecules, such as the cluster determinant 3 (CD3) molecular complex and the T-cell antigen receptor, which is found in close association with the CD3 complex. T cells recognize antigen through the cell surface T-cell antigen receptor (TCR). The structure and organization of this molecule are similar to those of antibody molecules, which are the B-cell receptors for antigen. During T-cell development, the T-cell receptor gene undergoes gene arrangements similar to those seen in B cells, but there are important differences between the antigen receptors on B cells and T cells. The T-cell receptor is not secreted, and its structure is somewhat different from that of antibody molecules. The way in which the B-cell and T-cell receptors interact with antigens is also quite different. T cells can respond to antigens only when these antigens are presented in association with MHC molecules on antigen-presenting cells. Effective antigen presentation involves the processing of antigen into small fragments of peptide within the antigen-presenting cell and the subsequent presentation of these fragments of antigen in association with MHC molecules expressed on the surface of the antigen-presenting cell. T cells can respond to antigen only when presented in this manner, unlike B cells, which can bind antigen directly, without processing and presentation by antigen-presenting cells.

There are two major subsets of mature T cells that are phenotypically and functionally distinct: T helper/inducer cells, which express the CD4 cell surface marker, and the T suppressor/cytotoxic cells, which express the CD8 marker. The expression of these markers is acquired during the passage of T cells through the thymus. CD4 T cells can provide help to B cells, resulting in the production of antibodies by B cells, and interact with antigen presented by antigen-presenting cells in association with MHC class II molecules. CD4 T cells can also act as helper cells for other T cells. CD8 T cells include cells that are cytotoxic (cells that can kill target cells bearing appropriate antigens), and they interact with antigen presented on target cells in association with MHC class I molecules. The CD8 T-cell subset also contains suppressor T cells. These T cells can inhibit the biologic functions of B cells or other T cells. Although the primary biologic role of cytotoxic T cells (CTLs) seems to be lysis of virus-infected autologous cells, cytotoxic immune T cells can mediate the lysis of tumor cells directly. Presumably, CTLs recognize antigens associated with MHC class I molecules on tumor cells through their antigen-specific T-cell receptor, setting off a series of events that ultimately results in the lysis of the target cell.

**Monocytes and Macrophages**

Monocytes and macrophages, which are myeloid cells, have important roles in both innate and adaptive immune responses; macrophages play a key part in the generation of immune responses. T cells do not respond to foreign antigens unless those antigens are processed and presented by antigen-presenting cells. Macrophages (and B cells) express MHC class II molecules and are effective antigen-presenting cells for CD4 T cells. Helper-inducer (CD4) T cells that bear a T-cell receptor of appropriate antigen and self-specificity
are activated by this antigen-presenting cell to provide help (various factors—lymphokines—that induce the activation of other lymphocytes). In addition to their role as antigen-presenting cells, macrophages play an important part in innate responses by ingesting and killing microorganisms. Activated macrophages, in addition to their many other functional capabilities, can act as cytotoxic, antitumor killer cells.

**Natural Killer Cells**

Natural killer cells are effector cells in an innate type of immune response: the nonspecific killing of tumor cells and virus-infected cells. Therefore, NK activity represents an innate form of immunity that does not require an adaptive, memory response for optimal biologic function, but the antitumor activity can be increased by exposure to several agents, particularly cytokines such as interleukin-2 (IL-2). Characteristically, NK cells have a large granular lymphocyte morphology. NK cells display a pattern of cell surface markers that differs from those characteristic of T or B cells. NK cells can express a receptor for the crystallizable fragment (Fc) portion of antibodies, as well as other NK-associated markers. Natural killer cells appear to be functionally and phenotypically heterogeneous, at least when compared with T or B cells. The cells that can carry out antibody-dependent cellular cytotoxicity, or antibody-targeted cytotoxicity, are NK-like cells. Antibody-dependent cellular cytotoxicity by NK-like cells has been shown to result in the lysis of tumor cells in vitro. The mechanisms of this tumor cell killing are not clearly understood, although close cellular contact between the effector cell and the target cell seems to be required.

**Biologic Response Modifiers**

Most immunotherapeutic agents used in the treatment of cancer have been nonspecific agents that, when introduced into the human system, elicit a generalized inflammatory reaction and immune response, probably mediated by the secretion of a range of cytokines by many different types of cells. These agents have diverse and broad biologic effects and are often referred to as immunomodulators or biologic response modifiers.

The response of a given patient to treatment with biologic response modifiers depends on the ability to react to treatment with a generalized immune response. It is possible that some elements of the immune response elicited by immunotherapeutic agents or biologic response modifiers may be counterproductive, possibly causing immune suppression, inducing the production of cytokines that enhance tumor growth or inducing an unfavorable or inappropriate immune response.

*Bacille Calmette-Guérin* (BCG) vaccine has been widely used in many tumor systems, either systemically, by injection into the lesion, or by scarification (62). Occasionally, it has been mixed with whole irradiated tumor cells and injected into the patient as a vaccine. In a large series, intracutaneous injection of melanoma lesions with BCG resulted in some tumor regression in patients with cutaneous recurrence, but visceral or parenchymal metastatic disease is resistant to this treatment. Although there have been some preliminary observations about the use of BCG as an adjuvant in children with acute lymphocytic leukemia and with stage II melanoma, randomized studies have not shown any appreciable responses.

**Cytokines, Lymphokines, and Immune Mediators**

Many events in the generation of immune responses (as well as during the effector phase of immune responses) require or are enhanced by cytokines, which are soluble mediator molecules (Table 6.5) (63–82). Cytokines are pleiotropic in that they have multiple biologic functions that depend on the type of target cell or its maturational state. Cytokines are also heterogeneous in the sense that most cytokines share little structural or amino acid homology. Cytokines are called monokines if they are derived from monocytes, lymphokines if they are derived from lymphocytes, interleukins if they exert
their actions on leukocytes, or interferons (IFNs) if they have antiviral effects. They are produced by a wide variety of cell types and seem to have important roles in many biologic responses outside the immune response, such as inflammation or hematopoiesis. They may also be involved in the pathophysiology of a wide range of diseases and show great potential as therapeutic agents in immunotherapy for cancer. Although cytokines are a heterogeneous group of proteins, they share some characteristics. For instance, most cytokines are low- to intermediate-molecular-weight (10–60 kd) glycosylated secreted proteins. They are also involved in immunity and inflammation, are produced transiently and locally (they act in an autocrine and paracrine rather than an endocrine manner), are extremely potent in small concentrations, and interact with high-affinity cellular receptors that are specific for each cytokine. The cell surface binding of cytokines by specific receptors results in signal transduction followed by changes in gene expression and, ultimately, by changes in cellular proliferation or altered cell behavior, or both. Their biologic actions overlap, and exposure of responsive cells to multiple cytokines can result in synergistic or antagonistic biologic effects.

**Interleukins**

The interleukins represent a family of molecules that play a major role in immune responses (Table 6.5).

**Interleukin-1**  
Interleukin-1 has a wide range of biologic activities, including direct effects on several cells involved in immune responses (63–82). It is involved in fever and inflammatory responses and may play a role in the pathogenesis of several diseases, such as rheumatoid arthritis. There are two defined forms of IL-1, IL-1α and IL-1β, which have similar biologic activities. Interleukin-1 can be released as a soluble form or can be found as a cell-associated molecule on the cell surface of macrophages. The primary sources of IL-1 are macrophages, the phagocytic cells of the liver and spleen, some B cells, epithelial cells, certain brain cells, and the cells lining the synovial spaces. Interleukin-1 has a broad range of target cells and biologic activities, as do most lymphokines. A principal role of IL-1 is in the initiation of early events in immune responses (62,68).

**Interleukin-2**  
Interleukin-2 is a lymphokine that was originally called T-cell growth factor, which indicates one of the major biologic activities of this molecule. Failure of T cells to produce IL-2 results in the absence of a T-cell immune response and a diminution of the antibody response. Natural human IL-2 is a 15-kd glycoprotein and is produced primarily by activated T cells. For IL-2 to exert its proliferation-inducing effects, it has to interact with a specific receptor for IL-2 on the surface of the target cell. The high-affinity receptor for IL-2 consists of two polypeptides, the α (75 kd) and β (55 kd) chains. After activation, T cells express greatly increased numbers of this high-affinity receptor for IL-2 and respond to IL-2 with increased proliferation. Stimulation of resting T cells with antigen presented in the context of self (antigen associated with an MHC molecule on the surface of an antigen-presenting cell) and with IL-1, therefore, induces synthesis and secretion of IL-2. During this activation process, responding T cells undergo an alteration in their cell surface receptors, including the expression of cell surface receptors for IL-2. Continuing exposure to IL-2 leads to the proliferation of T cells bearing the IL-2 receptor, thereby serving as an activation and response-amplification stage in the generation of immune responses. Activated T cells not only respond to IL-2 but also produce IL-2. Interleukin-2 can, therefore, act in an autocrine manner (the cells producing the lymphokine then respond to it) or in a paracrine fashion (the IL-2 produced by a T cell is taken up and responded to by neighboring cells). Since its original description as a T-cell growth hormone, IL-2 has been shown to have various other immune functions, including the promotion of B-cell activation and maturation and activation of monocytes and NK cells. Interleukin-2 can also lead directly or indirectly to the stimulation of the production of interferon and other cytokines.

IL-1, interleukin-1; T<sub>H1</sub>, type 1 T helper lymphocyte; NK cells, natural killer cells; T<sub>H2</sub>, type 2 T helper lymphocyte; IgE, immunoglobulin E; MHCII, major histocompatibility complex class II; Ag, antigen; IFN, interferon; TNF, tumor necrosis factor.

Interleukin-3  Interleukin-3, a factor that can increase the early differentiation of hematopoietic cells (82), may find a role in immunotherapy because of its ability to induce hematopoietic differentiation in people undergoing aggressive chemotherapeutic treatment or bone marrow transplantation.

Interleukin-4, Interleukin-5, and Interleukin-6  B-lymphocyte activation and differentiation to immunoglobulin-secreting plasma cells are promoted by cytokines produced by helper T lymphocytes or monocytes (Table 6.5) (55,56). Several cytokines originally described as B-cell stimulating factors (IL-4, IL-5, and IL-6) have additional biologic activities. For instance, IL-6 (a factor that can induce B-lymphocyte differentiation to immunoglobulin-secreting cells) is a pleiotropic cytokine with biologic activities that include the induction of cytotoxic T-lymphocyte differentiation, the induction of acute-phase reactant production by hepatocytes, and activity as a colony-stimulating factor for hematopoietic stem cell (64). Interleukin-6 is produced primarily by activated monocyte-macrophages and T lymphocytes. Interestingly, several types of tumor cells produce IL-6, and it has been proposed as an autocrine-paracrine growth factor in different types of neoplasms (64–69). It may prove to be an effective antitumor agent by virtue of its ability to enhance antitumor T-cell–mediated immune responsiveness (69,70).

Interleukin-8 and Interleukin-10  Interleukin-10, a 35- to 40-kd cytokine, is also called cytokine synthesis inhibitory factor because of its activity as an inhibitor of cytokine production. It is produced by a subset of CD4 cells, type 2 (T<sub>H2</sub>) cells, and inhibits the cytokine production by another CD4 cell subset, type 1 (T<sub>H1</sub>) cells (71). T<sub>H1</sub> and T<sub>H2</sub> are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: Clones of T<sub>H1</sub> produce IL-2 and interferon-γ (IFN-γ), whereas T<sub>H2</sub> clones produce IL-4, IL-5, IL-6, and IL-10 (72). A similar dichotomy between T<sub>H1</sub>- and T<sub>H2</sub>-type responses has been reported in humans (73,74). Human IL-10 inhibits the production of IFN-γ and other cytokines by human peripheral blood mononuclear cells (75) and by suppressing the
release of cytokines (IL-1, IL-6, IL-8, and TNF-α) by activated monocytes (76–78). Interleukin-10 also downregulates class II MHC expression on monocytes, resulting in a strong reduction in the antigen-presenting capacity of these cells (78). Together, these observations support the concept that IL-10 has an important role as an immune-inhibitory cytokine.

Because epithelial cancers of the ovary usually remain confined to the peritoneal cavity, even in the advanced stages of the disease, it has been suggested that the growth of ovarian cancer intraperitoneally could be related to a local deficiency of antitumor immune effector mechanisms (79). Studies have shown that ascitic fluid from patients with ovarian cancer contained increased concentrations of IL-10 (80). Various other cytokines are also seen in ascitic fluid obtained from women with ovarian cancer including IL-6, IL-10, TNF-α, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF) (81). A similar pattern was seen in serum samples from women with ovarian cancer with elevations of IL-6 and IL-10.

Tumor necrosis factor-α is a cytokine that can be directly cytotoxic for tumor cells, can increase immune cell–mediated cellular cytotoxicity, and can activate macrophages and induce secretion of monokines. Other biologic activities of TNF-α include the induction of cachexia, inflammation, and fever; it is an important mediator of endotoxic shock.

**Interferons**

There are three types of interferons: IFN-α, IFN-β, and IFN-γ (54,55,83). They can interfere with viral production in infected cells and have various effects on the immune system as well as direct antitumor effects. For instance, IFN-γ, a cytokine produced by T lymphocytes, can affect immune function by increasing the induction of MHC molecule expression, increasing the activity of antigen-presenting cells, and thereby increasing T-lymphocyte activation.

**Cytokines in Cancer Therapy**

Cytokines are extraordinarily pleiotropic with a bewildering array of biologic activities, including some outside the immune system (54,55,63,69). Because some cytokines have direct or indirect antitumor and immune-enhancing effects, several of these factors have been used in the experimental treatment of cancer.

The precise roles of cytokines in antitumor responses have not been elucidated. Cytokines can exert antitumor effects by many different direct or indirect activities. It is possible that a single cytokine could increase tumor growth directly by acting as a growth factor while at the same time increasing immune responses directed toward the tumor. The potential of cytokines to increase antitumor immune responses has been tested in experimental adoptive immunotherapy by exposing the patient’s peripheral blood cells or tumor-infiltrating lymphocytes to cytokines such as IL-2 in vitro, thus generating activated cells with antitumor effects that can be given back to the patient (84–86). Some cytokines can also exert direct antitumor effects. Tumor necrosis factor can induce cell death in sensitive tumor cells.

The effects of cytokines on patients with cancer might be modulated by soluble receptors or blocking factors. For instance, blocking factors for TNF and for lymphotoxin were found in ascitic fluid from patients with ovarian cancer (87). Such factors could inhibit the cytolytic effects of TNF or lymphotoxin and should be taken into account in the design of clinical trials of intraperitoneal infusion of these cytokines.

Cytokines have growth-increasing effects on tumor cells in addition to inducing antitumor effects. They can act as autocrine or paracrine growth factors for human tumor cells,
including those of nonlymphoid origin. For instance, IL-6 (which is produced by various
types of human tumor cells) can act as a growth factor for human myeloma, Kaposi’s
sarcoma, renal carcinoma, and epithelial ovarian cancer cells (63–69).

Clearly, cytokines are of great potential value in the treatment of cancer, but because of
their multiple—even conflicting—biologic effects, a thorough understanding of cytokine
biology is essential for their successful use (83–91).

Adoptive Immunotherapy

The *ex vivo* enhancement of antitumor immune cell responses, including the generation
of lymphokine-activated killer (LAK) cells or the activation of tumor-infiltrating lympho-
cytes (TIL), has provided new immune system–based approaches for antitumor responses.
The simultaneous treatment of patients with *ex vivo*–activated autologous cells, along with
IL-2, is the basis of adoptive immunotherapy, a form of experimental antitumor
immunotherapy. In particular, adoptive immunotherapy with IL-2 can produce regression
of tumor in various animals and human tumors, such as melanoma and renal cell carci-
noma, when used in conjunction with the adoptive transfer of autologous LAK cells
(84,85).

Exposure of peripheral blood monoclonal cells to cytokines *in vitro* (particularly IL-2)
leads to the generation of cytotoxic effect cells called LAK cells (85). These cells are cyto-
toxic for various tumor cells, including those that are resistant to NK-cell– or T-cell–
mediated lysis. Experimental treatment of human subjects with autologous *ex vivo–gener-
ated* LAK cells and IL-2 has yielded tumor regression in some cases (84–88). This treat-
ment has resulted in some complete responses (86); the combined response rate was 27%
in 146 patients with cancer who were treated in two separate studies (88–90). The overall
response rate to LAK treatment is low, however, and this type of adoptive immunotherapy
causes high morbidity (90). It is also costly and impractical in most medical settings.

Much current experimental work is aimed at developing more efficient and practical appli-
cations of adoptive immunotherapy (91–97). One approach involves the *ex vivo* generation
of immune effector cells from TILs and dendritic cells, which are lymphocytes that are
isolated from tumors and activated and expanded *in vitro* by exposure to IL-2. These cells
can be administered to the patient with IL-2 (91,92). This approach is hampered by the need
to expand a limited number of TILs *in vitro* to generate enough effector cells for treatment.
Recently, attention has been directed toward the development of new methods for the gener-
ation of LAK cells or TILs, including methods that use cytokines other than
IL-2 to stimulate these cells. Another approach that has been explored in animal studies
involves the targeting of activated T lymphocytes with a bifunctional monoclonal antibody
that binds to the CD3–T-cell receptor complex (on the target tumor cell) (93). This approach
has the potential advantage of allowing a large number of the activated lymphocytes to target
their effects directly on tumor cells, thereby reducing the need to amplify a large number of
effector cells from TILs. It also has the potential to avoid some of the side effects associated
with LAK treatment, which is a more nonspecific form of adoptive immunotherapy.

Factors That Trigger Neoplasia

Cell biology is characterized by considerable redundancy and functional overlap, so that a
defect in one mechanism does not invariably jeopardize the function of the cell. However,
when a sufficient number of abnormalities in structure and function occur, normal cell
function is jeopardized, and uncontrolled cell growth or cell death results. Either endpoint
may result from accumulated genetic mutations over time. Factors have been identified
that enhance the likelihood of genetic mutations, jeopardize normal cell biology, and may
increase the risk of cancer.

155
Increased Age

Increasing age is considered the single most important risk factor for the development of cancer (98). Cancer is diagnosed in as much as 50% of the population by 75 years of age (99). It has been suggested that the increasing risk of cancer with age reflects the accumulation of critical genetic mutations over time, which ultimately culminates in neoplastic transformation. The basic premise of the multistep somatic mutation theory of carcinogenesis is that genetic or epigenetic alterations of numerous independent genes results in cancer. Factors that have been associated with an increased likelihood of cancer include exposure to exogenous mutagens, altered host immune function, and certain inherited genetic syndromes and disorders.

Environmental Factors

A mutagen is a compound that results in a genetic mutation. A number of environmental pollutants act as mutagens when tested in vitro. Environmental mutagens usually produce specific types of mutations that can be differentiated from spontaneous mutations. As an example, activated hydrocarbons tend to produce GT transversions (100). A carcinogen is a compound that can produce cancer. It is important to recognize that all carcinogens are not mutagens and that all mutagens are not necessarily carcinogens.

Smoking

Cigarette smoking is perhaps the best known example of mutagen exposure that is associated with the development of lung cancer when the exposure is of sufficient duration and quantity in a susceptible individual. An association between cigarette smoking and cervical cancer has been recognized for decades. More recently, it has been determined that the mutagens in cigarette smoke are selectively concentrated in cervical mucus (52). It has been hypothesized that exposure of the proliferating epithelial cells of the transformation zone to cigarette smoke mutagens may increase the likelihood of DNA damage and subsequent cellular transformation.

Others have observed that human papillomavirus DNA is frequently inserted into the fragile histidine triad gene (FHIT) in cervical cancer specimens. The FHIT is an important tumor suppressor gene. Cigarette smoking might facilitate the incorporation of HPV DNA into the FHIT gene with subsequent disruption of correct tumor suppressor gene function.

Radiation

Radiation exposure can increase the risk of cancer. The overall risk of radiation-induced cancer is approximately 10% greater in women than in men (101). This difference has been attributed to gender-specific cancers, including breast cancer. Radiation-induced cancer may be the result of sublethal DNA damage that is not repaired (101). Normally, radiation damage prompts an S-phase arrest so that DNA damage is repaired. This requires normal \( p53 \) gene function. If DNA repair fails, the damaged DNA is propagated to daughter cells following mitosis. If a sufficient number of critical genes are mutated, cellular transformation may result.

Immune Function

Systemic immune dysfunction has been recognized as a risk factor for cancer for decades. The immunosuppressed renal transplant patient may have a 40-fold increased risk of cervical cancer (52). Patients infected with human immunodeficiency virus (HIV) who have a depressed CD4 cell count have been reported to be at increased risk of cervical dysplasia and invasive disease (96). Individuals who have undergone high-dose chemotherapy with stem cell support may be at increased risk of developing a variety of solid neoplasms. These examples illustrate the importance of immune function in host
surveillance for transformed cells. Another example of altered immune function that may be related to the development of cervical dysplasia is the alteration in mucosal immune function that occurs in women who smoke cigarettes (52). The Langerhans cell population of the cervix is decreased in women who smoke. Langerhans cells are responsible for antigen processing. It is postulated that a reduction in these cells increases the likelihood of successful human papillomavirus infection of the cervix.

Diet

The role of diet in disease prevention and predisposition is widely recognized but poorly understood (96,99). Dietary fat intake has been correlated with the risk of colon and breast cancer. Fiber is considered protective against colon cancer. With respect to the female reproductive system, epidemiologic studies provide conflicting results. Deficiencies of folic acid and vitamins A and C have been associated with the development of cervical dysplasia and cervical cancer. Considerable research must be performed to clarify the impact of diet on cancer prevention and development.

The female reproductive process involves the central nervous system (primarily hypothalamus), the pituitary gland, the ovary, and the uterus (endometrium). All must function appropriately for normal reproduction to occur.

Hypothalamic gonadotropin-releasing hormone (GnRH) simultaneously regulates both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in the pituitary, and does so by being secreted in a pulsatile manner. The pulse frequency determines the relative amounts of LH and FSH secretion.

The ovary responds to FSH and LH in a defined, sequential manner to produce follicular growth, ovulation, and corpus luteum formation. The cycle is designed to produce an optimal environment for pregnancy; should this not occur, the cycle begins again.

The ovary produces estrogen in the early menstrual cycle, which is responsible for endometrial growth. Following ovulation, progesterone is also produced in significant quantities, which transforms the endometrium to a form ideal for implantation of the embryo. If no pregnancy occurs, the ovary ceases to produce estrogen and progesterone, the endometrium is sloughed, and the cycle begins again.

The reproductive process in women is a complex and highly evolved interaction of many components. The carefully orchestrated series of events that contributes to a normal ovulatory menstrual cycle requires precise timing and regulation of hormonal input from the central nervous system, the pituitary gland, and the ovary. This delicately balanced process can be easily disrupted and result in reproductive failure, which is a major clinical issue confronting gynecologists. To effectively manage such conditions, it is critical that gynecologists understand the normal physiology of the menstrual cycle. The anatomic structures, hormonal components, and interactions between the two play a vital role in the function of the reproductive system. Fitting together the various pieces of this intricate puzzle will provide “the big picture”: an overview of how the reproductive system of women is designed to function.
Neuroendocrinology

Neuroendocrinology represents facets of two traditional fields of medicine: endocrinology, which is the study of hormones (i.e., substances secreted into the bloodstream that have diverse actions at sites remote from the point of secretion), and neuroscience, which is the study of the action of neurons. The discovery of neurons that transmit impulses and secrete their products into the vascular system to function as hormones themselves, a process known as neurosecretion, demonstrates that the two systems are intimately linked. For instance, the menstrual cycle is regulated through the feedback of hormones on the neural tissue of the central nervous system (CNS).

Anatomy

Hypothalamus

The hypothalamus is a small neural structure situated at the base of the brain above the optic chiasm and below the third ventricle (Fig. 7.1). It is connected directly to the pituitary gland and is the part of the brain that is the source of many pituitary secretions. Anatomically, the hypothalamus is divided into three zones: periventricular (adjacent to the third ventricle), medial (primarily cell bodies), and lateral (primarily axonal). Each zone is further subdivided into structures known as nuclei, which represent locations of concentrations of similar types of neuronal cell bodies (Fig. 7.2).
The hypothalamus is not an isolated structure within the CNS; instead, it has multiple interconnections with other regions in the brain. In addition to the well-known pathways of hypothalamic output to the pituitary, there are numerous less well-characterized pathways of output to diverse regions of the brain, including the limbic system (amygdala and hippocampus), the thalamus, and the pons (1). Many of these pathways form feedback loops to areas supplying neural input to the hypothalamus.

Several levels of feedback to the hypothalamus exist and are known as the long, short, and ultrashort feedback loops. The long feedback loop is composed of endocrine input from circulating hormones, just as feedback of androgens and estrogens onto steroid receptors is present in the hypothalamus (2,3). Similarly, pituitary hormones may feed back to the hypothalamus and serve important regulatory functions in short-loop feedback. Finally, hypothalamic secretions may directly feed back to the hypothalamus itself in an ultrashort feedback loop.

The major secretory products of the hypothalamus are the pituitary-releasing factors (Fig. 7.3):

1. Gonadotropin-releasing hormone (GnRH), which controls the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)
2. Corticotropin-releasing hormone (CRH), which controls the release of adrenocorticotropic hormone (ACTH)
3. Growth hormone–releasing hormone (GHRH), which regulates the release of growth hormone (GH)
4. Thyrotropin-releasing hormone (TRH), which regulates the secretion of thyroid-stimulating hormone (TSH)
The hypothalamus is the source of all neurohypophyseal hormone production. The neural posterior pituitary can be viewed as a direct extension of the hypothalamus connected by the fingerlike infundibular stalk. The discovery that the capillaries in the median eminence differ from those in other regions of the brain was a major one. Unlike the usual tight junctions that exist between adjacent capillary endothelial lining cells, the capillaries in this region are fenestrated in the same manner as capillaries outside the CNS. As a result, there is no blood–brain barrier in the median eminence.

The hypothalamic secretory products function as pituitary-releasing factors that control the endocrine function of the ovaries, the thyroid, and the adrenal glands.

Figure 7.3  The hypothalamic secretory products function as pituitary-releasing factors that control the endocrine function of the ovaries, the thyroid, and the adrenal glands.

**Pituitary**

The pituitary is divided into three regions or lobes: anterior, intermediate, and posterior. The anterior pituitary (adenohypophysis) is quite different structurally from the posterior neural pituitary (neurohypophysis), which is a direct physical extension of...
the hypothalamus. The adenohypophysis is derived embryologically from epidermal ectoderm from an infolding of Rathke’s pouch. Therefore, it is not composed of neural tissue, as is the posterior pituitary, and does not have direct neural connections to the hypothalamus. Instead, a unique anatomic relationship exists that combines elements of neural production and endocrine secretion. The adenohypophysis itself has no direct arterial blood supply. Its major source of blood flow is also its source of hypothalamic input—the portal vessels. Blood flow in these portal vessels is primarily from the hypothalamus to the pituitary. Blood is supplied to the posterior pituitary via the superior, middle, and inferior hypophyseal arteries. In contrast, the anterior pituitary has no direct arterial blood supply. Instead, it receives blood via a rich capillary plexus of the portal vessels that originate in the median eminence of the hypothalamus and descend along the pituitary stalk. This pattern is not absolute, however, and retrograde blood flow has occurred (4). This blood flow, combined with the location of the median eminence outside the blood–brain barrier, permits bidirectional feedback control between the two structures.

The specific secretory cells of the anterior pituitary have been classified based on their hematoxylin- and eosin-staining patterns. Acidophilic-staining cells primarily secrete GH and prolactin and, to a variable degree, ACTH (5). The gonadotropins are secreted by basophilic cells, and TSH is secreted by the neutral-staining chromophobes.

Reproductive Hormones

Hypothalamus

Gonadotropin-releasing Hormone

Gonadotropin-releasing hormone (GnRH) (also called luteinizing hormone–releasing hormone, or LHRH) is the controlling factor for gonadotropin secretion (6). It is a decapeptide produced by neurons with cell bodies primarily in the arcuate nucleus of the hypothalamus (7–9) (Fig. 7.4). Embryologically, these neurons originate in the olfactory pit and then migrate to their adult locations (10). These GnRH-secreting neurons project axons that terminate on the portal vessels at the median eminence where GnRH is secreted for delivery to the anterior pituitary. Less clear in function are multiple other secondary projections of GnRH neurons to locations within the CNS.

The gene that encodes GnRH produces a 92 amino acid precursor protein, which contains not only the GnRH decapeptide but also a 56 amino acid peptide known as GnRH-associated peptide, or GAP. The GnRH-associated peptide is a potent inhibitor of prolactin secretion as well as a stimulator of gonadotropin release.

Pulsatile Secretion

Gonadotropin-releasing hormone is unique among releasing hormones in that it simultaneously regulates the secretion of two hormones—FSH and LH. It is also unique among the body’s hormones because it must be secreted in a pulsatile fashion to be effective, and the pulsatile release of GnRH influences the release of the two gonadotropins (11–13). Using animals that had undergone electrical destruction of the
arcuate nucleus and had no detectable levels of gonadotropins, a series of experiments were performed with varying dosages and intervals of GnRH infusion (13,14). Continual infusions did not result in gonadotropin secretion, whereas a pulsatile pattern led to physiologic secretion patterns and follicular growth. Continual exposure of the pituitary gonadotroph to GnRH results in a phenomenon called downregulation, through which the number of gonadotroph cell surface GnRH receptors is decreased (15). Similarly, intermittent exposure to GnRH will “upregulate” or “autoprime” the gonadotroph to increase its number of GnRH receptors (16). This allows the cell to have a greater response to subsequent GnRH exposure. Similar to the intrinsic electrical pacemaker cells of the heart, this action most likely represents an intrinsic property of the GnRH-secreting neuron, although it is subject to modulation by various neuronal and hormonal inputs to the hypothalamus.

The continual pulsatile secretion of GnRH is necessary because GnRH has an extremely short half-life (only 2–4 minutes) as a result of rapid proteolytic cleavage. The pulsatile secretion of GnRH varies in both frequency and amplitude throughout the menstrual cycle and is tightly regulated (17,18) (Fig. 7.5). The follicular phase is characterized by frequent, small-amplitude pulses of GnRH secretion. In the late follicular phase, there is an increase in both frequency and amplitude of pulses. During the luteal phase, however, there is a progressive lengthening of the interval between pulses. The amplitude in the luteal phase is higher than that in the follicular phase, but it declines progressively over the two weeks. This variation in pulse frequency allows for variation in both LH and FSH throughout the menstrual cycle. For example, decreasing the pulse frequency of GnRH decreases LH secretion but increases FSH, an important aspect of enhancing FSH availability in the

![Figure 7.5](image-url) The pulsatile secretion of GnRH in the follicular and luteal phases of the cycle.
late luteal phase. The pulse frequency is not the sole determinant of pituitary response, however; additional hormonal influences, such as those exerted by ovarian peptides and sex steroids, can modulate the GnRH effect.

Although GnRH is primarily involved in endocrine regulation of gonadotropin secretion from the pituitary, it is now apparent that this molecule has autocrine and paracrine functions throughout the body. The decapeptide is found in both neural and nonneural tissues; receptors are present in many extrapituitary structures, including the ovary and placenta. The role of GnRH in the extrapituitary sites remains to be fully elucidated.

Gonadotropin-releasing Hormone Agonists

**Mechanism of Action**  Used clinically, GnRH agonists are modifications of the native molecule to either increase receptor affinity or decrease degradation (19). Their use, therefore, leads to a persistent activation of GnRH receptors, as if continuous GnRH exposure existed. As would be predicted by the constant GnRH infusion experiments, this leads to suppression of gonadotropin secretion. An initial release of gonadotropins is followed by a profound suppression of secretion. The initial release of gonadotropins represents the secretion of pituitary stores in response to receptor binding and activation. With continued activation of the gonadotroph GnRH receptor, however, there is a downregulation effect and a decrease in the concentration of GnRH receptors. As a result, gonadotropin secretion decreases and sex steroid production falls to castrate levels (20).

Additional modification of the GnRH molecule results in an analogue that has no intrinsic activity but competes with GnRH for the same receptor site (21). These GnRH antagonists produce a competitive blockade of GnRH receptors, preventing stimulation by endogenous GnRH and causing an immediate fall in gonadotropin and sex steroid secretion (22). The clinical effect is generally observed within 24 to 72 hours. Moreover, antagonists may not function solely as competitive inhibitors; recent evidence suggests they may also produce downregulation of GnRH receptors (23), further contributing to the loss of gonadotropin activity.

**Structure—Agonists and Antagonists**  As a peptide hormone, GnRH is degraded by enzymatic cleavage of bonds between its amino acids. Pharmacologic alterations of the structure of GnRH have led to the creation of agonists and antagonists (Fig. 7.4). The primary sites of enzymatic cleavage are between amino acids 5 and 6, 6 and 7, and 9 and 10. Substitution of the position-6 amino acid glycine with large bulky amino acid analogues makes degradation more difficult and creates a form of GnRH with a relatively long half-life. Substitution at the carboxyl terminus produces a form of GnRH with increased receptor affinity. The resulting high affinity and slow degradation produces a molecule that mimics continuous exposure to native GnRH (19). Thus, as with constant GnRH exposure, downregulation occurs. GnRH agonists are now widely used to treat disorders that are dependent on ovarian hormones (20). They are used to control ovulation induction cycles and to treat precocious puberty, ovarian hyperandrogenism, leiomyomas, endometriosis, and hormonally dependent cancers. The development of GnRH antagonists proved more difficult because a molecule was needed that maintained the binding and degradation resistance of agonists but failed to activate the receptor. Early attempts involved modification of amino acids 1 and 2, as well as those previously utilized for agonists. Commercial antagonists currently have structural modifications at amino acids 1, 2, 3, 6, 8, and 10. The treatment spectrum is expected to be similar to that of GnRH agonists, but with more rapid onset of action.

**Endogenous Opioids and Effects on GnRH**  The endogenous opioids are three related families of naturally occurring substances produced in the CNS that represent the natural ligands for the opioid receptors (24–26). There are three major classes of endogenous opioids, each derived from precursor molecules:
1. **Endorphins** are named for their endogenous morphinelike activity. These substances are produced in the hypothalamus from the precursor proopiomelanocortin (POMC) and have diverse activities, including regulation of temperature, appetite, mood, and behavior (27).

2. **Enkephalins** are the most widely distributed opioid peptides in the brain, and they function primarily in regulation of the autonomic nervous system. Proenkephalin A is the precursor for the two enkephalins of primary importance: methionine–enkephalin and leucine–enkephalin.

3. **Dynorphins** are endogenous opioids produced from the precursor proenkephalin B that serve a function similar to that of the endorphins, producing behavioral effects and exhibiting a high analgesic potency.

The endogenous opioids play a significant role in the regulation of hypothalamic–pituitary function. Endorphins appear to inhibit GnRH release within the hypothalamus, resulting in inhibition of gonadotropin secretion (28). Ovarian sex steroids can increase the secretion of central endorphins, further depressing gonadotropin levels (29).

Endorphin levels vary significantly throughout the menstrual cycle, with peak levels in the luteal phase and a nadir during menses (30). This inherent variability, although helping to regulate gonadotropin levels, may contribute to cycle-specific symptoms experienced by ovulatory women. For example, the dysphoria experienced by some women in the premenstrual phase of the cycle may be related to a withdrawal of endogenous opiates (31).

### Pituitary Hormone Secretion

**Anterior Pituitary**

The anterior pituitary is responsible for the secretion of the major hormone-releasing factors—FSH, LH, TSH, and ACTH—as well as GH and prolactin. Each hormone is released by a specific pituitary cell type.

**Gonadotropins**

The gonadotropins FSH and LH are produced by the anterior pituitary gonadotroph cells and are responsible for ovarian follicular stimulation. Structurally, there is great similarity between FSH and LH (Fig. 7.6). They are both glycoproteins that share identical α subunits and differ only in the structure of their β subunits, which confer receptor specificity (32,33). The synthesis of the β subunits is the rate-regulating step in
gonadotropin biosynthesis (34). Thyroid-stimulating hormone and placental human chorionic gonadotropin (hCG) also share identical α subunits with the gonadotropins. There are several forms of each gonadotropin, which differ in carbohydrate content as a result of posttranslation modification. The degree of modification varies with steroid levels and is an important regulator of gonadotropin bioactivity.

**Prolactin**

Prolactin, a 198–amino acid polypeptide secreted by the anterior pituitary lactotroph, is the primary trophic factor responsible for the synthesis of milk by the breast (35). Several forms of this hormone, which are named according to their size and bioactivity, are normally secreted (36). Prolactin gene transcription is principally stimulated by estrogen; other hormones promoting transcription are TRH (thyroid-releasing hormone) and a variety of growth factors.

Prolactin secretion is under tonic inhibitory control by the hypothalamic secretion of dopamine (37). Therefore, disease states characterized by decreased dopamine secretion or any condition that interrupts transport of dopamine down the infundibular stalk to the pituitary gland will result in increased synthesis of prolactin. In this respect, prolactin is unique in comparison with all other pituitary hormones: It is predominantly under tonic inhibition, and release of control produces an increase in secretion. Clinically, increased prolactin levels are associated with amenorrhea and galactorrhea, and hyperprolactinemia should be suspected in any individual with symptoms of either of these conditions.

Although prolactin appears to be primarily under inhibitory control, many stimuli can elicit its release, including breast manipulation, drugs, stress, exercise, and certain foods. Hormones that may stimulate prolactin release include TRH, vasopressin, γ-aminobutyric acid (GABA), dopamine, β-endorphin, vasoactive intestinal peptide (VIP), epidermal growth factor, angiotensin II, and possibly GnRH (38–40). The relative contributions of these substances under normal conditions remain to be determined.

**Thyroid-stimulating Hormone, Adrenocorticotropic Hormone, and Growth Hormone**

The other hormones produced by the anterior pituitary are TSH, ACTH, and GH. Thyroid-stimulating hormone is secreted by the pituitary thyrotrophs in response to TRH. As with GnRH, TRH is synthesized primarily in the arcuate nucleus of the hypothalamus and is then secreted into the portal circulation for transport to the pituitary. In addition to stimulating TSH release, TRH is also a major stimulus for the release of prolactin. Thyroid-stimulating hormone stimulates release of T3 and T4 from the thyroid gland, which in turn has a negative feedback effect on pituitary TSH secretion. Abnormalities of thyroid secretion (both hyper- and hypothyroidism) are frequently associated with ovulatory dysfunction as a result of diverse actions on the hypothalamic–pituitary–ovarian axis (41).

Adrenocorticotropic hormone is secreted by the anterior pituitary in response to another hypothalamic-releasing factor, CRH, and stimulates the release of adrenal glucocorticoids. Unlike the other anterior pituitary products, ACTH secretion has a diurnal variation with an early morning peak and a late evening nadir. As with the other pituitary hormones, ACTH secretion is negatively regulated by feedback from its primary end product, which in this case is cortisol.

The anterior pituitary hormone that is secreted in the greatest absolute amount is GH. It is secreted in response to the hypothalamic-releasing factor, GHRH, as well as by thyroid hormone and glucocorticoids. This hormone is also secreted in a pulsatile fashion but with peak release occurring during sleep. In addition to its vital role in the stimulation of linear growth, GH plays a diverse role in physiologic hemostasis. The hormone has been shown
to play a role in bone mitogenesis, CNS function (improved memory, cognition, and mood), body composition, breast development, and cardiovascular function. It also affects insulin regulation and acts anabolically. Growth hormone appears to have a role in the regulation of ovarian function, although the degree to which it serves this role in normal physiology is unclear (42).

**Posterior Pituitary**

**Structure and Function**

The posterior pituitary (neurohypophysis) is composed exclusively of neural tissue and is a direct extension of the hypothalamus. It lies directly adjacent to the adenohypophysis but is embryologically distinct, derived from an invagination of neuroectodermal tissue in the third ventricle. Axons in the posterior pituitary originate from neurons with cell bodies in two distinct regions of the hypothalamus, the supraoptic and paraventricular nuclei, named for their anatomic relationship to the optic chiasm and the third ventricle. Together these two nuclei compose the hypothalamic magnocellular system. These neurons can secrete their synthetic products directly from axonal boutons into the general circulation to act as hormones. This is the mechanism of secretion of the hormones of the posterior pituitary, oxytocin and arginine vasopressin (AVP). Although this is the primary mode of release of these hormones, numerous other secondary pathways have been identified, including secretion into the portal circulation, intrahypothalamic secretion, and secretion into other regions of the CNS (43).

In addition to the established functions of oxytocin and vasopressin, several other diverse roles have been suggested in animal models. These functions include modulation of sexual activity and appetite, learning and memory consolidation, temperature regulation, and regulation of maternal behaviors (44). It remains to be seen which, if any, of these functions also exist in humans.

**Oxytocin**

Oxytocin is a nine–amino acid peptide primarily produced by the paraventricular nucleus of the hypothalamus (Fig. 7.7). The primary function of this hormone in humans is the stimulation of two specific types of muscular contractions (Fig. 7.8). The first type, uterine muscular contraction, occurs during parturition. The second type of muscular contraction regulated by oxytocin is breast lactiferous duct myoepithelial contractions, which occur during the milk letdown reflex. Oxytocin release may be stimulated by suckling, triggered by a signal from nipple stimulation transmitted via thoracic nerves to the spinal cord and then to the hypothalamus, where oxytocin is released in an episodic fashion (45). Oxytocin release also may be triggered by olfactory, auditory, and visual clues, and it may play a role in the conditioned reflex in nursing animals. Stimulation of the cervix and vagina can cause significant release of oxytocin, which may trigger reflex ovulation (the Ferguson reflex) in some species.

**Arginine-vasopressin**

Also known as antidiuretic hormone, or ADH, AVP is the second major secretory product of the posterior pituitary (Fig. 7.7). It is synthesized
primarily by neurons with cell bodies in the supraoptic nuclei (Fig. 7.8). Its major function is the regulation of circulating blood volume, pressure, and osmolality (45). Specific receptors throughout the body can trigger the release of AVP. Osmoreceptors located in the hypothalamus sense changes in blood osmolality from a mean of 285 mOsm/kg. Baroceptors sense changes in blood pressure caused by alterations in blood volume and are peripherally located in the walls of the left atrium, carotid sinus, and aortic arch (46). These receptors can respond to changes in blood volume of more than 10%. In response to decreases in blood pressure or volume, AVP is released and causes arteriolar vasoconstriction and renal free-water conservation. This in turn leads to a decrease in blood osmolality and an increase in blood pressure. Activation of the renal renin–angiotensin system can also activate AVP release.

Menstrual Cycle Physiology

In the normal menstrual cycle, orderly cyclic hormone production and parallel proliferation of the uterine lining prepare for implantation of the embryo. Disorders of the
menstrual cycle and, likewise, disorders of menstrual physiology may lead to various pathologic states, including infertility, recurrent miscarriage, and malignancy.

Normal Menstrual Cycle

The normal human menstrual cycle can be divided into two segments: the ovarian cycle and the uterine cycle, based on the organ under examination. The ovarian cycle may be further divided into follicular and luteal phases, whereas the uterine cycle is divided into corresponding proliferative and secretory phases (Fig. 7.9). The phases of the ovarian cycle are characterized as follows:

**Figure 7.9** The menstrual cycle. The top panel shows the cyclic changes of FSH, LH, estradiol (E$_2$), and progesterone (P) relative to the time of ovulation. The bottom panel correlates the ovarian cycle in the follicular and luteal phases and the endometrial cycle in the proliferative and secretory phases.
1. **Follicular phase**—hormonal feedback promotes the orderly development of a single dominant follicle, which should be mature at midcycle and prepared for ovulation. The average length of the human follicular phase ranges from 10 to 14 days, and variability in this length is responsible for most variations in total cycle length.

2. **Luteal phase**—the time from ovulation to the onset of menses has an average length of 14 days.

A normal menstrual cycle lasts from 21 to 35 days, with 2 to 6 days of flow and an average blood loss of 20 to 60 mL. However, studies of large numbers of women with normal menstrual cycles have shown that only approximately two thirds of adult women have cycles lasting 21 to 35 days (47). The extremes of reproductive life (after menarche and perimenopause) are characterized by a higher percentage of anovulatory or irregularly timed cycles (48,49).

### Hormonal Variations

The relative pattern of ovarian, uterine, and hormonal variation along the normal menstrual cycle is shown in Fig. 7.9.

1. **At the beginning of each monthly menstrual cycle, levels of gonadal steroids are low and have been decreasing since the end of the luteal phase of the previous cycle.**

2. **With the demise of the corpus luteum, FSH levels begin to rise, and a cohort of growing follicles is recruited.** These follicles each secrete increasing levels of estrogen as they grow in the follicular phase. The increase in estrogen, in turn, is the stimulus for uterine endometrial proliferation.

3. **Rising estrogen levels provide negative feedback on pituitary FSH secretion, which begins to wane by the midpoint of the follicular phase.** In addition, the growing follicles produce inhibin-B, which also suppresses FSH secretion by the pituitary. Conversely, LH initially decreases in response to rising estradiol levels, but late in the follicular phase the LH level is increased dramatically (biphasic response).

4. **At the end of the follicular phase (just before ovulation), FSH-induced LH receptors are present on granulosa cells and, with LH stimulation, modulate the secretion of progesterone.**

5. **After a sufficient degree of estrogenic stimulation, the pituitary LH surge is triggered, which is the proximate cause of ovulation that occurs 24 to 36 hours later.** Ovulation heralds the transition to the luteal–secretory phase.

6. **The estrogen level decreases through the early luteal phase from just before ovulation until the midluteal phase, when it begins to rise again as a result of corpus luteum secretion.** Similarly, inhibin-A is secreted by the corpus luteum.

7. **Progesterone levels rise precipitously after ovulation and can be used as a presumptive sign that ovulation has occurred.**

8. **Progesterone, estrogen, and inhibin-A act centrally to suppress gonadotropin secretion and new follicular growth.** These hormones remain elevated through the lifespan of the corpus luteum and then wane with its demise, thereby setting the stage for the next cycle.
Cyclic Changes of the Endometrium

In 1950, Noyes, Hertig, and Rock described the cyclic histologic changes in the adult human endometrium (50) (Fig. 7.10). These changes proceed in an orderly fashion in response to cyclic hormonal production by the ovaries (Fig. 7.9). Histologic cycling of the endometrium can best be viewed in two parts: the endometrial glands and the surrounding stroma. The superficial two thirds of the endometrium is the zone that proliferates and is ultimately shed with each cycle if pregnancy does not occur. This cycling portion of the endometrium is known as the decidua functionalis and is composed of a deeply situated intermediate zone (stratum spongiosum) and a superficial compact zone (stratum compactum). The decidua basalis is the deepest region of the endometrium. It does not undergo significant monthly proliferation but, instead, is the source of endometrial regeneration after each menses (51).

The existence of endometrial stem cells has long been assumed but has proven difficult to document. Recently, researchers found a small population of human epithelial and stromal cells that possess clonogenicity, suggesting that they represent the putative endometrial stem cells (52). Further evidence of the existence of such cells, as well as their source, was provided by another study that showed endometrial glandular epithelial cells obtained from endometrial biopsies of women undergoing bone marrow transplants express the HLA type of the donor bone marrow (53). This finding suggests that not only do endometrial stem cells exist, but also that they reside in bone marrow and migrate to the basalis of

![Figure 7.10](Image) The number of oocytes in the ovary before and after birth and through menopause.
the endometrium. Furthermore, the timing of the appearance of these cells following the transplant was as long as several years. This fact may prove to be of clinical importance in patients with Asherman’s Syndrome who experienced a loss of functional endometrium; repair of the uterine anatomy may eventually result in a functioning endometrial cavity.

Proliferative Phase

By convention, the first day of vaginal bleeding is called day 1 of the menstrual cycle. After menses, the decidua basalis is composed of primordial glands and dense scant stroma in its location adjacent to the myometrium. The proliferative phase is characterized by progressive mitotic growth of the decidua functionalis in preparation for implantation of the embryo in response to rising circulating levels of estrogen (54). At the beginning of the proliferative phase, the endometrium is relatively thin (1–2 mm). The predominant change seen during this time is evolution of the initially straight, narrow, and short endometrial glands into longer, tortuous structures (55). Histologically, these proliferating glands have multiple mitotic cells, and their organization changes from a low columnar pattern in the early proliferative period to a pseudostratified pattern before ovulation. Throughout this time, the stroma is a dense compact layer, and vascular structures are infrequently seen.

Secretory Phase

In the typical 28-day cycle, ovulation occurs on cycle day 14. Within 48 to 72 hours following ovulation, the onset of progesterone secretion produces a shift in histologic appearance of the endometrium to the secretory phase, so named for the clear presence of eosinophilic protein-rich secretory products in the glandular lumen. In contrast to the proliferative phase, the secretory phase of the menstrual cycle is characterized by the cellular effects of progesterone in addition to estrogen. In general, progesterone’s effects are antagonistic to those of estrogen, and there is a progressive decrease in the endometrial cell’s estrogen receptor concentration. As a result, during the latter half of the cycle, estrogen-induced DNA synthesis and cellular mitosis are antagonized (54).

During the secretory phase, the endometrial glands form characteristic periodic acid–Schiff positive-staining, glycogen-containing vacuoles. These vacuoles initially appear subnuclearly and then progress toward the glandular lumen (50) (Fig. 7.10). The nuclei can be seen in the midportion of the cells and ultimately undergo apocrine secretion into the glandular lumen, often by cycle day 19–20. At postovulatory day 6–7, secretory activity of the glands is generally maximal, and the endometrium is optimally prepared for implantation of the blastocyst.

The stroma of the secretory phase remains unchanged histologically until approximately the seventh postovulatory day, when there is a progressive increase in edema. Coincident with maximal stromal edema in the late secretory phase, the spiral arteries become clearly visible and then progressively lengthen and coil during the remainder of the secretory phase. By around day 24, an eosinophilic-staining pattern, known as cuffing, is visible in the perivascular stroma. Eosinophilia then progresses to form islands in the stroma followed by areas of confluence. This staining pattern of the edematous stroma is termed pseudodecidual because of its similarity to the pattern that occurs in pregnancy. Approximately 2 days before menses, there is a dramatic increase in the number of polymorphonuclear lymphocytes that migrate from the vascular system. This leukocytic infiltration heralds the collapse of the endometrial stroma and the onset of the menstrual flow.

Menses

In the absence of implantation, glandular secretion ceases, and an irregular breakdown of the decidua functionalis occurs. The resultant shedding of this layer of the
endometrium is termed *menses*. The destruction of the corpus luteum and its production of estrogen and progesterone is the presumed cause of the shedding. With withdrawal of sex steroids, there is a profound spiral artery vascular spasm that ultimately leads to endometrial ischemia. Simultaneously, there is a breakdown of lysosomes and a release of proteolytic enzymes, which further promote local tissue destruction. This layer of endometrium is then shed, leaving the decidua basalis as the source of subsequent endometrial growth. Prostaglandins are produced throughout the menstrual cycle and are at their highest concentration during menses (53). Prostaglandin $\text{F}_2\alpha$ ($\text{PGF}_2\alpha$) is a potent vasoconstrictor, causing further arteriolar vasospasm and endometrial ischemia. $\text{PGF}_2\alpha$ also produces myometrial contractions that decrease local uterine wall blood flow and may serve to physically expel sloughing endometrial tissue from the uterus.

### Dating the Endometrium

The changes seen in secretory endometrium relative to the LH surge have long been thought to allow the assessment of the “normalcy” of endometrial development. Since 1950, it was felt that by knowing when a patient ovulated, it was possible to obtain a sample of endometrium by endometrial biopsy and determine whether the state of the endometrium corresponds to the appropriate time of the cycle. Traditional thinking held that any discrepancy of more than 2 days between chronologic and histologic date indicated a pathologic condition termed luteal phase defect; this abnormality has been linked to both infertility (via implantation failure) and early pregnancy loss (56).

Recent evidence, however, suggests a lack of utility for the endometrial biopsy as a diagnostic test for either infertility or early pregnancy loss (56). In a randomized, observational study of regularly cycling, fertile women, it was found that endometrial dating is far less accurate and precise than originally claimed, and does not provide a valid method for the diagnosis of luteal phase defect (57). Furthermore, a large prospective, multicenter trial sponsored by the National Institutes of Health showed that histologic dating of the endometrium does not discriminate between fertile and infertile women (58). Thus, after half a century of using this test in the evaluation of the subfertile couple, it has become clear that today the endometrial biopsy has no role in the routine evaluation of infertility or early pregnancy loss.

### Ovarian Follicular Development

The number of oocytes peaks in the fetus at 6 to 7 million by 20 weeks of gestation (59) (Fig. 7.10). Simultaneously (and peaking at the fifth month of gestation), atresia of the oogonia occurs, rapidly followed by follicular atresia. At birth, only 1 to 2 million oocytes remain in the ovaries, and *at puberty, only 300,000 of the original 6 to 7 million oocytes are available for ovulation* (59,60). Of these, only 400 to 500 will ultimately be released during ovulation. By the time of menopause, the ovary will be composed primarily of dense stromal tissue with only rare interspersed oocytes remaining.

A central dogma of reproductive biology is that in mammalian females there is no capacity for oocyte production postnatally. Because oocytes enter the diplotene resting stage of meiosis in the fetus and persist in this stage until ovulation, much of the deoxyribonucleic acid (DNA), proteins, and messenger ribonucleic acid (mRNA) necessary for development of the preimplantation embryo will have been synthesized by this stage. At the diplotene stage, a single layer of 8 to 10 granulosa cells surround the oogonia to form the primordial follicle. The oogonia that fail to become properly surrounded by granulosa cells undergo atresia (61). The remainder proceed with follicular development. Thus, most oocytes are lost during fetal development, and the remaining follicles are steadily “used up” throughout the intervening years until menopause.
Recent evidence has begun to challenge this theory. Studies in the mouse have shown that production of oocytes and corresponding folliculogenesis can occur well into adult life (62). The reservoir of germline stem cells responsible for this oocyte development appears to reside in the bone marrow (63). It is not clear whether such stem cells exist in adult humans, and if they do, what clinical function they might provide.

**Meiotic Arrest of Oocyte and Resumption**

Meiosis (the germ cell process of reduction division) is commonly divided into four phases: prophase, metaphase, anaphase, and telophase. The prophase of meiosis I is further divided into five stages: leptotene, zygotene, pachytene, diplotene, and diakinesis.

Oogonia differ from spermatogonia in that only one final daughter cell (oocyte) forms from each precursor cell, with the excess genetic material discarded in three polar bodies. When the developing oogonia begin to enter meiotic prophase I, they are known as primary oocytes (64). This process begins at roughly 8 weeks of gestation. Only those oogonia that enter meiosis will survive the wave of atresia that sweeps the fetal ovary before birth. The oocytes arrested in prophase (in the late diplotene or “dictyate” stage) will remain so until the time of ovulation, when the process of meiosis resumes. The mechanism for this mitotic stasis is believed to be an oocyte maturation inhibitor (OMI) produced by granulosa cells (65). This inhibitor gains access to the oocyte via gap junctions connecting the oocyte and its surrounding cumulus of granulosa. With the midcycle LH surge, the gap junctions are disrupted, granulosa cells are no longer connected to the oocyte, and meiosis I is allowed to resume.

**Follicular Development**

Follicular development is a dynamic process that continues from menarche until menopause. The process is designed to allow the monthly recruitment of a cohort of follicles and, ultimately, to release a single mature dominant follicle during ovulation each month.

**Primordial Follicles**

The initial recruitment and growth of the primordial follicles is gonadotropin independent and affects a cohort over several months (66). However, the stimuli responsible for the recruitment of a specific cohort of follicles in each cycle are unknown. At the primordial follicle stage, shortly after initial recruitment, FSH assumes control of follicular differentiation and growth and allows a cohort of follicles to continue differentiation. This process signals the shift from gonadotropin-independent to gonadotropin-dependent growth. The first changes seen are growth of the oocyte and expansion of the single layer of follicular granulosa cells into a multilayer of cuboidal cells. The decline in luteal phase estrogen, progesterone, and inhibin-A production by the now-fading corpus luteum from the previous cycle allows the increase in FSH that stimulates this follicular growth (67).

**Preantral Follicle**

During the several days following the breakdown of the corpus luteum, growth of the cohort of follicles continues, driven by the stimulus of FSH. The enlarging oocyte then secretes a glycoprotein-rich substance, the zona pellucida, which separates it from the surrounding granulosa cells (except for the aforementioned gap junction). With transformation from a primordial to a preantral follicle, there is continued mitotic proliferation of the encompassing granulosa cells. Simultaneously, theca cells in the stroma bordering the granulosa cells proliferate. Both cell types function synergistically to produce estrogens that are secreted into the systemic circulation. At this stage of development, each of the seemingly identical cohort members must either be selected for dominance or undergo atresia. It is likely that the follicle destined to ovulate has been selected before this point, although the mechanism for selection remains obscure.
Two-cell Two-gonadotropin Theory

The fundamental tenet of follicular development is the two-cell, two-gonadotropin theory (66,68,69) (Fig. 7.11). This theory states that there is a subdivision and compartmentalization of steroid hormone synthesis activity in the developing follicle. In general, most aromatase activity (for estrogen production) is in the granulosa cells (70). Aromatase activity is enhanced by FSH stimulation of specific receptors on these cells (71,72). However, granulosa cells lack several enzymes that occur earlier in the steroidogenic pathway and require androgens as a substrate for aromatization. Androgens, in turn, are synthesized primarily in response to stimulation by LH, and the theca cells possess most of the LH receptors at this stage (71,72). Therefore, a synergistic relationship must exist: LH stimulates the theca cells to produce androgens (primarily androstenedione), which in turn are transferred to the granulosa cells for FSH-stimulated aromatization into estrogens. These locally produced estrogens create a microenvironment within the follicle that is favorable for continued growth and nutrition (73). Both FSH and local estrogens
serve to further stimulate estrogen production, FSH receptor synthesis and expression, and granulosa cell proliferation and differentiation.

Androgens have two different regulatory roles in follicular development. At low concentrations (i.e., in the early preantral follicle), they serve to stimulate aromatase activity via specific receptors in granulosa cells. At higher levels of androgens, there is intense 5α-reductase activity that converts the androgens to forms that cannot be aromatized (68,74). This androgenic microenvironment inhibits the expression of FSH receptors on the granulosa cells, thereby inhibiting aromatase activity and setting the follicle on the path to atresia (75). Meanwhile, as the peripheral estrogen level rises, it negatively feeds back on the pituitary and hypothalamus to decrease circulating FSH levels (76). Increased ovarian production of inhibin-B further decreases FSH production at this point.

The falling FSH level that occurs with the progression of the follicular phase represents a threat to continued follicular growth. The resulting adverse environment can be withstood only by follicles with a selective advantage for binding the diminishing FSH molecules; that is, those with the greatest number of FSH receptors. The dominant follicle, therefore, can be perceived as the one with a richly estrogenic microenvironment and the most FSH receptors (77). As it grows and develops, the follicle continues to produce estrogen, which results in further lowering of the circulating FSH and creating a more adverse environment for competing follicles. This process continues until all members of the initial cohort, with the exception of the single dominant follicle, have suffered atresia. The stage is then set for ovulation.

**Preovulatory Follicle**

Preovulatory follicles are characterized by a fluid-filled antrum that is composed of plasma with granulosa-cell secretions. The granulosa cells at this point have further differentiated into a heterogeneous population. The oocyte remains connected to the follicle by a stalk of specialized granulosa known as the *cumulus oophorus*.

Rising estrogen levels have a negative feedback effect on FSH secretion. Conversely, LH undergoes biphasic regulation by circulating estrogens. At lower concentrations, estrogens inhibit LH secretion. At higher levels, however, estrogen enhances LH release. This stimulation requires a sustained high level of estrogen (200 pg/mL) for more than 48 hours (78). Once the rising estrogen level produces positive feedback, a substantial surge in LH secretion occurs. Concomitant to these events, the local estrogen-FSH interactions in the dominant follicle induce LH receptors on the granulosa cells. Thus, exposure to high levels of LH results in a specific response by the dominant follicle—the result is luteinization of the granulosa cells, production of progesterone, and initiation of ovulation. In general, ovulation will occur in the single mature, or Graafian, follicle 10 to 12 hours after the LH peak or 34 to 36 hours after the initial rise in midcycle LH (79–81).

As suggested previously, the sex steroids are not the only gonadotropin regulators of follicular development. Two related granulosa cell–derived peptides have been identified that play opposing roles in pituitary feedback (82). The first of these peptides, inhibin, is secreted in two forms: inhibin-A and inhibin-B. Inhibin-B is secreted primarily in the follicular phase and is stimulated by FSH (83), whereas inhibin-A is mainly active in the luteal phase. Both forms of inhibin act to inhibit FSH synthesis and release (84,85). The second peptide, activin, stimulates FSH release from the pituitary gland and potentiates its action in the ovary (86,87). It is likely that there are numerous other intraovarian regulators similar to inhibin and activin, each of which may play a key role in promoting the normal ovulatory process (88). Some of these include follistatin, insulinlike growth factor (ILGF)-1, epidermal growth factor (EGF), transforming growth factor (TGF)-α, TGF-β1, β-fibroblast growth factor (FGF), interleukin-1, tissue necrosis factor-α, OMI, and renin–angiotensin.

179
Ovulation

The midcycle LH surge is responsible for a dramatic increase in local concentrations of prostaglandins and proteolytic enzymes in the follicular wall (89). These substances progressively weaken the follicular wall and ultimately allow a perforation to form. Ovulation most likely represents a slow extrusion of the oocyte through this opening in the follicle rather than a rupture of the follicular structure (90). In fact, direct measurements of intrafollicular pressures have been recorded and have failed to demonstrate an explosive event.

Luteal Phase

Structure of Corpus Luteum  After ovulation, the remaining follicular shell is transformed into the primary regulator of the luteal phase: the corpus luteum. Membranous granulosa cells remaining in the follicle begin to take up lipids and the characteristic yellow lutein pigment for which the structure is named. These cells are active secretory structures that produce progesterone, which supports the endometrium of the luteal phase. In addition, estrogen and inhibin A are produced in significant quantities. Unlike the process that occurs in the developing follicle, the basement membrane of the corpus luteum degenerates to allow proliferating blood vessels to invade the granulosa-luteal cells in response to secretion of angiogenic factors such as vascular endothelial growth factor (91). This angiogenic response allows large amounts of luteal hormones to enter the systemic circulation.

Hormonal Function and Regulation  The hormonal changes of the luteal phase are characterized by a series of negative feedback interactions designed to lead to regression of the corpus luteum if pregnancy does not occur. Corpus luteum steroids (estradiol and progesterone) provide negative central feedback and cause a decrease in FSH and LH secretion. Continued secretion of both steroids will decrease the stimuli for subsequent follicular recruitment. Similarly, luteal secretion of inhibin also potentiates FSH withdrawal. In the ovary, local production of progesterone inhibits the further development and recruitment of additional follicles.

Continued corpus luteum function depends on continued LH production. In the absence of this stimulation, the corpus luteum will invariably regress after 12 to 16 days and form the scarlike corpora albicants (92). The exact mechanism of luteolysis, however, is unclear and most likely also involves local paracrine factors. In the absence of pregnancy, the corpus luteum regresses, and estrogen and progesterone levels wane. This, in turn, removes central inhibition on gonadotropin secretion and allows FSH and LH levels to again rise and recruit another cohort of follicles.

If pregnancy does occur, placental hCG will mimic LH action and continually stimulate the corpus luteum to secrete progesterone. Thus, successful implantation results in hormonal support to allow continued maintenance of the corpus luteum and the endometrium. Evidence from patients undergoing oocyte donation cycles has demonstrated that continued luteal function is essential to continuation of the pregnancy until approximately 5 weeks of gestation, when sufficient progesterone is produced by the developing placenta (93). This switch in the source of regulatory progesterone production is referred to as the luteal–placental shift.

Summary of Menstrual Cycle Regulation  Following is a summary of the regulation of the menstrual cycle:

1. GnRH is produced in the arcuate nucleus of the hypothalamus and secreted in a pulsatile fashion into the portal circulation, where it travels to the anterior pituitary.
2. Ovarian follicular development moves from a period of gonadotropin independence to a phase of FSH dependence.

3. As the corpus luteum of the previous cycle fades, luteal production of progesterone and inhibin A decreases, allowing FSH levels to rise.

4. In response to FSH stimulus, the follicles grow and differentiate and secrete increasing amounts of estrogen and inhibin-B.

5. Estrogen stimulates growth and differentiation of the functional layer of the endometrium, which prepares for implantation. Estrogens work with FSH in stimulating follicular development.

6. The two-cell two-gonadotropin theory dictates that with LH stimulation, the ovarian theca cells will produce androgens that are converted by the granulosa cells into estrogens under the stimulus of FSH.

7. Rising estrogen and inhibin levels negatively feed back on the pituitary gland and hypothalamus and decrease the secretion of FSH.

8. The one follicle destined to ovulate each cycle is called the dominant follicle. It has relatively more FSH receptors and produces a larger concentration of estrogens than the follicles that will undergo atresia. It is able to continue to grow despite falling FSH levels.

9. Sustained high estrogen levels cause a surge in pituitary LH secretion that triggers ovulation, progesterone production, and the shift to the secretory, or luteal, phase.

10. Luteal function is dependent on the presence of LH. However, the corpus luteum secretes estrogen, progesterone, and inhibin-A, which serve to maintain gonadotropin suppression. Without continued LH secretion, the corpus luteum will regress after 12 to 16 days. The resulting loss of progesterone secretion results in menstruation.

11. If pregnancy occurs, the embryo secretes hCG, which mimics the action of LH by sustaining the corpus luteum. The corpus luteum continues to secrete progesterone and supports the secretory endometrium, allowing the pregnancy to continue to develop.

PREVENTIVE AND PRIMARY CARE
Preventive health services that encompass screening and counseling for a broad range of health behaviors and risks are important components of general obstetric and gynecologic care.

Traditional gynecologic care—including cervical cytology testing, pelvic and breast screening examinations, and the provision of contraceptive services—is considered primary preventive care.

Routine health care assessments for healthy women include a medical history, physical examination, routine and indicated lab studies, assessment and counseling regarding healthy behaviors, and relevant interventions, taking into account the leading causes of morbidity and mortality within different age groups.

Evidence-based guidelines for the provision of periodic health evaluations, screening, and counseling have been developed by the American College of Obstetricians and Gynecologists (ACOG) and other organizations; these guidelines provide the basis for routine preventive health assessment and screening recommendations.

Preventive services for adolescents should be based on knowledge of the behavioral and medical health risks that place their future health at risk, including substance use and abuse, sexual behaviors that increase the risks of unintended pregnancy and sexually transmitted diseases (STDs), and impaired mental health.

Obesity, smoking, and alcohol abuse are preventable problems that have a major impact on long-term health; assessment, counseling, and referral for these health risks is a component of periodic health assessment and primary care.

Although obstetrician-gynecologists have focused on the management of abnormal gynecologic conditions, they also have a traditional role of providing primary and preventive care.
Primary care emphasizes health maintenance, preventive services, early detection of disease, and availability and continuity of care (1). The value of preventive services is apparent in such trends as the reduced mortality rate from cervical cancer, in large part resulting from the increased use of cervical cytology testing. Neonatal screening for phenylketonuria (PKU) and hypothyroidism are examples of effective mechanisms for prevention of mental retardation. Women often regard their gynecologist as their primary care provider; indeed, many women of reproductive age have had no other physician. As primary care physicians, obstetrician-gynecologists provide ongoing care for women through all stages of their lives—from reproductive age to postmenopause. In this role, some gynecologists include as a routine part of their practices screening for certain medical conditions, such as hypertension, diabetes mellitus, and thyroid disease, as well as management of those conditions in the absence of complications.

Some traditional aspects of gynecologic practice, such as family planning and preconception counseling, can be considered preventive health care. Preventive medical services encompass screening and counseling for a broad range of health behaviors and risks, including sexual practices; prevention of STDs; use of tobacco, alcohol, and other drugs; diet; and exercise.

The Institute of Medicine has defined primary care as “the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community.” Integrated care is further defined as being comprehensive, coordinated, and continuous. The definition states that primary care clinicians have the appropriate training to manage most problems that afflict patients (including physical, mental, emotional, and social concerns) and to involve other practitioners for further evaluation or treatment when appropriate (2). Using data from the National Ambulatory Medical Care Surveys, physician specialty groups were analyzed in a study to determine how well these Institute of Medicine primary care definitions applied to the care delivered by each specialty (3). In this analysis, obstetrics and gynecology as a specialty demonstrated some characteristics of primary care that applied to the traditional specialties of internal medicine, family and general physicians, and pediatrics. As a category, however, obstetrics and gynecology was more closely related to medical and surgical subspecialties (3). This analysis would be accepted by many practicing obstetrician-gynecologists who state that the specialty provides both primary and specialty care.

The Institute of Medicine definition includes referral, coordination, and follow-up care, but specifically does not include the function of “gatekeeper” as essential for a primary care clinician. The emphasis placed by health maintenance organizations on limiting access to specialist physicians through the use of a “gatekeeper” primary care clinician has declined over recent years as women have strongly supported direct access to obstetrician-gynecologists and patient rights’ legislation has evolved accordingly (4,5).

In recent years, there has been increasing emphasis on women’s health and gender-specific medicine. Physicians have become more knowledgeable about the differences in pathophysiologic aspects of diseases in women compared with men and thus better equipped to manage them. An example is an increasing emphasis on women’s cardiovascular health with preventive care and screening for risk factors.

Gynecologist as Primary Care Provider

The obstetrician-gynecologist frequently serves as a primary medical resource for women and their families, providing information, guidance, and referrals when
appropriate. Routine health care assessments for healthy women are based on age groups and risk factors. Health guidance takes into account the leading causes of morbidity and mortality within different age groups. Patient counseling and education require an ability to assess individual needs, and to use good communication skills to encourage behavioral changes and ongoing care (1). A team approach to care is frequently helpful, utilizing the expertise of medical colleagues, such as nurses; advanced practice nurses, such as nurse midwives and nurse practitioners; health educators; other allied health professionals, such as dieticians or physical therapists; relevant social services; and other physician specialists. All clinicians, regardless of the extent of their training, have limitations to their knowledge and skills and should seek consultation at appropriate times for the benefit of their patients in providing both reproductive and nonreproductive care (1).

The National Ambulatory Care Surveys from the Centers for Disease Control and Prevention include obstetrician-gynecologists among primary care specialties as opposed to medical or surgical subspecialty (6). Obstetrician-gynecologists provide most of general medical examinations for women of reproductive age (7). This fact indicates that obstetricians-gynecologists may already serve as the primary physicians for many of their patients. However, when women are asked to choose which type of physician they would select if they had only one physician for all of their general medical care, family or general medical practitioners are preferred over obstetrician-gynecologists (8).

Guidelines for primary and preventive services have been issued by a number of medical bodies: the American College of Obstetricians and Gynecologists (9,10), the American Academy of Family Physicians (11), the U.S. Preventive Services Task Force (USPSTF) (12), and the American Medical Association (13,14). The guidelines from various organizations differ somewhat in their specific details, and a national guideline clearinghouse for evidence-based clinical practice guidelines, sponsored by the Agency for Healthcare Research and Quality (AHRQ), is available to provide comparisons between guidelines for a given medical condition or intervention (15). Books specific to the provision of primary health care by obstetrician-gynecologists are now available (16–22).

In 1998 in the United States, there were approximately 500 million visits by women to ambulatory medical care providers. Eighteen percent of the visits (76 million) were made to gynecologists (23). Forty-six percent of ambulatory visits were made by individuals between the ages of 15 and 44 years (23). The most frequently cited reason for an office visit to an obstetrician-gynecologist by women older than 15 years of age was routine prenatal examination. The second most frequently cited reason was general medical examination. For women in this age group, obstetrician-gynecologists provided more general medical examinations than general and family practitioners and internists combined. For women of reproductive age (15–44 years), gynecologists provided nearly 4 times as many general medical examinations than did general and family practitioners, and almost 12 times as many examinations as internists (24).

When asked to characterize the nature of an office or clinic visit, obstetrician-gynecologists may or may not identify themselves as primary care providers, depending on variables (25). Those variables may include the patient’s age, pregnancy status, whether it is a new versus a return visit, the diagnosis, insurance or referral status, and even geographic practice region.

Surveys of practicing physicians who were asked to categorize themselves and the nature of their practices as that of a primary care physician, a specialist, or a consultant have found that approximately one half of obstetricians and gynecologists consider themselves to be primary care providers (24,26). Gynecologists younger than 35 years of age, those in the South Atlantic census region, and those who were paid by hospitals and medical centers may be more likely to consider themselves primary care providers.
Although not all obstetricians and gynecologists would describe themselves as being interested in serving as a primary care physician, one survey found that most considered themselves capable of serving as primary care gatekeepers without extensive additional training (27). In a 1995 survey of those completing their residencies, 87% of the respondents believed that obstetrics and gynecology was primary care, and 85% planned to practice accordingly after residency (28). However, only one half of residency training directors supported the inclusion of 6 months of primary care in the residency education program (29).

Recent changes in the Residency Review Committee’s (RRC) requirements for primary care training in obstetrics and gynecology focus on the integration of primary care training throughout the 4-year residency program. Residency review committee requirements call for a focus on reproductive health care and ambulatory primary health care for women, including health maintenance, disease prevention, diagnosis, treatment, consultation, and referral (30).

Obstetrician-gynecologists are less likely than other primary care physicians to refer their patients to other specialists. Data compiled by the National Center for Health Statistics (NCHS) indicate that gynecologists had a referral rate of 4%, general internists 7.3%, and family and general practitioners 7.3% (31). Although obstetricians-gynecologists frequently do provide preventive care and guidance, there is room for improvement in these aspects of care. Obstetrician-gynecologists are as likely as family physicians or those in general practice to counsel about exercise and to measure blood pressure, although somewhat less likely than other physicians to counsel about smoking cessation and weight loss or to screen for hyperlipidemia (32). Obstetrician-gynecologists, family physicians, and general physicians were all less likely than internists or cardiologists to provide these cardiovascular preventive services.

In 1993, ACOG commissioned a Gallup poll to assess how women viewed the care provided by their obstetrician-gynecologists (8). When compared with other physicians, obstetrician-gynecologists were more likely than other physicians to perform cervical cytology testing, pelvic examination, and breast examination. Obstetrician-gynecologists were as likely as other physicians to have checked blood pressure and referred patients for mammography. When compared with other physicians, they were slightly less likely to have checked cholesterol levels. Obstetrician-gynecologists are somewhat more likely than other physicians to have discussed family planning, preconception issues, and STDs, including human immunodeficiency virus (HIV). Other physicians were more likely than obstetrician-gynecologists to discuss medication use. Other physicians were as likely as obstetrician-gynecologists to have discussed diet and exercise, smoking, alcohol use, hormone replacement therapy, osteoporosis, emotional problems, illegal drug use, and physical abuse (8). More than one half of all women who reported seeing an obstetrician-gynecologist considered him or her to be their primary physician. As expected, the percentage was highest among women aged 18 to 29 years (69%) and lowest among women older than 40 years (45%) (8). Another survey of young, low-income women attending an ob-gyn clinic found that a similar percentage—nearly half—characterized the clinic as providing primary care (33).

**Approaches to Preventive Care**

Currently in health care, the focus is shifting from disease to prevention. Efforts are under way to promote effective screening measures that can have a beneficial effect on public and individual health. Following is a brief description of programs developed by ACOG, the USPSTF, and the American Medical Association to provide guidelines for preventive care.
Guidelines for Primary and Preventive Care

The initial evaluation of a patient involves a complete history, physical examination, routine and indicated laboratory studies, evaluation and counseling, appropriate immunizations, and relevant interventions. Risk factors should be identified and arrangements should be made for continuing care or referral, as needed. The leading causes of death and morbidity within different age groups are listed in Tables 8.1 and 8.2 (34).

Subsequent care should follow a specific schedule, yearly or as appropriate based on the patient's needs and age. The ACOG recommendations for periodic evaluation, screening, and counseling by age groups are shown in Tables 8.3–8.6. These tables also include recommendations for patients who have high-risk factors that require targeted screening or treatment; patients should be made aware of any high-risk conditions that require more specific screening or treatment (35). High-risk factors are listed in Table 8.7. Recommendations for immunizations are included in Table 8.8.

Guide to Clinical Preventive Services

The USPSTF, originally commissioned in 1984, was a 20-member nongovernmental panel of experts in primary care medicine, epidemiology, and public health. Initial and subsequent reviews and recommendations are being revised and periodically released on the Web site sponsored by the AHRQ (12). The charge to the panel was to develop recommendations for the appropriate use of preventive interventions based on a systematic review of evidence of clinical effectiveness. The panel was asked to rigorously evaluate clinical research to assess the merits of preventive measures, including screening tests, counseling, immunizations, and medications.

The task force uses systematic reviews of the evidence on specific topics in clinical prevention that serve as the scientific basis for recommendations. The task force reviews the evidence, estimates the magnitude of benefits and harms, reaches consensus about the net benefit of a given preventive service, and issues a recommendation. The task force grades the quality of the evidence as good, fair, or poor, and then issues a recommendation varying from strongly recommends to recommends against, or concludes that there is insufficient evidence to recommend for or against an intervention (35) (Table 8.9). The task force reviewed only those preventive services that would be provided for asymptomatic individuals. Primary preventive measures are those that involve intervention before the disease develops, for example, quitting smoking, increasing physical activity, eating a healthy diet, quitting alcohol and other drug use, using seat belts, and receiving immunizations. Secondary preventive measures are those used to identify and treat asymptomatic persons who have risk factors or preclinical disease but in whom the disease itself has not become clinically apparent. Examples of secondary preventive measures are well known in gynecology, such as screening mammography and cervical cytology testing.

The USPSTF is supported by an Evidence-based Practice Center (EPC), which conducts systematic reviews of the evidence that serve as the scientific basis for USPSTF recommendations. These reviews analyze the effectiveness of various screening measures and tests. Preventive medicine and the discipline of evidence-based medicine have grown and evolved since the release of the first Guide to Clinical and Preventive Services in 1989 (36).

This document accelerated the trend to replace consensus or expert opinion in clinical recommendations with a more systematic and explicit review of the evidence. Although evidence-based guidelines have become widely accepted, current recommendations are based on what has been described as a “more mature appreciation of their limitations,” including the recognition that evidence is lacking for much of medical practice, that waiting for better data from controlled trials is unrealistic, and that evidence-based guidelines could potentially cause unintended harm to patients, clinicians, and the health care system (38).

International efforts to categorize the effectiveness of treatments include the Cochrane Library, which produces and disseminates high-quality systematic reviews of health care interventions. These reviews and abstracts are published quarterly and are available online and on CD-ROM by subscription (39). The Cochrane Library provides searchable databases online and through institutional purchase of licenses. Evidence-based guidelines are published in journals available in print and online by discipline (i.e., medicine, mental health, and nursing). Another source of evidence-based information is Clinical Evidence, a subscription service published by the British Medical Journal in print and electronic versions (online, CD-ROM, and PDA) (40). This service summarizes the current state of knowledge and uncertainty about prevention and treatment, rating treatments as beneficial, likely to be beneficial, of unknown effectiveness, likely to be ineffective or harmful, unlikely to be beneficial, or a trade-off between benefits and harms. The advantages of Web-based sites are the ease of updating and the availability of evidence to clinicians in clinical practice sites. Other Web sites that provide tools and information about evidence-based health care include the Oxford-Centre for Evidence-Based Medicine (41), the Database of Abstracts of Reviews of Effects (DARE) (42), and the American College of Physicians (ACP) Journal Club (43).

Guidelines for Adolescent Preventive Services

Around the same time that clinicians were evaluating the primary health care needs of adults, clinicians who practice adolescent medicine (with backgrounds in pediatrics, internal medicine, family medicine, gynecology, nursing, psychology, nutrition, and other professions) recognized that the guidelines for adult and pediatric health services did not always fit the needs and health risks of adolescence. Neither the ACOG Guidelines for Primary Preventive Care (9) nor the USPSTF recommendations (12) is sufficiently comprehensive or focused on this age group, although both documents include many important aspects of adolescent health care. The American Medical Association, with the assistance of a national scientific advisory board, developed the Guidelines for Adolescent Preventive Services (GAPS) in response to this perceived need for recommendations for delivering comprehensive adolescent preventive services (13,14).

Obstetrician-gynecologists typically see adolescents in crisis to provide care for unintended pregnancies or STDs, including pelvic inflammatory disease. The need for preventing these crises is evident. The GAPS report extends the framework of services provided to adolescents. The impetus for developing GAPS was the belief that a fundamental

(Continued)
change in the delivery of adolescent health services was necessary. Gynecologists could easily provide most, if not all, of the recommended services; annual preventive visits to a gynecologist might well lead to the prevention of gynecologic health problems. There are numerous opportunities for primary preventive care of adolescents in a gynecologist’s office.

The GAPS report includes 24 recommendations (Table 8.10). These recommendations address the delivery of health care, focus on the use of health guidance to promote the health and well-being of adolescents and their families, promote the use of screening to identify conditions that occur relatively frequently in adolescents and cause significant suffering either during adolescence or later in life, and provide guidelines for immunizations for the primary prevention of specific infectious diseases (13).

The GAPS recommendations stem from the conclusion that the current health threats to adolescents are predominantly behavioral rather than biomedical, that more of today’s adolescents are involved in health behaviors with the potential for serious consequences, that adolescents are involved in health-risk behaviors at younger ages than previous generations, that many adolescents engage in multiple health-risk behaviors, and that most adolescents engage in at least some type of behavior that threatens their health and well-being (13). Gynecologists are in a good position to detect high-risk behaviors and to determine whether multiple risk-taking behaviors exist; for example, the early initiation of sexual activity and unsafe sexual practices are associated with substance use (43). Adolescents who are sexually active are much more likely than are adolescents who are not sexually active to have used alcohol (6.3 times greater risk), to have used drugs other than marijuana (4 times greater risk), and to have been a passenger in a motor vehicle with a driver who was using drugs (nearly 10 times greater risk) (44). Thus, by being aware of comorbidities, gynecologists can screen for these behaviors and potentially intervene before serious harmful health consequences occur.

In recognition of the role that obstetrician-gynecologists potentially could play in providing preventive services for adolescents, ACOG has issued guidelines that build on the

GAPS recommendations (10). These guidelines suggest an initial visit (not necessarily examination) to the obstetrician-gynecologist for health guidance, screening, and the provision of preventive health care service between the ages of 13 and 15 years and subsequent annual preventive health care visits (1,10).

Counseling for Health Maintenance

During periodic assessments, patients should be counseled about preventive care based on their age and risk factors. Obesity, smoking, and alcohol abuse are associated with preventable problems that can have major long-term impacts on health. Thus, patients should be counseled about smoking cessation and moderation in alcohol use and directed to appropriate community resources as necessary. Positive health behaviors, such as eating a healthy diet and engaging in regular exercise, should be reinforced. Adjustments may be necessary based on the presence of risk factors and the woman’s current lifestyle and condition. Efforts should focus on weight control, cardiovascular fitness, and reduction of risk factors associated with cardiovascular disease and diabetes (1,45–48).

Nutrition

Patients should be given general nutritional information and referred to other professionals if they have special needs (47). Assessment of the patient’s body mass index (weight in kilograms divided by height in meters squared [kilograms per square meter]) will give valuable information about the patient’s nutritional status. Tables and methods to calculate BMI are available in print and electronic resources. Patients who are

*See Table 8.7.

*Preconceptional and genetic counseling are appropriate for certain women in this age group.

*Despite a lack of definitive data for or against breast self-examination, breast self-examination has the potential to detect palpable breast cancer and can be recommended.

20% above or below the normal range require evaluation and counseling and should be assessed for systemic disease or an eating disorder. Of adult women in the United States, 62% are either overweight (BMI 25–29.9) or obese (BMI ≥ 30); 34% are obese (49). Overweight and obesity substantially increase the risk of morbidity from hypertension, dyslipidemia, type 2 diabetes, coronary artery disease, stroke, gallbladder disease, osteoarthritis, sleep apnea, and cancers of the endometrium, breast, and colon (50).

Central obesity—measured as waist-to-hip ratio—is an independent risk factor for disease. Women with a waist circumference greater than 35 inches are at higher risk of diabetes, dyslipidemia, hypertension, and cardiovascular disease (51).

Key nutritional recommendations have been issued by the Dietary Guidelines Advisory Committee to the U.S. Department of Agriculture (52). These recommendations are included in the new Food Guide Pyramid, which has been revised and individualized with an emphasis on whole grains, fruits, and vegetables (Fig. 8.1). The pyramid is based on the need to eat a variety of foods to get adequate energy, protein, vitamins, minerals, and fiber (52,53). It includes lean meats, poultry, fish, beans, eggs, and nuts, and is low in saturated fats, trans fats, cholesterol, salt, and added sugars. The new pyramid recognizes the need to balance food and physical activity.

Fiber content of the diet is being studied for its potential role in the prevention of several disorders, particularly colon cancer. Currently, it is recommended that the average diet for women contain 25 g of fiber per day (53). Whole-grain foods, as well as vegetables, citrus fruits, and some legumes, are high in fiber and are emphasized in the new guidelines for healthy foods.

Adequate calcium intake is important in the prevention of osteoporosis. A postmenopausal woman should ingest 1,500 mg/day. Adolescents require 1,300 mg/day. There is no evidence that moderate caffeine intake causes osteoporosis when calcium intake is adequate. Because it is difficult to ingest an adequate amount of calcium daily in an average diet, supplements may be required.

*See Table 8.7.

The Centers for Disease Control and Prevention has recommended that women of reproductive age who are capable of becoming pregnant take supplemental folic acid (0.4 mg daily) to help prevent neural tube defects in their infants (54). Women who are contemplating pregnancy should be counseled about the risk of fetal neural tube defects and the role of folic acid in their prevention.

Alcohol

Alcoholic beverages should be limited to one drink per day for women (52). A simple device called the T-ACE questionnaire can be used to elicit information about alcohol use and identify problem drinkers (Table 8.11). Women should be questioned in a nonjudgmental fashion about their alcohol use and directed to counseling services as required.

Exercise

Exercise can help control or prevent hypertension, diabetes mellitus, hypercholesterolemia, and cardiovascular disease and helps to promote overall good health, psychological well-being, and a healthy body weight. Moderate exercise along with calcium supplementation can help retard bone loss in postmenopausal women (55,56). During early menopause, weight-bearing exercise alone is not sufficient to prevent bone loss, although it will slow the rate of bone loss (55). Exercise helps promote weight loss, strength and fitness, and stress reduction. Federal exercise guidelines released with dietary guidelines in 2005 from the Department of Health and Human Services recommend “at least 30 minutes of moderate-intensity physical activity, above usual activity, at work or home on most days of the week” to reduce the risk of chronic disease in adulthood (52). The guidelines encourage physical activity of more vigorous intensity or longer duration to provide greater health benefits for most people. “Approximately 60 minutes of moderate- to vigorous-intensity activity on most days of the week” are recommended, coupled with adherence to caloric intake require-
To sustain weight loss in adulthood, 60 to 90 minutes of daily moderate-intensity physical activity are recommended (52). Cardiovascular conditioning, stretching exercises for flexibility, and resistance exercises or calisthenics for muscle strength and endurance are recommended for most people (52). Before beginning an exercise program, patients should be examined to ensure that exercise will not pose a risk to their health. Women should be counseled about safety guidelines for exercise. Factors that should be considered in establishing an exercise program include medical limitations, such as obesity or arthritis, and selection of activities that promote health and enhance compliance (48).

High-impact exercise is not necessary to achieve benefits, and it may be harmful. Regular low-impact or moderate aerobic exercise has been associated with improved long-term compliance and adequate health maintenance benefits.

Cardiovascular fitness can be evaluated by measurement of heart rate during exercise. As conditioning improves, the heart rate stabilizes at a fixed level. The heart rate at which conditioning will develop is called the target heart rate (48). The formula for calculating the target heart rate is 220 minus the patient’s age times 0.75. For example, a 50-year-old woman would target her heart rate at 119 (220 – 50 = 170 × 0.75 = 119).
Smoking is a major cause of preventable illness, and every opportunity should be taken to encourage patients who smoke to quit. Patient education about the benefits of smoking cessation, clear advice to quit smoking, and physician support improve smoking cessation rates, although 95% of smokers who successfully quit do so on their own. Self-help materials are available from the National Cancer Institute, as well as community-based support groups and local chapters of the American Cancer Society and the American Lung Association. The American Cancer Society concludes that for most people, the best way to quit includes a combination of medication, methods to enhance behavioral changes, and emotional support (57).

The AHRQ Clinical Practice Guideline on Smoking Cessation recommends nicotine replacement therapy for all smokers except pregnant women and people with cardiovascular disease (57). The “5 A’s”—Ask, Advise, Assess, Assist, and Arrange—are designed to be used to be used with smokers who are willing to quit. The Assist component typically includes first-line pharmacotherapy with bupropion or nicotine replacement in the form of gum, inhaler, nasal spray, or patch. In addition, ongoing visits for counseling and support are essential, and may include practical counseling and assistance with problem-solving skills as well as provide social support during and after treatment. Relapse prevention
CHAPTER 8  Preventive Health Care and Screening

Table 8.10 Guidelines for Adolescent Preventive Services

I. Recommendations for Delivery of Health Services

1. From ages 11 to 21 years, all adolescents should have an annual routine health visit.

2. Preventive services should be age and developmentally appropriate, and they should be sensitive to individual and sociocultural differences.

3. Physicians should establish office policies regarding confidential care for adolescents and how parents will be involved in that care. These policies should be made clear to adolescent and the parents.

II. Recommendations for Health Guidance

4. Parents or other adult caregivers should receive health guidance at least once during their child’s early adolescence, once during middle adolescence and, preferably, once during late adolescence.

5. All adolescents should receive health guidance annually to promote a better understanding of their physical growth, psychosocial and psychosexual development, and the importance of becoming actively involved in decisions regarding their health care.

6. All adolescents should receive health guidance annually to promote the reduction of injuries.

7. All adolescents should receive health guidance annually about dietary habits, including the benefits of a healthy diet, and ways to achieve a healthy diet and safe weight management.

8. All adolescents should receive health guidance annually about the benefits of physical activity and should be encouraged to engage in safe physical activity on a regular basis.

9. All adolescents should receive health guidance annually regarding responsible sexual behaviors, including abstinence. Latex condoms to prevent STDs, including HIV infection and appropriate methods of birth control, should be made available, as should instructions on how to use them effectively.

10. All adolescents should receive health guidance annually to promote avoidance of tobacco, alcohol, and other abusable substances, and anabolic steroids.

III. Recommendations for Screening

11. All adolescents should be screened annually for hypertension according to the protocol developed by the National Heart, Lung, and Blood Institute Second Task Force on Blood Pressure Control in Children.

12. Selected adolescents should be screened to determine their risk of developing hyperlipidemia and adult coronary heart disease following the protocol by the Expert Panel on Blood Cholesterol Levels in Children and Adolescents.

13. All adolescents should be screened annually for eating disorders and obesity by determining weight and stature, and asking about body image and dieting patterns.

14. All adolescents should be asked annually about their use of tobacco products, including cigarettes and smokeless tobacco.

15. All adolescents should be asked annually about their use of alcohol and other abusable substances, and about their use of over-the-counter or prescription drugs for nonmedical purposes, including anabolic steroids.

16. All adolescents should be asked annually about involvement in sexual behaviors that may result in unintended pregnancies and STDs, including HIV infection.

17. Sexually active adolescents should be screened for STDs.

18. Adolescents at risk for HIV infection should be offered confidential HIV screening with the ELISA and confirmatory test.

19. Female adolescents who are sexually active or any woman 18 years of age or older should be screened annually for cervical cancer by use of a PAP test.

20. All adolescents should be asked annually about behaviors or emotions that indicate recurrent or severe depression or risk of suicide.

21. All adolescents should be asked annually about a history of emotional, physical, and sexual abuse.

22. All adolescents should be asked annually about learning or school problems.

23. Adolescents should receive a tuberculin skin test if they have been exposed to active tuberculosis, have lived in a homeless shelter, have been incarcerated, have lived in or come from an area with a high prevalence of tuberculosis, or currently work in a health care setting.

(Continued)
SECTION III Preventive and Primary Care

IV. Recommendations for Immunizations

24. All adolescents should receive prophylactic immunizations according to the guidelines established by the federally convened Advisory Committee on Immunization Practices.

Table 8.11 T-ACE Questionnaire

Do you have a drinking problem?

Experts in treating alcohol abuse use the T-ACE questions below to help them find out whether a person has a drinking problem. These questions can also apply to other drugs.

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>T</td>
<td>How many drinks does it take to make you feel high (TOLERANCE)?</td>
</tr>
<tr>
<td>A</td>
<td>Have people ANNOYED you by criticizing your drinking?</td>
</tr>
<tr>
<td>C</td>
<td>Have you ever felt you ought to CUT DOWN on your drinking?</td>
</tr>
<tr>
<td>E</td>

</tr>
</tbody>
</table>

If your answer to the tolerance questions is more than two drinks, give yourself a score of 2. If you answer yes to any of the other questions, give yourself a score of 1 each. If your total score is 2 or more, you may have a drinking problem.

is also important, with congratulations for any successes and encouragement to remain abstinent. Patients who use tobacco but are unwilling to quit at the time of the visit should be treated with the “5 R’s” motivational intervention: Relevance, Risks, Rewards, Roadblocks, and Repetition (57).

References

CHAPTER 8 Preventive Health Care and Screening

• Empiric therapy for women with pneumonia should be based on the specific patient profiles and the severity of their pneumonia. All patients with possible community-acquired pneumonia should have a chest radiograph to establish the diagnosis and the presence of complications.

• Most patients with hypertension will require two or more antihypertensive medications to achieve optimal blood pressure control <140/90 or <130/80 mm Hg for patients with diabetes or kidney disease.

• The newer recommendations by the National Cholesterol Education Program (Adult Treatment Panel III) in 2001 will probably result in an increase use of cholesterol-lowering drugs, including the “statins,” a class of drugs that lower the cholesterol by blocking a liver enzyme necessary to produce cholesterol. These drugs have been very effective in reducing the risk of heart attacks and deaths in recent studies.

• Type 2 diabetes is frequently not diagnosed until complications appear, and approximately one third of all people with diabetes may be undiagnosed. Individuals at risk should be screened and a comprehensive plan of care initiated for those diagnosed with diabetes.

• The sensitive thyroid-stimulating hormone (TSH) assay has become the single best screening test for hyperthyroidism and hypothyroidism. In clinical hypothyroidism, the standard treatment is levothyroxine replacement, which must be tailored to the individual patient.

As health care providers for women, gynecologists have become responsible for providing care that extends beyond diseases of the reproductive organs to include much of the general medical care of their patients. Broadening the spectrum of care requires adjustments in practice, with less emphasis placed on the surgical aspects of the specialty. Early diagnosis and treatment of medical illnesses can have a major impact on a woman’s health. Although timely referral is important for complex and advanced diseases, many conditions can be recognized and treated initially by gynecologists.
Respiratory problems are the most common reasons patients seek care from a physician, so gynecologists should be aware of their pathophysiology. Cardiovascular disease has a significant impact on overall morbidity and is the main cause of death in women. Cardiovascular disease is associated with cigarette smoking, hypertension, hypercholesterolemia, and diabetes mellitus (DM). These conditions are responsive to screening, behavior modification, and control to lower risk factors. Thyroid disease is a major cause of morbidity for women. Because of the interaction of hormones and the overall effect on the endocrine system, thyroid disease can be of special significance in women. The gynecologist should provide screening and initial therapy for these conditions and assess the need for referral.

Respiratory Infections

Infections of the respiratory system can range from the common cold to life-threatening illness. Those with risk factors should be counseled about preventive measures. Vaccines against flu and pneumonia should be offered as indicated.

Sinusitis

A problem frequently encountered in women is self-diagnosed “sinus problems” (1). Many medical problems—headaches, dental pain, postnasal drainage, halitosis, and dyspepsia—may be related to sinus conditions. The sinuses are not an isolated organ, and diseases of the sinuses are often related to conditions that affect other portions of the respiratory system (i.e., the nose, bronchial tree, and lungs) (2). The entire respiratory system can be infected by one particular virus or pathogen (the sinobronchial or sinopulmonary syndrome); however, the most prominent symptoms are usually produced in one anatomic area. Therefore, during the evaluation of symptoms attributable to sinusitis, the presence of other infections should be investigated.

Multiple infectious and chemical agents or reactions to nervous, physical, emotional, or hormonal stimuli may cause an inflammatory response in the respiratory system (3). Systemic diseases such as connective tissue syndromes and malnutrition may contribute to chronic sinusitis. Environmental factors in the workplace and geographic conditions (e.g., cold and damp weather) may aggravate or accelerate the development of sinusitis. Factors contributing to the development of sinus disease include atmospheric pollutants, allergy, tobacco smoke, skeletal deformities, dental conditions, barotrauma from scuba diving or airline travel, and neoplasms.

Most infections begin with a viral agent in the nose or nasopharynx that causes inflammation, blocking the draining ostia. The location of the symptoms varies by anatomic site of infection: maxillary sinus over the cheeks, ethmoid sinus across the nose, frontal sinus in the supraorbital area and sphenoid sinus to the vertex of the head. Viral agents impede the sweeping motion of ciliary function in the sinus and, in combination with edema from inflammation, may lead to superinfection with bacteria. The most common bacterial agents infecting sinuses are Streptococcus pneumoniae and Haemophilus influenzae. Gram-negative organisms are usually limited to compromised hosts in intensive care units. Chronic sinusitis develops from either inadequate drainage or compromised local defense mechanisms. The flora usually are polymicrobial, consisting of aerobic and anaerobic organisms.

Sinus ailments frequently occur in middle-aged individuals. Acute infection is usually located in the maxillary and frontal sinuses. Classically, infection in the maxillary sinus is due to obstruction of the ostia found in the medial wall of the nose. Fever, malaise, a vague headache, and pain in the maxillary teeth are early symptoms. Reports of “fullness” in the
face or exploding pressure behind the eyes often are elicited. Pressure and percussion over
the malar areas can cause severe pain. Purulent exudates in the middle meatus of the nose
or in the nasopharynx are present. 

Five clinical findings are most useful in diagnosis: (i) maxillary toothache, (ii) poor response to nasal decongestants, (iii) abnormal transillumination, (iv) colored visible purulent nasal secretions, and (v) a history of colored nasal discharge. When four or more features are present, the likelihood of sinusitis is high, and when none is present, sinusitis is highly unlikely (4). Initial episodes of sinusitis do not require imaging studies; however, when persistent infections occur, studies and referral are indicated. Computed tomography of the sinuses has demonstrated that 90% of patients with colds have radiological evidence of sinus disease that usually will resolve in 2 to 3 weeks. Radiographic changes do not always reliably identify sinusitis secondary to bacteria. After sinus needle aspiration, only about 60% of patients with abnormal radiographic images have positive cultures (5). Unless culture samples are obtained by direct needle drainage, they are contaminated by oropharyngeal flora and are thus of no value. For this reason, therapy usually is empiric.

Broad antibiotic coverage of common aerobes and anaerobes is necessary but should be limited to patients with acute pain and purulent discharge. For acute, uncomplicated sinus infections, amoxicillin (500 mg three times a day) or trimethoprim/sulfamethoxazole (1 tablet twice a day) remains the treatment of choice. Amoxicillin is inexpensive, penetrates the sinus tissues well, and can be changed to another antibiotic if symptoms haven’t improved in 48 to 72 hours. If beta-lactam resistance is likely, amoxicillin/clavulanic acid (875 mg twice daily) or azithromycin (5-day course once a day) may be used. Other second-line drugs include cefuroxime (250 mg twice daily), ciprofloxacin (500 mg twice daily), clarithromycin (500 mg twice daily), levofloxacin (500 mg once a day), and loracarbef (400 mg twice daily). The usual treatment course is 10 to 14 days, and patients should be informed that relapses might occur if the full course of treatment isn’t completed.

Systemic decongestants containing pseudoephedrine are useful in shrinking the obstructive ostia and promoting sinus drainage and ventilation. Topical decongestants should be used for no longer than 3 days because prolonged use may lead to rebound vasodilation and worsening of symptoms. Mucolytics like guaifenesin may help thin sinus secretions and promote drainage. Antihistamines should be avoided in acute sinusitis because of their drying effects, which can lead to thickened secretions and poor drainage of the sinuses. Therapies to relieve symptoms include facial hot packs and analgesics. Fluticasone, a nasal steroid, may accelerate the recovery of patients with a history of chronic rhinitis or recurrent sinusitis who seek treatment of acute rhinosinusitis (6). Improvement should be apparent within 48 hours of treatment, but 10 days may be necessary for complete resolution of symptoms. When improvement is not rapid, resistance should be presumed, and other classes of antibiotics should be given. In persistent cases, referral to an otolaryngologist for sinus irrigation may be necessary.

Chronic sinusitis may result from repeated infections with inadequate drainage. The interval between infections becomes increasingly shorter until there are no remissions. Presenting symptoms are recurrent pain in the malar area or chronic postnasal drip. In the preantibiotic era, chronic sinusitis was the result of repeated acute sinusitis with incomplete resolution, whereas currently allergy is a more common cause. Injury of surface ciliated epithelium results in impaired removal of mucus. A vicious cycle ensues of incomplete resolution of infection, followed by reinfection, and ending with the emergence of opportunistic organisms. As mentioned previously, allergies have become an important factor in chronic sinusitis. The swelling and edema of the mucosa in conjunction with hypersecretion of mucus leads to ductal obstruction and infection. Chronic sinusitis is associated with chronic cough and laryngitis with intermittent acute infections. Treatment is directed at the underlying etiology: either allergy control or aggressive management of infections. Resistant cases require computed tomography and endoscopic
surgery for polyp removal. Nasoantral window formation is radical surgery that occasionally is necessary.

No clinical criteria can reliably identify those patients who might benefit from treatment with antibiotics. It is reasonable to treat women with presumed bacterial sinusitis if they have high fever, systemic toxicity, immune deficiency, or possible orbital or intracranial involvement (5). Although very rare, untreated sinus infections may have dire consequences, such as orbital cellulitis leading to orbital abscess, subperiosteal abscess formation of the facial bones, cavernous sinus thrombosis, and acute meningitis. Brain and dural abscesses also are rare; when they occur, it usually is the result of direct spread from a sinus. Computed tomography scanning is the most accurate diagnostic tool at present. The use of aggressive surgical approaches with broad-spectrum antibiotics is necessary for adequate drainage.

Otitis Media

Otitis media remains primarily a disease of children, but may affect adults, often secondary to a concurrent viral infection of the upper respiratory tract. Diagnosis in most cases reveals fluid behind the tympanic membrane. Treatment is directed to symptoms and usually involves the use of antihistamines and decongestants despite little data to support their use. Acute otitis media is usually a bacterial infection; *Streptococcus pneumoniae* and *Hemophilus influenza* are the most common pathogens. Symptoms include acute purulent otorrhea, fever, hearing loss, and leukocytosis (7). Physical examination of the ear reveals a red, bulging, or perforated membrane. Indicated treatment is broad-spectrum antibiotics such as amoxicillin/clavulanic acid, cefuroxime axetil and trimethoprim-sulfamethoxazole.

Bronchitis

Acute bronchitis is an inflammatory condition of the tracheobronchial tree. Most often it is viral in origin and occurs in winter. Common cold viruses (rhinovirus and coronavirus), adenovirus, influenza virus, and *Mycoplasma pneumoniae* (a nonviral pathogen) are the most common pathogens involved. Bacterial infections occur less commonly and may be secondary pathogens. Cough, hoarseness, and fever are the usual presenting symptoms. In the initial 3 to 4 days, the symptoms of rhinitis and sore throat are prominent; however, coughing may last as long as 3 weeks. Unfortunately, the prolonged nature of these infections promotes the use of antibiotics to “clear up the infection.” Sputum production commonly occurs and may be prolonged in cigarette smokers. Most serious bacterial infections occur in cigarette smokers, who have damage to the lining of the upper respiratory tree and changes in the host flora.

Physical examination discloses a variety of upper airway sounds, usually coarse rhonchi. Rales are usually not present on auscultation, and signs of consolidation and alveolar involvement are absent. During auscultation of the chest, signs of pneumonia such as fine rales, decreased breath sounds, and euphonia (“E to A changes”) should be sought. If the results of the physical examination are uncertain or the patient’s condition appears toxic, chest radiography should be performed to detect the presence of parenchymal disease. Paradoxically, as the initial acute syndrome subsides, sputum production may become more purulent. Sputum cultures are of limited value because of the polymicrobial nature of infections. In the absence of complications, treatment is directed to relief of symptoms. The use of antibiotics is reserved for patients in whom chest radiography findings are consistent with pneumonia. Cough is usually the most aggravating symptom and may be treated with antitussive preparations containing either dextromethorphan or codeine. The efficacy of any expectorants has never been proved.

Chronic bronchitis is defined as a productive cough from excessive secretions for at least 3 months in a year for 2 consecutive years. Prevalence has been estimated to be
between 10% and 25% of the adult population who are smokers. Previously the incidence has been lower in women than men, but as the prevalence of cigarette smoking in women has increased, so too has the incidence of bronchitis in women. Chronic bronchitis is usually classified as a form of chronic obstructive pulmonary disease (COPD, e.g., “blue bloaters”). Other causes include chronic infections and environmental pathogens found in dust. The cardinal manifestation of disease is an incessant cough, usually in the morning with expectoration of sputum. Because of frequent exacerbations and hospitalizations involved, and the complexity of medical management, these patients should be referred to an internist.

**Pneumonia**

Pneumonia is defined as inflammation of the distal lung that includes terminal airways, alveolar spaces, and the interstitium. Pneumonia may have multiple causes, including viral and bacterial infections or aspiration. Aspiration pneumonia is usually the result of depressed awareness commonly associated with the use of drugs and alcohol or anesthesia. Viral pneumonias are caused by multiple infectious agents, including influenza A or B, parainfluenza virus, or respiratory syncytial virus. Most viral syndromes are spread by aerosolization associated with coughing, sneezing, and even conversation. Incubation is short, requiring only 1 to 3 days before the acute onset of fever, chills, headache, fatigue, and myalgias. Symptom intensity is directly related to intensity of the host febrile reaction. Pneumonia develops in only 1% of patients who have a viral syndrome, but mortality rates may reach 30% in immunocompromised individuals and the elderly. An additional risk is the development of secondary bacterial pneumonias after the initial viral insult. These infections are more common in elderly patients and may explain the high fatality in this group (8). *Staphylococcus* pneumonias, which often arise from a previous viral infection, are extremely lethal regardless of patient age. The best treatment for viral pneumonia is prevention by immunization. Treatment is supportive and consists mostly of administration of antipyretics and fluids.

Bacterial pneumonia is classified as either community acquired or nosocomial, and the classification determines prognosis and antibiotic therapy in many cases. Risk factors that contribute to mortality are chronic cardiopulmonary diseases, alcoholism, diabetes, renal failure, malignancy, and malnutrition. Prognostic features associated with poor outcome include greater than two lobe involvement, respiratory rate greater than 30 breaths/minute on presentation, severe hypoxemia (<60 mm Hg on room air), hypoalbuminemia, and septicemia (9). Pneumonia is a common cause of adult respiratory distress syndrome (ARDS) with a mortality rate between 50% and 70% (10).

Signs and symptoms of pneumonia vary depending on the infecting organism and the patient’s immune status (11). In typical pneumonias, the usual presentation is a toxic-appearing patient with high fever, rigors, productive cough, chills, and/or pleuritic chest pain. Chest radiography often will show infiltrates. The following agents, listed in decreasing order, cause two thirds of all bacterial pneumonias: *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Klebsiella pneumoniae*, gram-negative organisms, and anaerobic bacteria. Atypical pneumonias are more insidious in onset than typical pneumonias. Patients have moderate fever without the characteristic rigors and chills. Additional symptoms include a nonproductive cough, headache, myalgias, and mild leukocytosis. Chest radiography reveals bronchopneumonia with a diffuse interstitial pattern; characteristically, the patient does not appear to be nearly as ill as the x-ray suggests. Common causes of atypical pneumonia include viruses, *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Chlamydia pneumoniae* (also called the TWAR agent), and other rare agents.

A strong index of suspicion is required for diagnosis, especially in elderly and immunocompromised individuals, who have altered response mechanisms. This is even true with “typical agents.” Subtle clues in the elderly include changes in mentation,
confusion, and exacerbation of other illnesses. The febrile response may be entirely absent, and the results of the physical examination are not predictable of pneumonia. Even in high-risk groups, an increased respiratory rate of greater than 25 breaths per minute remains the most reliable sign of infection. Mortality in these high-risk groups of patients is strongly correlated with the ability of the host to mount normal defenses to the symptoms of fever, chills, and tachycardia.

All women suspected of having pneumonia should undergo chest radiography to not only establish the diagnosis but also to detect alternative diagnoses such as congestive heart failure and tumors. In addition, the chest radiograph can detect complications like pleural effusions and multilobar disease. Laboratory studies helpful in identifying community-acquired pneumonia are sputum gram stain, sputum culture, and two sets of blood culture. An “adequate sputum” sample (defined as more than 25 neutrophils with less than 10 epithelial cells per low-powered field on microscopic examination) may be difficult to obtain. Respiratory therapists are an excellent resource for inducing sputum. Hospitalized patients also undergo assessment of blood–gas exchange by either oximetry or arterial blood–gas analysis. Diagnosis of Legionella pneumophila requires a different laboratory technique: measuring urinary antigen levels. Mycoplasma pneumoniae should be suspected when cold agglutinin findings are positive in the presence of the appropriate clinical symptoms.

The American Thoracic Society updated their original 1993 guidelines in 2001 (12,13). These clinical recommendations use an evidence-based approach for the diagnosis and management of community-acquired pneumonia. Therapy should be directed at the responsible or most likely pathogen, but in many cases of pneumonia, the exact cause cannot be determined, and empiric therapy should be initiated. The American Thoracic Society recommends empiric therapy based on four groups of specific patient profiles, the presence of modifying factors (Table 9.1), and pneumonia severity.

- **Group I. Outpatients with no cardiopulmonary disease (congestive heart failure or COPD) and no modifying factors.** These patients are in the lowest-risk group and are usually infected by pathogens such as Chlamydia pneumoniae, Mycoplasma pneumoniae, or Streptococcus pneumoniae. Patients should be treated with an advanced generation macrolide such as azithromycin or clarithromycin or doxycycline.
- **Group II. Outpatients with cardiopulmonary disease and/or modifying factors.** Patients in this group usually have some comorbidities and are older than 50 years of age. Aerobic gram-negative bacilli, mixed infections with atypical pathogens, and drug-resistant S. pneumoniae (DRSP) should be considered in this patient population. Drug recommendations include monotherapy with an antipneumococcal fluoroquinolone, such as gatifloxacin or levofloxacin; a combination of a macrolide (or doxycycline) with a beta-lactam such as cefpodoxime, cefuroxime, or amoxicillin-clavulanate; or parenteral ceftriaxone followed by cefpodoxime.
- **Group III. Inpatients who are not in the intensive care unit and have cardiopulmonary or modifying factors.** Drugs for these patients include intravenous fluoroquinolone monotherapy or a combination of an intravenous beta-lactam agent plus either intravenous or oral administration of an advanced macrolide or doxycycline. For the small group of inpatients who don’t have any cardiopulmonary diseases or modifying factors, intravenous azithromycin alone can be used. Alternatives include doxycycline plus a beta-lactam agent (if macrolide allergy or intolerance is present) or monotherapy with an antipneumococcal fluoroquinolone.
- **Group IV. Inpatients in the intensive care unit.** These patients usually have the most severe pneumonia, and all antibiotics are given intravenously. Immediate consultation with an internist, hospitalist, or infectious disease specialist is recommended.
Oxygen therapy and hydration should be initiated in addition to antibiotic therapy. Most patients will have an adequate clinical response within 3 days of treatment. Oral antibiotics may be given once patients have met the following criteria: ability to eat and drink, improvement in cough and dyspnea, afebrile (≤100°F) on two occasions 8 hours apart, and a decreasing white blood cell count. If other clinical features are favorable, patients may be switched to oral antibiotics even if febrile. They may also be discharged on the same day that oral antibiotics are started if other medical and social factors are favorable.

**Vaccination**

The *pneumococcal vaccine* should be given to people at high risk for pneumonia, which includes adults 65 years or older and people with special health problems, such as heart or lung disease, alcoholism, kidney failure, diabetes, human immunodeficiency virus (HIV) infection, or certain types of cancer. Repeat vaccination is recommended 5 years after the first dose is given. The vaccine is active against 23 types of pneumococcal strains, and most individuals develop protection within 2 to 3 weeks of inoculations.

The *influenza vaccine* should be given every fall to high-risk groups: individuals 50 years of age or older; anyone with serious long-term health problems such as heart disease, lung disease, kidney disease, diabetes, and weak immune systems as with HIV and acquired immunodeficiency syndrome (AIDS); individuals on long-term steroids or receiving cancer treatment; women who are pregnant during the flu season (November through April); and anyone coming in close contact with people at risk of serious influenza like physicians, nurses, and family members. Vaccination is best given from October to mid-November. Antiviral agents should not be used as a substitute for vaccination but may be a useful adjunct. The four agents approved for use in the United States are *amantadine, rimantadine, zanamivir,* and *oseltamivir.* These medicines

should be given within 2 days of the onset of symptoms to shorten the duration of uncomplicated illness caused by influenza (14).

### Cardiovascular Disease

The risk factors for coronary artery disease are presented in Table 9.2. Central to treating cardiovascular disease is the control of contributing diseases and risk factors through lifestyle modifications (Table 9.3). Aerobic exercise protects against cardiovascular disease (15). Additional aspects of prevention of myocardial disease, renal disease, and stroke include control of hypertension, identification and control of diabetes and obesity, and control of dietary fats, especially cholesterol, in susceptible individuals (Fig. 9.1). The presence or absence of target organ damage shown in Table 9.4 also determines the risk of coronary artery disease in hypertensive patients.

### Hypertension

The relationship between hypertension and cardiovascular events such as stroke, coronary artery disease, congestive heart disease, and renal disease is well known. More than 50 million people in the United States have hypertension. It is found in 15% of the population between the ages of 18 and 74 years; the incidence increases with age and varies with race. After age 50, women have a higher incidence of hypertension than men; however, this may be a confounding variable related to the overall mortality of men

at an earlier age (16). More than 60% of those individuals older than age 60 years can be
classified as hypertensive (17). The contribution of hypertension to overall cardiovascular
morbidity and mortality in women has been thought less important than in men, but this
may reflect the relative absence of research in women. Recognition and treatment of
hypertension may decrease the development of renal and cardiac disease.

**Epidemiology**

The incidence of hypertension is twice as high in African Americans than in whites.
Geographic variations also exist: The southeastern United States has a higher prevalence
of hypertension and stroke, regardless of race (18). One multi-institutional study
confirmed that not only is there an increased incidence of hypertension in African
Americans, but also that lower levels of education increase the incidence (19). Preventive
measures can be most effective in those at highest risk, such as in African-American
women and individuals from the lowest socioeconomic level (19). The influence of genetic
deviation is poorly understood. Studies of women have been limited to those that
determine side effects of medication and the impact of certain medications on long-term
lipid status (16).

Classically, hypertension is defined as blood pressure levels higher than 140/90 when measured on two separate occasions. Therapy, however, may be indicated only for individuals at high risk. Individuals at low risk, such as white women with no other risk factors, may benefit from lifestyle modification alone (19). In middle-age and elderly patients, elevation of systolic blood pressure was once considered innocuous; however, recent studies suggest that control of systolic blood pressure is more important than control of diastolic blood pressure (20). Middle-aged to elderly patients treated for systolic hypertension have a significant decrease in cerebral vascular accidents and coronary artery disease (21). Life insurance risk tables indicate that when blood pressure is controlled to lower than 140/90, normal survival occurs over a 10- to 20-year follow-up, regardless of sex. Current recommendations are based on sustained blood pressures higher than 140/90.

More than 95% of individuals with hypertension have primary or essential hypertension (cause unknown), whereas fewer than 5% have secondary hypertension resulting from another disorder. Key factors to be determined in the history and physical examination include presence of prior elevated readings, previous use of antihypertensive agents, a family history of cardiovascular death before age 55, and excessive alcohol and sodium. Lifestyle modification is considered important in the therapy of hypertension; thus, a detailed history of diet and physical activity should be obtained (22). Baseline laboratory evaluations to rule out reversible causes of hypertension (secondary hypertension) are listed in Table 9.5. Diagnosis and management are based on the classification of blood pressure readings presented in Table 9.6.

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) released their seventh report in 2003. The purpose was to

provide an evidence-based approach to the prevention and management of hypertension (23). Following are key points of this report:

- Systolic blood pressure in those older than 50 years is a more important cardiovascular risk factor than diastolic blood pressure.
- Beginning at 115/75 mm Hg, the risk of cardiovascular disease doubles for each increment of 20/10 mm Hg.
- Those who are normotensive at 55 years of age will have a 90% lifetime risk of developing hypertension.
- Patients with prehypertension (systolic blood pressure 120–139 mm Hg or diastolic blood pressure 80–89 mm Hg) require health-promoting lifestyle modifications to prevent the progressive rise in blood pressure and cardiovascular disease.
- For uncomplicated hypertension, thiazide diuretic should be used in most cases for medical treatment, either alone or combined with drugs from other classes.
- Other antihypertensive drug classes (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, beta-blockers, calcium channel blockers) should be used in the presence of specific high-risk conditions (Table 9.7).
- Two or more antihypertensive medications are required to achieve optimal blood pressure levels (<140/90 mm Hg, or <130/80 mm Hg) for patients with diabetes or chronic kidney disease.
- For patients whose blood pressure is more than 20 mm Hg above the systolic blood pressure goal or more than 10 mm Hg above the diastolic blood pressure goal, initiation of therapy using two agents, one of which will be a thiazide diuretic, should be considered.

Regardless of therapy or care, hypertension will be controlled only if patients are motivated to maintain their treatment plan. If blood pressure control is not easily achieved, if the systolic blood pressure is higher than 180 mm Hg, or if the diastolic reading is higher than 110 mm Hg, referral to an internist is recommended. Referral is also indicated if secondary hypertension is suspected or evidence of end-organ damage (renal insufficiency or congestive heart failure) is present.

Measurement of Blood Pressure

An often overlooked but essential variable in evaluation of hypertension is how measurements are obtained and the need to standardize measurements (24). “White coat” or office hypertension may occur in up to 30% of patients. For patients who have repeated normal measures outside of the office, it is reasonable to use ambulatory or home monitoring devices. In most patients, office readings are all that are necessary to adequately diagnose and monitor hypertension and eliminate problems of reliability with commercial devices and patient interpretation skills.

Blood pressure protocols for measurement should be standardized. The patient should be allowed to rest for 5 minutes in a seated position and the right arm used for measurements (for unknown reasons, the right arm has higher readings). The cuff should be applied 20 mm above the bend of the elbow and the arm positioned parallel to the floor. The cuff should be inflated to 30 mm Hg above the disappearance of the brachial pulse, or 220 mm Hg. The cuff should be deflated slowly at a rate no more than 2 mm Hg/second.

The cuff size is important, and most cuffs are marked with “normal limits” for the relative size they can accommodate. The most common clinical problem encountered is small cuffs used with obese patients, resulting in “cuff hypertension.” Phase IV Korotkoff’s sounds are described as the point when pulsations are muffled, whereas phase V is complete disappearance. Most experts in hypertension advocate the use of phase V Korotkoff sounds, but phase IV sounds may be used in special circumstances, with the reason documented.

The use of automated devices may help eliminate discrepancies in measurements. Regardless of the method or device used, two measurements should be obtained with less than a 10 mm Hg disparity to be judged adequate. When repeated measures are performed, there should be a 2-minute rest period between readings. Blood pressure has a diurnal pattern, so determinations preferably should be done at the same time. Ambulatory monitoring is not cost-effective in all patients, but may be used to evaluate resistance to therapy, to assess “white coat” hypertension, and to determine whether syncopal episodes are related to hypotension or episodic hypertension (25).

 Therapy

Nonpharmacologic interventions or lifestyle modifications should be attempted before initiation of medication unless the systolic blood pressure exceeds 139 mm Hg or the diastolic blood pressure exceeds 89 mm Hg. Drug therapy should also be initiated for systolic blood pressure greater than 130 mm Hg or diastolic blood pressure greater than 80 mm Hg in those with diabetes or chronic renal failure. An important element in lifestyle modifications is to modify all contributors to cardiovascular disease. In obese patients, weight loss, especially in individuals with truncal and abdominal obesity, can play a significant role in the prevention of atherosclerosis (26). A loss of just 10 pounds has been reported to lower blood pressure (27). Inquiries into dietary practices should be made to eliminate excess salt in the diet, specifically certain food groups that are high in sodium, such as canned goods, snack food, pork products, and soy sauce. By reducing salt intake to 3 grams a day, British researchers estimated that mortality per year would decrease by 70,000 deaths (28). Cholesterol and fat intake in the diet should be limited. An exercise program, weight loss, and moderating alcohol intake (to no more than 2 drinks per day) contribute to overall cardiovascular health. Aerobic exercise alone may prevent hypertension in 20% to 50% of normotensive individuals (29).

The goal of therapy is for the patient to lower blood pressure into the “normal range”: a systolic reading less than or equal to 120 mm Hg and a diastolic reading less than or equal to 80 mm Hg. If lifestyle modifications are not sufficient to control blood pressure, then pharmacologic intervention is indicated (Fig. 9.2).
Diuretics

The most commonly used medication for initial blood pressure reduction is the **thiazide diuretic**. The mechanism of action is to reduce plasma and extracellular fluid volume. This lowering of volume is thought to decrease peripheral resistance. Cardiac output initially decreases and then normalizes. The important long-term effect is a slight decrease in extracellular fluid volume. The maximum therapeutic dose of thiazides should be lowered to 25 mg, rather than the commonly used 50 mg. The benefit of higher doses is eliminated by the corresponding increase in side effects. Potassium-sparing diuretics (spironolactone, triamterene, or amiloride) are usually available in fixed doses and should be prescribed to prevent the development of hypokalemia. Potassium supplementation is less effective than the use of potassium-sparing agents.

Thiazide diuretics are best used in patients with creatinine levels less than 2.5 g/L. Loop diuretics (furosemide) work better than thiazide diuretics at lower glomerular filtration rates and higher serum creatinine levels. Control of hypertension with concurrent renal insufficiency is difficult and is probably best handled by an internist or nephrologist. Thiazides and loop diuretics should not be used concurrently because profound diuresis may occur and lead to renal impairment. Concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) limits the effectiveness of this class of drugs. Other side effects that further limit the usefulness of thiazide diuretics include hyperuricemia, which may contribute to acute gout attacks, glucose intolerance, and hyperlipidemias (30). The metabolic side effects of these drugs have limited their popularity recently.

Adrenergic Inhibitors

Beta-blockers have been used extensively for years as antihypertensive agents. The mechanism of action is decreasing cardiac output and plasma renin activity with some increase...
in total peripheral resistance. As a class, they are an excellent source of first-line therapy, especially for migraine sufferers. The original formulation, propranolol, was a highly lipid soluble that contributed to bothersome side effects such as depression, sleep disturbances (nightmares in the elderly), and constipation in higher doses. Propranolol has a relative lack of beta selectivity, which promotes other undesirable phenomenon. Formulations such as atenolol are water soluble, are beta₁ selective, and have fewer side effects than propranolol. At higher doses, however, beta₂ effects emerge. There is no evidence to support speculation that beta₁ selective agents may be safe for use in individuals who have asthma. An additional advantage of water-soluble agents is a longer half-life. Reduced dosing schedules improve compliance. Side effects of beta-blockers include an increase in triglyceride levels and a decrease in high-density lipoprotein (HDL) cholesterol and blunting of adrenergic release in response to hypoglycemia. NSAIDs may also decrease the effectiveness of beta-blockers. Contraindications to beta-blockers are asthma, sick sinus syndrome, or bradyarrhythmia. Beta-blockers are often used for the treatment of angina and after myocardial infarctions. However, if these drugs are acutely withdrawn, a rebound phenomenon of ischemia may occur leading to acute myocardial infarction. Despite these potential problems, beta-blockers continue to be useful in counteracting reflex tachycardia, which often occurs with the use of smooth muscle relaxing drugs.

Use of alpha₁-adrenergic drugs became popular in men because of their minimal effects on potency and unique relationship to lipids. Interestingly, they may contribute to stress urinary incontinence in women because of altered urethral tone (31). As single agents, they decrease total cholesterol and low-density lipoprotein (LDL) cholesterol while increasing HDL cholesterol, in contrast to the metabolic effects of beta-blocking agents. Their mode of action is to promote vascular relaxation by blocking postganglionic norepinephrine vasoconstriction in the peripheral vascular smooth muscle. Prazosin and doxazosin are two preparations available in this class. A serious side effect of these drugs, which is most commonly described in the elderly patients, is called the “first-dose effect.” In susceptible individuals, severe orthostasis has been reported when therapy was initiated and subsided after several days. When alpha₁-adrenergic drugs are used in combination with diuretics, hypotension may be further exacerbated. Therapy should begin with small doses taken at bedtime followed by incremental increases. Other side effects that may limit the usefulness of these agents in some patients include tachycardia, weakness, dizziness, and mild fluid retention.

Angiotensin-Converting Enzyme Inhibitors

The angiotensin-converting enzyme (ACE) inhibitors have rapidly become first-line drugs in the treatment of hypertension. Their rapid rise in popularity is due to the introduction of new formulations, which allow dosing once or twice a day with a good therapeutic response. There are relatively few side effects; chronic cough is the most worrisome and is a common reason of discontinuing the use of this group of drugs. Other side effects are occasional first-dose hypotension and blood dyscrasias. Occasionally, patients will suffer from rashes, loss of taste, fatigue, or headaches. Other agents should be considered for patients at risk for pregnancy (a strict contraindication). ACE inhibitors can be used in combination with other agents, including diuretics, calcium channel antagonists, and beta-blocking agents. In contrast to beta-blocking agents, these medications can be used in patients with asthma, depression, and peripheral vascular disease. For unknown reasons, they are less effective in African Americans unless a diuretic is used concomitantly. Use with diuretics increases the effectiveness of both drugs, but hypovolemia may result. If renal failure is present, hyperkalemia may result from potassium supplementation and altered tubular metabolism. Any NSAID, including aspirin, may decrease the antihypertensive effectiveness. Use of NSAIDs, volume depletion, and renal artery stenosis may precipitate acute renal failure when administration an ACE inhibitor is initiated. Therefore, creatinine levels should be measured at the start of therapy and 1 week after initiation of
any ACE inhibitor. An increase of up to 35% of the baseline creatinine value is acceptable, and treatment should be continued unless hyperkalemia develops.

**Angiotensin-receptor Blockers**

The angiotensin-receptor blockers such as **losartan** and **valsartan** interfere with the binding of angiotensin II to AT1 receptors. As with ACE inhibitors, they are effective in lowering blood pressure without causing the side effect of coughing. Angiotensin-receptor blockers also have favorable effects on the progression of kidney disease in individuals who have diabetes, as well as on those without diabetes and heart failure.

**Calcium-channel Blockers**

Calcium-channel blockers represent a major therapeutic breakthrough for patients with coronary artery disease. They have been found to be effective in patients with hypertension and peripheral vascular disease. The mechanism of action is to block calcium movement across smooth muscle, therefore promoting vessel wall relaxation. Calcium channel blockers are useful in treating concurrent hypertension and ischemic heart disease as an alternative to beta-blockers, if needed. Additionally, these drugs have been shown to be particularly effective in the elderly and African Americans. Side effects noted include headache, dizziness, constipation, gastroesophageal reflux, and peripheral edema. The addition of long-acting calcium-channel blockers has made these preparations more amenable for use in hypertension. A relative contraindication for use of these drugs is the presence of heart failure or conduction disturbances.

**Direct Vasodilators**

**Hydralazine** is a potent vasodilator used for years in obstetrics for severe hypertension associated with preeclampsia/eclampsia. The mechanism of action is direct relaxation of vascular smooth muscle, primarily arterial. Major side effects include headaches, tachycardia, and fluid (sodium) retention that may result in paradoxical hypertension. Several combinations have been used to counter the side effects and enhance antihypertensive effects. Diuretics may be added to reverse fluid retention caused by excess sodium. When used in combination with beta-blockers, tachycardia and headaches may be controlled without compromising the objective of lowering blood pressure. Drug-induced lupus has been widely stated as a potential side effect but is rare with normal therapeutic doses of 25 to 50 mg three times daily. **Minoxidil** is another extremely potent drug in this class, but is of limited use to the gynecologist because of its side effects in women (beard growth). Because of minoxidil’s potency, only experienced practitioners should use it.

**Central-acting Agents**

Central-acting agents (methyllopa and clonidine) have long been used in obstetrics. The mechanism of action is to inhibit the sympathetics in the central nervous system, resulting in peripheral vascular relaxation. Side effects, including taste disorders, dry mouth, drowsiness, and the need for frequent dosing (except for the transdermal form of **clonidine**), have limited the popularity of this group of drugs. **Sudden withdrawal of clonidine may precipitate a hypertensive crisis and induce angina.** The **clonidine** withdrawal syndrome is more likely to occur with concomitant use of beta-blockers. Compliance is always a major issue, and side-effect profiles contribute significantly to patient nonadherence. With the introduction of new classes of drugs with improved efficacy and reduced side effects, use of medications in this class is expected to decline.

**Monitoring Therapy**

Blood pressure readings should be monitored frequently by a nurse, the patient, or in the office at 1- to 2-week intervals. If the patient has other diseases (i.e., cardiovascular,
renal), therapy should be initiated earlier and directed to the target organ. If lifestyle modification alone is successful, close monitoring is necessary at 3- to 6-month intervals. When lifestyle modification is unsuccessful, a blood pressure medication should be started to decrease target organ disease.

When beginning therapy, concurrent medical conditions treatable with a common agent should be sought. Sex is not an important consideration in choosing an antihypertensive agent. **Concurrent diseases or race are important for patients who:**

- Have migraine headaches, for which beta-blockers or calcium channel agonists may be the best choice
- Are African American and are likely to respond better to a combination of diuretics and calcium channel blockers
- Have diabetes, chronic kidney disease, and heart failure, for which ACE inhibitors should be used
- Have had myocardial infarctions and should receive beta-blockers because they reduce the risk for sudden death and recurrent myocardial infarctions.

A summary of the compelling indications for individual drug classes is listed in Table 9.7.

Once antihypertensive medications are initiated, monitoring should be instituted at approximately monthly intervals to determine blood pressures and to assess side effects. Patients with stage 2 hypertension or with complicated comorbid illnesses may need more frequent monitoring. The serum creatinine and potassium levels should be monitored 1 to 2 times per year. When blood pressure goals are reached, patients may be seen in the office at 3- to 6-month intervals. Selected agents and dosages for therapy are listed in Table 9.8 and are not meant to be all inclusive. Patients capable of home blood pressure monitoring should be encouraged to measure blood pressure at the same time twice weekly (32). A log should be maintained for physician review of effectiveness of therapy.

If intolerable side effects develop, a different class of medications should be used and the patient’s progress monitored. Patients whose blood pressure is difficult to control with two agents should be considered for referral. Causes of resistance to therapy include diseases missed during the initial evaluation, unrecognized early end-stage disease, and poor compliance. Patients with evidence of target organ disease should also be considered for referral to the appropriate specialist for more intensive diagnostic workup and therapy.

**Cholesterol**

The observation “cholesterol is the most highly decorated small molecule in biology” is testimony to the complexity of its role in cardiovascular disease (33). The dietary influence of cholesterol on atherosclerosis and its relationship to hypertension and cardiovascular events (myocardial infarction and stroke) has been widely debated in both the scientific and lay communities (34). The controversy centers on the effect of dietary cholesterol in assessing risk and prevention of cardiovascular disease (35). Many assume that all cholesterol and fat in the diet have negative health consequences. Furthermore, cholesterol metabolism is complex, and our understanding in some cases is extrapolated from animal models. The role of cholesterol testing (who, when, and at what age) is hotly debated among health care professionals, and the test itself is fraught with multiple variables that affect results. Understanding the metabolism of cholesterol will help identify and treat patients at risk of complications from hypercholesterolemia.

**Terms and Definitions**

Cholesterol is usually found in an esterized form with various proteins and glycerides that characterize the stage of metabolism. The following components are important lipid particles in cholesterol metabolism.

(Continued)
**Chylomicrons**  This large lipoprotein particle consists of dietary triglycerides and cholesterol. Chylomicrons are secreted in the intestinal lumen, absorbed in the lymph, and then passed into general circulation. In adipose tissue and skeletal muscle, they adhere to binding sites on the capillary wall and are metabolized for energy production.

**Lipoprotein Particle**  A lipoprotein particle is made from three major components. The core consists of nonpolar lipids (triglycerides and cholesterol esters), which are present in varying amounts depending on the stage of the metabolic pathway in which they are found. Surrounding the nonpolar core is a surface coat of phospholipids, which are made of apoproteins and structural proteins.

**Apolipoprotein**  Attached to all lipoprotein particles is an apolipoprotein. This is a specific recognition protein exposed at the surface of a lipoprotein particle. Apolipoproteins have specific receptors and demarcate the stage of cholesterol metabolism. Certain apolipoproteins are associated with specific types of cholesterol. For example, apolipoprotein A-I and apolipoprotein A-II are associated with HDL cholesterol, the so-called scavenger cholesterol. Apolipoprotein CII has additional activity as a cofactor for lipoprotein lipase.

**Lipoprotein Classes**  Lipoprotein particles are separated into five classes based on physical characteristics. Lipoprotein classes are determined by the separation of lipids in an electrophoretic field; however, *in vivo* they are in a continuum. The various cholesterol metabolites are separated by density. As lipoprotein particles are metabolized and lipids are removed for energy production, they become more dense. Additionally, attached apoproteins are modified as cholesterol moves from the so-called exogenous pathway (dietary) to the endogenous pathway (postabsorption and metabolized by the liver).

Following are the subdivisions of the lipoprotein classes (Fig. 9.3).

**Prehepatic Metabolites**

Chylomicrons and remnants are composed of major lipids and apoproteins of the A, B-48, C, and E classes. Their density is 1.006 g/mL. As expected, these are large particles made up of dietary cholesterol molecules that are absorbed with triglycerides.

**Posthepatic Metabolites**

Very low-density lipoproteins (VLDL) are transient remnants found after initial liver metabolism and compose only 10% to 15% of cholesterol particles. They consist of
endogenously synthesized triglycerides with a density of 1.006 g/mL. The diameter is considerably smaller than the chylomicrons, ranging from 300 to 800 nm.

Intermediate density lipoproteins (IDL) consist of cholesterol esters, which are posthepatic remnants derived from dietary sources. Associated apoproteins are B-100, CIII, and E. Apoprotein B-48 is lost after the initial hepatic metabolism, and B-100 is substituted. Apoprotein E, which is a liver recognition apoprotein, is found only in VLDL and IDL. Metabolites of IDL are transient lipoproteins measured only in certain pathologic conditions. The density is 1.019 g/mL with a diameter of 250 nm—a significant drop in diameter from 800 nm found in the VLDL.

Low-density lipoprotein (LDL) is mainly composed of the cholesterol ester and is associated with B-100 apoprotein. LDL cholesterol is approximately 60% to 70% of total cholesterol. Elevated levels of LDL cholesterol have been associated with increased myocardial infarction in women older than 65 years of age. There is structural class called LDL (a’) that is associated with myocardial infarction. A family history of structurally abnormal B-100 apoprotein indicates a high risk for myocardial infarction resulting from lipid buildup and premature atherosclerosis (36). Density ranges from 1.019 to 1.063, with a diameter of 180 to 280 nm.

High-density lipoprotein (HDL) is composed of cholesterol esters with apoproteins A-I and A-II. These particles are 20% to 30% of total cholesterol and are the most dense with a weight of 1.063 to 1.120 g/mL. The diameter of this group of proteins is 50 to 120 nm.
Cholesterol metabolism is divided into two pathways: (i) the exogenous pathway derived from dietary sources, and (ii) the endogenous pathway or the lipid transport pathway. Individuals vary in their ability to metabolize cholesterol, with patients classified as normals, hyporesponders, and hyperresponders (37). Hyporesponders may be given cholesterol-loaded diets with no effect on serum cholesterol measurements. Hyperresponders, in contrast, have high serum cholesterol levels, regardless of dietary intake. Explanations for these differences are well described in animal models, but not in humans.

Once a meal is eaten, cholesterol is transported as dietary fat. The average daily American diet contains approximately 100 g of triglyceride and approximately 1 g of cholesterol daily. Dietary fats are saponified in the intestinal lumen by pancreatic lipases and synthesized into chylomicrons, which are first absorbed by active transport into intestinal lymph and then into the general circulation. Capillaries in the adipose tissue and skeletal muscle are able to incorporate triglycerides and fats by the action of lipoprotein lipase, as depicted in Figure 9.3. Metabolic utilization may occur during either phase of metabolism dietary or endogenous. During absorption and synthesis of chylomicrons, apoproteins are incorporated. Apoprotein C-II is important as a cofactor to activate lipoprotein lipase, which enzymatically liberates fatty acids (for energy) and monoglycerides. These fatty acids may enter endothelial, adipose, or muscle cells, where they are either oxidized into active metabolic products or re-esterified to triglycerides.

Triglycerides are found in the core lipoprotein particles and are removed through the capillary endothelium and the chylomicron. Predominant apoproteins are B-48 or B-100 and E apoproteins. When chylomicron synthesis occurs in the intestine, the primary B apoprotein is B-48; upon leaving adipose cells, muscle cells, or the liver, the second B apoprotein or B-100 is substituted. Abnormal forms of B-100 are associated with premature cardiovascular disease and are currently used as genetic markers in research laboratories (38). Another apoprotein added during cellular metabolism is apoprotein E. Apoprotein E is important in liver recognition of chylomicron remnants. Theories suggest that hyporesponders to dietary cholesterol may occur secondary to the liver’s ability to recognize and metabolize apoprotein E (39). In the animal model, populations with large numbers of liver receptors for apoprotein E easily metabolize cholesterol and are labeled hyporesponders. Individuals with a reduced number of apoprotein E receptors are unable to metabolize cholesterol as readily, which increases the number of lipid particles. These individuals are considered hyperresponders. Despite dietary cholesterol modification, these individuals continue to have high serum cholesterol levels.

After metabolic degradation of dietary chylomicrons, apoprotein substitution occurs and liver metabolism of cholesterol esters begins. Lipid transport is now in the endogenous pathway. Carbohydrates are synthesized to fatty acids and esterified with glycerol to form triglycerides. These newly formed triglycerides are not of dietary origin and are placed in the core of VLDL. These particles are relatively large and carry five to ten times more triglyceride than cholesterol esters with apoprotein B-100. Hypertriglyceridemia is an independent risk factor for cardiovascular disease (40). The relationship between hypertriglyceridemia and cardiovascular disease is well known but poorly defined.

VLDL particles are transported to tissue capillaries, where they are broken down to usable fuels, monoglycerides, and fatty acids. Apoproteins C and E are still present within this lipoprotein particle. After metabolic enzymatic degradation in the peripheral tissues, IDL remains and is either catabolized in the liver by binding to LDL receptors or modified in the peripheral tissues. As noted previously, they are associated with apoprotein E receptors, the liver recognition receptors. During the transformation from IDL to LDL cholesterol, all apoproteins are removed, except apoprotein B-100. The LDL cholesterol, or the so-called high-risk cholesterol, is found in high circulating levels.
Despite the negative connotation of LDL in cardiovascular disease, it is a very important cellular metabolite and precursor for adrenocortical cells, lymphocytes, and renal cells. LDL receptors on cell surfaces allow for incorporation of LDL into cellular metabolism. In target cells, these lipid particles are hydrolyzed to form cholesterol for use in membrane synthesis and as precursors for steroid hormones (such as estrogen and progesterone). Once the cell has incorporated the necessary cholesterol, the cell surface receptor reforms, limiting further absorption. The liver uses LDL for synthesis of bile acids and free cholesterol, which is secreted into the bile. In the normal human, 70% to 80% of LDL is removed from the plasma each day and secreted in the bile by utilization of the LDL receptor pathway.

The final metabolic pathway is the transformation of HDL cholesterol in extrahepatic tissue. HDL cholesterol carries the plasma enzyme lecithin cholesterol acyltransferase (LCAT). LCAT allows HDL cholesterol to resynthesize lipids to VLDL cholesterol and recycle the lipid cascade. The fate of newly synthesized VLDL cholesterol is the same as absorbed VLDL, and it eventually becomes LDL cholesterol. HDL cholesterol acts as a “scavenger” and therefore reverses the deposit of cholesterol into tissues. There is good evidence that HDL cholesterol is responsible for the reversal of atherosclerotic changes in vessels, hence the term good cholesterol.

Hyperlipoproteinemia

When cholesterol is measured, various fractions are reported. Plasma cholesterol or total cholesterol consists of cholesterol and unesterified cholesterol fractions. If triglycerides are analyzed in conjunction with cholesterol, then assumptions can be made concerning which metabolic pathway may be abnormal. Elevation of both total cholesterol and triglycerides signifies a problem with chylomicrons and VLDL synthesis. If the triglyceride-to-cholesterol ratio is greater than 5:1, the predominant fractions are chylomicrons and VLDL. A triglycerides-to-cholesterol ratio less than 5:1 signifies a problem in the VLDL and LDL fractions.

Hyperlipoproteinemias are defined by establishing a “normal population” and then setting various limits at the 10th and 90th percentiles. Recent standards for women set the 80th percentile for cholesterol at 240 mg/dL and the 50th percentile at 200 mg/dL. Researchers continue to debate different cutoff limits depending on the amount of fat versus vegetable and fiber consumption within the diet of specific populations.

Plasma elevations of chylomicrons, LDL, VLDL, various remnants of IDL, and VLDL are classified by the elevated fraction. This adds to the confusion of an already complex topic. Unfortunately, this classification of hyperlipoproteinemias is the basis of studying of disease states.

Evaluation

The consensus of most researchers is that office laboratory analysis of total cholesterol is virtually worthless as an accurate measure of cholesterol levels. The measurement techniques and standardization of machines are difficult to maintain, and there is a wide variation in readings. Therefore, despite their popularity, these techniques are totally inadequate for either screening or monitoring the treatment of patients with hypercholesterolemia.

There are multiple environmental causes of variation in cholesterol measurements. Major sources of variation within individuals include diet, obesity, smoking, ethanol intake, and the effects of exercise. Other clinical conditions that affect cholesterol measurements include hypothyroidism, diabetes, acute or recent myocardial infarction, and recent weight changes. Measurements also can be altered by fasting, position of the patient.
while the sample is drawn, the use and duration of venous occlusion, various anticoagu-
lants, and the storage and shipping conditions (46).

Factors Affecting Test Results

Intrapersonal variation has been well described. If a single individual has total cholesterol
measured four times during the day, the variation is 2.5%. If retested within 1 month, on a
twice-weekly basis, the coefficient of variation increases to 4.8%. Monthly measurements
over 1 year may result in a variation as high as 6.1%. Therefore, at least two and prefer-
ably four specimens should be taken 1 month apart should be collected in the same
dietary state in order for a lipid value to be considered accurate.

Age and sex contribute to variations in total cholesterol measurements. Before age 50,
women have lower lipid values than men, after which age the level in women is higher
than in men. This finding may be modified by exogenous oral conjugated estrogens.
The genetic basis for interpersonal variability is thought to be a mediated by apolipopro-
tein receptors.

Seasonal variation also occurs. In December or January, lipid samples have been found to
be approximately 2.5% higher than those measured in June or July. LDL and total choles-
terol levels were higher, whereas there was no significant variation found for HDL. The

LDL, low-density lipoprotein; HDL, high density lipoprotein.
Adapted from the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on
the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. JAMA
index population was found to weigh approximately 6% more in December and January than in June or July, which may account for the differences.

**The effect of diet and obesity has been well established.** Some researchers felt this effect may be related to hypo- and hyperresponder status. However, weight reduction in an obese individual generally affects the triglyceride level, which may decrease as much as 40%. Total cholesterol and LDL decrease less than 10% with diet; however, HDL increases approximately 10%. Weight gain negates any benefit from prior weight loss. Therefore, accuracy of lipid measurements depends on the stability of the patient’s weight.

Alcohol and cigarette smoking are well-known modifiers of cholesterol. Moderate sustained alcohol intake increases HDL and decreases LDL; however, there is a complimentary increase in triglycerides. Alcohol has a protective effect when taken in moderation (defined as approximately 2 ounces of absolute alcohol/day), but this effect is negated in higher quantities. The increase in HDL is in the HDL₃ fraction, which is important in the scavenger mechanism of removing LDL. Smoking has the opposite effect, increasing LDL and triglyceride levels and decreasing HDL. HDL₃ decreases with cigarette smoking. The critical number of cigarettes smoked is 15 to 20 per day, regardless of sex, and a variation in the number smoked will affect results. Caffeine has a mixed effect on lipoprotein measurements but should be avoided in the 12 hours before blood collection.

**Exercise is an important variable in the overall risk management of heart disease.** Moderate levels of exercise are as important in overall cardiovascular health as control of hypertension and cessation of cigarette smoking. Strenuous exercise lowers the concentrations of triglycerides and LDL and increases HDL in the serum. Because of these acute blood changes, vigorous exercise should be avoided within 12 hours of drawing of the blood for testing.

**Certain disease states and medications affect cholesterol measurements.** Use of diuretics and propranolol increases triglycerides and decreases HDL. Diuretics may also increase total cholesterol levels. Diabetes, especially in the presence of poor control, may be associated with very high levels of triglycerides and LDL and decreased levels of HDL. This may explain why these individuals are prone to cardiovascular diseases. Patients with diabetes under tight control generally have improved lipoprotein profiles.

**Pregnancy is associated with decreased total cholesterol in the first trimester and continuous increases of all fractions over the second and third trimesters** (47). The LDL and triglyceride concentrations are the lipoproteins most affected by pregnancy. Limited studies have been done on standardization of lipid levels in pregnancy. Because of the short span, interventions are of little clinical significance.

**Patients with hypothyroidism also have increased levels of total cholesterol and LDL.**

**Testing**

Because the diurnal variation of blood triglycerides, blood samples should be collected in the morning after a 12-hour fast. Excessive quantities of water should not be consumed before blood is drawn. The patient should be sitting quietly for approximately 15 minutes before blood drawing. Patients who were placed in the supine position for 30 minutes and then required to stand for 30 minutes had a 9% increase in total cholesterol, LDL, and VLDL fractions, while HDL increased by 10% and triglycerides increased by 12%. Additionally, if the tourniquet is in place more than 5 minutes, causing vascular stasis, all measurements increase by 10% to 15%. After even 2 minutes of venous occlusion, serum cholesterol levels can increase 2% to 5%. Therefore, the sample used for cholesterol testing should be collected first if multiple blood samples are required. Finger
sticks are approximately 8.5% lower for all component measurements than venous blood as a result of contamination from interstitial and lymph fluids.

**Collection tube anticoagulants may have a profound effect on lipoproteins.** The total cholesterol has been observed to change depending on the anticoagulant used: EDTA increases measurements by 3%, oxalate increases by 9%, citrate increases by 14%, and fluoride by 18%. EDTA is considered the standard anticoagulant for cholesterol measurement. If cholesterol measurements cannot be analyzed within a reasonable time, the samples may be stored at 0ºC for up to 4 days, at −20ºC for 6 months, or at −50º to −80º indefinitely. Specimens transported by mail should be placed on dry ice.

One of the most important aspects of overall standardization of lipoprotein measurements is the laboratory used. Currently, laboratory levels should be within ±5% of the Centers for Disease Control and Prevention standards for lipoprotein measurements. Approximately 80% of labs in one study met these criteria (48). Therefore, to accurately assess cholesterol values, the clinician should be knowledgeable about the laboratory used. It may be worthwhile to consult a clinical pathologist to determine if the laboratory complies with CDC standards for cholesterol and lipoprotein measurements.

**Management**

Once hyperlipidemia is confirmed on at least two separate occasions, secondary causes should be diagnosed or excluded by taking a detailed medical and drug history, measuring serum creatinine and fasting glucose levels, and testing thyroid and liver function. Causes of secondary dyslipidemia include diabetes, hypothyroidism, obstructive liver disease, chronic renal failure, and use of medications such as progestins, anabolic steroids, and corticosteroids. **Therapeutic lifestyle changes should be initiated in all patients to reduce their risk of coronary heart disease:**

1. Reduced intakes of saturated fats (<7% of total calories) and cholesterol (<200 mg/d)
2. Therapeutic options for enhancing LDL lowering, such as plant stanols/sterols (2 g/d) and increased viscous (soluble) fiber (10–25 g/d)
3. Weight reduction
4. Increased physical activity

Figure 9.4 is a suggested algorithm for cholesterol control based on LDL levels. Cholesterol fat-lowering diet books abound in most bookstores and allow the patient to choose a diet she will best follow. **The role of exercise and cigarette cessation should be stressed to all patients. Patients with a family history of cardiovascular disease (history of premature coronary artery problems and strokes) should be tested and started on conservative programs in their 20s.** After 3 to 6 months, if the LDL remains above 160 mg/dL with zero to one risk factor or above 130 mg/dL with two or more risk factors, then medical therapy should be initiated. Any woman with coronary heart disease or equivalents such as diabetes or other forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease) should initiate lifestyle changes if her LDL is ≥100 mg/dL and drug therapy if her LDL is ≥130 mg/dL. Anyone with an LDL ≥190 mg/dL should be considered for drug therapy (49).

The bile acid-binding resins cholestyramine and colestipol were long the mainstay of therapy. Their usefulness is limited by side effects such as constipation, bloating, nausea, and heartburn, as well as by their tendency to interfere with the absorption of other drugs. **Nicotinic acid 500 mg three times daily decreases triglycerides, LDL, and**
lipoprotein(a) and increases HDL more than any other drug. However, flushing, pruritus, gastrointestinal distress, and, rarely, hepatotoxicity are a few of the adverse effects of nicotinic acid. Starting at a low dose and pretreating with aspirin 325 mg or ibuprofen 200 mg can minimize the facial flushing. Fibric acid derivatives like clofibrate and gemfibrozil are used mainly to lower triglycerides and increase HDL but may increase LDL in some patients. The HMG-CoA reductase inhibitors (statins) include atorvastatin, fluvastatin, lovastatin, pravastatin, and simvastatin. These medicines inhibit HMG-CoA (3-hydroxy-3methyl-glutaryl-coenzyme A) reductase, the enzyme that catalyzes the rate-limiting step in cholesterol synthesis. Several clinical trials have shown that pravastatin, simvastatin, and lovastatin have a beneficial effect in cardiovascular disease. Statins are generally better tolerated than other lipid-lowering drugs, but reported effects include severe myalgias, muscle weakness with increases in creatine phosphokinase, and, rarely, rhabdomyolysis leading to renal failure. Symptomatic hepatitis is rare, but serum glutamic oxaloacetic transaminases should be measured at baseline, at 6 and 12 weeks after initiation of therapy, and semiannually once therapeutic levels are reached. Atorvastatin, lovastatin, and simvastatin are metabolized by the CYP3A4 enzyme system (50). Medications that inhibit this enzyme include the azoles antifungals, erythromycin, clarithromycin (Biaxin), verapamil (Calan), diltiazem (Cardizem), nefazodone (Serzone), fluvoxamine (Luvox), and cyclosporine. Grapefruit juice can also inhibit the action of CYP3A4. When these medications are used with the aforementioned statins, their levels can be increased, which increases the risk of myopathy and rhabdomyolysis. All the statins except pravastatin can increase the effect of warfarin and lead to an increase in the coagulation time as reflected by an increase in international normalized ratio (INR). Thus,

![Figure 9.4 Treatment decisions based on the LDL cholesterol.](image_url)
patients taking these drugs in combination should be closely monitored. The commonly used statins are listed in Table 9.10.

## Diabetes Mellitus

Diabetes mellitus is a chronic disorder of altered carbohydrate, protein, and fat metabolism resulting from a deficiency in the secretion or function of insulin. The disease is defined by the presence of either fasting hyperglycemia or elevated plasma glucose levels based on an oral glucose tolerance testing (OGTT). The major complications of DM are primarily vascular and metabolic. The prevalence of DM is higher in women and certain ethnic groups, although a background rate in the general population is 2.5% (51). **Risk factors for DM are:**

1. Age greater than 45 years
2. Adiposity or obesity
3. A family history of diabetes
4. Race/ethnicity
5. Hypertension (140/90 or greater)
6. HDL cholesterol less than or equal to 35 mg/dL and/or a triglyceride level greater than or equal to 250 mg/dL
7. History of gestational diabetes or delivery of baby more than 9 pounds

Major complications of DM include blindness, renal disease, gangrene of an extremity, heart disease, and stroke. Diabetes is one of the four major risk factors for cardiovascular disease (52).

### Classification

In January 1999, the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus published a report revising the system that had been in use since 1979 (53,54). The goal of the revision is to provide guidelines for nomenclature and testing that may reduce diagnostic confusion and improve patient well-being (Table 9.11). The terms
Insulin dependent diabetes mellitus (IDDM) and noninsulin dependent diabetes mellitus (NIDDM) should no longer be used and have been replaced by the terms type 1 and type 2 diabetes mellitus.

**Type 1 Diabetes Mellitus**

With type 1 diabetes, the major metabolic disturbance is the absence of insulin from destruction of beta cells in the pancreas. Insulin is necessary for glucose metabolism and cellular respiration. When insulin is absent, ketosis results. The cause of type 1 diabetes is unknown; however, data suggest an autoimmune association from either a viral infection or toxic components in the environment. Studies in the past decade have shown a correlation between many autoimmune diseases and the human leukocyte antigens (HLA).

Insulin-sensitive tissues (muscle, liver, and fat) fail to metabolize glucose efficiently in the absence of insulin. In uncontrolled type 1 diabetes, an excess of counterregulatory hormones (cortisol, catecholamines, and glucagon) contributes to further metabolic dysfunction. In the absence of adequate amounts of insulin, increasing breakdown products of muscle (amino acid proteolysis), fat (fatty acid lipolysis), and glycogen (glucose glycogenolysis) are recognized. Additionally, there is an increase in glucose production from noncarbohydrate precursors as a result of gluconeogenesis and ketogenesis in the liver. If not promptly treated, severe metabolic decompensation (i.e., diabetic ketoacidosis) will occur and may lead to death.

**Type 2 Diabetes Mellitus**

Type 2 diabetes mellitus is a heterogeneous form of diabetes that commonly occurs in older age groups (>40 years) and is more frequently noted to have a familial tendency than type 1 diabetes. This form of diabetes mellitus accounts for approximately 90% to 95% of those with diabetes. The presence of risk factors strongly influences the development of type 2 diabetes in susceptible populations.
Risk factors for type 2 diabetes include ethnicity, obesity, family history of DM, sedentary lifestyle, impaired glucose tolerance, upper-body adiposity, and a history of gestational diabetes and hyperinsulinemia.

In contrast to an absence of insulin that occurs with type 1 diabetes, in type 2 diabetes altered metabolism of insulin results in insulin resistance. This condition is characterized by impaired glucose uptake in target tissues. A compensatory increase in insulin secretion results, causing higher-than-normal circulating insulin levels (55). Obesity is present in 85% of affected patients. The cause of type 2 diabetes is unknown, but defects in both the secretion and action of insulin are suspected.

Many patients diagnosed with type 2 diabetes at an early age eventually exhaust endogenous pancreatic insulin and require injected insulin. When under severe stress, such as infection or surgery, they may develop diabetic ketoacidosis or a hyperglycemic hyperosmolar nonketotic state.

**Diagnosis**

Three methods are available to diagnose diabetes mellitus in nonpregnant women:

1. A single fasting blood glucose greater than or equal to 126 mg/dL on two separate occasions
2. A random blood glucose equal to or above 200 mg/dL in an individual with classic signs and symptoms of diabetes (polydipsia, polyuria, polyphagia, and weight loss)
3. A 2-hour OGTT greater than or equal to 200 mg/dL (fasting sample, 60-, and 120-minute samples) after a 75-g load of glucose. A 2-hour OGTT should not be performed if the first two criteria are present.

Diagnostic criterion for impaired glucose intolerance (IGT) is a fasting glucose greater than or equal to 100 mg/dL but less than 126 mg/dL (54).

A 2-hour OGTT should be performed under the following conditions:

1. A 10-hour fast should precede morning testing.
2. The patient should sit throughout the procedure.
3. No smoking is permitted during the test interval.
4. Caffeinated beverages should not be consumed.
5. More than 150 g of carbohydrates should be ingested for 3 days before the test.
6. No drugs should be taken before the test.
7. The patient should not be bedridden or under stress.

Patients who should be considered for diabetes testing are:

- All individuals 45 years of age or older (repeat at 3-year intervals)
- Persons with classic signs and symptoms of diabetes (i.e., polyuria, polydipsia, polyphagia, and weight loss)
- Ethnic groups at high risk (Pacific Islanders, Native Americans, African Americans, Hispanic Americans, and Asian Americans)
- Obesity (body mass index $\geq 27$ kg/m$^2$)
• History of a first-degree relative with diabetes
• Women with gestational diabetes or have delivered a baby more than 9 pounds
• Individuals with hypertension (\(>140/90\))
• An HDL cholesterol level less than or equal to 35 mg/dL or triglyceride level greater than or equal to 250 mg/dL
• Presence of impaired glucose tolerance on previous testing

Assessment of Glycemic Control

The only acceptable method for assessment of glycemic control is determination of blood glucose by direct enzyme analysis and not by measurement of urine values, which do not correlate. In the past decade, multiple adequate techniques using test strips and meters have been introduced. These machines work well but reflect whole blood determinations, not serum values. Upgrades of testing strips (in which blood does not need to be wiped away) and Glucometers with memory storage have made home glucose monitoring more reliable. Physician treatment guidelines are in Table 9.12 and patient guidelines in Table 9.13. A 10-multicenter study, the diabetes control and complication trial (DCCT) performed under the auspices of the National Institutes of Health, showed a marked reduction (40%–50%) in complications of neuropathy, retinopathy, and nephropathy when patients with type 1 diabetes received intensive therapy (accomplished by a team approach) as compared with those who received standard therapy.

SECTION III Preventive and Primary Care

Treatment

Type 2 diabetes is treated by a combination of lifestyle adjustments and medications.

Lifestyle

Diet is the most important component of DM management and usually the hardest way to achieve control. Three major strategies are used: weight loss, low-fat diet (≤30% of calories from fat), and physical exercise. Obese patients should reduce their weight to ideal body weight. Metabolic advantages of weight reduction are improved lipid profile and improved glucose control secondary to increased insulin sensitivity and decreased insulin resistance. The greater the weight loss, the greater the improvement in lipid disorders. Physical exercise promotes weight loss and improves insulin sensitivity and dyslipidemia in those people who are in high-risk groups for cardiovascular and microvascular diseases (56).

Oral Hypoglycemic Agents

Oral hypoglycemic agents are recommended for many type 2 diabetic patients (57). The first oral hypoglycemic agents introduced were first- and second-generation sulfonylureas. Other classes of drugs—such as biguanides, thiazolidinediones, alpha-glucosidase inhibitors, and insulin secretagogues—have been introduced that have different effects in patients with type 2 diabetes. Commonly used formulations of this class of drugs are listed in Table 9.14. The mode of action of sulfonylureas is based on two different mechanisms: (i) enhanced insulin secretion from the pancreas, and (ii) an extrapancreatic effect that is poorly understood. Endogenous insulin secretion (as measured by C-peptide) is necessary for OHA to work. Additionally, if the fasting blood glucose on an adequate diabetic diet is greater than 250 mg/dL, there is little effect. Frequent evaluation to monitor control (every 3–4 months) is important. If glucose levels cannot be controlled with oral hypoglycemic agents (i.e., sulfonylureas) or other medicines (i.e., metformin, a biguanide), insulin therapy should be initiated and referral should be considered because of the increased rate of complications.

Thyroid Diseases

Thyroid disorders are more common in women and some families although the exact rate of inheritance is unknown (58). In geriatric populations, the incidence may be as high as 5% (59). Unfortunately, the laboratory diagnosis of thyroid disease can be difficult because of altered hormonal states such as pregnancy and exogenous hormones. Thyroid hormones act in target tissues by binding to nuclear receptors, which induce change in gene expression (60). Extrathyroidal conversion of thyroxine (T₄) to triiodothyronine (T₃) takes

</tbody>
</table>

place in target tissue. T$_3$ binds the nuclear receptor with higher affinity than T$_4$, which makes T$_3$ more biologically active. Pituitary thyroid stimulating hormone (TSH) and hypothalamic thyrotropin-releasing hormone (TRH) regulate hormone production and thyroid growth by normal feedback physiology. Thyroid-stimulating immunoglobulins (TSI), once known as long-acting thyroid stimulator (LATS), bind to the TSH receptor, which results in hyperthyroid Graves’ disease.

More than 99% of circulating T$_4$ and T$_3$ concentrations are bound by plasma proteins, predominately to thyroxine-binding globulin (TBG), and the remaining 1% of thyroid hormones are free. Free levels of thyroid hormones remain constant despite physiologic or pharmacologic alterations. Regardless of total serum protein levels, active thyroid hormone remains stable. In healthy women, transitions from puberty to menopause do not alter free thyroid hormone concentrations. Excess endogenous or exogenous sources of estrogen increase TBG plasma concentration by decreasing hepatic clearance. Androgens (especially testosterone) and corticosteroids have the opposite effect by increasing hepatic TBG clearance.

Thyroid function tests may be misleading in women receiving exogenous sources of estrogen because of altered binding characteristics. In euthyroid individuals, elevations of thyroid hormone concentrations arise from three mechanisms: (i) increased protein binding because of altered albumin and estrogen states, (ii) decreased peripheral conversion of T$_4$ to T$_3$, or (iii) congenital tissue resistance to thyroid hormones, which is rare. Hormonal replacement therapy and pregnancy alter laboratory findings and complicate interpretation of thyroid function studies. Most laboratories compensate by reporting a free T$_4$ level that mathematically corrects for physiologic alterations. If questions arise, a clinical pathologist should be consulted.

### Hypothyroidism

Overhypothyroidism occurs in 2% of women, and at least an additional 5% develop subclinical hypothyroidism. This is especially true in the elderly, in whom many of the signs and symptoms are subtle. The principal cause of hypothyroidism is autoimmune thyroiditis (Hashimoto’s thyroiditis). A familial predisposition is observed in many cases, but the specific genetic or environmental trigger is unknown. The incidence of autoimmune thyroiditis increases with age, affecting up to 15% of women older than 65 years.
Many have subclinical hypothyroidism, which is defined as an elevated serum TSH concentration with a normal serum free T₄ level. It is uncertain whether treatment will improve quality of life in otherwise healthy patients who have subclinical hypothyroidism (61). Autoimmune thyroiditis may be associated with other endocrine (e.g., type 1 diabetes, primary ovarian failure, adrenal insufficiency, and hypoparathyroidism) and nonendocrine (e.g., vitiligo and pernicious anemia) disorders (62). Therefore, when autoimmune diseases are present, there should be a high degree of suspicion for concurrent thyroid disorders. Iatrogenic causes of hypothyroidism occur after surgical removal or radioactive iodine therapy for hyperthyroidism or thyroid cancer. Radiation was used to treat acne and other dermatologic disorders 45 years ago; patients undergoing such treatment have an increased risk of thyroid cancer and require close monitoring.

Hypothyroidism rarely occurs secondary to pituitary or hypothalamic diseases from TSH or TRH deficiency, but this must be considered if symptoms occur after neurosurgical procedures.

**Clinical Features**

Manifestations of hypothyroidism include a broad range of signs and symptoms: fatigue, lethargy, cold intolerance, nightmares, dry skin, hair loss, constipation, periorbital carotene deposition (causing a yellow discoloration), carpal tunnel syndrome, weight gain (usually less than 5–10 kg), depression, irritability, and impaired memory. Menstrual dysfunction is common, either as menorrhagia or amenorrhea. Infertility may arise from anovulation, but exogenous thyroid hormone is not useful for anovulatory euthyroid women. Empirical use of thyroid extract, which was common many years ago, should be discouraged.

Hypothyroidism is not a cause of premenstrual syndrome (PMS), but worsening PMS may be a subtle manifestation of hypothyroidism (63). Hypothyroidism may cause precocious or delayed puberty. Hyperprolactinemia and galactorrhea are unusual manifestations of hypothyroidism; however, assessment of thyroid function should be considered. To distinguish primary hypothyroidism from a prolactin-secreting pituitary adenoma, TSH levels should be assessed in women who have amenorrhea, galactorrhea, and hyperprolactinemia.

**Diagnosis**

Suspected hypothyroidism should always be confirmed with laboratory studies. Primary hypothyroidism is characterized by the combination of an elevated serum TSH with a low serum free T₄ level. Autoimmune thyroiditis can be confirmed by the presence of serum antithyroid peroxidase (formerly referred to as antimicrosomal) antibodies. Central hypothyroidism, although rare, is distinguished by a low or low-normal serum free T₄ level with either a low or inappropriate normal serum TSH concentration.

**Therapy**

Synthetic L-thyroxine (T₄) is the treatment of choice for hypothyroidism and is available as generic levothyroxine or Synthroid®, Levoxyl®, or Unithroid®. The mode of action is by conversion of T₄ to T₃ in peripheral tissues. Levothyroxine should be taken on an empty stomach. Absorption may be poor when taken in combination with aluminum hydroxide (common in antacids), cholestyramine, ferrous sulfate, or fatty meals. The usual T₄ requirement is weight related (approximately 1.6 µg/kg) but decreases for the elderly. Normal daily dosage is 0.1 to 0.15 mg but should be adjusted to maintain TSH levels within the normal range. TSH levels should be checked in 6 weeks when dosages or brands are changed.

In the early 1980s, many clinicians thought that increasing the serum T₄ to mildly elevated levels would enhance conversion of T₄ to T₃. Subsequent data have proven that even a mild increase of T₄ was associated with cortical bone loss and atrial fibrillation, particularly in older women (64). A low initial T₄ dose (0.025 mg/day) should be initiated in the elderly.
CHAPTER 9 Primary Care in Gynecology

or patients with known or suspected coronary artery disease. Rapid replacement may worsen angina and in some cases induce myocardial infarction.

Hyperthyroidism

Hyperthyroidism affects 2% of women during their lifetime, most often during their childbearing years. Graves’ disease represents the most common disorder; it is associated with orbital inflammation causing the classic exophthalmus associated with the disease and a characteristic dermopathy, pretibial myxedema. The etiology of Graves’ disease in genetically susceptible women is unknown. Autonomous functioning benign thyroid neoplasias are less common causes of hyperthyroidism and are associated with toxic adenomas and toxic multinodular goiter. Transient thyrotoxicosis may be the result of unregulated glandular release of thyroid hormone in postpartum (painless, silent, or lymphocytic) thyroiditis and subacute (painful) thyroiditis. Other rare causes of thyroid overactivity include hCG-secreting choriocarcinoma, TSH-secreting pituitary adenoma, and struma ovarii. Factitious ingestion or iatrogenic overprescribing should be considered in patients with eating disorders.

Clinical Features

Symptoms of thyrotoxicosis include fatigue, diarrhea, heat intolerance, palpitations, dyspnea, nervousness, and weight loss. In young patients there may be paradoxical weight gain from an increased appetite. Thyrotoxicosis may cause vomiting in pregnant women, which may be confused with hyperemesis gravidarum (65). Tachycardia, lid lag, tremor, proximal muscle weakness, and warm moist skin are classic physical findings. The most dramatic physical changes are ophthalmologic and include lid retraction, periorbital edema, and proptosis. These eye findings, however, occur in less than one third of women. In elderly adults, symptoms are often more subtle, with presentations of unexplained weight loss, atrial fibrillation, or new onset angina pectoris (66). Menstrual abnormalities span from regular menses to light flow to anovulatory menses and associated infertility. Goiter is common in most younger women with Graves’ disease, but may be absent in older women. Toxic nodular goiter is associated with nonhomogeneous glandular enlargement, whereas in subacute thyroiditis the gland is tender, hard, and enlarged.

Diagnosis

Most thyrotoxic patients have elevated total and free T₄ and T₃ concentrations (measured by radioimmune assay). In thyrotoxicosis, serum TSH concentrations are virtually undetectable, even with very sensitive assays (sensitivity measured to 0.1 units). Sensitive serum TSH measurements may aid in the diagnosis of hyperthyroidism. Radioiodine uptake scans are useful in the differential diagnosis of established hyperthyroidism. Scans with homogeneous uptake of radioactive iodine are suggestive of Graves’ disease, whereas heterogeneous tracer uptake is suggestive of a diagnosis of toxic nodular goiter. In distinction, thyroiditis and medication-induced thyrotoxicosis have diminished glandular radioisotope concentration.

Therapy

Antithyroid medications, either propylthiouracil (PTU 50–300 mg every 6–8 hours) or methimazole (10–30 mg per day) are used for initial therapy. After metabolic control is obtained, definitive therapy is obtained by thyroid ablation with radioiodine, which results in permanent hypothyroidism. Both antithyroid drugs block thyroid hormone biosynthesis and may have additional immunosuppressive effects on the gland. The primary difference in oral medications is that PTU partially inhibits extrathyroidal T₄-to-T₃ conversion, whereas methimazole does not. However, methimazole has a longer half-life and permits single daily dosing, which may encourage compliance. Euthyroidism is typically restored in 3 to 10 weeks, and treatment with oral antithyroid agents is continued for 6 to 24 months, unless total ablation with radioiodine or surgical resection is performed. Surgery
SECTION III Preventive and Primary Care

has become less popular because it is invasive and may result in inadvertent parathyroid removal, which commits the patient to lifelong calcium therapy.

The relapse rate with oral antithyroid medications is 50% over a lifetime. Lifelong follow-up is important when medical therapy is used solely because of the high relapse rate. Both medications have infrequent (5%) minor side effects, which include fever, rash, or arthralgias. Major toxicity (e.g., hepatitis, vasculitis, and agranulocytosis) occurs in less than 1%. Agranulocytosis cannot be predicted by periodic complete blood counts; therefore, patients who have sore throats or fevers should stop taking medication and call their physician immediately.

Therapy with iodine-131 provides a permanent cure of hyperthyroidism in 90% of patients. The principal drawback to radioactive iodine therapy is the high rate of postablatative hypothyroidism, which occurs in at least 50% of patients immediately after therapy with additional cases developing at a rate of 2% to 3% per year. Based on the assumption that hypothyroidism will develop, patients should be given lifetime thyroid replacement. Beta-adrenergic blocking agents such as propranolol or atenolol are useful adjunctive therapy for control of sympathomimetic symptoms such as tachycardia (67). An additional benefit of beta-blockers is the blocking of peripheral conversion of T₄ to T₃. In rare cases of thyroid storm, PTU, beta-blockers, glucocorticoids, and high-dose iodine preparations (intravenous sodium iodide) should be administered immediately, and referral to an intensive care unit is advisable.

Thyroid Nodules and Cancer

Thyroid nodules are common and found on physical examination in up to 5% of patients. Nodules may be demonstrated on ultrasound in approximately 50% of 60-year-old persons. The vast majority of nodules when discovered are asymptomatic and benign; however, malignancy and hyperthyroidism must be excluded (68). Ultrasound-guided fine-needle aspiration is recommended in the presence of the following factors: history of radiation to the head, neck, or upper chest, family history of thyroid cancer, ultrasound findings suggestive of malignancy, or a nodule larger than 1.5 cm in diameter (69).

Thyroid function tests should be performed before fine-needle aspiration and, if results are abnormal, the underlying disease should be treated. Because most nodules are “cold” on scanning, it is more cost-effective to proceed with tissue sampling rather than scanning. Biopsy is successful and provides a diagnosis in 95% of cases; however, in the 5% of patients in whom the diagnosis cannot be established, surgical biopsy is necessary. Only 20% of surgical biopsies of an “indeterminate aspiration” are found to be malignant (70). Lesions that are confirmed malignant on biopsy should be treated with surgery, and benign nodules should be palpated every 6 to 12 months. Thyroxine suppressive therapy for benign nodules is not recommended (69).

Papillary thyroid carcinoma is the most common malignancy, found in 75% of cases. Patients younger than 50 years of age with a primary tumor of less than 4 cm at presentation, even with associated cervical lymph node metastasis, are usually cured. In the elderly, anaplastic tumors have a poor prognosis and progress rapidly despite therapy.

**CHAPTER 9 Primary Care in Gynecology**

---
SECTION III Preventive and Primary Care

The most common methods of contraception used in the United States are sterilization, oral contraceptives, and condoms, in that order.

Latex condoms and other barriers reduce the risk of sexually transmitted diseases (STDs) and cervical cancer.

The two intrauterine devices (IUDs) available in the United States, the *copper T380A* (ParaGard) and the *levonorgestrel T* (Mirena), are as effective as tubal sterilization and are associated with long-term risk of pelvic infection that is no greater than that in the general population.

The combination estrogen–progestin oral contraceptives, patch, and vaginal ring all provide excellent contraception when used correctly, and all increase the risk of venous thrombosis and thromboembolism.

Present low-dose estrogen–progestin combinations do not increase the risk of heart attack among nonsmokers younger than age 35 years who have no other risks for vascular disease.

Oral contraceptives do not increase the risk of breast cancer.

Use of progestin-only injectable and implant hormonal contraceptives results in very low pregnancy rates without the estrogen-associated risk of thrombosis.

Hormonal contraceptives provide extensive contraceptive and noncontraceptive health benefits, including reduced risk for endometrial and ovarian cancer.

*Levonorgestrel 1.5 mg* (Plan B) is the most effective hormonal means of emergency contraception. Efficacy is greatest within 24 hours of intercourse but is still high at 5 days. Emergency contraception with the *copper T 380A* IUD is highly effective up to 7 days after intercourse.

Safe, long-term contraception is provided with laparoscopy and bipolar electrocautery application to three adjacent sites on each tube, the Silastic band, or the Filshie clip.
• Hysteroscopic insertion of the Essure system provides highly effective permanent sterilization for women without the use of general anesthesia or abdominal incision.

• Vasectomy provides highly effective, low-cost sterilization for men and is associated with neither heart disease nor prostate cancer.

• Abortion mortality rates fell rapidly with legalization; currently, the overall mortality risk is less than 1 per 100,000, well below the maternal mortality rate.

• The risk of abortion mortality increases with gestational age, from 0.1 per 100,000 at 8 weeks or less, but even at 16 to 20 weeks, abortion is safer than continuing pregnancy.

The history of contraception is a long one, dating to ancient times; however, the voluntary control of fertility is even more important in modern society (1). With each woman expected to have no more than one or two children, most of her reproductive years are spent trying to avoid pregnancy. Effective control of reproduction is essential to a woman’s ability to accomplish her individual goals. From a larger perspective, the rapid growth of the human population in this century threatens the survival of all. At its present rate, the population of the world will double in 54 years, and that of many of the poorer countries of the world will double in about 20 years (2) (Fig. 10.1). For the individual and

![Figure 10.1](image-url)
for the planet, reproductive health requires careful use of effective means to prevent both pregnancy and sexually transmitted diseases (STDs) (3).

From puberty until menopause, women are faced with concerns about childbearing or its avoidance: The only options are sexual abstinence, contraception, or pregnancy. The contraceptive choices made by couples in the United States in 2002, when the last national fertility survey of a large national probability sample was conducted by the government, are shown in Table 10.1 (4). The oral contraceptive was first choice, used by 18.9% of women aged 15 to 44 years. Female sterilization was second choice, used by 16.7%. However, with the addition the 5.7% of couples relying on male sterilization, 22.4% of couples were relying on sterilization, making this the first choice of contraception. Condoms were third choice, used by 11.1%. Oral contraceptive use declines with age, and the rate of sterilization increases. As a result, 41% of women younger than 35 to 39 years and 50% of women aged 40 to 44 years have had female sterilization. About 10% of women used more than one method of contraception. Condoms were the second most common method.

Although use of contraception is high, a significant proportion of sexually active couples (7.4%) do not use contraception, and each year, two of every 100 women aged 15 to 44 years have an induced abortion (4,5). Abortion is an obvious indicator of unplanned pregnancy. Abortion ratios by age group indicate that the use of abortion is greatest for the youngest women and least for women in their late 20s and early 30s (Fig. 10.2). Use increases as women age. Young women are much more likely to experience unplanned pregnancy because they are more fertile than older women and because they are more likely to have intercourse without contraception. The effect of age on pregnancy rates with different contraceptive methods is shown in Figure 10.3.

### Efficacy

Factors affecting whether pregnancy will occur include the fecundity of both partners, the timing of intercourse in relation to the time of ovulation, the method of contraception used,
the intrinsic effectiveness of the contraceptive method, and the correct use of the method. It is impossible to assess the effectiveness of a contraceptive method in isolation from the other factors. The best way to assess effectiveness is long-term evaluation of a group of sexually active women using a particular method for a specified period to observe how frequently pregnancy occurs.

A pregnancy rate per 100 women per year can be calculated using the Pearl formula (dividing the number of pregnancies by the total number of months contributed by all couples, and then multiplying the quotient by 1,200). With most methods, pregnancy rates decrease with time as the more fertile or less careful couples become pregnant and drop out of the calculations. More accurate information is provided by the life-table method. This method calculates the probability of pregnancy in successive months, which are then added over a given interval. Problems relate to which pregnancies are counted: those occurring among all couples or those in women the investigators deem to have used the method correctly. Because of this complexity, rates of pregnancy with different methods are best calculated by reporting two different rates derived from multiple studies (i.e., the lowest rate) and the usual rate as shown in Table 10.2.

Safety

Some contraceptive methods have associated health risks; areas of concern are listed in Table 10.3. All of the methods are safer than the alternative (pregnancy with birth), with the possible exception of oral contraceptive (OC) use by women older than 35 years of age.

Most methods provide noncontraceptive health benefits in addition to contraception. Oral contraceptives reduce the risk of ovarian and endometrial cancer and ectopic pregnancy. Barrier methods provide some protection against STDs, cervical cancer, and tubal infertility.

Cost

Some methods, such as intrauterine devices (IUDs) and subdermal implants, require an initial high investment but provide prolonged protection for a low annual cost. The results of a complex cost analysis based on the cost of the method plus the cost of pregnancy if the method fails are shown in Table 10.4. Sterilization and the long-acting methods are the least expensive over the long term.

Nonhormonal Methods

Coitus Interruptus

Coitus interruptus is withdrawal of the penis from the vagina before ejaculation. This method, along with induced abortion and late marriage, is believed to account for most of the decline in fertility of preindustrial Europe. Coitus interruptus remains

The table shows the percentage of women experiencing accidental pregnancy within the first year of use and the percentage continuing use at the end of the first year for different contraceptive methods. Notably, male sterilization has a cumulative 5-year pregnancy rate of 0.15%, and female sterilization has a rate of 0.10%. This method has obvious advantages: immediate availability and no cost. The penis must be completely withdrawn both from the vagina and from the external genitalia. Pregnancy has occurred from ejaculation on the female external genitalia without penetration. Coitus...

HIV, human immunodeficiency virus; IUD, intrauterine device; PID, pelvic inflammatory disease; MI, myocardial infarction; DMPA, depomedroxyprogesterone acetate.

interruptus has been found to reduce transmission of human immunodeficiency virus (HIV) in couples who are mutually monogamous (9). Theoretically, some reduction of risk from other STDs would be expected, but this phenomenon does not appear to have been studied. Efficacy is estimated to range from 4 pregnancies per 100 women in the first year with perfect use to 27 per 100 with typical use (Table 10.2).

Breastfeeding

Breastfeeding can be used as a form of contraception and can be effective depending on individual variables. The use of contraception during lactation should take into consideration the women’s needs as well as the need to maintain lactation.
Lactation Amenorrhea

Ovulation is suppressed during lactation. The suckling of the infant elevates prolactin levels and reduces gonadotropin-releasing hormone (GnRH) from the hypothalamus, reducing luteinizing hormone (LH) release and thus inhibiting follicular maturation (10). The duration of this suppression is variable and is influenced by the frequency and duration of nursing, length of time since birth, and probably by the mother’s nutritional status. Even with continued nursing, ovulation eventually returns but is unlikely before 6 months, especially if the woman is amenorrheic and is fully breastfeeding with no supplemental foods given to the infant (11). For maximum contraceptive reliability, feeding intervals should not exceed 4 hours during the day and 6 hours at night, and supplemental feeding should not exceed 5% to 10% of the total amount of feeding (12). Six-month pregnancy rates of 0.45% to 2.45% have been reported for couples relying solely on this method (13). To prevent pregnancy, another method of contraception should be used from 6 months after birth, or sooner if menstruation resumes. Breastfeeding reduces the mother’s lifetime risk of breast cancer. In a very large study in Korea, 13 to 24 months of lactation reduced the risk of breast cancer by 30%, and there was a clear trend of decreasing breast cancer risk with increasing duration of lactation (14).

Contraception during Lactation

Use of combination OCs generally is not advised during lactation because they reduce the amount and quality of breast milk. Combination OCs can be used after 6 weeks, once milk production is established. Progestin-only OCs, implants, and injectable contraception do not affect milk quality or quantity (12). Labeling of the U.S. Food and Drug Administration (FDA) and guidelines from the American College of Obstetricians and Gynecologists suggest that progestin-only OCs can be started 2 to 3 days postpartum, whereas depot medroxyprogesterone acetate (Depo Provera) injections or implants can begin at 6 weeks. These recommendations are not based on any observed adverse effect of early administration (12), and many maternity programs begin injectable contraception with progestin at the time of hospital discharge. Barrier methods, spermicides, and the copper T380A IUD (ParaGard) are also good options for nursing mothers. Because levonorgestrel implants have no adverse effect on breastfeeding, none should be expected from the levonorgestrel T IUD, which releases levonorgestrel but is associated with lower blood levels than the implants.

*a For every $1.00 spent on vasectomy, the amount shown would be spent on the method indicated.

Fertility Awareness

Periodic abstinence, also described as “natural contraception” or “fertility awareness,” requires avoiding intercourse during the fertile period around the time of ovulation. A variety of methods are used: the calendar method, the mucus method (Billings or ovulation method), and the symptothermal method, which is a combination of the first two methods. With the mucus method, the woman attempts to predict the fertile period by feeling the cervical mucus with her fingers. Under estrogen influence, the mucus increases in quantity and becomes progressively more slippery and elastic until a peak day is reached. The mucus then becomes scant and dry under the influence of progesterone until onset of the next menses. Intercourse may be allowed during the “dry days” immediately after menses until mucus is detected. Thereafter, the couple must abstain until the fourth day after the “peak” day.

In the symptothermal method, the first day of abstinence is predicted either from the calendar, by subtracting 21 from the length of the shortest menstrual cycle in the preceding 6 months, or the first day mucus is detected, whichever comes first. The end of the fertile period is predicted by use of basal body temperature. The woman takes her temperature every morning and resumes intercourse 3 days after the thermal shift, the rise in body temperature that signals that the corpus luteum is producing progesterone and that ovulation has occurred. The postovulatory method is a variation in which the couple has intercourse only after ovulation is detected.

A system of hormone monitoring designed to better define the fertile period involves placement of disposable test sticks in a small battery-powered device to detect urinary estrone-3 glucuronide and L.H. This device (Persona or Clear Plan Easy Fertility Monitor) can serves as both an aid to fertility and a form of contraception (15).

Efficacy

Efforts to study the effectiveness of fertility awareness with randomized trials have proven frustrating because of the very high dropout rate of the subjects despite intensive training and ongoing support. Nonetheless, the ovulation method was evaluated by the World Health Organization in a five-country study. Women who successfully completed three monthly cycles of teaching were then enrolled in a 13-cycle efficacy study. There was a 3.1% probability of pregnancy in 1 year for the small proportion of couples who used the method perfectly and 86.4% probability of pregnancy for the rest (16). A review of 15 national surveys from developing countries estimated a 12-month gross failure rate of 24 pregnancies per 100 (17). The personal hormone-monitoring device has been tested in a three-country study of 710 women. The pregnancy rate was 12.1% over a 13-cycle interval. Despite the pregnancies, the continuation rate was 78% after 13 cycles (15).

Because sperm may survive 5 to 7 days in the female genital tract, even a week’s abstinence around the time of actual ovulation offers no guarantee against pregnancy. Also, ovulation can occur even in the absence of menstruation. Pregnancies have occurred after a single act of coitus 7 days before apparent ovulation indicated by basal body temperature. Vaginal infections increase vaginal discharge, complicating the detection of preovulatory mucus.

Risks

Conceptions resulting from intercourse remote from the time of ovulation more often lead to spontaneous abortion than conceptions from midcycle intercourse (18). However, malformations are not more common (18).
**Condoms**

In the 1700s, condoms made of animal intestine were used by the aristocracy of Europe, but condoms were not widely available until the vulcanization of rubber in the 1840s (1). Modern condoms are usually made of latex rubber, although condoms made from animal intestine are still sold and are preferred by some who feel they afford better sensation. Until recently, condoms in the United States were made with a relatively thick wall (0.065–0.085 mm) to prevent breakage. Japanese condoms as thin as 0.02 mm are now available in the United States (2). New condoms made from nonlatex materials—such as polyurethane or synthetic elastomers that are thin, odorless, transparent, and transmit body heat—also are available. Although the nonlatex condoms may break more easily than the latex varieties, substantial numbers of study participants preferred them and would recommend them to others (19).

**Condoms prelubricated with the spermicide nonoxynol-9 are more effective than condoms without spermicide** (20). The risk of condom breakage is about 3% (21) and is related to friction. Use of water-based lubricants may reduce the risk of breakage. Petroleum-based products such as mineral oil must be avoided because even brief exposure to them markedly reduces the strength of condoms (22).

**Sexually Transmitted Diseases**

Latex condoms and other barrier methods reduce the risk of STDs. Gonorrhea, ureaplasma, and pelvic inflammatory disease (PID) and its sequel (tubal infertility) are reduced with consistent use of barrier methods (23,24). A comparison of infertile women with postpartum women showed a 40% reduction in infertility with use of condoms or the diaphragm (25). Tested in vitro, *Chlamydia trachomatis*, herpes virus type 2, human immunodeficiency virus (HIV), and hepatitis B did not penetrate latex condoms but did cross through condoms made from animal intestine (26). Follow-up of sexual partners of HIV-infected individuals has shown that condom use provides considerable protection (27). Consistent condom use provides more protection than inconsistent use (28,29). In one study, couples who use condoms 0% to 50% of the time had an HIV seroconversion rate of 20.8 per 100 couple years, whereas those who used condoms 100% of the time had a conversion rate of only 2.3 per 100 couple years (29). Nonoxynol-9 **should not be used with condoms for HIV protection because it has been associated with genital lesions. Nonoxynol-9 does not add to the protection afforded by condoms alone** (29,30).

**Condoms also offer protection from cervical neoplasia.** In one study, the relative risk of severe dysplasia among users of condoms or diaphragms was 0.4 at 5 to 9 years of use and only 0.2 when the barriers had been used for 10 years or more, a 60% to 80% reduction (31). Another study compared women with invasive cervical cancer to controls. The relative risk for invasive cervical cancer was 0.4 when those who had used condoms or diaphragms were compared with those who had never used them (32). The presumed mechanism of protection is reduced transmission of human papillomavirus (HPV).

**Latex allergy could lead to life-threatening anaphylaxis in either partner from latex condoms.** Nonlatex condoms of polyurethane and Tactylon should be offered to couples who have a history suggestive of latex allergy.

**Female Condom**

The female condom is a vaginal pouch made of polyurethane. It is recommended for prevention of pregnancy and STDs, including HIV. Breakage may occur less often with the female condom than the male condom; however, slippage appears to be more common, especially for those new to its use (33). Exposure to seminal fluid is slightly higher than with the male condom (34). Initial U.S. trials showed a pregnancy rate of 15% in 6 months; however, reanalysis suggests that with perfect use, the pregnancy rate may be only 2.6%. This rate is comparable to perfect use of the diaphragm and cervical cap, the other female
barrier methods (35). As with the male condom, failure rates fall with increasing experience. Colposcopic studies of women using the female condom demonstrate no signs of trauma or change in the bacterial flora (36). However, clinical trials suggest both men and women find the female condom less acceptable than the male condom (37).

Vaginal Spermicides

Currently available vaginal spermicides combine a spermicidal chemical, either nonoxynol-9 or octoxynol, with a base of cream, jelly, aerosol foam, foaming tablet, film, suppository, or a polyurethane sponge. Nonoxynol-9 is a nonionic surface-active detergent that immobilizes sperm. In simulated intercourse under laboratory conditions, aerosol foams provided rapid dispersal throughout the vagina and offered the best protection. Jellies and melting suppositories provided poor distribution (34). Nonoxynol-9 spermicides alone appear considerably less effective in preventing pregnancy than condoms or diaphragms. Women using nonoxynol-9 spermicides frequently have higher rates of genital lesions than women not using spermicides. These lesions may increase their risk for STDs and HIV (38). In the same studies of serodiscordant couples in which condoms were proved effective in preventing transmission of HIV, nonoxynol-9 spermicides were not effective (29).

Concerns have been raised about possible teratogenicity of spermicides. Nonoxynol-9 is not absorbed from the human vagina, however (36,39), and several large studies have found no greater risk of miscarriage, birth defects, or low birth weight in spermicide users than in other women (40,41).

Nonoxynol-9 is toxic to the lactobacilli that normally colonize the vagina. Women who use spermicides regularly have increased vaginal colonization with the bacterium Escherichia coli and may be predisposed to E. coli bacteriuria after intercourse (42).

Vaginal Barriers

At the beginning of the 20th century, four types of vaginal barriers were used in Europe: vaginal diaphragm, cervical cap, vault cap, and Vimule. All of these barriers are still made and sold in England. Vaginal diaphragms and cervical caps are used in the United States. When used consistently, vaginal barriers can be highly effective. They are safe, and, as with condoms, they have the noncontraceptive benefit of relative protection from STDs, tubal infertility, and cervical neoplasia. Recent interest in finding alternatives to condoms for HIV prevention in high-prevalence areas has rekindled interest in vaginal barriers (43).

Diaphragm

The diaphragm consists of a circular spring covered with fine latex rubber (Fig. 10.4). There are several types of diaphragm, as determined by the spring rim: coil, flat, or arcing. Coil-spring and flat-spring diaphragms become a flat oval when compressed for insertion. Arcing diaphragms form an arc or half moon when compressed; they are easiest to insert correctly. The practitioner must not only fit the diaphragm for the patient, but also instruct her in its insertion and verify by examination that she can insert it correctly to cover the cervix and upper vagina. Spermicide is always prescribed for use with the diaphragm; however, whether this practice is necessary is not well studied. In a small trial, women using the diaphragm without spermicide had a higher (19.3 per 100 woman-years) but statistically not significant risk for pregnancy than those who used the diaphragm with spermicide (12.3 per 100 woman-years) (44). Conversely, a different study found that women who wore the diaphragm constantly, removing, washing, and reinserting the diaphragm daily without using a spermicide, had lower pregnancy rates than women who used the diaphragm in the conventional fashion, with a spermicide, only when needed (45). Proper fitting and use are key to the effectiveness of the diaphragm.
Fitting Diaphragms

Fitting of a diaphragm should be performed as follows:

1. A vaginal examination should first be performed. With the first and second fingers in the posterior fornix, the thumb of the examining hand is placed against the first finger to mark where the first finger touches the pubic bone. The distance from the tip of the middle finger to the tip of the thumb is the diameter of the diaphragm that should first be tried.

2. A set of test diaphragms of various sizes is used, and the test diaphragm is inserted and checked by palpation. The diaphragm should open easily in the vagina and fill the fornices without pressure. The largest diaphragm that fits comfortably should be selected. A size 65, 70, or 75 diaphragm will fit most women.

3. The patient should practice insertion and should be reexamined to confirm proper position of the device. About 1 teaspoon of water-soluble spermicidal jelly or cream is placed in the cavity of the dome. The diaphragm is inserted with the dome downward so that the cervix will sit in a pool of the spermicide.

4. The diaphragm can be inserted several hours before intercourse. If intercourse is repeated, additional spermicidal jelly should be inserted into the vagina without removing the diaphragm. The diaphragm should be left in place at least 6 hours after intercourse to allow for immobilization of sperm. It is then removed, washed with soap and water, allowed to dry, and stored away from heat. It should not be dusted with talc because genital exposure to talc may increase the risk of ovarian cancer.

Risks

Diaphragm use, especially prolonged use during multiple acts of intercourse, appears to increase the risk of bladder infections. The risk of cystitis increases with the numbers of days the diaphragm is used in a week (relative risk, 1.42, 2.83, and 5.68 for use 1, 3, or 5 days in a week, respectively) (46). A smaller-sized, wide-seal diaphragm or a cervical cap can be used if recurrent cystitis is a problem, although the problem may relate not only to mechanical obstruction but also to alterations in vaginal flora produced by the spermicide. An epidemiologic study comparing cases of toxic shock with controls found no increased risk from diaphragm use (47).
Other Barriers

The *Prentif* cervical cap made of latex rubber is no longer available in the United States. It had been in continuous use for most of the 20th century, but competition from other methods made its continued production impractical. Studies of the efficacy of the *Prentif* caps revealed a range of results. A multicenter study of 3,433 women found a first-year pregnancy rate of 11.3 per 100 women. Women whose pattern of use was described as “near perfect” had a first-year pregnancy rate of 6.1 per 100, one half that of the overall rate (48). By 1 year, 49% of women discontinued use or were lost to follow-up. In randomized trials, the cervical cap was as effective as the diaphragm overall, but the failure rates with perfect use were considerably higher for the cap than for the diaphragm (49). Parous women using the cap had more failures than nulliparous women.

The *FemCap*

A new version of the cervical cap made of silicone rubber was approved by the FDA in 2003. It is marketed under the name *FemCap*. It looks like a sailor’s hat with the dome covering the cervix and the brim fitting into the vaginal fornices; the brim serves to form a seal against the vaginal wall, thereby acting as a funnel to direct the ejaculate fluid into the groove facing the vaginal opening, which is filled with spermicide (50). This groove could also be used for microbicides, if they are available in the future. Additionally, the *FemCap* features a small strap that facilitates removal. It is made in three sizes—22-, 26-, and 30-mm diameter—and can be expected to be reusable for 2 years. It is used with spermicide and should be left in place for at least 6 hours after intercourse; however, it may be left in place as long as 48 hours at a time. The *Femcap* requires a clinician’s fitting and prescription for use.

Lea’s Shield

*Lea’s Shield* is another vaginal barrier device made of silicone rubber and recently approved by the FDA. It is shaped like an elliptical bowl with a central air valve, approximately the size of a diaphragm, featuring an anterior loop to assist its removal. The posterior end is thicker and therefore less likely to rotate when in place. It comes in one size; proper fitting requires only that it cover the cervix, sit behind the symphysis, and be comfortable. A prescription is required (51). Safety and efficacy are similar to that of other vaginal barrier methods, and acceptability among users compares favorably. Approximately 87% of those responding to the question stated that they would recommend its use to a friend (51).

Risks

In one large trial of the *Prentif* cap, negative cervical cytology progressed to dysplasia in 4% of cap wearers and in 2% of diaphragm wearers (48). In contrast, another study found cap wearers to be protected from dysplasia when compared with controls using other methods (52). The results of cervical cytology appeared to improve during use. Cap use was associated neither with cystitis (48,52) nor with toxic shock (47).

The Sponge

The *Today sponge* is a polyurethane dome-shaped device containing *nonoxynol-9*. It is moistened with water and then inserted high in the vagina to cover the cervix. It combines the advantages of a disposable barrier with spermicide and provides protection for 24 hours. Initially introduced into the United States in 1983, it rapidly became the best-selling over-the-counter method for female contraception. It was withdrawn from the market in 1995 but recently has been reintroduced. Trials in the United States indicate that the contraceptive efficacy appears to differ with parity. Nulliparous women are reported to have a pregnancy rate of 9% per year, whereas parous women have a pregnancy rate of 20% with perfect use (Table 10.2). A trial comparing the sponge with a vaginal spermicide preparation showed the sponge had a slightly lower pregnancy rate (53).
Intrauterine contraceptive devices are very important worldwide but play a minor role in contraception in the United States because of a fear of infection that is no longer justified. Two IUDs are now in use in the United States: the copper T380A (ParaGard) and the levonorgestrel-releasing T (Mirena). The copper T380A has bands of copper on the cross arms of the T in addition to copper wire around the stem, providing a total surface area of 380 mm of copper, almost double the surface area of copper of earlier copper devices (Fig. 10.5). It is approved for up to 10 years of continuous use. The levonorgestrel T (Fig. 10.6) is approved in the United States for 5 years of use, although studies through 7 years of use show no loss of efficacy (54). Both provide safe, long-term contraception with effectiveness equivalent to tubal sterilization.

Mechanism of Action

Intrauterine devices cause the formation of “biologic foam” within the uterine cavity that contains strands of fibrin, phagocytic cells, and proteolytic enzymes. Copper IUDs continuously release a small amount of the metal, producing an even greater inflammatory response. All IUDs stimulate the formation of prostaglandins within the uterus, consistent with both smooth muscle contraction and inflammation. Scanning electron microscopy studies of the endometrium of women wearing IUDs show alterations in the surface morphology of cells, especially of the microvilli of ciliated cells (55).
are major alterations in the composition of proteins within the uterine cavity, and new proteins and proteinase inhibitors are found in washings from the uterus (56). The altered intratubercine environment interferes with sperm passage through the uterus, preventing fertilization. The levonorgestrel in the T device is much more potent than natural progesterone. Blood levels of the hormone are about one half those seen with the levonorgestrel subdermal implant (Norplant) and are sufficient to block ovulation in some women (53). About 85% remain ovulatory. Levonorgestrel is thought to produce endometrial atrophy as well as an intratubercine inflammatory response (57).

The IUD is not an abortifacient. The contraceptive effectiveness does not depend on interference with implantation, although this phenomenon also occurs and is the basis for using copper IUDs for emergency contraception. Sperm can be obtained by laparoscopy in washings from the fallopian tubes of control women at midcycle; fewer sperm are present in the tubal washings from women wearing IUDs (57). Ova flushed from the tubes at tubal sterilization showed no evidence of fertilization in women wearing IUDs (58), and studies of serum β-human chorionic gonadotropin levels in women wearing IUDs do not indicate pregnancy (59).

Effectiveness

The copper T380A and the levonorgestrel T have remarkably low pregnancy rates, less than 0.2 per 100 woman-years. Total pregnancies over a 7-year period were only 1.1 per 100 for the levonorgestrel T and 1.4 for the copper T380A (53). Twelve-year data on the copper T380A showed a cumulative pregnancy rate of only 1.9 per 100 women (60).

Benefits

Modern IUDs provide excellent contraception without continued effort by the user. Both the copper T 380A and the levonorgestrel T protect against ectopic pregnancy. The levonorgestrel T, by releasing levonorgestrel, reduces menstrual bleeding and cramping. It has been used extensively to treat heavy menstrual bleeding and is used in Europe and the United Kingdom as an alternative to hysterectomy for menorrhagia (61). Additional noncontraceptive benefits include a reduced risk of endometrial cancer (62) and improvement in symptoms of endometriosis (63,64).

Risks

Infection The Women’s Health Study (65) found the Dalkon Shield device (now withdrawn from the market) to increase the risk of pelvic inflammatory disease (PID) eightfold when women hospitalized for PID were compared with control women hospitalized for other illnesses. In contrast, risk from the other IUDs was markedly less: Relative risk for PID was 2.2 for the Progestasert, 1.9 for the Copper 7, 1.3 for the Saf-T-Coil, and 1.2 for the Lippes Loop (65). Increased risk was detectable only within 4 months of insertion of the IUD. A still larger, prospective World Health Organization study revealed that PID increased only during the first 20 days after insertion. Thereafter, the rate of diagnosis of PID was about 1.6 cases per 1,000 women per year, the same as in the general population (66).

Exposure to sexually transmitted pathogens is a more important determinant of PID than is wearing an IUD. In the Women’s Health Study, women who were currently married or cohabiting and who said they had only one sexual partner in the past 6 months had no increase in PID (65). In contrast, previously married or single women had marginal increase in risk, even though they had only one partner in the previous 6 months (67). The only pelvic infection that has been unequivocally related to IUD use is actinomycosis (68). It appears that PID with actinomycosis has been reported only in women wearing an IUD.
Rates of colonization with actinomycosis increase with duration of use for plastic devices but appear to be much less for copper-releasing IUDs.

When PID is suspected in a woman wearing an IUD, appropriate cultures should be obtained, and antibiotic therapy should be administered. Removal of the IUD is not necessary unless symptoms do not improve after 72 hours of treatment (69). Pelvic abscess, if suspected, should be ruled out by ultrasound examination.

**Ectopic Pregnancy** If pregnancy occurs in an IUD wearer, it will be ectopic in about 5% of cases. This is because the fallopian tubes are less well protected against pregnancy than is the uterus. Compared with women using no contraception, however, women wearing either the copper T380A or the levonorgestrel T have an 80% to 90% reduction in the risk of ectopic pregnancy (53), which is a greater reduction than that seen for users of barrier methods. Women using OCs have a 90% reduced risk (69,70). One study reported an increased risk of ectopic pregnancy among past users of older IUDs, but it did not include the current higher-dose copper IUD (Copper T 380A) or the levonorgestrel T (71).

**Fertility** Tubal factor infertility is not increased among nulligravid women who have used copper IUDs, but exposure to sexually transmitted pathogens such as *C. trachomatis* does increase risk (72). The Oxford Study found that women gave birth just as promptly after IUD removal as they did after discontinuing use of the diaphragm (73).

**Clinical Management**

Contraindications to IUD use listed by the World Health Organization include pregnancy, puerperal sepsis, PID or sexually transmitted diseases current or within the past 3 months, endometrial or cervical cancer, undiagnosed genital bleeding, uterine anomalies, and fibroid tumors that distort the endometrial cavity (69). Infection with HIV is not considered a contraindication for IUD use. No increase in pelvic infection, female-to-male transmission, or viral shedding has been found among HIV-1 infected women. (74,75) Copper allergy and Wilson’s disease are contraindications to the use of copper IUDs.

**Insertion**

At the initial visit, the patient’s history is obtained; a physical examination, cervical culture for *Neisseria gonorrhoeae*, and a test for chlamydia are performed; and detailed counseling regarding risks and alternatives is provided. The patient should avoid intercourse until returning for insertion of the device at a second visit. Premedication with oral prostaglandin inhibitors such as ibuprofen is strongly advised. Antibiotic prophylaxis has not been found beneficial, probably because the risk of pelvic infection with IUD insertion is so low. A large randomized trial of 1,985 patients receiving either oral azithromycin or placebo found no difference in rates of IUD removal during the first 90 days after insertion and no difference in rates of salpingitis (76). These women were screened for STDs only by self-history. The IUD usually is inserted during menses to be sure the patient is not pregnant, but it can be inserted at any time in the cycle if the patient is already using effective contraception (77).

The technique of insertion is as follows:

1. **The cervix is exposed with a speculum.** The vaginal vault and cervix are cleansed with a bacteriocidal solution, such as an iodine-containing solution.

2. **The uterine cavity should be measured with a uterine sound.** The depth of the cavity should measure at least 6 cm from the external os. A smaller uterus is not likely to tolerate currently available IUDs.
3. A paracervical block with 10 mL of 1% lidocaine mixed with atropine (0.5 mg) can be used to avoid vasovagal syncope and minimize discomfort. In some women, serious cardiac arrhythmia, which can occur with cervical stimulation, can be avoided by these measures.

4. Use of a tenaculum for insertion is mandatory to prevent perforation. The cervix is grasped with a tenaculum and gently pulled downward to straighten the angle between the cervical canal and the uterine cavity. The IUD, previously loaded into its inserter, is then gently introduced through the cervical canal.

5. With the copper T380A, the outer sheath of the inserter is withdrawn a short distance to release the arms of the T and is then gently pushed inward again to elevate the now-opened T against the fundus. The outer sheath and the inner stylet of the inserter are withdrawn, and the strings are cut to project about 2 cm from the external cervical os.

6. The Levonorgestrel T IUD is inserted somewhat differently from the copper T380A. The inserter tube is introduced into the uterus until the preset sliding flange on the inserter is 1.5 to 2 cm from the external os of the cervix. The arms of the T device are then released upward into the uterine cavity, and the inserter is pushed up under them to elevate the IUD up against the uterine fundus.

Intrauterine Devices in Pregnancy

A woman with an IUD in place who has amenorrhea should have a pregnancy test and pelvic examination. If an intrauterine pregnancy is diagnosed and the IUD strings are visible, the IUD should be removed as soon as possible to prevent later septic abortion, premature rupture of the membranes, and premature birth (78). When the strings of the IUD are not visible, an ultrasound examination should be performed to localize the IUD and determine whether expulsion has occurred. If the IUD is present, there are three options for management:

1. Therapeutic abortion
2. Ultrasound-guided intrauterine removal of the IUD
3. Continuation of the pregnancy with the device left in place

If the patient wishes to continue the pregnancy, ultrasound evaluation of the location of the IUD is advised (79). If the IUD is not in a fundal location, ultrasound-guided removal using small alligator forceps is advised. If the location is fundal, the IUD should be left in place. When pregnancy continues with an IUD in place, the patient must be warned of the symptoms of intrauterine infection and should be cautioned to seek care promptly for fever or flu-like symptoms, abdominal cramping, or bleeding. At the earliest sign of infection, high-dose intravenous antibiotic therapy should be given and the pregnancy evacuated promptly.

Duration of Use

Annual rates of pregnancy, expulsions, and medical removals decrease with each year of use (80,81). Therefore, a woman who has had no problem by year 5, for example, is very unlikely to experience problems in the subsequent years. The Copper T380A is approved for 10 years and the levonorgestrel T for 5 years. Actinomyces can be detected by cervical cytology. Should actinomyces-like particles be found, removal of the IUD and treatment with oral penicillin is recommended.
**Choice of Devices**

Both of the IUDs available in the United States, the *Copper T380A* and the *Levonorgestrel T*, provide protection for many years, have remarkably low pregnancy rates, and reduce the risk of ectopic pregnancy substantially. The *levonorgestrel T* reduces the amount of menstrual bleeding and dysmenorrhea. The *copper T380A* can be expected to increase menstrual bleeding. It is also the most effective means for emergency contraception.

**Hormonal Contraception**

Hormonal contraceptives are female sex steroids, synthetic estrogen and synthetic progesterone (progestin), or progestin only. They can be administered in the form of OCs, patches, implants, and injectables. The most widely used hormonal contraceptive is the combination OC. Combination OCs can be monophasic, with the same dose of estrogen and progestin administered each day, or multiphasic, in which varying doses of steroids are given through a 21-day cycle. Typically, they are administered for 21 days beginning on the Sunday after a menstrual period, then discontinued for 7 days to allow for withdrawal bleeding that mimics the normal menstrual cycle. Alternatively, OCs can be started on the first day of menstruation. The 28-day version provides placebo tablets for the last 7 days of the cycle so the user simply takes one pill a day and starts a new pack as soon as the first pack is completed. Progestin-only formulations contain no estrogen. These are taken every day without interruption. Other forms of hormonal contraception include transdermal administration with the patch, injectable progestins and estrogen–progestin combinations, subdermal implants that release progestin, and the vaginal rings that release either estrogen–progestin or progestin alone.

**Steroid Hormone Action**

Sex steroids were originally defined by their biologic activity. They are characterized by their affinity for specific estrogen, progesterone, or androgen receptors, as well as by their biologic effects in different systems. Sex steroids are rapidly absorbed in the gut but go directly into the liver through the portal circulation, where they are rapidly metabolized and inactivated. Therefore, large doses of steroids are required when they are administered orally. The addition of the ethinyl group to carbon-17 of the steroid molecule hinders degradation by the liver enzyme 17-hydroxysteroid dehydrogenase.

**Progestins**

Progestins are synthetic compounds that mimic the effect of natural progesterone but differ from it structurally. The progestins differ from each other in their affinities for estrogen, androgen, and progesterone receptors; their ability to inhibit ovulation; and their ability to substitute for progesterone and antagonize estrogen. Some are directly bound to the receptor (*levonorgestrel, norethindrone*), whereas others require bioactivation as, for example, desogestrel, which is converted in the body to its active metabolite, etonogestrel. The 17-acetoxy progestins (e.g., *medroxyprogesterone acetate*) are bound by the progesterone receptor. *Norgestrel* exists as two stereoisomers, identified as dextronorgestrel and levonorgestrel. Only levonorgestrel is biologically active. Three newer progestins (*norgestimate, desogestrel*, and *gestodene*) are viewed as more “selective” than the other 19-nor progestins, in that they have little or no androgenic effect at doses that inhibit ovulation. The FDA has approved *norgestimate* and *desogestrel*-containing OCs, and *gestodene* is available in Europe. *Gestodene* is a derivative of levonorgestrel that is more potent than the other preparations, i.e., very little of it is required for antifertility effects. Similarly, *norelgestromin* is an active metabolite of *norgestimate* and more potent than the parent compound. It is used in the transdermal patch. *Drospirenone*, a novel progestin recently introduced in the United States, is a derivative of...
the diuretic spironolactone. It has high affinity for progesterone receptors, mineralocorticoid receptors, and androgen receptors. It acts as a progesterone agonist but is a mineralocorticoid antagonist and androgen antagonist (85). Comparative studies suggest a small decrease in body weight and in blood pressure, with equivalent cycle control and contraceptive efficacy, in women taking an OC containing 3 mg of drospirenone/30 μg ethinyl estradiol versus women taking a 150 μg levonorgestrel/30 μg ethinyl estradiol preparation (86). Pilot studies of women with polycystic ovary syndrome have shown good cycle control and reduction in androgen levels with no change in weight, blood pressure, or glucose metabolism (87). There are no studies published to date that compare the effects of drospirenone OC with conventional OCs in these patients.

**Figure 10.7** Progestins of interest for contraception.

In the United States, OCs contain either one of two estrogens: mestranol or ethinyl estradiol (EE). Mestranol is EE with an extra methyl group. It requires bioactivation in the liver, where the methyl group is cleaved, releasing the active agent, EE. Oral contraceptives with
Antifertility Effects

Combination Estrogen–Progestin Contraceptives

Ovulation can be inhibited by estrogen or by progestin alone. Pharmacologic synergism is exhibited when the two hormones are combined and ovulation is suppressed at a much lower dose of each agent. Combination OCs, patches, and the NuvaRing suppress basal follicle-stimulating hormone FSH and LH. They diminish the ability of the pituitary gland to synthesize gonadotropins when it is stimulated by the hypothalamic GnRH (89). Ovarian follicles do not mature, little estradiol is produced, and there is no midcycle LH surge. Ovulation does not occur, the corpus luteum does not form, and progesterone is not produced. This blockade of ovulation is dose related. Newer low-dose OCs do not provide as dense a block and allow somewhat higher baseline FSH and LH levels than higher dose formulations (90). This makes ovulation somewhat more likely to occur if pills are missed or if the patient takes another medication that reduces blood levels of the contraceptive steroids.

Progestin-only Preparations

The mode of action of progestin-only contraceptives is highly dependent on the dose of the compound (91). With low levels of progestin in the blood, ovulation will occur part of the time. With the progestin-only “minipill,” which supplies 0.3 mg of norethindrone per day (Micronor), 40% of cycles are ovulatory, 25% have inadequate luteal function, 18% have follicular maturation without ovulation, and 18% have complete suppression of follicle development. At moderate levels of progestin in the blood, normal basal levels of FSH and LH are present, and some follicle maturation may occur. Estradiol production is present, and the surge of estradiol that would normally trigger pituitary release of LH occurs; there is no answering LH surge, however, and hence ovulation does not occur. At higher levels of progestin in the blood, the amount of basal FSH is reduced, and there is less follicular activity, less estradiol production, and no LH surge.

Transdermal Hormonal Contraception

The patch (OrthoEvra), which is affixed to the user’s skin, and the vaginal NuvaRing both contain combinations of EE and a potent progestin. Both provide sustained release of the steroids and result in relatively constant serum levels that are less than peak levels seen with OCs but sufficient to prevent ovulation.

Hormonal Implants

With the subdermal implant that releases levonorgestrel there is some follicular maturation and estrogen production, but LH peak levels are low and ovulation is often inhibited. In the first year of use, ovulation is believed to occur in about 20% of cycles. The proportion of ovulatory cycles increases with time, probably as a result of the decline in hormone release. By the fourth year of use, 41% of cycles are ovulatory. The more potent progestin released by the etonogestrel implant is even more effective at preventing ovulation (92). The mechanisms of action of low-dose progestins are believed to include effects on the cervical mucus, endometrium, and tubal motility. The scant, dry cervical mucus that occurs in women using these preparations inhibits sperm migration into the upper tract. Progestins decrease nuclear estrogen receptor levels, decrease progesterone receptors, and induce activity of the enzyme 17-hydroxysteroid dehydrogenase, which metabolizes natural estradiol 17β (92).

The sustained release offered by contraceptive implants allows for highly effective contraception at relatively low blood levels of the steroid. Figure 10.8 depicts expected
steroid blood levels with implants, injectables, and oral contraceptives. An additional mechanism for contraception has been discovered with the antiprogesterone mifepristone (RU486). In the normal cycle, there is a small amount of progesterone production from the follicle just before ovulation. This progesterone appears essential to ovulation, because if the antiprogesterone is given before ovulation, this can be delayed for several days (93,94).

Efficacy of Hormonal Contraception

When used consistently, combination OCs have pregnancy rates as low as 2 to 3 per 1,000 women per year. Progestin-only OCs are less effective than combination estrogen–progestin preparations, with best results of 3 to 4 pregnancies per 100 woman-years. All methods have the potential for user error; therefore, there may be a 10-fold difference between the best results and results in typical users of OCs. Injectable progestins and implants are much less subject to user error than OCs. The difference between the best results and results in typical users is small and is comparable to pregnancy rates after tubal sterilization (Table 10.2). Pregnancy rates with the Ortho Evra patch (95) and the NuvaRing (96) were equivalent to those of OCs in studies published to date; however, because it is easier to use these methods consistently, larger studies may well demonstrate better typical user results than with OCs.
Metabolic Effects and Safety

**Venous Thrombosis**  Older studies linked OC use to venous thrombosis and embolism, cerebral vascular accidents, and heart attack (97,98). More recent studies have found a much lower risk (99). A reevaluation of the older literature on venous thrombosis reveals that absolute risk was strongly determined by other very obvious predisposing causes of thrombosis that are now considered contraindications to OC use: previous thrombosis, preexisting vascular disease, coronary artery disease, leukemia, cancer, and serious trauma (100).

Normally, the coagulation system maintains a dynamic balance of procoagulant and anticoagulant systems in the blood. Estrogens affect both systems in a dose-related fashion. For most women, fibrinolysis (anticoagulation) is increased as much as coagulation, maintaining the dynamic balance at increased levels of production and destruction of fibrinogen (101,102) (Fig. 10.9). Current low-dose OCs have less measurable effect on the coagulation system, and fibrinolytic factors increase at the same rate as procoagulant factors (103,104). Lower estrogen dose (30 to 35 μg EE) reduces the risk of a thromboembolic event when compared with higher dose (50 μg estrogen) OCs (105) (Table 10.5). Theoretically, thrombosis risk should be even lower with current OCs containing only 20 μg of EE, but this finding has not been demonstrated.

The absolute risk of thrombosis in OC users taking pills containing 30 to 35 μg EE is 3 per 10,000 per year, compared with 1 per 10,000 reproductive-aged women not using OCs and 6 per 10,000 in pregnancy (106). Thrombosis risk is apparent by 4 months after starting estrogen-containing OCs and does not increase further with continued use. Risk is highest during the first year of use (107).

**Thrombophilia** Changes in the coagulation system are detectable in all women, including those taking lower-dose OCs; however, some women are genetically predisposed to

![Figure 10.9](image-url) Dynamic balance of hemostasis. (From Winkler UH, Buhler K, Schlinder AE. The dynamic balance of hemostasis: implications for the risk of oral contraceptive use. In: Runnebaum B, Rabe T, Kissel L [eds]. Female contraception and male fertility regulation. Advances in Gynecological and Obstetric Research Series. Confort, England: Parthenon Publishing Group, 1991:85–92, with permission.)
thrombosis when challenged by pregnancy or administration of exogenous estrogen. In one study, hemostatic variables in women given low-dose OCs who had previous thrombosis with OCs were compared with women with no thrombosis (108). Women known to have inherited thrombophilic disorders were excluded. Both groups of women had significant changes in clotting factors: increased factor VII, factor VIII, and protein C; and decreased antithrombin, activated protein C sensitivity ratio, and protein S. However, the women with a history of thrombosis who were taking OCs had more pronounced changes. They were “high hemostatic responders” when exposed to OCs. Women with inherited deficiencies of antithrombin III, protein C, or protein S are at very high risk for thrombosis with pregnancy or estrogen therapy, but they make up a very small proportion of potential OC users. A much more common variation, factor V Leiden, has been identified. This genetic variation exists in 3% to 5% of the white population. It codes for a one amino acid mutation in the factor V protein, inhibiting cleavage of the protein by activated protein C, which is an essential step in maintaining the balance between coagulation and fibrinolysis (109).

Risk for a first thromboembolic episode among women using OCs was 2.2 per 10,000 woman-years for women without the factor V mutation and 27.7 per 10,000 woman-years for women with the mutation (110). Cigarette smoking did not affect this risk. There are pronounced ethnic differences in the presence of this mutation. The Leiden allele is found in 3% to 5% of whites but is rare in Africans, Asians, Amerindians, Eskimos, and Polynesians (111). A similar mutation is found in the prothrombin gene at position 20210 and is described as prothrombin G20210A. It is found in 3% of the European population and is also strongly associated with venous thrombosis in women taking OCs (112).

Pregnancy is an even greater challenge for women with inherited defects of anticoagulation (113). A woman who sustains a venous event while using OCs should be evaluated thoroughly after she has recovered. Assessment should include measurement of antithrombin III, protein C, and protein S levels; resistance to activated protein C, serum homocysteine, factor V Leiden mutation, and the prothrombin G20210A mutation; and testing for antiphospholipid antibody. It should not be assumed that hormonal contraception was the unique cause of the thrombotic episode.

In a study of routine screening for factor V Leiden, the authors concluded that routine screening of patients before hormonal contraception is taken is not justified because effective contraception would be denied to 5% of white women, and only a small number of fatal pulmonary emboli would be prevented (114). Furthermore, if pregnant women were screened and those who screened positive were then treated with heparin, the number of cases of fatal bleeding might equal or exceed the number of fatal pulmonary emboli. However, screening women with a personal or family history of deep vein thrombosis before starting estrogen-containing hormonal contraception or pregnancy is strongly recommended.

**Thrombosis and the New Progestins** Several studies have found a modest increased risk of venous thrombosis when users of OCs containing the newer progestins desogestrel

*Baseline risk used to calculate risk for higher doses.

or gestodene combined with 20 to 30 μg of EE were compared with users of levonorgestrel combined with the same doses of estrogen (115). A great controversy ensued, which continues to this day. Some have concluded that the biases “attrition of susceptibles,” “adverse selection,” and “healthy user bias” explain the apparent increase in thrombosis. Most cases of venous thrombosis attributable to OCs occur during the initial months of use (116). Hence, comparing new users to women already taking OCs for some time without incident will demonstrate an apparent increase with the new product that is artificial. Also, physicians may presume that newer drugs are safer and prescribe them selectively for women with risk factors. Analysis of data from a large European study of women who experienced thrombosis with different OCs has shown that the apparent risk of thrombosis was lowest with the first low-dose pills introduced and highest with those recently introduced, even though the newest pill had the lowest estrogen dose (115) (Fig. 10.10). In contrast, two large meta-analyses of the available studies have concluded that there may be a low level of increased risk for venous thrombosis and embolism (VTE) in users of OCs containing desogestrel or gestodene (117,118). A relative risk of 1.7 was found in both analyses. The absolute risk of VTE in young women was estimated as 1.5 per 10,000 with OCs containing EE/levonorgestrel and 2.6 per 10,000 with OCs containing EE and either desogestrel or gestodene. Because the absolute risk is still very small, the issue cannot be unequivocally resolved with observational data (117).

Ischemic Heart Disease Ischemic heart disease and stroke were the major causes of death attributed to OC use in the past. It is now known that the principal determinants of risk are advancing age and cigarette smoking (119). With the higher-dose OCs used in the 1980s, smoking had a profound effect on risk. Women smoking 25 or more cigarettes per

Contraception 1996;54:5–13, with permission.)
day had a 30-fold increased risk for myocardial infarction if they used OCs, compared with nonsmokers not using OCs (120) (Fig. 10.11). Use of OCs is now much safer because most women are taking low-dose pills and because physicians prescribe selectively, excluding women with major cardiovascular risk factors. A very large study in the United States confirms the safety of OCs as currently prescribed. A total of 187 women aged 15 to 44 years with confirmed myocardial infarction were identified during 3.6 million woman-years of observation in the Kaiser Permanente Medical Care Program in California from 1991 to 1994. This is a rate of 3.2 per 100,000 woman-years (121). Nearly all of the current users took OCs with less than 50 μg of EE. After adjusting for age, illness, smoking, ethnicity, and body mass index, risk for myocardial infarction was not increased by OC use (OR, 1.14; CI 95%, 0.27 to 4.72). Of heart attack victims, 61% smoked; only 7.7% were current users of OCs. In a later study, the same investigators pooled results from the California study with a similar study from Washington State. The results were the same. Current users of low-dose OCs had no increased risk for myocardial infarction after adjustment for major risk factors and sociodemographic factors (122). Past use of OCs does not increase risk for subsequent myocardial infarction (123).

One of the larger studies of so-called third-generation OCs found that OCs containing the new progestins desogestrel or gestodene are less likely to be associated with myocardial
infarction than OCs with similar estrogen doses and levonorgestrel (124). Myocardial infarction risk was strongly increased among smokers, even after adjustment for OC use, but smokers who used OCs with the new progestins were less likely to have myocardial infarction than smokers who used the older OCs (124,125). These findings are biologically plausible based on the beneficial effect on lipids of OCs containing the new progestins.

Oral Contraceptives and Stroke In the 1970s, OC use appeared to be linked to risk of both hemorrhagic and thrombotic stroke, but these studies failed to take into consideration preexisting risk factors (126). Although a rare form of cerebrovascular insufficiency, moyamoya disease, is clearly linked to OC use (127), new information shows no risk for women who are otherwise healthy and who use currently available low-dose pills. One study identified all Kaiser Permanente Medical Care Program patients aged 15 to 44 years who sustained fatal or nonfatal stroke in California from 1991 to 1994 (128). Hypertension, diabetes, obesity, current cigarette smoking, and black race were strongly associated with stroke risk, but neither current nor past OC use was associated with stroke in this study. A World Health Organization (WHO) study of cases from 1989 to 1993 from 17 countries in Europe and the developing world included women taking higher-dose OCs as well as low-dose OCs. European women using low-dose OCs had no increased risk for either type of stroke, thrombotic or hemorrhagic. Those taking higher-dose OCs did have measurable risk (129,130). Women in developing countries had an apparent modest increase in risk, but this finding was attributed to undetected existing risk factors. Another study from Europe found less stroke risk from low-dose pills than from older, higher-dose pills, and that risk was less if the patient’s blood pressure was checked before starting OCs. The authors concluded that a small risk from low-dose OCs could be controlled if women with hypertension were not given OCs (131).

Women who smoke and those who have hypertension and diabetes are clearly at increased risk for cardiovascular disease regardless of whether they use oral contraceptives. The important question is whether risk is further increased if they use low-dose OCs, and if so, by how much. The World Health Organization study described previously provides some insight: Smokers taking OCs had seven times the risk of ischemic (thrombotic) stroke when compared with smokers who did not use OCs, and hypertensive women had 10-fold increased risk if they took OCs, but a fivefold risk if they did not (129). Similarly, a study from Denmark found that women with diabetes had a fivefold increase risk for stroke, which increased to 10-fold if they took OCs (132). Unfortunately, these data were not limited to low-estrogen OCs. The data suggest that although risk is primarily determined by the predisposing condition—hypertension, diabetes, or cigarette smoking—the risk can be magnified by OC use, even when the OCs are low dose. The current practice in the United States of limiting OC use by women older than 35 years of age to nonsmokers without other vascular disease risk factors is prudent.

Blood Pressure Oral contraceptives have a dose-related effect on blood pressure. With the older high-dose pills, as many as 5% of patients could be expected to have blood pressure levels greater than 140/90 mm Hg. The mechanism is believed to be an estrogen-induced increase in renin substrate in susceptible individuals. Current low-dose pills have minimal blood pressure effects, but surveillance of blood pressure is advised to detect the occasional idiosyncratic response.

Glucose Metabolism Oral estrogen alone has no adverse effect on glucose metabolism, but progestins exhibit insulin antagonism (133). Older OC formulations with higher doses of progestins produced abnormal glucose tolerance tests with elevated insulin levels in the average patient. The effect on glucose metabolism, similar to the effect on lipids, is related to androgenic potency of the progestin and to its dose.

Lipid Metabolism Higher-dose OCs could have significant adverse effects on lipids (134). Androgens and estrogens have competing effects on hepatic lipase, a liver enzyme
critical to lipid metabolism. Estrogens depress low-density lipoproteins (LDL) and elevate high-density lipoproteins (HDL), changes that can be expected to reduce the risk of atherosclerosis (135). Androgens and androgenic progestins can antagonize these beneficial changes, reducing HDL and elevating LDL levels. Estrogens elevate triglyceride levels. Low-dose formulations have minimal adverse effect on lipids (136), and the newer formulations (with desogestrel and norgestimate as the progestin) produce potentially beneficial changes by elevating HDL and lowering LDL (137). Although average values of a large group show only small lipid changes with the use of current OCs, an occasional patient may have exaggerated effects. Women whose lipid values are higher than the mean before treatment are more likely to experience abnormalities during treatment (136).

**Other Metabolic Effects** Oral contraceptives can produce changes in a broad variety of proteins synthesized by the liver. The estrogen in OCs increases circulating thyroid-binding globulin, thereby affecting tests of thyroid function that are based on binding, increasing total thyroxine (T_4_) levels, and decreasing triiodothyronine (T_3_) resin uptake. The results of actual thyroid function tests, as measured by free T_4_ and radiiodine tests, are normal (138).

**Oral Contraceptives and Neoplasia**

**Endometrial Cancer and Ovarian Cancer** Combination OCs reduce the risk of subsequent endometrial cancer and ovarian cancer (139,140). Two-year use of OCs reduces the risk of endometrial cancer by 40%, and 4 or more years of use reduces the risk by 60%. Another study found a 50% reduction in ovarian cancer risk for women who took OCs for 3 to 4 years and an 80% reduction with 10 or more years of use (141). There was some benefit from as little as 3 to 11 months of use. Benefit continues for at least 15 years from last use (125,127,142). National vital statistics data from England support these observations. In England and Wales, ovarian cancer mortality is declining in women younger than 55 years of age, and this decline has been attributed to OC use (143). Low-dose pills provide protection equivalent to older, higher-dose OCs (144). A similar reduction of risk of ovarian epithelial cancer has been found in a prospective study from Norway and Sweden, with borderline tumor risk equally reduced. Progestin-only contraceptives provided risk reduction equivalent to that of combined OCs (145).

**Cervical Cancer** There may be a weak association between OC use and squamous cancer of the cervix. A systematic review of 28 epidemiologic studies of cervical cancer in OC users compared with those who never used OCs reported summary relative risks of 1.1 (95% CI 1.1–1.2) at less than 5 years of pill use, 1.6 (1.4–1.7) at 5 to 9 years, and 2.2 (1.9–2.4) at 10 or more years (146). A critique of this study argued that causation is not proved because few of the studies cited adequately control for the key behavioral factors of partners, use of barrier contraception, and adequacy of cervical cancer screening (147). Important risk factors are early sexual intercourse and exposure to HPV. Women who have used OCs typically started sexual relations at younger ages than women who have not used OCs and, in some studies, report having had more partners. These factors also increase one’s chance of acquiring HPV, the most important risk factor for cervical cancer. Because barrier contraceptives reduce the risk of cervical cancer, use of alternative choices for contraception can compound the difficulty in establishing an association with OC use alone (148). The presence of HPV types 16 or 18 is associated with a 50-fold increase in risk for preneoplastic lesions of the cervix (149). Adenocarcinomas of the cervix are rare, but they are not as easily detected as other lesions by screening cervical cytology, and the incidence appears to be increasing. One study found a doubling of risk for adenocarcinoma with OC use that increased with duration of use, reaching a relative risk of 4.4 if total use of OCs exceeded 12 years (150). The results of this study were adjusted for history of genital warts, number of sexual partners, and age at first intercourse. Because adenocarcinoma of the cervix is rare, absolute risk is low. If this apparent association is real, the cumulative risk of long-term OC use to 55 years of age would be about 1 in 1,000 patients (151).
Use of OCs is, at most, a minor factor in causation of cervical cancer; however, these findings emphasize the need to provide cervical cancer screening as part of contraceptive services. To reduce risk, women who are not in mutually monogamous relationships should be advised to use barrier methods in addition to hormonal contraception.

**Breast Cancer** There is a large volume of conflicting literature on the relationship between OC use and breast cancer (152). Generally, no increase in overall risk is found from OC use, but some studies have found that risk may increase in women who used OCs before their first term pregnancy, used OCs for many years, are nulligravid, are young at the time of diagnosis, or continue using OCs in their 40s. A meta-analysis of 54 studies of breast cancer and hormonal contraceptive use reanalyzed data on 53,297 women with breast cancer and 100,239 controls from 25 countries, representing about 90% of the epidemiologic data available worldwide at that time (153). Current use of OCs was associated with a very small but statistically stable 24% increased risk (RR, 1.24; 95% CI, 1.15–1.33). The risk fell rapidly after discontinuation, to 16% 1 to 4 years after stopping and to 7% 5 to 9 years after stopping. Risk disappeared 10 years after cessation (RR, 1.01; 95% CI, 0.96–1.05). Results did not differ in any important way by ethnic group, reproductive history, or family history. Since the meta-analysis was published, subsequent studies have found no increased risk. A case control study of 4,575 women with breast cancer and 4,682 controls aged 35 to 64 years living in five cities in the United States concluded that breast cancer risk was not increased for current or past users of OCs and did not increase with prolonged or with higher-estrogen OC use (154). Neither family history of breast cancer nor beginning use at a young age was associated with increased risk. A similar study in Sweden compared 3,016 women aged 50 to 74 years who had invasive breast cancer with 3,263 controls of the same age. No relation was found between past use of OCs and breast cancer (155).

The controversy over the association between breast cancer and OC use is likely to continue. For the present, however, the best information available is reassuring that there is little or no connection.

**Liver Tumors** Oral contraceptives have been implicated as a cause of benign adenomas of the liver. These hormonally responsive tumors can cause fatal hemorrhage. They usually regress when OC use is discontinued; risk is related to prolonged use (156). There is a strong correlation between OC use and hepatocellular adenoma. Fortunately, the tumors are rare; about 30 cases per 1,000,000 users per year have been predicted with older formulations. Presumably, newer low-dose products pose less risk. A link to hepatic carcinoma has been proposed. This cancer is closely associated with chronic hepatitis B and C infections and is usually seen in cirrhotic livers. There are case reports of hepatocellular carcinoma in young women with no risk factors other than long-term OC use (157). However, a large study from six countries in Europe found no association between use of OCs and subsequent liver cancer (158).

**Health Benefits of Oral Contraceptives** Oral contraceptives have important health benefits (Table 10.6). These include contraceptive and noncontraceptive benefits (159).

**Contraceptive Benefits** Oral contraceptives provide highly effective contraception, preventing unwanted pregnancy, an important public health problem. Where safe abortion services are not available, women seek unsafe services and risk death from septic abortion. Combination OCs block ovulation and offer marked protection from ectopic pregnancy. Risk of ectopic pregnancy in a woman taking combination OCs is estimated to be 1/500 of the risk of women not using contraception; however, progestin-only OCs appear to increase risk of ectopic pregnancy (160).
Noncontraceptive Benefits

As noted earlier, OC use produces strong and lasting reduced risk for endometrial and ovarian cancer. In addition, protection has been found for women with known hereditary ovarian cancer. Any past use of OCs conferred a 50% reduction in ovarian cancer risk when women with this history who took OCs were compared with their sisters as controls (OR, 0.5; 95% CI, 0.3–0.8). Protection increased with increasing duration of use (161). The mechanism of action of OCs in the prevention of ovarian cancer is unknown but may involve selective induction of apoptosis (programmed cell death). Macaques treated with EE plus levonorgestrel or levonorgestrel alone showed an increase in the proportion of ovarian epithelial cells in apoptosis in comparison with animals fed a diet containing no hormones (162).

Chlamydial colonization of the cervix appears more likely in OC users than in nonusers but, despite this finding, several case control studies have found a reduced risk of acute pelvic inflammatory disease among OC users (163,164). In contrast, a recent study found no protection with OC use (165).

Other documented benefits of OC use include a significant reduction in the need for biopsies for benign breast disease and surgery for ovarian cysts (166). Use of OCs also

helps relieve dysmenorrhea (166). Oral contraceptives offer effective therapy for women with menorrhagia and dysfunctional uterine bleeding (163).

All combination OCs offer some protection from functional ovarian cysts, but multiphasic preparations offer less protection than other forms of combination OCs (167). Oral contraceptives also appear to decrease the risk of developing leiomyomata (168).

All combination OCs reduce circulating androgen levels and usually improve acne. Two OCs have been specifically FDA approved for acne treatment: the norgestimate/EE triphasic (TriCyclen) and a norethindrone/EE multiphasic (Estrostep) (163).

There is growing evidence that OC use is protective against colon cancer. A case-control study in Italy comparing women with colon cancer with controls found a 37% reduction in colon cancer and a 34% reduction in rectal cancer (colon cancer OR, 0.63; 95% CI 0.45–0.87 and rectal cancer OR, 0.66; 95% CI 0.43–1.01). Longer use produced more protection against colon cancer (169). Results of the U.S. Nurses Health Study also disclosed some degree of protection. Women who had used OCs for 96 months or more had a 40% lower risk of colorectal cancer (RR, 0.60; 95% CI, 1.15–2.14) (170). The mechanism of protection has not been identified.

Fertility after OC Use

After discontinuing OCs, return of ovulatory cycles may be delayed for a few months. Women who have amenorrhea more than 6 months after discontinuation of OCs should undergo a full evaluation because of the risk for prolactin-producing pituitary tumors. This risk is not related to OC use but rather to the probability that the slow-growing tumor was already present and produced menstrual irregularity, prompting the patient to take OCs (171).

Sexuality

In a study that recorded all episodes of female-initiated sexual behavior throughout the menstrual cycle, an increase in sexual activity at the time of ovulation was noted. This increase was not present in women who were taking OCs (172).

Teratogenicity

A meta-analysis of 12 prospective studies, including 6,102 women who used OCs and 85,167 women who did not, revealed no increase in overall risk for malformation, congenital heart defects, or limb reduction defects with the use of OCs (173). Progestins have been used to prevent miscarriage. A large study compared women showing signs of threatened abortion who were treated with progestins (primarily medroxyprogesterone acetate) with women who were not treated. The rate of malformation was the same among the 1,146 exposed infants as among the 1,608 unexposed infants (174). Conversely, estrogens taken in high doses in pregnancy can induce vaginal cancer in exposed female offspring in utero.

Interaction of Oral Contraceptives with Other Drugs

Some drugs (e.g., rifampin) reduce the effectiveness of oral contraceptives; conversely, OCs can augment or reduce the effectiveness of other drugs (e.g., benzodiazepines) (175,176). Perhaps of greatest clinical significance are six antiepileptic drugs: phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate, and topiramate (177). These drugs and the antibiotic rifampin all induce synthesis of liver cytochrome P450 enzymes and reduce plasma levels of EE in women taking OCs, increasing the likelihood of contraceptive failure (175). Several other antiseizure agents have no effect on the levels of contraceptive steroids in the blood. These agents include valproic acid, vigabatrin, lamotrigine, gabapentin, tiagabine, levetiracetam, zonisamide, ethosuximide, and the benzodiazepines (177). St. John’s wort induces cytochrome P450 as well and is reported to increase clearance of EE and norethindrone (178). The antifungal agents griseofulvin, ketoconazole, and itraconazole also induce these hepatic enzymes and may reduce OC efficacy (176). Ampicillin and tetracycline have been implicated in numerous case reports of OC failure. They kill gut bacteria (primarily clostridia) that are responsible for hydrolysis of steroid glucuronides in
the intestine, which allows reabsorption of the steroid through the enterohepatic circulation. In human studies, however, it has not been possible to demonstrate reduced plasma levels of EE. Although women taking OCs who will be treated with antibiotics are commonly advised to use condoms as well, controlled studies of OC users have found no difference in pregnancy rates with exposure to penicillins, cephalosporins, and tetracyclines (179). Nevirapine reduces blood levels of both EE and norethindrone. Oral contraceptives should not be the primary method of contraception for women treated with this drug (180).

Certain drugs actually appear to increase plasma levels of contraceptive steroids. Ascorbic acid (vitamin C) and acetaminophen may elevate plasma EE.

An example of OCs affecting the metabolism of other drugs is seen with diazepam and related compounds. Oral contraceptive use reduces the metabolic clearance and increases the half-life of those benzodiazepines that are metabolized primarily by oxidation: chlorodiazepoxide, alprazolam, diazepam, and nitrazepam. Caffeine and theophylline are metabolized in the liver by two of the P450 isozymes, and their clearance is also reduced in OC users. Cyclosporine is hydroxylated by another of the P450 isozymes, and its plasma concentrations are increased by OCs. Plasma levels of some analgesic drugs are decreased in OC users. Salicylic acid and morphine clearances are enhanced by OC use; therefore, higher doses could be needed for adequate therapeutic effect. Clearance of ethanol may be reduced in OC users.

Oral Contraceptives have the potential to alter a number of clinical laboratory tests and Clinical Chemistry as a result of estrogen-induced changes in hepatic synthesis; however, a large study comparing OC users with pregnant and nonpregnant controls found minimal changes (181). Hormone users took a variety of OCs containing 50 to 100 μg of estrogen, higher doses than are used today. Compared with nonpregnant women who were not using OCs, the OC users had an increase in T4 that is explained by increased circulating thyroid-binding protein, no change in creatinine and globulin levels, slight reduction in mean fasting glucose values and serum glutamic oxaloacetic transaminase, and a decrease in total bilirubin and alkaline phosphatase.

The oral contraceptives currently available in the United States are listed in Table 10.7. With the introduction of OCs containing the new progestins, new preparations with 20 μg of EE, new variations of multiphasic preparations, plus branded generic formulations of older OCs, an array of choices are possible.

The lowest-dose OCs all contain the same amount of the same estrogen, 20 μg of EE. However, the amount of progestins they contain differs: norethindrone acetate, levonorgestrel, desogestrel, or norgestimate (Table 10.7). The first 20-μg EE OC (LoEstrin 1-20) contained 1 mg norethindrone acetate. A comparison of this OC with a triphasic OC with 35 μg of EE and norgestimate (Tri-Cyclen) found considerable more breakthrough bleeding and spotting and more episodes of missed menses with the 20-μg norethindrone acetate/EE than with the higher-estrogen OC containing norgestimate. There was no difference in compliance, discontinuation rates, or adverse events (182). In a three-way trial, the 35-μg norgestimate/EE triphasic OC (Tri-Cyclen) was compared with two new 20-μg EE pills, one containing 100 μg of levonorgestrel (Allese), the other containing 150 μg desogestrel, followed by 2 hormone-free days and 5 days of 10 μg EE per day (Mircette) (183). Contraceptive efficacy was not significantly different. Women starting on OCs had more breakthrough bleeding and bleeding in the second half of the cycle with Allese than with the other two OCs in the first two cycles, but thereafter there was little difference except that Mircette users had more breakthrough bleeding in cycle 4. Women taking Tri-Cyclen consistently experienced more frequent estrogenic side effects of bloating, breast tenderness, and nausea than did women taking either 20-μg EE OC. These authors concluded that for the specific OCs evaluated, changing to the lowest estrogen dose was beneficial.

(Continued)
Oral contraceptives can be taken continuously for an indefinite time by discarding the placebo tablets from each pack. Continuous oral contraceptive use has been prescribed for endometriosis, pelvic pain, and bleeding disorders. Seasonale provides the same low dose of levonorgestrel and EE found in Nordette and several other OCs, but packages 84 active tablets with 7 placebos for continuous use with one withdrawal bleed every 4 months (184).

For the average patient, the first choice of preparation for contraceptive purposes is a low-estrogen OC (25–35 μg of EE) or a very-low-estrogen OC (20 μg EE).

1. Breakthrough bleeding and spotting are common at first and generally improve with time. If the problem persists, it may be relieved by changing from a multiphasic to monophasic version at the same estrogen level.

2. If bleeding remains a problem, a temporary increase in estrogen should be tried: 20 μg of EE daily for 7 days while continuing the OC (185).

Side effects—nausea, breast tenderness, mood changes, and weight gain—are less common with current formulations than with previous OCs and usually resolve after the first few cycles.

1. If symptoms persist, the lowest-dose, most effective formulations could be tried (i.e., those containing only 20 μg of EE).

2. In patients who have persistent breast tenderness, the type of OC could be changed to one with more progestin activity, for example, the 20- to 30-μg
**SECTION III  Preventive and Primary Care**

*EE* pills that contain *levonorgestrel*. Oral contraceptives that contain high-potency progestin produce fewer breast symptoms

3. Nausea is generally related to the estrogen component, and changing to a 20-µg *EE* preparation may be beneficial. The patient should be reminded to expect spotting and breakthrough bleeding at first when changing to a lower-dose OC.

4. Patients with apparent weight gain from fluid retention while taking OCs, or with hirsutism or acne that has not responded to other OCs, may benefit from a change to the *drospirenone/EE* pill.

### Transdermal Hormonal Contraception

The *OrthoEvra* patch and the *NuvaRing* both provide combinations of ultrapotent progestins with *EE*. Both patch and ring provide almost constant low levels of the contraceptive steroids that are considerably less than peak levels seen with OCs. Both offer greater convenience to the user, which improves compliance. Because both contain estrogen, the concerns about venous thrombosis and vascular disease with OCs must be considered to apply to these methods as well.

The patch has a surface area of 20 cm². It delivers a daily dose of 150 µg norelgestromin, the active metabolite of norgestimate, and 20 µg of *EE*. The patch is worn for 1 week, then replaced with a new patch for 7 days, continuing for 3 consecutive weeks followed by a week with no patch. The patch was compared with a multiphasic OC containing *levonorgestrel*, 50 to 125 µg, and 30 to 40 µg *EE* (*Triphasil*) in a randomized trial of 1,417 women (95). The overall and method failure Pearl Index were 1.24 and 0.99 pregnancies per 100 woman-years in the patch group and 2.18 and 1.23 in the OC group, respectively, and numerically less in the patch group but not statistically significant. Patch users had more breakthrough bleeding/spotting in the first two cycles, but thereafter this did not differ from the OC users. Patch users reported more breast discomfort, dysmenorrhea, and abdominal pain than the OC users, but other adverse events were uncommon and did not differ. Importantly, perfect compliance was reported for 88.2% of patch users’ cycles versus 77.7% of the pill users’ cycles (*p* < 0.001). Pregnancy risk appears to be higher for women weighing more than 90 kg.

The *NuvaRing* is 54 mm in outer diameter and has a cross section of 4 mm. It delivers daily doses of 120 µg of *etonogestrel*, the active metabolite of desogestrel, with 15 µg of *EE*. The soft, flexible ring is worn in the vagina for 3 weeks, and then removed for 1 week, after which time a new ring is inserted. In a pharmacokinetic study comparing the ring with a combination OC containing 150 µg of desogestrel and 30 µg of *EE*, maximum blood levels of *EE* with the ring were about one third of those seen with the OC, and the *etonogestrel* level was about 40% of that produced by the OC. Despite these findings, ovulation was inhibited in all women studied (96). **Women wearing the ring are reported to have fewer days of irregular bleeding/spotting than women taking an OC** with 150 µg of *levonorgestrel* and 30 µg of (186). A large study found a total pregnancy rate of 1.18 (95% CI 0.73–1.80) per 100 woman-years and 0.77 (0.37–1.40) pregnancies per 100 woman-years with perfect use (187). Some women prefer to remove the ring for intercourse, although this is not necessary. It should be reinserted within 3 hours to avoid loss of efficacy.

### Injectable Hormonal Contraceptives

**Depomedroxyprogesterone Acetate** *Depomedroxyprogesterone acetate* (*DMPA*), a suspension of microcrystals of a synthetic progestin, was approved for contraception in 1992. A single 150-mg intramuscular dose
will suppress ovulation in most women for 14 weeks or longer (188). **The regimen of 150 mg every 3 months is highly effective, producing pregnancy rates of about 0.3 per 100 women per year.** Probably because of the high blood levels of the progestin, efficacy appears not to be reduced by administration of other drugs and is not dependent on the patient’s weight. Women treated with DMPA experience disruption of the menstrual cycle and have initial spotting and bleeding at irregular intervals. Eventually, total amenorrhea develops in most women who take DMPA; with continued administration, amenorrhea develops in 50% of women by 1 year and in 80% by 3 years (Fig. 10.12). **Persistent irregular bleeding can be treated by adding low-dose estrogen temporarily;** for example, conjugated estrogens, 1.25 mg per day, can be given for 10 to 21 days at a time. Irregular bleeding with DMPA may be related to the downregulation of endometrial estrogen receptors it produces. Treatment with 50 mg of mifepristone every 2 weeks increases endometrial estrogen receptors and reduces breakthrough bleeding in new users of both DMPA and progestin implants (189). *Depomedroxyprogesterone acetate* persists in the body for several months in women who have used it for long-term contraception, and return to fertility may be delayed. In a large study, however, 70% of former users desiring pregnancy conceived within 12 months, and 90% conceived within 24 months (190).

![Figure 10.12](image-url)  
**Figure 10.12**  Bleeding pattern and duration of use of depomedroxyprogesterone acetate (DMPA): percentage of women who have bleeding, spotting, or amenorrhea while taking DMPA 150 mg every 3 months. (From Schwallie PC, Assenzo JR. Contraceptive use-efficacy study utilizing medroxyprogesterone acetate administered as an intramuscular injection once every 90 days. *Fertil Steril* 1973;24:331–339, with permission.)
Safety

Depomedroxyprogesterone acetate suppresses ovarian estrogen production, which could be expected to affect bone density. Prospective studies have demonstrated bone loss during DMPA therapy, with recovery of bone mass after DMPA use is discontinued (191). Similar bone loss and then recovery occurs with lactation. Adolescents are of especial concern because they normally gain bone mass; in fact, most of adult bone mass is attained by age 20. A small study comparing DMPA with implant or OC users found that DMPA blocked the usual rapid increase in bone density normally seen in adolescents (167,192). Estrogen injections prevented the bone loss and allowed adolescent women to gain bone density despite use of DMPA. The FDA has issued a “black box warning” proposing that DMPA treatment be limited to 2 years at a time unless the patient has no other good options for contraception.

The effect of DMPA on plasma lipids has been inconsistent; in general, DMPA users appear to have reduced total cholesterol and triglyceride levels, slight reduction in HDL cholesterol, and no change or slight increase in LDL cholesterol, all of which are consistent with a reduction in circulating estrogen levels. In some studies, the decrease in HDL and increase in LDL are statistically significant, although the values remain within normal ranges (193). The use of DMPA has not been associated with myocardial infarction. Glucose tolerance tests disclose a small elevation of glucose in DMPA users. There is no change in hemostatic parameters, with the exception that antithrombin III levels are sometimes found to be reduced with chronic therapy (193). DMPA has not been linked to thrombotic episodes in women of reproductive age. However, thrombotic episodes have occurred in elderly women with advanced cancer who were treated with a variety of agents, including DMPA and tamoxifen (194,195). Such patients are at high risk for thrombosis regardless of the use of DMPA. Women taking DMPA appear to experience a weight gain of 2 to 3 pounds more than nonusers over several years. Its use has not been associated with teratogenesis. It is safe for use by lactating women and, as with other progestin-only hormonal methods, appears to increase milk production. Depomedroxyprogesterone acetate has not been associated with affective disorders or mood changes, although the data are limited (196,197).

Benefits

Depomedroxyprogesterone acetate appears to have many of the noncontraceptive benefits of combination oral contraceptives (184). Decreases in anemia, PID, ectopic pregnancy, and endometrial cancer have been reported. No association between DMPA and cervical cancer has been demonstrated (198). Ovarian cancer has been found to be unrelated to the use of DMPA (199). The risk of breast cancer during the first 4 years of use appears to be slightly increased, but there is no relation to long-term use and no overall increase in breast cancer risk; hence, any causal relationship between DMPA and breast cancer is unlikely (200).

Subcutaneous DMPA

Depo-subQ Provera 104, a new lower-dose DMPA preparation for subcutaneous administration, received FDA approval in 2005. The total dose is 30% less than that of the older DMPA intramuscular preparation. Because the dose is administered subcutaneously, blood levels are adequate to completely suppress ovulation for more than 13 weeks in all subjects tested, with a mean time of 30 weeks for return to ovulatory function (201). Contraception efficacy is superb, with no pregnancies in a total of 16,023 woman-cycles in the phase three studies done in the United States (202). Blood levels were lower in very obese women but still sufficient to suppress ovulation completely. The weight gain reported with the 150 mg DMPA remained a problem with the lower dose DMPA: Mean weight gain was 3.5 lb in the first year of use. Unfortunately, loss of bone density was observed with this dosage of DMPA, as with the larger intramuscular
dose. The FDA warning still applies against use beyond 2 years unless other methods of contraception are inadequate for the patient.

**Once-a-Month Injectable**

A once-a-month injectable contraception containing only 25 mg of *DMPA* in combination with 5 mg of the long-acting estrogen *estradiol cypionate* was briefly available in the United States, but was withdrawn by the manufacturer because of a packaging problem (184). Originally developed by the World Health Organization, it is described as *CycloFem* or *CycloProvera* in the literature and was marketed in the United States as *Lunelle* (203). Given once a month, this combination produces excellent contraceptive effects. Monthly withdrawal bleeding is similar to a normal menses, leading to high continuation rates despite the need for a monthly injection (204). Whether it will be reintroduced into the United States is uncertain.

**Subdermal Implants**

*Levonorgestrel* subdermal implants are no longer available in the United States. The original *Levonorgestrel* implant (*Norplant*) consisted of six rods.

A two-rod version (*Jadelle™, Norplant II*) is as effective as *Norplant* and easier to insert and remove (205). The two-rod system is marketed in Europe and has been approved by the FDA, but it currently is not marketed in the United States.

*Implanon* is a single-rod subdermal system containing *etonogestrel*, the metabolite of *desogestrel* used in the *NuvaRing*. FDA approval is expected soon. The implant releases 60 μg of *etonogestrel* per day, enough to completely inhibit ovulation for at least 3 years. The single-rod system is easily inserted and removed. In the United States trial, mean time for insertion was only 0.5 minute, and removal required a mean time of 3.5 minutes (206). There were no pregnancies in 474 woman-years of use. In fact, no pregnancies have occurred in worldwide clinical trials including many thousands of women. Irregular bleeding is a problem but occurs most frequently in the first 90 days of use and decreases over time. This is the main reason given by women for discontinuing use. The other most commonly reported side effects are headache, vaginitis, acne, dysmenorrhea, and emotional lability. In the United States trial, with 330 women participating, two adverse effects were considered serious and possibly related to the implant: one ruptured ovarian follicular cyst and one acute exacerbation of depression (206). The *etonogestrel* implant offers amazing efficacy and convenience, and because it contains no estrogen, it should not be associated with an increased risk of thrombosis.

**Emergency Contraception**

Implantation of the fertilized ovum is believed to occur on the sixth day after fertilization. This interval provides an opportunity to prevent pregnancy even after fertilization occurs. Prevention of pregnancy can be accomplished using hormonal agents, singly or in combination, or IUDs.

**Estrogens**

The principle of emergency contraception was first demonstrated with high-dose estrogen, which taken within 72 hours of coitus prevents pregnancy. The mechanism of action of postcoital estrogen use may involve altered tubal motility, interference with corpus luteum function mediated by prostaglandins, or alteration of the endometrium. In an analysis of more than 3,000 women treated after coitus with 5 mg of *EE* daily for 5 days, the pregnancy rate was 0.15% (207).

**Estrogen and Progestin in Combination**

High-dose estrogen was replaced by the combination of *EE* 0.200 mg and *levonorgestrel* 2 mg (2 *Ovral* tablets followed by 2 more tablets 12 hours later), as first described by
Levonorgestrel Alone

Levonorgestrel alone, 0.75 mg initially followed by another 0.75 mg 12 hours later, is more effective than the combination of EE and lower-dose levonorgestrel and is clearly the emergency contraceptive method of choice at present. This preparation is sold in the United States as Plan B. The World Health Organization conducted a randomized trial with 1,998 women assigned to the Yuzpe method or to levonorgestrel alone, started within 72 hours of intercourse. The pregnancy rate was 3.2% with the Yuzpe method, and only 1.1% with levonorgestrel alone (RR for pregnancy, 0.32; 95% CI, 0.18–0.70). Nausea and vomiting occurred much less frequently with levonorgestrel alone (23.1% versus 50.5%, and 5.6% versus 18.8%, respectively) (211). The efficacy of both methods declines as time since intercourse increases. Even after 49 to 72 hours, however, the pregnancy rate with the levonorgestrel treatment was only 2.7% (Fig. 10.13). A single dose of 1.5 mg levonorgestrel is just as effective as two doses of 0.75 mg, has no more side effects, and is more convenient for the patient (212). There is evidence these doses of levonorgestrel have almost as much efficacy at 3 to 5 days after intercourse; hence, women who present after 3 days but before 5 days should not be refused treatment.
Four cases of cerebrovascular events have been reported in women who used the Yuzpe method. One of them had preexisting severe migraine. No cerebrovascular complications have been reported with levonorgestrel emergency contraception. Neither deep vein thrombosis nor pulmonary embolism has been reported with either method (213).

Copper Intrauterine Device

Postcoital insertion of a copper IUD within 7 days appears to be even more effective than steroids for emergency contraception (214). In 879 patients treated with an IUD, only one pregnancy occurred (207). No pregnancies occurred during the first month after insertion of copper IUDs as long as 7 days after coitus. It is likely that the levonorgestrel IUD would also work for this purpose, but there are as yet no studies of its use after coitus.

Danazol

A weak androgen, danazol has also been used for emergency contraception. The pregnancy rate was 2% among 998 women (207). Levonorgestrel is a better choice because of low cost and fewer side effects.

Mifepristone

The antiprogesterone mifepristone (RU486) is also highly effective for postcoital contraception and appears to have no significant side effects. The usual abortifacient dose is 200 mg, but a dose of only 10 mg is effective for emergency contraception. In one study, 2,065 women were randomized to either mifepristone, 10 mg, or levonorgestrel, two doses of 0.75 mg, and included women up to 120 hours after intercourse (215). The crude pregnancy rate was 1.3% for mifepristone and 2.0% for levonorgestrel (p = 0.46). Side effects were the same, and both methods were judged highly acceptable by the subjects. Mifepristone is also highly effective in inducing menstruation when taken on day 27 of the menstrual cycle, well beyond the 72- to 120-hour window usually considered for postcoital contraception. Of 62 women treated in this fashion with 600 mg of mifepristone, only one conceived (207).

Contraception for Women with Chronic Illness

Women with chronic illness may present special problems that should be considered in the choice of a method of contraception. The illness may make pregnancy more complicated and dangerous for these women, thus making effective contraception all the more important. Some common conditions and considerations about contraception are listed in Table 10.8. For many women, an important strategy is to prescribe a progestin-only method and to avoid estrogen-containing hormonal contraceptives (184).

Hormonal Contraception for Men

The same negative feedback of sex steroids that can block ovulation in women will also suppress spermatogenesis in men, but it will produce loss of libido and potentially extinguish sexual performance. The principle was first demonstrated in 1974 using oral estrogen and methyl testosterone (216). Testosterone given alone can suppress sperm production to very low levels while maintaining normal libido and sexual performance. Over many years investigators have studied long-acting testosterone salts for male contraception (217,218). Ethnicity is an important predictor of efficacy of sperm suppression with testosterone therapy. Asian men virtually always achieve azospermia or oligospermia when treated with testosterone undecanoate, 500 to 1,000 mg monthly, whereas only 86% of white men achieved oligospermia or azospermia with similar testosterone regimens (218). However, pregnancy has occurred in partners of androgen-treated oligospermic men with sperm counts as low as 3 million/mL (219).

Combining testosterone with a progestin allows a lower dose of the androgen with efficacy comparable to use of testosterone alone. One promising regimen combined injections of
SECTION III  Preventive and Primary Care

Table 10.8 Contraception for Women with Chronic Illness

### Psychiatric disorders
- OCs, implants, DMPA, and IUDs are good choices.
- Use of barrier methods should be encouraged to decrease risk for STDs.

### Coagulation disorders
- Hemorrhagic disorders: OCs may be indicated to prevent hemorrhagic ovarian cysts and menstrual hemorrhage.
- Thrombotic disorders: Avoid estrogen-containing OCs.

### Dyslipidemia
- May use low-dose OCs if lipid abnormality is successfully managed by diet or drug therapy, but lipids should be monitored at 3–6 months.
- Avoid OCs if triglycerides are elevated.
- Select less androgenic OCs.
- Progestin-only OCs, DMPA, and IUDs are acceptable.

### Hypertension
- Young women with no other risk factors with well-controlled hypertension may use low-dose OCs under close supervision.
- Older women, smokers, and those with poorly controlled hypertension should probably avoid combination OCs.
- DMPA, Norplant, IUDs, and progestin-only OCs are good alternatives.

### Diabetes
- Young diabetic women without vascular disease can use low-dose OCs.
- Older women or women with vascular disease probably should not use combination OCs.
- DMPA, Norplant, IUDs, and progestin-only OCs are good alternatives.

### Headache
- Migraine without aura, without neurologic symptoms, does not rule out OCs if use is closely supervised.
- Norplant and DMPA may be used safely.

### Epilepsy
- OCs do not increase the risk for seizure, but antiseizure drugs reduce efficacy of OCs and Norplant.
- OCs with 50 μg estrogen can be used, as can DMPA. IUDs are not contraindicated.

DMPA, depomedroxyprogesterone acetate; IUD, intrauterine device; OCs, oral contraceptives; STDs, sexually transmitted diseases.

**testosterone undecanoate** with **norethindrone enanthate** given at 6-week intervals. This regimen produced azospermia in 90% of subjects (220). Adverse lipid changes have been noted with DMPA and androgen combinations, raising concern about vascular disease with prolonged use. Liver cancer is also a concern with long-term androgen therapy (221).

### Sterilization
Surgical sterilization is the most common method of fertility control used by couples in the United States (4). Laparoscopic techniques for women and vasectomy for men are safe and readily available throughout the United States. The mean age at sterilization is 30 years. Age younger than 30 years when sterilized and divorce and remarriage are predictors of sterilization regret, which may lead to a request for reversal of sterilization (222).
Female Sterilization

Hysterectomy is no longer considered for sterilization because morbidity and mortality are too high in comparison with tubal sterilization. Vaginal tubal sterilization, which has been associated with occasional pelvic abscess, is rarely performed in the United States. Five procedures are used in the United States.

1. Tubal sterilization at the time of laparotomy for a cesarean delivery or other abdominal operation
2. Postpartum minilaparotomy soon after vaginal delivery
3. Interval minilaparotomy
4. Laparoscopy
5. Hysteroscopy

Postpartum tubal sterilization at the time of cesarean delivery adds no risk other than a slight prolongation of operating time; however, cesarean birth poses more risk than vaginal birth, and planned sterilization should not influence the decision to perform a cesarean delivery. Minilaparotomy can be performed in the immediate postpartum state. The uterus is enlarged, and the fallopian tubes lie in the midabdomen, easily accessible through a small, 3- to 4-cm subumbilical incision.

Interval minilaparotomy, first described by Uchida (223), was rediscovered and popularized in the early 1970s in response to the increased demand for sterilization procedures and a simpler alternative to laparoscopy. In the nongravid state, the uterus and tubes lie deep in the pelvis. A short transverse suprapubic incision is made, and the uterus and tubes are then elevated upward, just beneath the incision, by use of a uterine-elevating probe placed into the uterine cavity through the vagina. Interval minilaparotomy is usually performed as an outpatient procedure and can be accomplished readily with local anesthesia and conscious sedation.

**Surgical Technique**

The procedure usually elected for tubal sterilization is the Pomeroy or modified Pomeroy technique (Fig. 10.14). In the classic Pomeroy procedure, a loop of tube is excised after ligating the base of the loop with a single absorbable suture. A modification of the procedure is excision of the midportion of the tube after ligation of the segment with two separate absorbable sutures. This modified procedure has several names: partial salpingectomy, Parkland Hospital technique, separate sutures technique, and modified Pomeroy. In the Madlener technique, now abandoned because of too many failures, a loop of tube is crushed by cross-clamping its base, ligated with permanent suture, and then excised. Pomeroy and partial salpingectomy procedures have failure rates of 1 to 4 per 1,000 cases (224). In contrast, pregnancy is almost unheard of after tubal sterilization by the Irving or Uchida methods (223,225). In the Irving method, the midportion of the tube is excised, and the proximal stump of each tube is turned back and led into a small stab wound in the wall of the uterus and sutured in place, creating a blind loop. With the Uchida method, a saline-epinephrine solution (1:1,000) is injected beneath the mucosa of the midportion of the tube, separating the mucosa from the underlying tube. The mucosa is incised along the antimesenteric border of the tube, and a tubal segment is excised under traction so that the ligated proximal stump will retract beneath the mucosa when released. The mucosa is then closed with sutures, burying the proximal stump and separating it from the distal stump. In Uchida’s personal series of more than 20,000 cases, there were no pregnancies (223).
Laparoscopy

In the standard laparoscopy technique, the abdomen is inflated with a gas (carbon dioxide or nitrous oxide) through a special needle inserted at the lower margin of the umbilicus (226). A hollow sheath containing a pointed trocar is then pushed through the abdominal wall at the same location, the trocar is removed, and the laparoscope is inserted into the abdominal cavity through the sheath to visualize the pelvic organs. A second, smaller trocar is inserted in the suprapubic region to allow the insertion of special grasping forceps. Alternatively, an operating laparoscope that has a channel for the instruments can be used; thus, the procedure can be performed through a single small incision. Laparoscopic sterilization is usually performed in the hospital under general anesthesia but can be performed under local anesthesia with conscious sedation. Overnight hospitalization for laparoscopy is rarely needed.

Open Laparoscopy

Standard laparoscopy carries with it a small but definite risk for injury to major blood vessels with insertion of the sharp trocar. With the alternative technique of open laparoscopy, neither needle nor sharp trocar is used; instead, the peritoneal cavity is opened directly through an incision at the lower edge of the umbilicus (227). A special funnel-shaped sleeve, the Hasson cannula, is then inserted, and the laparoscope is introduced through it.

Techniques of Laparoscopic Sterilization

Sterilization is accomplished by any of four techniques: bipolar electrical coagulation, application of a small Silastic rubber band (Falope ring) (228), the plastic and metal Hulka clip (226), or the Filshie clip (229). The Filshie clip is new to the United States, although it has been used extensively in the United Kingdom and Canada (230). It is a hinged device made of titanium with a liner of silicone rubber tubing.

In the bipolar electrocoagulation technique, the midisthmic portion of the tube and adjacent mesosalpinx are grasped with special bipolar forceps, and radiofrequency electric current is applied to three adjacent areas, coagulating 3 cm of tube (Fig. 10.15). The tube alone is then recoagulated in the same places. The radiofrequency generator must deliver...
at least 25 watts into a 100-ohm resistance at the probe tips to ensure coagulation of the complete thickness of the fallopian tube and not just the outer layer; otherwise, the sterilization will fail (231).

To apply the Falope ring, the midisthmic portion of the tube is grasped, with tongs advanced through a cylindrical probe that has the ring stretched around it. A loop of tube is pulled back into the probe, and the outer cylinder is advanced, releasing the Silastic ring around the base of the loop of tube, producing ischemic necrosis (Fig. 10.16). If the tube cannot be pulled easily into the applicator, the operator should stop and change to electrical coagulation rather than persist and risk lacerating the tube with the Falope ring applicator. The banded tube must be inspected at close range through the laparoscope to demonstrate that the full thickness of the tube has been pulled through the Falope ring.

The Hulka clip is also placed across the midisthmus, ensuring that the applicator is at right angles to the tube and that the tube is completely contained within the clip before the clip is closed. The Filshie clip (Fig. 10.17) is also placed at right angles across the midisthmus, taking care that the anvil of the posterior jaw can be visualized through the mesosalpinx beyond the tube to ensure that the complete thickness of the tube is completely within the jaws of the clip before it is closed.

The electric and band or clip techniques each have advantages and disadvantages. Bipolar coagulation can be used with any fallopian tube. The Falope ring and Hulka and Filshie clips cannot be applied if the tube is thickened from previous salpingitis. There is more pain during the first several hours after Falope ring application. This can be prevented by bathing the tubes with a few milliliters of 2% lidocaine just before ring placement. Failures of the Falope ring or the clips generally result from misapplication, and pregnancy, if it occurs, is usually intrauterine. After bipolar sterilization, pregnancy may result from tuboperitoneal fistula and is ectopic in more than 50% of cases. If inadequate electrical energy is used, a thin band of fallopian tube remains that contains the intact lumen and allows intrauterine pregnancy to occur. Thermocoagulation, the use of heat probes rather than electrical current, is employed extensively in Germany for laparoscopic tubal sterilization but has had little use in the United States.

Figure 10.15 Technique for bipolar electrocoagulation tubal sterilization.
Hysteroscopy

In 2002, the FDA approved a new hysteroscopic method of permanent birth control: the *Essure* system. *Essure* is a microinsert consisting of a soft stainless steel inner coil and a dynamic nickel titanium alloy outer coil (Fig. 10.18). The device is introduced into the uterus with a 5-mm operating channel hysteroscope and guided into the proximal section of the Fallopian tube at the uterotubal junction (Fig. 10.19). Over time, fibrous tissue grows into the device, occluding the tubes permanently. Placement of *Essure* can be performed under local anesthesia in an outpatient setting. No incision is needed. A non-steroidal antiinflammatory drug is given 1 to 2 hours before the procedure to decrease tubal spasm. The hysteroscope is introduced through the cervix, and the uterus is distended with saline. The tubal ostia are visualized. The *Essure* device is inserted through the operating channel of the hysteroscope on the end of a slender delivery wire and guided into the tubal opening and advanced into the tube. Once in place, an outer sheath is retracted, releasing the microinsert, which expands to anchor it in place. The delivery wire is detached and

![Figure 10.16 Placement of the Falope ring for tubal sterilization.](image)
removed and the procedure repeated for the other tube. When properly placed, three to eight of the end coils of the microinsert are visible inside the uterus. The rest is inside the fallopian tube (232). Currently the FDA requires a 3-month follow-up x-ray hysterosalpingography examination to document tubal occlusion. The patient should continue to use contraception until this is demonstrated.

**Risks of Tubal Sterilization**

*Tubal sterilization is remarkably safe.* In 1983, the total complication rate in a large series from several institutions was 1.7 per 100 (233). Complications were increased by use of general anesthesia, previous pelvic or abdominal surgery, history of PID, obesity, and diabetes mellitus. The most common significant complication was unintended laparotomy for sterilization after intraabdominal adhesions were found. In another series, 2,827 laparoscopic sterilizations were performed with the Silastic band using local anesthesia and intravenous sedation. Only four cases could not be completed (a technical failure rate of 0.14%), and laparotomy was not needed (234). Rarely, salpingitis can occur as a complication of the surgery. This occurs more often with electric coagulation than nonelectric techniques. From 1977 to 1981, there were 4 deaths per 100,000 procedures in the United States, less than the risk of one pregnancy; almost one half of the deaths were from complications of general anesthesia, usually related to the use of mask ventilation (235). The last
U.S. national study was of sterilizations performed from 1979 to 1980. There were a total of 9 to 10 deaths per 100,000 sterilizations, but only 1 to 2 per 100,000 were attributed to the sterilization procedure alone (236). When general anesthesia is used for laparoscopy, endotracheal intubation is mandatory because the pneumoperitoneum increases the risk of aspiration. International data from the Association for Voluntary Surgical Contraception show a similar record of safety from third world programs: 4.7 deaths per 100,000 female sterilizations and 0.5 deaths per 100,000 vasectomies (237).

Family Health International has reported large randomized multicenter trials of the different means of tubal sterilization. The Filshie and Hulka clips were compared in two trials. A total of 2,126 women were studied, of which 878 had either clip placed by minilaparotomy and 1,248 had either clip placed by laparoscopy. The women were then evaluated at up to 24 months (238). Pregnancy rates were 1.1 per 1,000 women with the Filshie clip and 6.9 per 1,000 with the Hulka clip at 12 months, a difference in rates that approached statistical significance \( p = 0.06 \). This same group compared the Filshie clip with the Silastic tubal ring in a similar study with a total of 2,746 women, of which 915 had the devices placed at minilaparotomy and 1,831 at laparoscopy (239). Pregnancy rates at 12 months were the same for the Filshie clip and the tubal ring: 1.7 per 1,000 women. The ring was judged more difficult to apply, but the Filshie clip was expelled spontaneously by three women during the 12 months of follow-up.

Possible but uncommon risks of the Essure system of hysteroscopic tubal sterilization include perforation of the device at insertion and expulsion of the device. There is theoretical risk of mutagenic or carcinogenic effect to the fetus from nickel alloy should pregnancy occur, although no such injury has been reported (232).

**Benefits of Tubal Sterilization**

In addition to providing excellent contraception, tubal ligation is associated with reduced risk for ovarian cancer that persists for as long as 20 years after surgery (240).

**Sterilization Failure**

Many “failures” occur during the first month after laparoscopy and are the result of a pregnancy already begun when the sterilization was performed. Contraception should be continued until the day of surgery, and a sensitive pregnancy test should be routinely performed on the day of surgery. Because implantation does not occur until 6 days after conception, however, a woman could conceive just before the procedure and...
there would be no way to detect it. Scheduling sterilization early in the menstrual cycle obviates the problem but adds to the logistic difficulty. Another cause of failure is the presence of anatomic abnormalities, usually adhesions surrounding and obscuring one or both tubes. An experienced laparoscopic surgeon with appropriate instruments usually can lyse the adhesions, restore normal anatomic relations, and positively identify the tube. In some circumstances, however, successful sterilization will not be possible by laparoscopy, and the surgeon must know before surgery whether the patient is prepared to undergo laparotomy, if necessary, to accomplish sterilization. Most studies of sterilization failure are short term. The Centers for Disease Control and Prevention’s Collaborative Review of Sterilization (CREST) reported on a cohort of 10,685 women sterilized from 1978 to 1986 at any of 16 participating centers in the United States who were followed from 8 to 14 years (241). The true failure rates for 10 years obtained by the life-table method are given in Table 10.9. Pregnancies resulting from sterilization during the luteal phase of the cycle in which the surgery was performed were excluded. Of all remaining pregnancies, 33% were ectopic. The most effective methods at 10 years were unipolar coagulation at laparoscopy and postpartum partial salpingectomy, generally a modified Pomeroy procedure. Bipolar tubal coagulation and the Hulka-Clemens clip were least effective. Younger women had higher risk for failure, as would be expected because of their greater fecundity.

Over the years since the CREST study began, sterilization by unipolar electrosurgery was abandoned because of the risk of bowel burns and was replaced with bipolar electrosurgery or the nonelectric methods (tubal ring, Hulka-Clemens clip, and more recently, the Filshie clip). An important later analysis of the CREST data found that bipolar sterilization could have a very low long-term failure rate if an adequate portion of the tube is coagulated. CREST study subjects who were sterilized with bipolar electrosurgery from 1985 to 1987 had lower failure rates than those sterilized earlier (1978–1985). The important difference was in the technique of application of the electric energy to the tubes. Women whose bipolar procedure involved coagulation at three sites or more had low 5-year failure rates (3.2 per 1,000 procedures), whereas women who had fewer than three sites of tubal coagulation had a 5-year failure rate of 12.9 per 1,000 (p = 0.01) (242).

In a large multicenter study, the Essure microinsert was successfully placed in 92% of the 707 women treated. Reasons for failure of insertion were tubal obstruction or stenosis or difficulty in accessing the tubal ostia. Correct placement was confirmed at 3 months in 96%, and complete bilateral occlusion occurred in 92%. Of those patients with complete occlusion, there were no pregnancies in 5,305 woman-months of use (243).

| Table 10.9 Ten-year Life-table Cumulative Probability of Pregnancy per 1,000 Procedures with Different Methods of Tubal Sterilization, United States, 1978–1986 |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Unipolar coagulation | 7.5 | Postpartum partial salpingectomy | 7.5 | Silastic band (Falope or Yoon) | 17.7 | Interval partial salpingectomy | 20.1 |
| Bipolar coagulation | 24.8 | Hulka-Clemens clip | 36.5 | Total: all methods | 18.5 |

**Reversal of Sterilization**

Reversal of sterilization is more successful after mechanical occlusion because the latter method destroys much more of the tube. With modern microsurgical techniques and an isthmus-to-isthmus anastomosis, pregnancy follows in about 75% of cases (244). A substantial risk for ectopic pregnancy exists after reversal. Hysteroscopic sterilization by the *Essure* procedure should be considered irreversible. Reversal has not been reported and would have to involve cornual resection and reimplantation of the fallopian tubes, a procedure with a very low success rate.

**Late Sequelae of Tubal Sterilization**

Increased menstrual irregularity and pain have been attributed to previous tubal sterilization. In patients who underwent the older laparoscopy technique with unipolar electrical destruction of a major portion of the tube, these concerns may be warranted (245). Study of the problem is complicated by the many women develop these symptoms even though they have not had tubal surgery and OCs reducing pain and creating an artificially normal menstrual cycle. Therefore, women who discontinued OC use concurrent with tubal sterilization will experience more dysmenorrhea, which is entirely unrelated to the sterilization. The best answer available also comes from the CREST study (246). A total of 9,514 women who had undergone tubal sterilization were compared with 573 women whose partners had undergone vasectomy. Both groups were followed up to 5 years with annual standardized telephone interviews. Women who had undergone tubal sterilization were no more likely to report persistent changes in intermenstrual bleeding or length of the menstrual cycle than women whose partners had vasectomy. The sterilized women, in fact, reported decreases in days of bleeding, amount of bleeding, and menstrual pain but were slightly more likely to report cycle irregularity (OR, 1.6; 95% CI, 1.1–2.3). Hence, the CREST study found no evidence to support the existence of a post–tubal ligation syndrome.

**Vasectomy**

Vasectomy, excision of a portion of the vas deferens, is readily accomplished with local anesthesia in an office setting. It does not decrease sexual performance (247). The basic technique is to palpate the vas through the scrotum, grasp it with fingers or atraumatic forceps, make a small incision over the vas, and pull a loop of the vas into the incision. A small segment is removed, and then a needle electrode is used to coagulate the lumen of both ends. Improved techniques include the no-scalpel vasectomy, in which the pointed end of the forceps is used to puncture the skin over the vas. This small variation reduces the chance of bleeding and avoids the need to suture the incision. Another variation is the open-ended vasectomy, in which only the abdominal end of the severed vas is coagulated while the testicular end is left open. This is believed to prevent congestive epididymitis (248).

**Reversibility**

Vasectomy must be regarded as a permanent means of sterilization; however, with microsurgical techniques, vasovasostomy will result in pregnancy about one half the time. The longer the interval since vasectomy, the poorer is the chance of reversal.

**Safety**

Operative complications include scrotal hematomas, wound infection, and epididymitis, but serious sequelae are rare. There have been no reports of deaths from vasectomy in the United States in many years, and the death rate in a large third world series was only 0.5 per 100,000. Studies of vasectomized monkeys showed accelerated atherosclerosis, but several large-scale human studies have found no connection between vasectomy and vascular disease (249,250). Concerns about long-term safety recurred with the report of a possible association between prostate cancer and vasectomy (251). Prostate cancer is largely a disease of the western world and is strongly linked to dietary intake of animal fat,
family history, and race (252). In the west, it is more common in men of African American ancestry and rare in men of Asian descent. Recent studies are reassuring. A large, multi-ethnic, case control study from the United States and Canada compared 1,642 men with prostate cancer to 1,636 controls and found no overall association (OR, 1.1; 95% CI, 0.83–1.3) (253). A large case control study from Washington state reached the same conclusion (254). This study was especially important because of the high use of vasectomy in the community studied. Older reports may reflect bias, perhaps that higher-status men, with diets higher in animal fat, were more likely than lower-status men to choose vasectomy.

Abortion

Given the desire in developed countries to limit families to one or two children and the efficacy of contraception in general use, it is extremely likely that any normal couple will experience at least one unwanted pregnancy at some time during their reproductive years. In third world countries, desired family size is larger, but access to effective contraception is limited. As a result, abortion is common. Worldwide, about 46 million women have abortions each year, and about half of these procedures are illegal and considered “unsafe” by the World Health Organization definition: procedures carried out either by an unskilled person or in unsafe conditions, or both (255). Where abortion is legal, it is generally reasonably safe; where it is illegal, complications are common, and about 78,000 women die every year from these complications (255). Societies cannot prevent abortion, but they can determine whether it will be illegal and dangerous or legal and safe. Many countries in which abortion is completely illegal have very high rates of clandestine abortion. Abortion rates in representative countries are given in Table 10.10 (256).

Death from illegal abortion was once common in the United States. In the 1940s, more than 1,000 women died each year of complications from abortion (257). In 1972, 24 women died of complications of legal abortion and 39 died from known illegal abortions. In 2000, the last year for which complete data are available, there were 11 deaths from legally induced abortion, and no deaths from illegal abortion (abortion induced by a nonprofessional) in the entire United States (258). The American Medical Association’s Council on Scientific Affairs has reviewed the impact of legal abortion and attributes the decline in deaths during this century to the introduction of antibiotics to treat sepsis; the widespread use of effective contraception beginning in the 1960s, which reduced the number of

SECTION III Preventive and Primary Care

unwanted pregnancies; and, more recently, the shift from illegal to legal abortion (259). The United States has a serious problem with teenage pregnancy. Without legal abortion, there would be almost twice as many teenage births each year.

The number of abortions reported each year in the United States—1,313,000 in 2000 according to the Alan Guttmacher Institute—has been decreasing since the 1980s (260). In 2001, the national abortion ratio was 246 abortions for every 1,000 live births, and the national abortion rate was 16 per 1,000 women aged 15 to 44 years. Most women who obtain abortions are unmarried (82% in 2001), and the ratio of abortions to live births is 9 times higher for unmarried women than for married women (261). Use of abortion varies markedly with age. In 2001, 18% of women obtaining abortions were 19 years of age or younger, and 51.3% were 24 years of age or younger. In 2001, the abortion ratio for women younger than 15 years of age was 744 per 1,000 live births, almost as many abortions as births (Fig. 10.2). The lowest abortion ratio, 147 per 1,000 live births, is for women aged 30 to 34 years. Legal abortion rates and ratios reached their highest in the early 1980s as they replaced illegal abortions, and both have declined since, especially for the youngest women (Fig. 10.20) (258).

Regardless of personal feelings about the ethics of interrupting pregnancy, health professionals have a duty to know the medical facts about abortion and to share them.

with their patients (261). Providers are not required to perform abortions against their ethical principles, but they have a duty to help patients assess pregnancy risks and to make appropriate referrals.

Safety

The overall annual risk of death with legal abortion has decreased markedly, from 4.1 per 100,000 in 1972 to 1.8 in 1976, and has remained less than 1 per 100,000 since 1987. Risk of death with vacuum curettage was 0.1 per 100,000 at or before 8 weeks in 1993 to 1997 and 0.2 per 100,000 at 9 to 10 weeks (262). Risk increases exponentially with gestational age, reaching 2.7 per 100,000 for dilatation evacuation abortion at 16 to 20 weeks, and 7.2 per 100,000 at 21 weeks or more. The maternal mortality rate in the United States is 7 to 8 per 100,000; hence, abortion by dilation and evacuation (D&E) is safer than continuing pregnancy through 20 weeks. It has been estimated that 87% of the legal abortion deaths occurring after 8 weeks would have been prevented had the woman been able get abortion services by 8 weeks (263).

For individual women with high-risk conditions (e.g., cyanotic heart disease), even late abortion is a safer alternative to birth. Because of the availability of low-cost, out-of-hospital, first-trimester abortion, 88% of legal abortions are performed during the first trimester (before 13 weeks of amenorrhea), when abortion is the safest. The type of procedure is another determinant of risk. First-trimester abortions are virtually all performed by vacuum curettage; however, in the midtrimester, a variety of techniques can be used. The last published national review by both gestational age and type of procedure was for the period 1973 to 1987 (264) (Table 10.11). The data clearly show the greater safety of instrumental evacuation of the uterus (D&E) performed in the early midtrimester.

Techniques for First-trimester Abortion

Vacuum Curettage

Most first-trimester abortions are performed by vacuum curettage. Most are performed with local anesthesia with or without conscious sedation, and usually on an outpatient basis in a freestanding specialty clinic or doctor’s office (265). Cervical dilatation is accomplished with metal dilators, or by laminaria tents or misoprostol, 400 μg, given vaginally or by the buccal route 3 to 4 hours before the procedure (266). Plastic vacuum cannula of 5- to 12-mm diameter are used with a manual vacuum source or an electric vacuum pump. Manual vacuum provided by a modified 50-mL syringe has been found as effective as the electric pump through 10 menstrual weeks (267). Doxycycline or minocycline generally are given to prevent infection and have been proven effective (268).

Complications of a large number of vacuum curettage procedures before 14 weeks of gestation from Planned Parenthood of New York City are presented in Table 10.12. Mild infection not requiring hospitalization and retained tissue or clot requiring resuctioning in the clinic were the most common complications. Somewhat fewer than 1% experienced any complication, and fewer than 1/1,000 were hospitalized (269). More extensive descriptions of the management of complications are published elsewhere (270,271).

### Medical Means for First-trimester Abortion

*Mifepristone (RU486)*, an analogue of the progestin *norethindrone*, has strong affinity for the progesterone receptor but acts as an antagonist, blocking the effect of natural progesterone. Given alone, the drug was moderately effective in causing abortion of early pregnancy; however, the combination of *mifepristone* with a low dose of *prostaglandin* proved very effective, producing complete abortion in 96% to 99% of cases (272). The FDA approved a protocol of *mifepristone*, 600 mg orally, followed 2 days later by *misoprostol*, 400 mg, also taken orally in women no more than 49 days from start of the last menstrual period. However, investigators have determined that 200 mg of *mifepristone* is as effective as 600 mg, and vaginal *misoprostol*, 800 µg, provides high efficacy within 63 days of amenorrhea (273,274). The *misoprostol* can be taken at 24, 48, or 72 hours after *mifepristone* with equal efficacy (275). Women may safely self-administer the *misoprostol* at home (276). *Contraindications to medical abortion with mifepristone/misoprostol include ectopic pregnancy; an IUD in place (remove IUD first); chronic adrenal failure;..."
concurrent long-term corticosteroid therapy; history of allergy to mifepristone, misoprostol, or other prostaglandin; and the inherited porphyries (277). The mifepristone–misoprostol combination has been studied for gestations at 9 to 13 weeks; although it is almost as effective as earlier in pregnancy, a larger proportion of patients will experience heavy bleeding and require vacuum curettage (278).

**Methotrexate–Misoprostol and Misoprostol Alone**

The antifolate methotrexate provides another medical approach to pregnancy termination but takes longer than the technique using mifepristone/misoprostol (279). Medical abortion can also be induced with misoprostol alone. Vaginal misoprostol, 800 µg, repeated in 24 hours if fetal expulsion has not occurred, produces a complete abortion in 91% of pregnancies up to 56 days of amenorrhea (280).

**Complications of Medical Abortion**

Heavy or prolonged bleeding is the principal complication, with up to 8% of women experiencing some bleeding for as long as 30 days (277). Need for surgical curettage is predicted by gestational age when the mifepristone is administered. Two percent of women treated at 49 days or less, 3% of those treated at 50 to 56 days, and 5% of those treated at 57 to 63 days needed curettage for bleeding or failed abortion in a large study with 200 mg of mifepristone and 800 µg of vaginal misoprostol (281). Late bleeding, at 3 to 5 weeks after expulsion of the pregnancy, accounted for more than half of the curettages. The complications reported to the manufacturer of mifepristone from the first 80,000 patients treated have been published (282). One woman died of ectopic pregnancy after refusing care. Another patient survived severe sepsis, and another, a 21-year-old woman with no risk factors, survived an acute myocardial infarction. Other severe sepsis cases have since occurred. A 27-year-old woman participating in a clinical trial in Canada died of multiple organ system failure from Clostridium sordelli sepsis after complete expulsion of a 5.5-week pregnancy despite receiving excellent care (283). Four other similar sepsis deaths have been reported in the popular press. **The five deaths in the United States occurred among approximately 500,000 women treated with mifepristone/misoprostol, allowing estimation of a case fatality rate of one per 100,000, comparable to the rate of death with surgical abortion and much less than the risk of childbirth** (284).

**Second-trimester Abortion**

Abortions performed after 13 weeks include those done because of fetal defects, medical illness, or psychiatric problems that had not manifested earlier in pregnancy, and changed social circumstances, such as abandonment by the father. Young age is the single greatest factor determining the need for late abortion. In 2001, 25.8% of abortions in women younger than 15 years of age were midtrimester, whereas 16.9% of abortions for women 15 to 19 years of age and only 9.2% of abortions for women 30 to 34 years of age were performed after 12 weeks of gestation (258). These proportions have changed little in a decade.

**Dilation and Evacuation**

Dilation and evacuation (D&E) is the most commonly used method of midtrimester abortion in the United States. Typically, the cervix is prepared by insertion of hygroscopic dilators, stems of the seaweed Laminaria japonicum (laminaria). Placed in the cervical canal as small sticks, these devices take up water from the cervix and swell, triggering dilation. When the laminaria are removed the following day, sufficient cervical dilation is accomplished to allow insertion of strong forceps and a large-bore vacuum cannula to extract the fetus and placenta (285,286). Ultrasound guidance during the procedure is helpful (287). For more advanced procedures, laminaria are inserted sequentially over 2 or more days to achieve a greater degree of cervical dilation (288). At the end of the midtrimester, procedures
that combine serial multiple laminaria dilation of the cervix with intrafetal injection of digoxin, induction of labor, and assisted expulsion of the fetus are used (289). Pretreatment with buccal misoprostol, 600 mg 2 to 4 hours before the procedure, is reported either to produce sufficient dilation to 14 mm or to permit easy forcible dilation to this diameter and is increasingly replacing laminaria in the early midtrimester (290).

Intact D&E is another modification useful for procedures at the end of the midtrimester. After wide cervical dilatation is achieved with multiple laminaria, the membranes are ruptured and an assisted breech delivery performed, with decompression of the aftercoming fetal head to allow delivery of the fetus intact (291).

**Labor-induction Methods**

Intra-amniotic hypertonic saline or urea were widely employed techniques for labor induction abortion in the 1970s but have largely been supplanted by the use of synthetic prostaglandins.

**Prostaglandins**

Oxygernated metabolites of C_{20} carboxylic acid, prostaglandins are found naturally in most biologic tissues, where they act as modulators of cell function. They act through specific receptors of the G-protein family that are coupled to a variety of intracellular signal mechanisms, which may stimulate or inhibit adenyl cyclase or phosphatidylinositol (292). Prostaglandins of the E and F series can cause uterine contraction at any stage of gestation. These agents can be given by intra-amniotic infusion, by intramuscular injection, or by vaginal suppository. The 15 methyl analogues of prostaglandin F_{xa} (carboprost) and prostaglandin E_{2} (dinoprostone) are highly effective but frequently produce side effects of vomiting and diarrhea. Misoprostol is a 15 methyl analogue of PGE_{1}. A vaginal dose of 200 µg every 12 hours was shown to be as effective as dinoprost suppositories (20 mg every 3 hours) in patients with fetal death or intact pregnancy at 12 to 22 weeks of gestation (293). Misoprostol-treated patients experienced fewer side effects of fever, uterine pain, vomiting, and diarrhea. Misoprostol is much less expensive and easier to administer. In this study, patients with a living fetus were treated with ultrasound-guided intracardiac injection of potassium chloride to ensure fetal death before administration of misoprostol. A comparison of 200-, 400-, and 600-µg doses of misoprostol at 12-hour intervals produced rates of abortion of 70.6%, 82%, and 96%, respectively, within 48 hours; however, the side effects of vomiting, diarrhea, and fever increased with increasing doses (294). In a comparison of three dosing regimens, 400 µg of misoprostol vaginally every 6 hours was optimal for efficacy without increasing side effects (295). Uterine rupture has been reported in three women with previous cesarean delivery treated with misoprostol in the midtrimester, but in a case series of 101 women with one or more previous cesarean births and three smaller case series totaling 87 patients, no ruptures occurred (296). Larger series are needed to quantify the risk.

Transient fetal survival is not infrequent after prostaglandin inductions. In the United States, it is common to produce fetal demise before induction. Intra-amniotic digoxin, 1 to 1.5 mg, or fetal intracardiac potassium chloride (3 mL of a 2-mmol solution) are commonly used for this purpose. Induction of fetal death with intracardiac administration of potassium chloride also has been shown to shorten the interval to fetal expulsion when abortion is induced with vaginal dinoprostone, and it is likely the same effect would occur with misoprostol induction (297).

Retained placenta is another common problem of abortions in which labor is induced. Rectal administration of 800 µg of misoprostol has been reported to produce prompt placental expulsion (298).

**Midtrimester Mifepristone/Misoprostol**

Mifepristone pretreatment markedly increases the abortifacient efficacy of both gemeprost and misoprostol. The mean interval from start of the progesterin to fetal expulsion is reduced to 7 to 9 hours, much
shorter than with the prostaglandin alone (299). Mifepristone, 200 mg, is just as effective for this purpose as 600 mg (300).

**High-dose Oxytocin**  
*Oxytocin in very high doses is as effective as dinoprostone at 17 to 24 weeks of pregnancy* (301). Patients initially receive an infusion of 50 units of oxytocin in 500 mL of 5% dextrose and normal saline over 3 hours; 1 hour of no oxytocin, followed by a 100-unit, 500-mL solution over 3 hours; another hour of rest; and then a 150-unit, 500-mL solution over 3 hours, alternating 3 hours of oxytocin with 1 hour of rest. The oxytocin is increased by 50 units in each successive period until a final concentration of 300 units per 500 mL has been reached.

**Complications**

The labor-induction methods share common hazards: failure of the primary procedure to produce abortion within a reasonable time, incomplete abortion, retained placenta, hemorrhage, infection, and embolic phenomena. Failed abortion can lead to serious infection and continued blood loss. If fetal expulsion has not occurred within 24 to 36 hours, consideration should be given to a D&E procedure.

**Selective Reduction**

*Multifetal pregnancies are at risk for extremely preterm birth and major neonatal complications. To prevent this, selective reduction of higher-order multiple gestations often is practiced*. The largest series describes 3,513 pregnancies treated with ultrasound-guided fetal intracardiac injection of potassium chloride (0.2–0.4 mL of a 2-mmol solution in the first trimester, 0.5–3.0 mL in the second trimester). The rate of fetal loss fell as operators gained experience. Loss was higher with higher starting number of gestations (starting number greater than six, 15.4% loss, decreasing to 6.2% loss for starting number of two gestations), and also higher if more fetuses were left intact (finishing number three, 18.4% loss, decreasing to 7.6% for finishing number of gestations of one) (302). Another indication for selective reduction is the presence of one anomalous fetus in a multifetal gestation. In a series of 402 patients treated for this indication, rates of pregnancy loss after the procedure by gestational age at the time of procedure were 5.4% at 9 to 12 weeks, 8.7% at 13 to 18 weeks, 6.8% at 19 to 24 weeks, and 9.1% at 25 weeks or more (303). No maternal coagulopathy occurred, and no ischemic damages or coagulopathies were seen in the surviving neonates. **Selective reduction should not be attempted with monoamniotic twins or with twin–twin transfusion syndrome because of the possibility of embolic phenomena and infarction in the surviving twin**. Maternal serum α-fetoprotein remains elevated into the second trimester after first-trimester procedures.

**The Future**

**Spermicides**

Synthetic analogues of *zidovudine* have been found to be nontoxic in the reproductive tracts of rabbits and monkeys. These agents markedly reduce the ability of sperm to fertilize oocytes, and they have potent anti-HIV activity in HIV replication assays (304). Several novel nonnucleoside inhibitors have been synthesized that also are spermicides with high anti-HIV activity under laboratory conditions.

**Intrauterine Devices**

The GyneFix, a frameless copper IUD now available in Europe, consists of a surgical suture with small copper cylinders crimped to it. The knot on the proximal end of the suture is pushed 1 cm into the uterine wall with a special inserter. Comparative trials have found it more effective than the *copper T380A* and to have fewer instances of expulsion and to require removal for pain and bleeding less often (305). It is of considerable interest for these reasons as well as for its excellent retention after postabortal insertion.
**Vaginal Rings**

Silastic vaginal rings releasing either progestin or progestin–estrogen combinations have been studied for years and are now undergoing field trials in a number of countries. The presently available NuvaRing contains both estrogen and progestin and has the same safety concerns as the other estrogen-containing hormonal methods. Interest continues in development of a progestin-only ring for high contraceptive efficacy without estrogen (82).

**Simple Means for Female Sterilization**

Another critical area for contraceptive development is a nonsurgical means of sterilization of both men and women. Intrauterine quinine is the most promising method for nonsurgical female sterilization, but the method is embroiled in controversy because it was largely developed in the third world and moved quickly to widespread use without adequate proof of safety (306). The technique is very simple: Pellets containing 252 mg of quinacrine are inserted into the uterus through an IUD inserter during the proliferative phase of the cycle and again 1 month later. Intrauterine quinine produces sclerosis of the proximal fallopian tube. In a large trial in Vietnam, the 1-year pregnancy rate for 9,461 women who received 2 doses was 2.63 per 100 woman-years. The rate of ectopic pregnancy was 0.89 per 1,000 woman-years (307). A subsequent study with 2,551,355 woman-years of exposure found the rate of ectopic pregnancy to be 0.26 per 1,000 women treated with quinine, which was similar to surgical sterilization and the IUD, OC pills, and condoms (0.42–0.45 per 1,000) and less than nonusers of contraception (1.18 per 1,000) (308). Ongoing studies in developed countries will hopefully replicate these results (306).

**Contraceptive Vaccines**

Immunologic contraception–sterilization with vaccination against human chorionic gonadotropin was pursued for many years in India but appears to have been abandoned (309). Zona pellucida glycoproteins are another target for a potential vaccine, but application in humans appears blocked by the ovarian dysfunction observed in animal studies (310). The search continues for target proteins unique to reproduction to which a vaccine could be employed without adversely effecting other functions.

**Male Contraception**

As described earlier, considerable progress has been made in hormonal contraception for men based on long-acting androgens and androgen–progestin combinations. Nonhormonal male methods are being investigated. These include efforts to target and specifically interfere with spermatogenesis, epididymal sperm maturation, and sperm function (311).

Chinese researchers have developed a method of percutaneous occlusion of the vas that was used in more than 100,000 men; it is effective and appears to be reversible. Polyurethane elastomer is injected into the vas, where it solidifies and forms a plug, providing an effective block to sperm. The plugs are removed using local anesthesia, and fertility returns in most cases after as long as 4 years with the plugs in situ (312).

Gossypol, an extract of cottonseed, was evaluated in China as a male contraceptive but abandoned because of problems with hypokalemia in users. More recently there has been an explosion in research in gossypol chemistry and biology because of its potential as an antineoplastic agent. It is being used successfully for contraception seemingly without complications in China in a purified form at reduced doses (313). A multinational study also found hypokalemia not to be a problem. Of 151 men treated, 65% had sperm counts fewer than 1 million/mL. About half of men followed more than 1 year after treatment reverted to a normal sperm count. Gossypol may become an alternative to vasectomy (314).

Perhaps the most important current area of contraceptive research is the development of nontoxic spermicides that would also prevent HIV transmission and nonsurgical means for male and female sterilization (305).

Most young men and young women have multiple serial sexual partners but use condoms inconsistently, thereby exposing themselves to sexually transmitted diseases (STDs) and unintended pregnancies.

Sexual response is mediated by a complex interplay of psychological, interpersonal, environmental, and biological (hormonal, vascular, muscular, neurological) factors.

Numerous factors can affect sexual response, including age; relationship duration and quality; personal psychological factors stemming from relationships in childhood with parental figures; previous losses, traumas, and ways of coping with emotions generally; illness; and use of medication, alcohol, and illicit drugs.

Physical, emotional, and economic stressors of pregnancy may negatively affect emotional and sexual intimacy. Sexual attitudes and behavior during pregnancy and postpartum are influenced by sexual value systems, folklore, religious beliefs, physical changes, and medical restrictions.

Despite the importance of issues relating to sexuality, many women may find it difficult to talk to their physicians about sexual concerns, and many physicians are uncomfortable discussing sexual issues with their patients.

Asking about sexual concerns gives physicians an opportunity to educate patients about the risk of STDs, encourage safer sex practices, evaluate the need for contraception, dispel sexual misconceptions, and identify sexual dysfunction.

Many of the sexual problems couples encounter are due to a deficit of knowledge or experience, sexual misconceptions, or inability of the couple to communicate about their sexual preferences.

Sexual problems are common in the general population in the United States. Vaginismus is an involuntary reflex precipitated by real or imagined attempts...
SECTION III  Preventative and Primary Care

at vaginal entry. Dyspareunia may affect two thirds of women during their lifetime.

• Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime. The terms sexual abuse survivor and assault survivor are preferable to victim.

• Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that as many as one third of adult women were sexually abused as children.

• Women who have been sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting.

• The National Women’s Study revealed that 13%, or one of eight adult women, are survivors of at least one completed rape during their lifetime.

Most women feel that sexuality is an important part of their lives. Providing patients with information about normal sexual changes that occur with puberty, pregnancy and postpartum, menopause, and older age is part of routine obstetric and gynecologic care. Sexual dysfunction can arise from gynecologic diseases such as endometriosis, procedures such as those associated with infertility, and treatments such as pelvic radiation, bilateral salpingo-oophorectomy, and use of gonadotropin-releasing hormone antagonists (1–6). Sexual abuse can have long-lasting effects on sexuality as well as other psychophysiologic aspects of a patient’s life (3). Inquiry about sexual concerns and explanation of the implications of a disease and its treatment are integral components of gynecologic care.

Sexuality

The spectrum of normal sexual response varies from one woman to another and throughout a woman’s lifetime (4,5). Physicians should be aware of their patients’ sexual values, attitudes about specific practices, and concerns about their sexuality. Maintaining open communication with patients about their sexuality allows the physician to counsel them about sexual issues and problems as well as other aspects of their reproductive health.

Sexual Practices

Sexual activity among adolescents in the United States has increased during the past 20 years (3). The average age for first intercourse for both men and women is 16 years. By 19 years of age, as many as three quarters of women will have had intercourse. Most young men and young women have multiple serial sexual partners but use condoms inconsistently, thereby exposing themselves to STDs and unintended pregnancies. A survey of men and women between the ages of 18 and 59 in the United States reported that most men and women were satisfied with their sexual lives even if sex was infrequent (4). Approximately 47% of women had sexual activity with their partners a few times each month, 31% estimated they had sexual activity 2 to 3 times a week, and 7% more than 4 times a week. Twelve percent of women had sex a few times a year, and approximately 3% had never been sexually active. Most men and women stated they were monogamous. Of those who were married, 85% and 75% of women and men, respectively, said they have never been unfaithful. Homosexual activity in the previous year was reported by 3% of women and 2.7% of men and at some time in the past by 3.8% of women and 7.1% of men. Although 22% of women said they had been forced to do something sexual, usually by someone they loved, only 3% of men admitted to forcing themselves sexually on a woman.
Sexual Physiology

For most women, their clitoral tissue is the most sexually sensitive part of their anatomy, and its stimulation produces the most intense sexual feelings and the most intense orgasms. However, many women first need to experience nonphysical and nongenital physical stimulation before clitoral stimulation can be enjoyed. In the absence of arousal, direct clitoral stimulation can be unpleasant and be perceived as too intense and even painful. Recent immunohistologic studies have identified neurotransmitters thought to be associated with sensation concentrated right under the epithelium of the glans clitoris (1). Clitoral tissue extends far beyond the visible portion when the clitoral hood is retracted. It includes the clitoral head, shaft, rami running along the pubic arch, periurethral tissue in front of the anterior vaginal wall, and the bulbar tissue under the superficial perineal muscles surrounding the anterior distal vagina. Other sexually sensitive areas include the nipples, breasts, labia, much of the skin generally, and to some extent, the vagina. Although the lower third of the vagina is responsive to touch, the upper two thirds are sensitive primarily to pressure. The rich supply of nerves in the fascia anterior to the upper vagina (Halban’s fascia) and the proximity of the clitoral type of spongy tissue around the urethra anterior to the vagina contribute to the pleasurable sensations of intercourse. However, many women experience orgasm more easily from direct clitoral touch, possibly provided at the same time as intercourse.

There has been speculation about the existence of a “G-spot,” named after Ernest Gräfenberg, who had first described it in 1944 (1,2). This area of the vagina, located anteriorly midway between the symphysis pubis and cervix, is thought to be exquisitely sensitive to deep pressure. Stimulation of this area has been associated with orgasm and loss of fluid that has not been scientifically proven to be anything other than dilute urine. Women who are normally continent often leak urine at orgasm; this is not abnormal and does not require medical intervention.

Sexual Response Cycle

Sexual response is mediated by a complex interplay of psychological, interpersonal, environmental, and biological (hormonal, vascular, muscular, neurological) factors. The initial phase of the sexual response cycle may be one of desire, but more often women, particularly those in long-term relationships, are motivated by factors other than sexual desire (2–6). Women initiate or consent to sex for many reasons, including a desire to increase emotional intimacy with their partners. By directing her attention to sexual stimulation, a woman’s subjective sexual arousal/pleasure/excitement triggers sexual desire. Desire and arousal coexist and compound each other (Fig. 11.1). Sexual satisfaction (with

---

**Figure 11.1** The blended sex response cycle showing the many reasons/incentives for initiating/accepting sexual activity.
one, or many, or no orgasms) can be achieved if a woman can stay focused, her pleasure continues, the duration of the stimulation is sufficiently long, and there is no negative outcome (e.g., pain or partner dysfunction). The response is circular, with phases overlapping and in variable order (e.g., desire may follow arousal, and higher arousal may follow the first orgasm). Desire, once triggered, increases the motivation to respond to sexual stimuli and to agree to or ask for more intensely erotic forms of stimulation. Any initial spontaneous desire will augment the response.

Desire and Arousability

Sexual desire provides strong motivation to be sexual. Feelings of desire may be triggered by both internal (e.g., fantasies, memories, feelings of arousal) and external (e.g., an interested and interesting partner) sexual cues and are dependent on adequate neuroendocrine function (5). Multiple neurotransmitters, peptides, and hormones modulate desire and subjective arousal. Substances that promote sexual response include norepinephrine, dopamine, oxytocin, and serotonin. Prolactin and GABA inhibit sexual response. These peptides and neurotransmitters are themselves modulated by sex hormones. However, it is clear that biological factors do not act independently from environmental factors, a finding in human as well as animal models. Dopamine and progesterone, acting on receptors in the hypothalamus, both cause an increase in sexual behavior in female rats that have undergone oophorectomy and received estrogen. However, the presence of a male animal in an adjacent cage can cause an identical change in sexual behavior (7). Likewise, the ability to be aroused and intensity of response can be increased in women by giving them a modest dose of testosterone, by administering bupropion (dopaminergic), or by a change of partner (8,9). Even in rodents, complex networks exist whereby the female assesses the context of potential sexual activity and relates it to past experience and, therefore, expectation of reward (10). In women, sexual interest is influenced by their psychological mind-set, beliefs and values, expectations, sexual orientation, preferences, and the presence of a safe and erotic environmental setting. Sexual desire, interest, and arousability are most strongly influenced by mental health and feelings for the partner, both generally and specifically, at the time of sexual interaction (11–13). Sexual desire also is strongly influenced by fatigue; as a result, sex late at night is not usually attractive to a busy woman. Similarly, chronic illness typically reduces desire and arousability.

Sexual Arousal

Accompanying the subjective excitement and erotic feelings of arousal are a number of physical changes. These changes include genital swelling; increased vaginal lubrication; engorgement of the breasts and nipple erection; increases in skin sensitivity to sexual stimulation; changes in heart rate, blood pressure, muscle tone, breathing, body temperature; mottling of the skin; and a “sex flush” of vasodilation over the chest, breasts, and face. With sexual stimulation, brain activity in the hypothalamus and other areas influencing the genital response are activated, triggering the autonomic nervous system to allow increased blood flow to the vagina. Vasodilation of the arterioles in the submucosal vaginal plexus increases transudation of interstitial fluid, which moves from capillaries between the epithelial intercellular spaces and into the vaginal lumen. Simultaneously, the autonomic nervous system allows relaxation of the smooth muscle cells surrounding blood spaces (sinusoids) in the clitoris and labia, causing clitoral swelling and vasodilation in the labia. Recent immunohistologic studies indicate nerves containing nitric oxide are present in the genital skin covering the clitoris and labia (1).

With arousal, the vagina lengthens, distends, and dilates, and the uterus elevates out of the pelvis. With increased sexual stimulation, vasocongestion reaches a maximum intensity. Genitally, the labia become more swollen and darker red and the lower third of the vagina swells and thickens to form an “orgasmic platform.” The clitoris becomes more swollen and elevates to a position near the symphysis pubis, and the uterus elevates fully.
out of the pelvis. The breasts become more engorged, the skin more mottled, and the
nipples more erect.

The neurobiology of arousal is incompletely understood but the genital vasoconges-
tive responses appear to be highly automated, occurring within seconds of an erotic
stimulus (14). Parasympathetic nerves release nitrous oxide and vasointestinal polypep-
tide (VIP), mediating vasodilation (12,15). Acetylcholine (ACh) blocks noradrenergic
vasoconstrictive mechanisms and promotes nitrous oxide release from endothelium. The
parasympathetic and sympathetic nervous systems and the somatic system function less
independently than was previously believed. Communication has been identified between
the cavernous nerves to the clitoris containing nitrous oxide and the distal portion of the
(somatic) dorsal nerve of the clitoris from the pudendal nerve (1). The pelvic sympathetic
nerves primarily release (vasoconstrictive) noradrenaline and adenosine triphosphate, but
some release ACh, nitrous oxide, and VIP. Nitric oxide is thought to be the major neuro-
transmitter involved in vulvar engorgement (1,15). In the vagina, VIP, nitrous oxide, and
other unidentified neurotransmitters are involved (15).

Even in women without any sexual dysfunction, there is highly variable correlation
between the degree of subjective sexual excitement and the increase in congestion
around the vagina (14,16). This correlation has been shown repeatedly over the past 25
years based on psychophysioligic studies using a tamponlike photoelectric device placed
in the vagina while the woman views an erotic video. Congestion in response to the
sexual video is reduced in women with disruption of the autonomic nerve supplying the
vulva and vagina (e.g., from non-nerve-sparing radical hysterectomy). However, other-
wise healthy women experiencing chronic lack of arousal (including lack of subjective
excitement and lack of any awareness of genital congestion), show increases in vaginal
congestion from erotic stimuli that are similar those in control women (14,17). With the
so-called cervico-motor reflex, cervical touch (in the laboratory with a balloon-tipped
catheter, which might be replicated by penile pressure) leads to a reduction in pressure in
the upper portion of the vagina and an increase in pressure in the middle and lower
portions. Simultaneously, an increase in electromyoographic activity in the levator ani and
puborectalis muscles was recorded. It is thought that during intercourse penile thrusting
on the cervix might cause contraction of the pelvic muscles to facilitate “ballooning” of
the upper vagina, perhaps to facilitate pooling of semen. The same muscle contraction
constricts the lower vagina, which may afford increased stimulation of the partner’s penis,
thereby maintaining rigidity (18).

A further reflex demonstrated in laboratory studies shows reduced uterine tone in
response to mechanical or electrical stimulation of the glans of the clitoris.
Background activity of the uterine muscle was abolished by clitoral stimulation if either
the glans clitoris or the uterus was anesthetized. Uterine pressure declined on clitoral
stimulation. This reflex may underlie the known increase in size and the elevation
of the uterus with sexual arousal (19).

Orgasm

Orgasm is described as the most intensely pleasurable of the sexual sensations. It
involves a myotonic response of smooth and striated muscle associated with feelings
of sudden release of the sexual tension built up during arousal. Reflex rhythmic contrac-
tions (3–20 0.8/sec) of the muscles surrounding the vagina and anus occur. Uterine contrac-
tions also are experienced by many women during orgasm, who may perceive a difference
in their orgasms after hysterectomy. The majority of women most easily experience orgasm
from direct clitoral stimulation. More direct contact with the clitoris is possible from contact
of pubis to pubis after the man has ejaculated and penile size is reduced. The bodies are
more closely approximated and the woman can move her pelvis on his at a rate that is
most conducive to her orgasm. Breast stimulation, kissing and clitoral stimulation during
intercourse are other commons means of experiencing orgasm. Women are potentially
multiorgasmic, capable of experiencing a number of orgasms close together during one sex response cycle and of resuming sexual activity without any refractory period.

Resolution

Following the sudden release of sexual tension brought about by orgasm, women experience a feeling of relaxation and well-being. The gradual lessening of pelvic engorgement contrasts with the quicker loss of penile firmness in men. Nongenital changes that took place during arousal are reversed, and the body returns to a resting state after some 5 to 10 minutes. With further stimulation, however, the response can resume. Women who enjoy arousal without orgasm and without any sense that orgasm is very close but frustratingly absent report a similar sense of well-being and relaxation.

Recent research has indicated that these phases of sexual response are not discrete entities in an invariable order, as was originally described by Masters and Johnson and Kaplan, but rather circular in nature. They differ from one woman to another and can be affected by a variety of factors.

Factors Affecting Sexual Response

Numerous factors can affect sexual response (20–23). They include age; relationship duration and quality; personal psychological factors stemming from relationships in childhood with parental figures; previous losses, traumas, and ways of coping with emotions generally; illness; and use of medication, alcohol, and illicit drugs.

Mental Health

Lack of emotional well-being was one of the stronger predictors of sexual distress in the North American National Probability Sample (24). It has also been shown that lack of mental well-being, even if it does not meet the criteria of a clinical diagnosis of mental disorder, is strongly linked to women’s symptoms of low desire (25). One study showed a strong association between decreased sexual interest and self-reporting of negative emotional and psychological feelings, including low self-esteem, feelings of insecurity, and lost femininity (25). Impaired sexual desire has been noted in most studies of women with depression, even before the administration of antidepressants with sexually negative side effects (26). Paradoxically, depressed women may masturbate more frequently than women who are not depressed despite an increased prevalence of dyspareunia and difficulties with arousal and orgasm (27).

Aging

The degree to which aging and the marked changes in ovarian function associated with menopause may affect women’s sexual response has recently been addressed in large population studies. Some studies have shown little increase in sexual problems with age (3), whereas in others almost 40% of the sample reported reductions in responsiveness and an increased desire for nongenital sexual expression (20,28). In one study, the prevalence of reduced desire increased significantly as a function of both menopause status and age, from 22% in the premenopausal group to 32% in the postmenopausal group (29). Low levels of desire were strongly associated with other sexual problems, including difficulties with arousal and orgasm. One large cohort of women studied over 10 years from peri- to postmenopause showed a decline in desire and responsiveness as a function of both age and menopause (13). The independent effect of menopause, however, was indirect. The number of menopausal symptoms experienced influenced well-being, which in turn affected sexual responsiveness and sexual desire and interest.

Many studies of sexuality and aging show that older women report less distress about lack of desire when compared with younger women (11,24,30). In a nonclinical study of 102 women, the determinants of sexual satisfaction in those younger than 45 years of
age were compared with those of women older than 45 years of age (11). There was no
difference in sexual satisfaction achieved either by intercourse or noncoital sexual activi-
ties. However, older women reported lower frequency of orgasm and different ratings on
certain dimensions of sexual satisfaction. For the older women, the dominant qualities
important to their satisfaction were those related to an emotional sense of calm and to
factors such as feeling secure with their partner, whereas for younger women the subjec-
tive physical experience was more important.

Despite reports of reduced sexual interest and desire by some women, most retain
some interest and maintain the potential for sexual pleasure for their entire lives. In
older women, a strong predictor of continued sexual interest is sexual behavior and
enjoyment at an earlier age. A discrepancy between sexual interest and actual sexual
activity occurs in many cases because an adequate partner is no longer available. In other
instances, the cessation of sexual activity with age is more an expression of emotional
problems resulting from lack of tenderness, communication, and attraction.

In addition to partner availability, an older women’s sexuality is influenced by her
partner’s general and sexual health (31,32) and the relationship itself, which will
determine how well the couple can adapt to changes in their sexual function as they
age. Although some older women may retain negative societal attitudes to sex that is not
“natural” (i.e., not intercourse oriented), studies have shown a shift from genital sex to inti-
macy as people age, indicating that any activity that involves affection, romance, intimacy,
and companionship may help satisfy the sexual needs of older adults (33). Whether this
will change with the evolution of safe and more effective medications for treating erectile
dysfunction remains to be seen. For some older women, it is clear that the setting, whether
nursing home or grown-up child’s home, will be important factor in realizing sexual goals.

If intercourse is perceived as a necessary component of sexual activity with a partner,
some older women will lose motivation and interest as a result of discomfort and
dyspareunia associated with lack of estrogen. Although the increase in vaginal congestion
in response to visual sexual stimulation has been shown to be similar in women with and
without estrogen, baseline vaginal blood flow is lower in estrogen-deficient women (14,34).
Thus, the increase in lubrication may be insufficient. Also, there may be loss of elasticity and
thinning of the vaginal epithelium, which becomes vulnerable to damage from intercourse.
Estrogen depletion predisposes women to vulvar vaginitis and urinary tract infections, both
of which contribute to dyspareunia and reduce sexual self-image. Women who remain sexu-
ally active, alone or with a partner, have less vulvar and vaginal atrophy than inactive women.

Adrenal production of testosterone precursors gradually decreases with age, beginning in
the late 30s. Recent attempts to correlate testosterone levels with sexual function or
dysfunction in premenopausal women are conflicting, and there is even less clarity regarding
postmenopausal women (35,36). In surgically menopausal women, testosterone
supplementation, given in combination with estrogen at levels equal to or only
slightly above premenopausal values, has been shown to improve arousal, sexual
responsiveness, orgasmic intensity and frequency, and desire (8,37). Older studies used
pharmacological doses of testosterone. The whole question of supplementing testosterone
in women is complicated by many factors. An age-related decrease in adrenal androgen
precursors generates markedly reduced intracellular testosterone activity (38,39).
However, intracellular testosterone levels correlate poorly with serum testosterone levels
because testosterone acts within the cell and is metabolized there, and only the metabolites
spill back into the blood stream (39). This finding may contribute to the reason for conflict-
ing studies regarding the relationship between testosterone (measured as serum levels) and
sexual function or dysfunction. Furthermore, available testosterone assays for serum levels
are neither accurate nor sensitive at the low levels of testosterone found in women (the
assays were designed for the male range) (23). This lack of clarity applies whether
bioavailable, free, or total testosterone levels are measured.
Illnesses that accompany aging may also have an impact on sexual dysfunction. However, the association is weaker than that between male erectile dysfunction and hypertension, hyperlipidemia, diabetes, and coronary artery disease. Some sexual activities (e.g., intercourse) or responses (e.g., orgasmic intensity) may be inhibited by arthritic, cardiac, or respiratory disorders.

**Personality Factors**

Studies have shown that, compared with functional women, those who have concerns about low levels of desire and arousability are characterized as having vulnerable self-esteem, high levels of anxiety and guilt, negative body image, introversion, and somatization (25). Studies tend not to identify psychopathology in women who report low desire (11). The clinical impression of women with orgasmic disorder is that many are extremely uncomfortable in conditions in which they are not in control of circumstances or their bodily reactions. For many women with vaginismus, there is a phobic quality to the fear of vaginal penetration. A subgroup of women with vulvar vestibulitis showed a marked fear of negative evaluation by others, conscientiousness, and self-criticism, as well as an increase in somatization (40,41).

**Relationships**

Most women who report loss of desire and arousability indicate that their partnerships are stable and satisfactory. However, an environment free of conflict, abuse, and the threat of separation or divorce is insufficient to nurture a woman’s sexual desire. Commonly, the woman reports that her partner is not emotionally intimate with her and not willing to reveal his (or her) feelings, fears, and hopes. Additionally, the woman’s need for eroticism and variety of sexual stimulation may not be met. Women frequently classify their relationship as being “very good friends.” Such a context is insufficiently sexual for nurturing or triggering a woman’s sexual desire. Change of partner has been shown to be a major factor in increasing women’s desire and responsiveness, and there is a lessening of innate desire with the duration of a relationship (20,21). The woman’s feelings for her partner is one of the major determinants of lack of distress about sex (24); similarly, the woman’s feelings for her partner, or a change of partner, were major determinants of a woman’s desire (20,24,42).

**Sexual Dysfunction in the Partner**

Multiple aspects of a woman’s circumstances can influence her sexual function, and one of the most important aspects is sexual dysfunction in a male partner (43). Successful treatment of a male partner’s erectile dysfunction can result in reversal of the woman’s sexual problems, including difficulties with sexual arousal, lubrication, orgasm satisfaction, and pain (32).

**Infertility**

Infertility evaluation and assisted reproductive techniques can have negative effects on a woman’s body image and feelings of sexual self-worth. Infertility may cause her to feel hopeless and sexually undesirable. The loss of sexual spontaneity resulting from the goal-oriented approach to sex while trying to conceive with scheduled intercourse may lead to sexual dysfunction. The stress of testing and waiting for results may disrupt emotional intimacy, causing further damage to sexual function. Unfortunately, these changes do not always reverse with a successful pregnancy. Often there are unresolved feelings of guilt over personal responsibility for the infertility and feelings of resentment of the multiple procedures required for women compared with one semen analysis for men.

**Drugs**

Prescription and nonprescription medications, including alcohol and illicit drugs, can alter the normal sexual response (Table 11.1). Adjustments in dosage or formulation of
medication may be required. A number of pharmacological agents might improve or reverse the loss of arousal, desire, and orgasm commonly associated with serotonergic antidepressants (SSRIs). A recent Cochrane Review could make no recommendations for women but did note that bupropion may be effective based on the results of one of two randomized controlled trials (44).

### Chronic Illness

Chronic illness can affect sexual function in a number of ways (Table 11.2).

</table>

Chronic illness can affect sexual function in a number of ways (Table 11.2).
### Preventative and Primary Care

#### Chronic Pelvic Inflammatory Disease/Endometriosis

Chronic dyspareunia, remitting temporarily or not at all with surgical or medical therapy, typically is associated with loss of sexual motivation/interest. Although definitive therapy is the overall goal, encouragement of nonpenetrative sex is very important for preservation of the woman’s sexual enjoyment, sexual self-esteem, and relationship.

#### Polycystic Ovarian Syndrome

There is no evidence that the higher androgen levels associated with polycystic ovarian syndrome (PCOS) afford protection from low sexual desire or low sexual arousability. Rather, a sample of 30 women with PCOS presenting for treatment for hirsutism were found to have levels of sexual desire significantly lower than those in the control group (45).

#### Recurrent Herpes

Fear of spreading an STD may reduce sexual motivation and arousability. Clear guidance regarding safer sexual practices is needed, along with a discussion of the causes of the woman’s lowered sexual motivation. A recognized difficulty with recurrent herpes is viral shedding despite lack of skin lesions and uncertainty whether long-term antiviral therapy prevents shedding.

#### Lichen Sclerosis

Tethering of the clitoral hood, which occurs with lichen sclerosis, may cause pain with clitoral stimulation. When this skin disorder involves the introitus, it may cause dyspareunia or prevent entry of penis, dildo, or fingers. Topical corticosteroid administration is the primary treatment, although topical testosterone cream may be beneficial when loss of sexual sensitivity occurs.

#### Breast Cancer

Sexual dysfunction following breast cancer treatment is likely to persist more than 1 year after diagnosis of breast cancer (46). Chemotherapy appears to be responsible for most of the resulting sexual difficulties, including loss of desire, subjective arousal, vaginal dryness, and dyspareunia (47). A model for predicting sexual interest, function, and satisfaction after breast cancer has evolved from two large independent groups of breast cancer survivors (47). The most important predictors of sexual health were absence of vaginal dryness, presence of emotional well-being, positive body image, better quality of relationship, and lack of partner sexual problems. A temporary “medical menopause” from adjuvant gonadotropin-releasing hormone agonist treatment is associated with reversible sexual dysfunction (48). Use of tamoxifen does not consistently alter sexual function (49).

#### Diabetes

A systematic review of women with diabetes disclosed a lack of clear correlation between the degree of complication of disease and sexual dysfunction. Psychophysiologic studies have not supported any difference between increases in congestion in response to erotic stimulation or increases in subjective arousal between women with and without diabetes (50). Nevertheless, in the clinical setting, higher rates of overall sexual dysfunction have been found in women with diabetes compared with women who do not have diabetes, but statistical significance was only met for the symptom of decreased lubrication (51). Significant predictors were the quality of the marital relationship and presence or absence of depression. It is clear that psychological as opposed to somatic factors largely account for sexual problems in women who have diabetes.
CHAPTER 11  Sexuality, Sexual Dysfunction, and Sexual Assault

Hysterectomy

Simple Hysterectomy  Despite speculation that there might be different sexual outcomes depending on whether hysterectomy was vaginal, subtotal, or total abdominal, this difference has not been supported by recent studies (52,53). In a large prospective observational study of 413 women undergoing three different types of hysterectomy (vaginal, supracervical, and total abdominal hysterectomy), sexual pleasure was noted to improve in most women, independent of the type of hysterectomy (53). The prevalence of one or more bothersome sexual problems 6 months after vaginal, supracervical, and total abdominal hysterectomy was 43%, 41%, and 39%, respectively. The results of another prospective trial of 158 women randomized to total abdominal hysterectomy and 161 to supracervical abdominal hysterectomy showed no difference in sexual outcomes (52). A retrospective study of 108 women undergoing classic intrafascial supracervical hysterectomy and 125 undergoing total hysterectomy did not find any sexual benefits of classic intrafascial supracervical hysterectomy over total hysterectomy (54). There was no difference between groups in time from surgery to first intercourse, change in libido, sexual frequency, or frequency or degree of orgasm. Overall, two thirds of the women in the study experienced either no change or an improvement in sexual function, regardless of which procedure was performed. Both this study and a study comparing total laparoscopic hysterectomy with laparoscopically assisted vaginal hysterectomy found similar effects on sexual function (55).

Radical Hysterectomy  Techniques have been developed to avoid the portions of the inferior hypogastric plexus in the cardinal and broad ligaments (56). The results of studies of the sexual outcome on women who underwent radical hysterectomy using these nerve-sparing techniques are now awaited. In one study, 12 women with simple hysterectomy and 12 with radical hysterectomy (Piver-Rutledge Class III) were compared with 17 sexually healthy women. All women were premenopausal, and very few had any symptoms of sexual dysfunction. The maximal increase in vaginal congestion was highest in the control group and lowest in the women who underwent nonnerve-sparing radical hysterectomies. However, subjective arousal was lowest in women who underwent simple hysterectomy, and there was no difference in subjective arousal or excitement levels between women in the control group and those who had received radical hysterectomies (57). Early results of ongoing studies of women with cervical cancer who received either radical or simple hysterectomy show that the level of sexual dysfunction is associated with a tendency to monitor their gynecologic and other symptoms. Sexual dysfunction is associated with their general level of distress and is not related to surgery type, use of radiation, or whether bilateral oophorectomy was performed (58).

Cancer of the Cervix  Sexual symptoms encountered in women with cancer of the cervix include reduced vaginal lubrication secondary to surgical menopause or radiation damage. A study conducted in Croatia has shown the importance of fear of dyspareunia. Of 210 women treated with combinations of surgery, radiation, and chemotherapy, 50% reported a marked fear of pain. However, only six patients identified actual dyspareunia and only three patients found penetration impossible (59).

There is marked synergy between cancer of the cervix and sexual abuse as a cause of sexual dysfunction (60). An absence of sexual satisfaction was reported by 20% of women with neither abuse nor cancer of the cervix, by 31% of women who had been sexually abused and did not have cancer of the cervix, by 28% of women with cancer of the cervix who had not been abused, but by 45% of women with a history of both abuse and cancer of the cervix. The lack of sexual satisfaction resulted in a decrease in well-being in
18% of women with neither a history of abuse nor cancer of the cervix, 39% of women who had been abused and did not have cancer of the cervix, 23% of women with cancer of the cervix who had not been abused, and in 44% of women with a history of both abuse and cancer of the cervix. Dyspareunia was extremely rare in women without cancer of the cervix, but it was reported by 12% of those with cancer of the cervix and by 30% of those with cancer of the cervix and past sexual abuse.

Pregnancy

Physical, emotional, and economic stressors of pregnancy may negatively affect emotional and sexual intimacy. Sexual attitudes and behavior during pregnancy and postpartum are influenced by sexual value systems, folklore, religious beliefs, physical changes, and medical restrictions. In the absence of preterm labor, antepartum bleeding, or an incompetent cervix, there is no evidence that sexual activity, orgasm, or intercourse increases the risk of pregnancy complications. Normal changes that occur with sexual activity during pregnancy include increased breast tenderness, increased sensitivity to uterine contractions with orgasm, general discomfort, less mobility, and fatigue. Sexual satisfaction in pregnancy is closely related to feeling happy about the pregnancy, continuing to feel attractive, and understanding that in healthy pregnancy sexual activity and orgasm do not harm the fetus.

Toward the end of the third trimester the need for closeness, emotional support, and nurturing may be far greater than any desire for orgasms or intercourse. Difficulties may arise from the partner’s reaction to the woman’s pregnancy, the physical changes of pregnancy, lack of information regarding sex and pregnancy, and lack of direction from the physician when complications arise. A general lessening of sexual desire in both pregnancy and the postpartum period is common and considered normal. A prospective analysis of sexual function of 40 healthy pregnant women showed a reduction in desire and in all aspects of sexual response beginning in the first trimester, changing little in the second, and reducing further in the third trimester (61).

Postpartum

The ongoing vaginal bleeding and discharge, perineal discomfort, hemorrhoids, sore breasts, and decreased vaginal lubrication associated with nursing, compounded by fatigue from disturbed nights, all contribute to decreased motivation for sexual activity. Further complicating factors include fear of waking the baby, a decreased sense of attractiveness, change of body image, or mood change. Many couples resume sexual activity and include intercourse by 6 to 8 weeks postpartum, but some couples wait as long as a year before resuming their prepregnancy level of sexual intimacy. Typically women who nurse report less sexual activity and less satisfaction than those who bottle feed. There is no definite correlation between sexual activity and method of delivery, although women who undergo cesarean birth tend to resume intercourse earlier (62). Few studies record whether episiotomy influences sexual function.

Physicians can provide considerable help to patients and their partners by acknowledging and discussing the normal fluctuations in sexual desire and frequency of sexual activity during and after pregnancy. Couples should generally be encouraged to continue their usual patterns of lovemaking during pregnancy if they are emotionally and physically comfortable and there are no contraindications to either orgasm or intercourse.

Assessment of Sexual Problems

Despite the importance of issues relating to sexuality, many women may find it difficult to talk to their physicians about sexual concerns, and many physicians are
uncomfortable discussing sexual issues with their patients. In one survey, 71% of adults said they thought their doctor would dismiss any concerns about sexual problems they might introduce, and 68% said they were afraid that discussing sexuality would embarrass their physician (63). Through the use of a structured questionnaire and review of the records of 1,065 women who consecutively attended 37 family practices in areas of high, medium, and low socioeconomic status, 40% of women were found to have at least one form of sexual dysfunction according to diagnostic criteria of the international statistical classification of disease (ICD-10). Only 4% had a prior entry in their medical record relating to sexual problems (29).

There are numerous reasons physicians are reluctant to discuss issues relating to sexuality with their patients. Physicians may be anxious about their perceived inability to treat sexual problems or feel that they have too little time to accurately assess sexual concerns in their practice. They also may be distressed by their patients’ history of sexuality-related violence or may experience personal discomfort when discussing sexual matters with their patients. Not asking about sexual function suggests to patients that sexuality is not important and should not be discussed, however, which results in a missed opportunity for counseling about sexuality as well as other important related issues.

Asking about sexual concerns gives physicians an opportunity to educate patients about the risk of STDs, encourage safer sex practices, evaluate the need for contraception, dispel sexual misconceptions, and identify sexual dysfunction. Many sexual concerns can be resolved by providing factual information and reassurance. Management of sexual dysfunction, however, requires appropriate biopsychosocial assessment and intervention. Even when patients currently have no sexual problems, they learn that future sexual issues can be addressed in a professional, confidential, and nonjudgmental setting.

Interviewing Techniques

To be comfortable enough to establish rapport and trust with patients, physicians should be familiar with the components of a sensitive, detailed, sexual assessment and the general principles of management of dysfunction. Good listening skills and attention to nonverbal cues are helpful. Physicians should use straightforward language that patients can understand and acknowledge that many people find it difficult to discuss these sensitive, intimate, and extremely common issues.

A few open-ended questions can initiate the subject of sexual function (Fig. 11.2). Sexual inquiry is part of the medical history taken during a routine gynecologic assessment. Listed in Table 11.3 are some examples of screening questions related to particular obstetric–gynecologic circumstances.

Optimally, the detailed assessment is obtained from both partners. Questions can be directed to the couple or the individual partners, depending on the circumstances (Table 11.4). When dyspareunia is present, detailed questioning is necessary (Table 11.5).

Physical Examination

Routine pelvic examination is an essential component of general medical care; however, this is not the case with women who seek care for sexual concerns. Given the prevalence of negative past sexual experiences, including abuse, a pelvic examination should be performed only in the presence of a definite indication, and the procedure should be clearly explained to the patient (Table 11.6). Management of dyspareunia mandates careful vulvar, vaginal, and pelvic examination. It should be noted that although a physical examination can confirm normal anatomy and the healthy nonaroused state of the
Nonsexual rewards: emotional intimacy, well-being, lack of negative effects from sexual avoidance

Multiple reasons/incentives for instigating or agreeing to sex

Willingness to find/be receptive

Spontaneous "innate" desire

Sexual stimuli with appropriate context

Sexual satisfaction +/- orgasms

Arousal & responsive desire

Subjective Arousal

genitalia, it does not confirm healthy sexual function. Nevertheless, such an examination can be both instructive and therapeutic.

**Diagnostic Criteria**

Similar to phases of sexual response overlap, types of women’s sexual dysfunctions also overlap (11, 29). The Second International Consensus on Sexual Dysfunctions in Men and Women (18) provides evidence-based recommendations for the diagnosis of sexual dysfunction and encompasses the recently proposed revisions to the American Psychiatric Association’s Diagnostic and Statistical Manual Text Revised (DSM-IV-TR) definitions of women’s sexual dysfunction (64, 65) (Table 11.7).

Each disorder is then further classified by the following descriptors:

1. **Lifelong or acquired**
2. **Generalized or situational**
3. **The degree of distress—mild, moderate, or marked**
4. **Presence of contextual factors**
   A. Past factors from developmental history affecting psychosexual development
   B. Present contextual factors—interpersonal, environmental, societal, and cultural
   C. Medical factors

Many of the sexual problems couples encounter are due to a deficit of knowledge or experience, sexual misconceptions, or inability of the couple to communicate about their sexual preferences. Brief counseling and education by the obstetrician–gynecologist regarding the circular sex response cycle can identify the areas where sexual dysfunction can occur.

<thead>
<tr>
<th>Situation in which Screening Question Is Necessary</th>
<th>Suggested Screening Question</th>
</tr>
</thead>
<tbody>
<tr>
<td>Before surgery or instituting medication or hormone therapy</td>
<td>Your surgery or medication is not expected to interfere with your sexual function. I need to check, though, whether you have any difficulties now with sexual desire, arousal, or enjoyment; or is there any pain?</td>
</tr>
<tr>
<td>Routine antenatal visit</td>
<td>Women’s sexual needs can change during pregnancy. Do you have any problems or questions now? There is no evidence that intercourse or orgasm leads to miscarriage. Of course, any bleeding or spotting will require checking and postponing sexual activity until we have evaluated you. Many women find fatigue and/or nausea reduce their sexual life in the first 3 months, but usually things get back to normal for the middle 3 months and sometimes right up to term.</td>
</tr>
<tr>
<td>Complicated antenatal visit</td>
<td>These complications may well have already caused you to stop being sexual. Specifically, you should not have intercourse/have orgasms.</td>
</tr>
<tr>
<td>After one or more miscarriages</td>
<td>Some women temporarily lose desire for sex after a miscarriage—this is quite normal. Many couples concentrate on affectionate touching while they both grieve about what has happened. Do allow yourselves some time. If any sexual problems persist, we can address them.</td>
</tr>
<tr>
<td>Infertility</td>
<td>All this testing and timed intercourse and disappointment, plus the financial burdens that are coming up, can be very stressful on your sex life. Try to have times when you and your partner are sexual just for pleasure and intimacy’s sake—not when you are trying to conceive. Do you have any problems now?</td>
</tr>
<tr>
<td>Postpartum</td>
<td>It may be some weeks or months before you have the energy to be sexual, especially if your sleep is really interrupted. This is normal. If problems persist, or if you have pain, this can be addressed. Do you have any questions right now?</td>
</tr>
<tr>
<td>Perimenopause or postmenopause</td>
<td>We know many women have very rewarding sex after menopause—more time, more privacy. If you find the opposite or you begin to have pain or difficulty getting aroused, these things can be addressed. Do you have any concerns now?</td>
</tr>
<tr>
<td>Woman who is depressed</td>
<td>I know you are depressed right now, but our studies tell us that sex is still important for many women who are depressed. We also know that some of the medications we prescribe interfere with sexual enjoyment. Do you have any problems right now?</td>
</tr>
<tr>
<td>Chronic illness</td>
<td>Arthritis/multiple sclerosis can interfere with a woman’s sex life. Are you having any problems?</td>
</tr>
<tr>
<td>Potential damaging surgery</td>
<td>Obviously the focus right now is to remove your cancer entirely when we do your surgery. The nerves and blood vessels that allow sexual sensations and lubrication may be temporarily and sometimes permanently damaged. If when you have recovered you notice any sexual problems that persist, they can be addressed. Do you have any concerns now?</td>
</tr>
<tr>
<td>Bilateral oophorectomy</td>
<td>Your surgery will remove a major source of estrogen and approximately one half of the testosterone your body has been making. Testosterone will still be made by adrenal glands (small glands on top of the kidneys), and some of this gets converted into estrogen. Many women find that these reduced amounts of sex hormones are quite sufficient for sexual enjoyment, but others do not. Any sexual problems that do occur almost certainly can be addressed. Do you have any problems now?</td>
</tr>

Assessment of Each Partner Alone

| Partner’s own assessment of the situation | Sometimes it is easier to acknowledge symptoms, e.g., total lack of desire, in the partner’s absence |
| Sex response with self-stimulation | Also ask about sexual thoughts and fantasies |
| Past sexual experiences\( ^{1} \) | Positive, negative aspects |
| Developmental history\( ^{1} \) | Relationships to others in the home while growing up, losses, traumas, how they coped. To whom (if anyone) was this person close? Who showed them affection, loved them, respected them? Clarify if some of these themes are playing out now in the current sexual relationship. |
| Ask about sexual, emotional, and physical abuse\( ^{1} \) | Explain abuse questions are routine and do not necessarily imply causation of the problems. |

*These items of the single patient interview may sometimes be omitted (e.g., for a recent problem after decades of healthy sexual function).

The PLISSIT Model

Although gynecologists may sometimes need to provide detailed management for certain conditions (e.g., for the chronic dyspareunia of vulvar vestibulitis syndrome [VVS]), frequently the first two levels of a model known as PLISSIT are sufficient to address women’s sexual problems. The model is as follows:

1. **Permission.** The consent of permission is the validation of the patient’s concerns and confirmation that the gynecologist’s office is an appropriate setting to address them.

2. **Limited Information.** The patient is provided with information about sexual physiology and behavior so misunderstandings, myths, lack of knowledge, and inadequate sexual skills can be addressed.

3. **Specific Suggestions.** This stage may involve prescribing hormones and medications, advising different forms of sexual stimulation, evaluating sexual context, reeducating patients about specific attitudes and practices, addressing mental health issues, and identifying interpersonal factors.

4. **Referral for Intensive Therapy.** This step may be necessary for intrapsychological issues stemming from childhood that impair women’s ability to be aroused and interest/desire, including past traumas and abuse, couples who need more specialized help in sexual communication, and male sexual dysfunctions.

As an example of a PLISSIT approach, a woman with chronic dyspareunia from VVS is first given validation of her pain and is provided with the information that VVS is common.
and that many women find intercourse is precluded by the pain. The patient and her partner are encouraged to focus on nonpenetrative aspects of lovemaking. The next level is the provision of limited information about chronic pain mechanisms, the role of psychological stress, and genetic and possible immune factors. Specific suggestions could include encouragement to remove intercourse as one of the ways the couple interact sexually, prescription of medications for chronic pain, prophylaxis for overgrowth of candidiasis when this is relevant, and referral to a pelvic muscle physiotherapist if necessary. Referral for intensive therapy may be indicated for the woman in whom depression is precipitated, for couple counseling if the relationship cannot cope with the stress, or to a gynecologist specializing in vulvar surgery if vestibulectomy is considered.

<table>
<thead>
<tr>
<th>Diagnosis</th>
<th>Definition</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Sexual desire/interest disorder</strong></td>
<td>Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies and a lack of responsive desire. Motivations (here defined as reasons/incentives) for attempting to become sexually aroused are scarce or absent. The lack of interest is beyond a normative lessening with life cycle and relationship duration.</td>
<td>Minimal spontaneous sexual thinking or desiring of sex ahead of sexual experiences does not necessarily constitute disorder. Additional lack of responsive desire is integral to the diagnosis.</td>
</tr>
<tr>
<td><strong>Combined sexual arousal disorder</strong></td>
<td>Absent or markedly reduced feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of stimulation and absent or impaired genital sexual arousal (vulval swelling and lubrication).</td>
<td>There is minimal sexual excitement (subjective arousal) from any type of stimulation—erotic material, stimulating the partner, genital and nongenital stimulation. There is no awareness of the reflexive genital vasocongestion.</td>
</tr>
<tr>
<td><strong>Subjective sexual arousal disorder</strong></td>
<td>Absent or markedly reduced feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of stimulation. Vaginal lubrication and other signs of physical response still occur.</td>
<td>Despite lack of sexual excitement/subjective arousal, lubrication is noted by the woman or partner. Intercourse is comfortable without use of external lubricant.</td>
</tr>
<tr>
<td><strong>Genital arousal disorder</strong></td>
<td>Absent or impaired genital sexual arousal—minimal vulval swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia. Subjective sexual excitement still occurs from nongenital sexual stimuli.</td>
<td>Subjective arousal (sexual excitement) from nongenital stimuli (erotica, stimulating the partner, receiving breast stimulation, kissing) is key to this diagnosis. Early studies indicate reduced vasocongestion in some but not all cases. Loss of sexual sensitivity of physiologically congested tissues accounts for others.</td>
</tr>
<tr>
<td><strong>Orgasmic disorder</strong></td>
<td>Despite the self-report of high sexual arousal/excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any kind of stimulation.</td>
<td>Women with arousal disorders frequently do not experience orgasm. Their correct diagnosis is one of an arousal disorder.</td>
</tr>
<tr>
<td><strong>Vaginismus</strong></td>
<td>Persistent or recurrent difficulties of the women to allow vaginal entry of a penis, finger or any object despite the woman’s expressed wish to do so. There is often phobic avoidance and anticipation/fear/experience of pain, along with variable and involuntary pelvic muscle contraction. Structural or other physical abnormalities must be ruled out/addressed.</td>
<td>Confirmation of this diagnosis is not possible until there has been therapy sufficient to allow a careful introital and vaginal examination. It is a presumptive diagnosis initially.</td>
</tr>
<tr>
<td><strong>Dyspareunia</strong></td>
<td>Persistent or recurrent pain with attempted or complete vaginal entry and or penile vaginal intercourse.</td>
<td>There are many causes, including localized provoked vestibulodynia (vulvar vestibulitis syndrome) and vulvar atrophy from estrogen deficiency.</td>
</tr>
</tbody>
</table>

Sexual Dysfunction

Sexual problems are common in the general population in the United States. Surveys have found that approximately 30% of women report they lack interest in sex (11,63,66–69). Almost as many find sex affords little pleasure (3). Approximately 10% to 15% of women experience chronic dyspareunia (3,64). Few surveys ask questions about sexual excitement/subjective arousal, focusing instead on just one component of arousal, vaginal lubrication. One study of a nationally representative sample of 979 women aged 18 to 70 years found 17% identified problems with arousal (as distinct from vaginal dryness) (64). Insufficient lubrication is reported by 10% to 30% of women, which approaches the incidence postmenopause, and lack of orgasm is reported by 20% to 27% of women (2,3).

There are two important caveats regarding prevalence of sexual dysfunctions: first, comorbidity is typical (11,29), and second, not all women reporting a lack of interest/desire/arousal/orgasm see it as a problem or are distressed by it. Older women are less distressed than younger women about lack of sexual desire and interest (29). Studies show a correlation between sexual problems and poor self-esteem, poor physical and emotional health, being unmarried and less educated, having experienced sexual victimization, being sexually inexperienced, having negative experiences in prior sexual relationships, and not enjoying physical affectionate contact (3,66).

The duration of ongoing sexual difficulties (e.g., lasting more than 6 months) also is relevant. A study of women younger than 44 years of age in Great Britain found that although 41% of women reported lack of sexual interest for at least 1 month in the past year, only 10% reported it lasting longer than 6 months (66). Women who reported inability to experience orgasm for durations of 1 month and 6 months were 14.4% and 3.7%, respectively.

Chronic dyspareunia ranges in prevalence from 8% to 22% and decreases with age. Unexplained vulvar burning that interferes with intercourse, probably resulting from vulvar vestibulitis in most women, is thought to affect approximately 9% of women, with approximately 5% of women experiencing this condition before age 25 (68). Not surprisingly, most women with chronic dyspareunia perceive it as a problem.

Construction of the woman’s sex response cycle showing the various breaks can be highly therapeutic for the woman and her partner. Figure 11.3 shows the various breaks subsequent to infertility testing. The couple learns that it is “normal” for the woman to have low motivation to be sexual when emotional intimacy has suffered. If the issues distancing the couple cannot be addressed in the gynecologist’s office (i.e., they extend over and beyond the common reactions to infertility testing and procedures), referral to a relationship counselor may be necessary. The gynecologist can address the sexual context and the type of stimulation that is provided. The need of most women for more nonphysical stimulation, more nongenital physical stimulation, and more nonintercourse sexual stimulation can be stressed. Privacy issues, time of day, and emotional closeness at the time of lovemaking can all be discussed. Factors personal to the woman that may be impairing her ability to be aroused, such as low sexual self-image and distractions, can be identified. Referral may be necessary when low self-image appears ingrained and stems from developmental factors. Biological factors influencing arousability, including fatigue, medication effect, and depression, may be involved. Fears regarding outcome, such as lack of adequate birth control or partner dysfunction, can be identified. Inquiring about the patient’s thoughts at the time of potential lovemaking can be helpful. Some women admit to evoking negative thoughts or allowing spontaneously emerging negative thoughts to intrude when there is a sexual opportunity (70). Guilt about sex and about women having sexual pleasure may be present. If the woman is a new mother, she may feel on one level
that sex now is “wrong.” Experiences of assisted reproduction technique or delivery may lead to the woman feeling loss of control; this in turn may lead to a need to regain control in all aspects of her life, which may suppress her sexual feelings. Insight-oriented psychotherapy may allow patients to identify the negative feelings that inhibit erotic impulses (11). Meeting with a couple for a few sessions to assess their sexual knowledge, attitudes, and practices is often beneficial.

Genital Arousal Disorder

Management of the “genital deadness” of genital arousal disorder is unclear. Early research suggests that some of these women have demonstrably reduced genital vasocongestion in response to erotic stimuli (71). Those with reduced vasocongestion may benefit from investigational use of a phosphodiesterase inhibitor (71). Unfortunately, the role in clinical practice of psychophysiological study to monitor increases in pelvic vasocongestion in response to erotic stimuli is unclear, and these tests usually are not available. When local (or systemic) use of estrogen does not relieve the lack of genital sensitivity, the investigational use of phosphodiesterase inhibitor, with precautions against concomitant use of nitrates or alpha blocking agents, may be appropriate. Similarly, the investigational use of local testosterone (e.g., 2% testosterone applied to the clitoral area) has not been validated with scientific study. One theory is that the loss of genital sensitivity, despite physiological congestion, may be related to lack of androgen effect in the vulva.

Orgasmic Dysfunction

Lifelong orgasmic disorder is more common than acquired loss of orgasm. Some women acquire orgasmic dysfunction in association with relationship problems, depression, substance abuse, medication (especially use of SSRIs), or chronic illness (e.g., multiple sclerosis). Aside from those using SSRIs, most women who experience lack of orgasm are found on careful questioning to have modest degrees of subjective excitement (i.e., their true diagnosis is either subjective or combined arousal disorder). Sometimes women
just need reassurance that most couples do not experience orgasm simultaneously, that most women experience orgasm far more easily from direct clitoral stimulation, and that this does not constitute dysfunction.

**Common causes of lack of orgasm include obsessive self-observation and monitoring during the arousal phase, sometimes accompanied by anxiety and distracting negative and self-defeating thoughts** (72). The woman may be so intent on monitoring her own and her partner’s response and concerned about “failing” that she is unable to allow her natural reflexes to take over and trigger an orgasm. Lack of orgasm may be related to negative feelings toward sexuality, low self-esteem, poor body image, a history of sexual abuse, and fear of losing control, as well as ineffective sexual technique. **The only evidenced-based therapy is encouragement of self-stimulation, accompanied by erotic fantasy: so-called directed masturbation.** Several excellent self-help books are available to help women become orgasmic through self-stimulation (73). A vibrator may be helpful if the plateau of high arousal is reached but there is still no orgasmic release. When the woman has experienced orgasm with self-stimulation with or without the use of a vibrator, she may or may not be able to teach the technique to her partner. Issues of trust may then surface, and more intense psychological help may be needed.

**Sexual Pain Disorders**

**Vaginismus**

Vaginismus is an involuntary reflex precipitated by real or imagined attempts at vaginal entry. It may be generalized, in which the woman is unable to place anything in her vagina, even her own finger or a tampon, or it may be situational, in which she can use a tampon and can tolerate a pelvic examination but cannot have intercourse. Couples frequently cope with this difficulty for many years before they seek help and then do so to begin a family. Often there are no obvious circumstances predisposing to vaginismus, such as an unpleasant past sexual experience or trauma, sexual abuse, or a painful first pelvic examination. Despite the theories, there is no scientific evidence that vaginismus is secondary to religious orthodoxy, negative sexual upbringing, or concerns about sexual orientation. Women with vaginismus typically have an extreme fear of vaginal entry and misconceptions about their anatomy and the size of their vagina. They fear that harm will come from something the size of a penis entering the vagina and similarly fear they would be damaged by vaginal delivery.

The **diagnosis of vaginismus is provisional until a very careful introital and vaginal examination can be done.** This is not possible until the woman has learned to be able to abduct her thighs, open the labia with her fingers or permit the examiner to do so, and to tolerate introital touch. The therapy for vaginismus must begin before the diagnosis is confirmed:

1. **Encourage the couple to engage in sexual activities that exclude any attempt at intercourse.** They may need to again have “dates” and deliberately provide sexual contexts.

2. **Explain to the patient the reflex contraction of pelvic muscles around the vagina to touch, especially when touch has been associated only with negative emotions and physical pain.** These women rarely use tampons and avoid the introitus and vagina in sexual play and thus have not experienced any neutral or positive sensations from this area of their bodies.

3. **Institute self-touch on a daily basis for a few minutes as close to the vaginal opening as possible.** This may be done while the woman is in the bathtub or relaxing by herself on the bed. This is not sexual, and at first it will be highly anxiety provoking. Providing she does this daily, the anxiety will quickly decrease.
SECTION III  Preventative and Primary Care

4. **Suggest adding visual imagery to the previous exercise** so that she imagines being able to have a limited vaginal examination, sitting up on the couch at about a 70-degree angle to, with the aid of a mirror, view the vaginal opening and separate her labia, and be in control of what happens.

5. **As soon as she is ready, perform the partial vulvovaginal examination as in step 4.** If possible, encourage her to touch the vagina, moving her finger past the hymen, possibly afterward doing the same with the physician’s gloved finger.

6. **Once the vagina has been adequately examined, prescribe a series of vaginal inserts of gradually increasing diameter.** When symptoms suggestive of VVS are also present—especially burning with semen ejaculation, dysuria, or vulvodynia after intercourse attempts—she should use only the smallest insert before a repeat examination takes place.

7. **Repeat the examination with the woman checking for allodynia with a cotton swab.** Sometimes the physician can do this; it depends entirely on the amount of anxiety and apprehension the woman retains. However, the number of false-positive findings for allodynia can be limited if the patient touches the rim of the vaginal opening. Vestibulitis or other gynecologic findings should be treated. Once the patient is able to use larger inserts, the following steps can be undertaken:
   a. **Encourage the woman to allow her partner to assist her in placing the insert in her vagina.**
   b. **Encourage the couple during their sexual times to briefly use the insert** (to prove to her that the insert will still go in when her body is physiologically aroused).
   c. **Once she has used the insert on a number of occasions during sexual play, encourage her to follow it immediately with insertion of her partner’s penis.** It is usually preferable for the woman to hold her partner’s penis in the same position she used with the insert and to insert the penis herself. He must allow his pelvis to move forward with gentle pressure as she tries to insert it. The use of external lubrication is advised in these first attempts at penile entry.

Phosphodiesterase type 5 inhibitors may be used to treat temporary situational partner erectile dysfunction that occurs at the crucial moment when the woman is finally able to accommodate her partner’s penis.

---

**Dyspareunia**

**Dyspareunia, one of the most common types of sexual dysfunction seen by gynecologists, may affect two thirds of women during their lifetime** (74). Because dyspareunia is a psychophysiological condition, both psychological and physical factors must be considered in patient assessment. Generally, women with dyspareunia report more physical symptoms, psychological distress, and relationship issues than women who do not have pain during intercourse (75). Some women with VVS have an intense need to excel in all areas of their life and are particularly self-critical (40). Such internal stressors are thought to be involved in the maintenance of this chronic pain condition.

**There are three aspects to the management of dyspareunia.**

1. **Assisting the couple to have rewarding sexual intimacy even if initially intercourse is precluded.**

2. **Identifying the psychological issues contributing to and arising from the chronic pain.**
Treating, whenever possible, the underlying pathophysiology that has triggered the chronic pain circuits.

It is helpful to clarify that the popular depiction of sex as foreplay followed by “real sex” (i.e., intercourse) is not the reality for many sexually satisfied couples. The couple can be encouraged to consider the many varieties of human sexual interaction and ways of giving and receiving genital and nongenital sexual pleasure. It is important for the couple to see removal of intercourse from the menu of sexual activity as an opportunity to be more explorative and creative, and not as a loss.

**Psychological Factors**

Psychological factors contributing to dyspareunia include:

1. **Developmental factors** (e.g., upbringing that invested sex with guilt and shame)
2. **Traumatic factors** (e.g., past physical, sexual, or emotional abuse)
3. **Relationship factors** (e.g., anger or resentment toward the sexual partner)

The goal of the assessment is to clarify the extent to which these three factors contribute to dyspareunia. Once that has been established, relevant referral may be necessary.

Reactions to chronic pain include loss of sexual self-confidence, guilt, anger, resentment, and feeling “used” when sexual activity with penetration continues, despite the presence of pain. It is important that the physician allows these negative emotions to be expressed (this is what referred by as “permission” in the PLISSIT model) and their cause validated so that the woman can move on to accepting her situation and finding ways of triggering and expressing her sexuality. It is important to include the partner in the assessment and evaluation of chronic dyspareunia, allowing his feelings to be addressed and his compliance with nonpenetrative sex encouraged. The couple rendered emotionally distant because of chronic dyspareunia may find it difficult to adapt to alternative forms of lovemaking.

**Underlying Pathophysiology**

The pathophysiology of the most common type of dyspareunia, VVS, is unclear. The current understanding is that there is neurogenic inflammation that has led to chronic pain circuits with both central and peripheral sensitization. This means that there are physical changes within the central nervous system that perpetuate the pain cycles and that can be targeted by chronic pain drugs. Figure 11.4 shows the different aspects of pathophysiology underlying VVS and the placement of medication and pelvic muscle physiotherapy.

Introital pain may be caused by conditions other than VVS. The differential diagnosis includes recurrent tears of the posterior fourchette, which may be treated with the topical application of estrogen or testosterone and, if necessary, a perineorrhaphy. Other diagnoses are congenital abnormalities, including a hymenal ring that is rigid, scar tissue (e.g., from episiotomy repairs), a vaginal septum, and, much more commonly, vaginitis or vulvitis, sometimes resulting from the use of over-the-counter vaginal sprays and douches. One important common cause of dyspareunia is friction from inadequate genital sexual arousal. Estrogen deficiency with inadequate lubrication, progressing to loss of elasticity and thinning of the epithelium from vaginal atrophy, is another common cause. This condition is easily treated with local estrogen therapy. Deep dyspareunia resulting from pelvic disease, including endometriosis, is managed by treatment of the underlying conditions.
**Sexual Dysfunction Midlife and Later**

Because sexual dysfunction in older women can be related to a variety of factors, broad-spectrum treatment approaches are needed in which individual, interpersonal, and sexual aspects can be addressed simultaneously. The following steps in therapy are recommended:

- To encourage the woman to take responsibility for discovering what provides sexual arousal and to learn to guide her partner toward stimuli that are pleasurable to her now, as they may be different and less effective than the ones she enjoyed when she was a younger woman.
- To assist her to understand that a more rewarding outcome will increase her sexual motivation. Factors relating to the couple’s sexual style and even sexual dysfunction in the partner may need to be addressed.
- To counsel her that women can begin rewarding sexual experiences in the absence of desire, which can be reassuring and therapeutic.
- To acknowledge that resentment, frustration, and disappointment toward her partner is therapeutic and may benefit from referral for relationship counseling.

---

**Figure 11.4** Schematic of proposed pathophysiological mechanisms underlying the chronic pain of vulvar vestibulitis syndrome and therapeutic interventions. WBC, white blood cells.
• To advise that deep-seated psychological distress from factors in her development or current refractory mood disorders may require referral to a psychologist/psychiatrist.

Practical suggestions for aging patients might include taking a warm bath before lovemaking to loosen stiff joints, making love in the morning when the couple is less fatigued, or having neither intercourse nor orgasm as a necessary goal. Local estrogen supplementation can alleviate vaginal dryness, urinary tract symptoms, and dyspareunia, restoring vaginal cell health, decreasing pH, and increasing vulvar/vaginal blood flow. The aging couple should be encouraged to use low-key, more prolonged sexual stimulation because the rate of sexual response is slower. Systemic estrogen supplementation may improve insomnia and hot flushes, thus improving sexual function. **Because oral estrogen can decrease free testosterone levels by nearly 50% by increasing levels of sex hormone-binding globulin, topical estrogen is a preferable formulation for women with sexual difficulties.**

In women with sexual dysfunction associated with salpingo-oophorectomy, the first published study of testosterone supplementation to levels at or only slightly higher than those found in premenopausal women showed improved arousability/response but not an increase in desire as in sexual thinking/fantasizing (8). Recent multicentered randomized controlled trials of naturally and surgically menopausal women have shown improved “total satisfying sexual activity” and improvement in the desire domain on the sexual questionnaires used (48, 76-79).

Unwanted effects of testosterone include acne, hirsutism, deepening of the voice, clitoromegaly, alopecia, hepatotoxicity, and undesirable changes in lipoprotein levels. **Women receiving supplemental testosterone should undergo long-term monitoring for these conditions.** Given the data on increased insulin resistance with higher levels of endogenous androgens (80), insulin resistance must be carefully monitored, especially in obese women. Women should be prescribed the lowest effective dose of testosterone and counseled that the treatment is investigational (23). Currently, the transdermal route appears optimal. The need for simultaneous use of systemic estrogen is another confounding variable in view of the lack of safety/efficacy data in randomized controlled trials recruiting women who begin estrogen therapy using transdermal formulations for sexual symptoms at menopause.

**Sexual Assault**

Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime (81–83). Sexual assault is a crime of violence and aggression, not passion, and encompasses a continuum of sexual activity that ranges from sexual coercion to contact abuse (unwanted kissing, touching, or fondling) to forcible rape. **The terms sexual abuse survivor and assault survivor are preferable to victim.**

In a survey of female family practice patients, 47% reported some type of contact sexual victimization during their lifetime; 25% reported attempted rape, and 13% had been forcibly raped, many as children (84). Among battered women, approximately 68% experience marital rape as an element of their repetitive abuse (85). Uninvited sexual attention in the workplace is reported by 50% of women in the United States (86). Spousal rape is reported infrequently because of fear of retribution and economic dependency (87). Obstetrician–gynecologists should routinely inquire about a history of childhood sexual abuse or adult sexual assault. These experiences are common and often have a lasting and profound effect on a woman’s mental and sexual function as well as her general health and well-being.
SECTION III Preventative and Primary Care

Childhood Sexual Abuse

Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that as many as one third of adult women were sexually abused as children. Childhood sexual abuse is often accompanied by another type of household dysfunction, such as physical abuse, violence against other family members, or substance abuse by parental figures (83). Younger children are more often exposed to genital fondling or noncontact abuse (exhibitionism, forced observation of masturbation, or posing in child pornography), and children older than 10 years of age are more likely to be forced to have intercourse or oral sex (88). As children age, they are more likely to experience sexual abuse outside the home and more likely to be victimized by strangers. As adolescents, women survivors of childhood sexual abuse are at risk for early unplanned pregnancy, STDs, prostitution, antisocial behavior, running away from home, lying, stealing, eating disorders, and multiple somatic symptoms. These women are more likely to engage in health risk behaviors such as smoking, substance abuse, and early sexual activity with multiple partners (89). They may be less likely to use contraception (90). Survivors often avoid pelvic examinations and are less likely to have Pap tests because of the association between vaginal examinations and pain. They often receive inadequate prenatal care and are more likely than women who have not been abused to experience suicidal ideation and depression during their pregnancies and to deliver smaller and less mature babies (83).

Obstetrician–gynecologists can assist their sexual assault patients by validating their feelings and concerns and giving them control over their examination. It is important to ask the patient for permission to perform the examination, give her the opportunity to have an advocate in the room with her, and let her know that she has the right to stop the examination at any time (83).

Survivors may be unable to trust or establish rapport with adults. Some women blame themselves for the abuse and come to believe that they are not entitled to assistance from others. Thus, they risk continuing to enter abusive relationships. Women survivors of childhood sexual abuse often develop feelings of powerlessness and helplessness and may become chronically depressed. They experience a high incidence of self-destructive behavior, including suicide and deliberate self-harm, such as cutting or burning themselves (83,91,92). The most extreme mental health symptoms in assault survivors are associated with the onset of abuse at an early age, frequent abuse over a long period, use of force, or abuse by a parent. Survivors are also at risk for becoming victimized again later in life (93). Of women who report being abused as children, 50% are abused again as adults. Women who are sexually abused as children carry the effects of abuse into adulthood. As adults, they have the same level of physical symptoms and psychological distress as women who do not report childhood sexual abuse but are currently experiencing sexual or physical abuse (94).

Women who have been sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting (95). Chronic sexual concerns may include fear of intimate relationships, lack of sexual enjoyment, difficulty with desire and arousal, and anorgasmia. Compared with women who have not been sexually assaulted, they are more likely to experience depression, suicide attempts, chronic anxiety, anger, substance abuse problems, dissociative personality disorder, borderline personality disorder, fatigue, low self-esteem, feelings of guilt and self-blame, and sleep disturbance (94,96–98). They often experience social isolation, phobias, feelings of vulnerability, fear, humiliation, grief, and loss of control (99,100). Survivors of sexual assault represent a disproportionate number of patients with chronic headaches and chronic pelvic pain (they have a lower pain threshold) and are more likely to have somatic symptoms that do not respond to routine medical treatment (97,101). Women with common gynecologic symptoms, such as dysmenorrhea, menorrhagia, and
sexual dysfunction, are much more likely to have a history of sexual assault (102). If they have been forced to perform oral sex, they may have a dental phobia and avoid preventive dental care.

Survivors may develop posttraumatic stress disorder (PTSD), in which characteristic symptoms are exhibited following a psychologically traumatic event outside of normal human experience. Symptoms of PTSD include blunting of affect, denial of symptoms, intrusive re-experiencing of the incident, avoidance of stimuli associated with the assault, and intense psychological distress and agitation in response to reminders of the event (81, 91). Women affected by PTSD are more likely to commit suicide. The cognitive sequelae include flashbacks, nightmares, disturbances in perception, memory loss, and dissociative experiences (103). These women may not be able to tolerate pelvic examinations and may avoid seeking routine gynecologic care because these examinations may remind them of the sexual abuse they experienced as children. However, they are more likely to use the medical care system for nongynecologic concerns (104). Women with PTSD are at greater risk for being overweight and having gastrointestinal disturbances (89).

Rape

Although the legal definition of sexual assault may vary from state to state, most definitions of rape include the following elements:

1. The use of physical force, deception, intimidation, or the threat of bodily harm

2. Lack of consent or inability to give consent because the survivor is very young or very old, impaired by alcohol or drug use, unconsciousness, or mentally or physically impaired

3. Oral, vaginal, or rectal penetration with a penis, finger, or object

The National Women’s Study provides the best statistics available about the incidence of forcible rape in the United States (99). This study revealed that 13%, or one of eight adult women, are survivors of at least one completed rape during their lifetime. Of the women they surveyed, 0.7% had been raped during the past year, equaling an estimated 683,000 adult women who were raped during a 12-month period. Of the women surveyed, 39% were raped more than once. Most disturbing, however, is the finding that most rapes occurred during childhood and adolescence; 29% of all forcible rapes occurred when the survivor was younger than 11 years of age, and 32% occurred between the ages of 11 and 17 years. Indeed, “rape in America is a tragedy of youth” (99). Twenty-two percent of rapes occurred between the ages of 18 and 24 years, 7% between the ages of 25 and 29 years, and only 6% occurred when the survivor was older than 30 years of age. Although women of all ages and cultures are vulnerable to sexual assault, prisoners, adolescents, drug users, the elderly, those who experienced sexual assault as children, women in abusive relationships, and women with emotional and physical disabilities are at most risk (106).

There are many myths about rape. Perhaps the most common myth is that women are raped by strangers. In fact, only about 20% to 25% of women are raped by someone they do not know. Most women are raped by a relative or acquaintance (9% by husbands or ex-husbands, 11% by fathers or stepfathers, 10% by boyfriends or ex-boyfriends, 16% by other relatives, and 29% by other nonrelatives) (99). Although acquaintance rape may seem to be less traumatic than stranger rape, survivors of acquaintance rape often take longer to recover. Another common misconception about rape is that most survivors sustain serious physical or life-threatening injury. Sixty percent of rape
SECTION III Preventative and Primary Care

survivors report some physical injury. General body injury is more than twice as common as genital and anal injury (107). Serious injury is rare, occurring 4% of the time, although almost half of the rape survivors report being fearful of serious injury or death during the assault (99). The most common genital injuries from a sexual assault are vaginal lacerations resulting in bleeding and pain. Intraperitoneal extension of a vaginal laceration or damage to the anal mucosa is rare (108). Common nongenital injuries in survivors include cuts, bruises, scratches, broken bones and teeth, and knife or gunshot wounds (109). About 0.1% of sexual assaults result in death. Common causes of death during a sexual assault include mechanical asphyxiation, trauma, lacerations, drowning, and gunshot wounds (108).

There are at least four types of rapists (110):

1. **Opportunist rapists** (30%) exhibit no anger toward the women they assault and usually use little or no force. These rapes are impulsive and may occur in the context of an existing relationship (date or acquaintance rape). The highest incidence of acquaintance rape is among women in the twelfth grade of high school and in the first year of college (111). As many as half of college women report date rape. Many of these women may have been unable to give consent because they are impaired by alcohol or so-called date rape drugs (Rohypnol and gamma-hydroxy butyrate [GHB]). Date rape may have even greater psychological consequences than rape by a stranger because it involves a violation of trust (108).

2. **Anger rapists** (40%) usually batter the survivor and use more physical force than is necessary to overpower her. This type of sexual assault is episodic, impulsive, and spontaneous. An anger rapist often physically assaults his victim, sexually assaults her, and forces her to perform degrading acts. The rapist is angry or depressed and is often seeking retribution—for perceived wrongs or injustices he imagines have been done to him by others, especially women. He may victimize the very young or the very old.

3. **Power rapists** (25%) do not intend to physically harm their victim but rather to possess or control her to gain sexual gratification. However, a power rapist may use force or the threat of force to overcome his victim. These assaults are premeditated and repetitive, and they may increase in aggression over time. The rapist is usually anxious and may give orders to his victim, ask her personal questions, or inquire about her response during the assault. This assault may occur over an extended period while the victim is held captive. These rapists are insecure about their virility and are trying to compensate for their feelings of inadequacy and low self-esteem.

4. **Sadistic rapists** (5%) become sexually excited by inflicting pain on their victim. These rapists may have a thought disorder and often exhibit other forms of psychopathology. This type of assault is calculated and planned. The victim is often a stranger. The rape may involve bondage, torture, or bizarre acts and may occur over an extended period of time. The victim often suffers both genital and nongenital injuries and may be murdered or mutilated. Other rapists may act out of impulse, as when they encounter a victim during the course of another crime such as burglary. Some rapists believe they are entitled to their victim, as in acquaintance rape or father–daughter incest (112). A consistent finding among all types of rapists is a lack of empathy for the survivor.

Even when sexual assaults are reported (only 16% of rapes are ever reported to the police), few rapists are arrested, and even fewer are brought to trial and convicted. Fewer than 1% of rapists ever serve a prison term (110,113). Successful prosecution
of rapists is often dependent upon the extent of the survivor’s injuries and the completion of a detailed forensic examination (114). Many women do not report the assault to the police because they are concerned about their name being disclosed by the news media, fear retaliation from the perpetrator, are afraid they will not be believed, or do not trust the judicial process (115). Assault is more likely to be repeated if survivors in abusive relationships do not seek medical care, report the incident to police, or seek an order of protection (85).

Only 26% of rape survivors seek medical attention after an assault (85). Women are more likely to immediately seek treatment after sexual assault if weapons were involved, serious physical injury occurred, or physical coercion or confinement was used in the assault (116). Many rape survivors do not inform their physicians about the assault and may never volunteer information about the assault unless they are directly asked. Therefore, when obtaining a medical history, physicians should routinely ask, “Has anyone ever forced you to have sexual relations?”

The responsibilities of physicians providing immediate treatment for sexual assault survivors are listed in Table 11.8. Because of the legal ramifications, consent must be obtained from the patient before obtaining the history, performing the physical examination, and collecting evidence. Documentation of the handling of specimens is especially important, and the chain of evidence for collected material must be carefully maintained. Everyone who handles the evidence must sign for it and hand it directly to the next person in the chain. The patient should be interviewed in a quiet and supportive environment by an examiner who is objective and nonjudgmental. Support personnel and patient advocates, such as family, friends, or, if available, a counselor from a rape crisis service, should be encouraged to accompany the patient. It is important not to leave the survivor alone and to give her as much control as possible over the

Effects of Rape

Following sexual assault, women have many concerns, including pregnancy, STIDs (including human immunodeficiency virus [HIV] infection), being blamed for the assault, having their name made public, and having their family and friends find out about the assault. The initial reactions to sexual assault may be shock, numbnness, withdrawal, and possibly denial. It is difficult to predict how any assaulted individual will react. Despite their recent trauma, women presenting for medical care may appear calm and detached (114).

The rape trauma syndrome is a constellation of physical and psychological symptoms, including fear, helplessness, disbelief, shock, guilt, humiliation, embarrassment, anger, and self-blame. The acute, or disorganization, phase of the syndrome lasts from days to weeks. Survivors may experience intrusive memories of the assault, blunting of affect, and hypersensitivity to environmental stimuli. They are anxious, do not feel safe, have difficulty sleeping and eating, and experience nightmares and a variety of somatic symptoms (112,117,118). They may fear that their assailant will return to retaliate or rape them again.

In the weeks to months following the sexual assault, survivors often return to normal activities and routines. They may appear to have dealt successfully with the assault, but they may be repressing strong feelings of anger, fear, guilt, and embarrassment. In the months following the assault, survivors begin the process of integration and resolution. During this phase, they begin to accept the assault as part of their life experience, and somatic and emotional symptoms may decrease progressively in severity. However, the sequelae of rape are often persistent and long lasting (91). Over the long term, survivors may have difficulty with work and with family relationships. Disruption of existing relationships is not uncommon. Nearly half of the survivors lose their jobs or are forced to quit in the year following the rape, and half change their place of residency (100).
SECTION III Preventative and Primary Care

To provide useful forensic information, the examination should be performed as soon as possible after the incident occurred. The history should include the following information:

1. A general medical history and a gynecologic history must be obtained, including last menstrual period; prior pregnancies; past gynecologic infections; tetanus status; history of liver disease, thrombosis, or hypertension (possible contraindications to emergency contraception with estrogens); contraceptive use; prior sexual assault; and last consensual intercourse before the assault.

2. It is important to ascertain whether the survivor bathed, douched, used a tampon, urinated, defecated, brushed her teeth, or changed her clothes after the assault.

3. A detailed description of the sexual assault should be obtained, including the place, time, and date of the assault; number of assailants; use of drugs or alcohol in relation to the assault; loss of consciousness; use of weapons, threats, and restraints; and any physical injuries that may have occurred.

4. A detailed description of the type of sexual contact must be obtained, including whether vaginal, oral, or anal contact or penetration occurred; insertion of a foreign object with a description of the object; whether the assailant used a condom; and whether there were other possible sites of ejaculation, such as the hands, clothes, or hair of the survivor.

5. The emotional state of the survivor should be observed and recorded.

The physical examination serves to detect, evaluate, and treat all injuries and to collect forensic evidence (119). The survivor should undress while standing on clean examination.
CHAPTER 11  Sexuality, Sexual Dysfunction, and Sexual Assault

table paper to catch any hair or fibers falling from her clothing. All of her clothing should be placed by the survivor (to avoid contamination) in individually labeled paper bags, sealed, and given to the proper authorities. Wet or damp clothing should be air dried before packaging because DNA evidence degrades quickly if it is moist (106). During the physical examination, the degree of injury to the survivor should be assessed, and any injuries should be documented for use as evidence. The nature, size, and location of all injuries should be carefully documented, using photographs or body charts (traumagram) if possible. Nongenital injuries occur in 20% to 50% of all rapes, so it important to examine the entire body (119,120).

The most common injuries are bruises and abrasions of the head, neck, and arms (112), as well as genital injuries accompanied by bleeding and pain. Hair and skin should be examined for dirt, foreign material, dried blood, and dried semen (119). Ruptured blood vessels in the retina may be the result of trauma from choking. If oral penetration has taken place, injuries of the mouth and pharynx may occur (121). Injury to the oral cavity, including a torn frenulum, broken teeth, trauma to the uvula, and injuries of the hard and soft palate, are related to forced fellatio.

The most common genital findings are erythema and small tears of the vulva, perineum, and introitus. A Foley catheter, placed in the distal vaginal vault and then inflated, allows for full visualization of hymenal injuries (105). There may be bleeding, mucosal tears, erythema, or a hematoma noted around the rectum if penetration has occurred. Identification of small lacerations of the genitalia or rectum may be aided by colposcopy or by staining with toluidine blue, which has an affinity for the nuclei of exposed submucosal cells (120–123). Toluidine blue should be applied before the speculum examination, as insertion of the speculum itself can cause small lacerations and false-positive results. Toluidine blue is also spermicidal and should not be applied until all forensic evidence is collected (122). Bite marks are not uncommon and frequently are found on the breasts or genitalia. Foreign bodies may be found in the vagina, rectum, or urethra.

Samples should be obtained from any sites of contact (vagina, rectum, or mouth) and tested for gonorrhea and chlamydia. A vaginal wet prep examination should be performed for evidence of trichomonas. A urine or serum pregnancy test should be performed, as well as baseline testing for syphilis, hepatitis B, and HIV.

Evidence must be properly collected for legal purposes according to the following procedures:

1. Examination of the patient with a Wood light may help identify semen, which will fluoresce blue-green to orange. Areas of fluorescence should be swabbed with a cotton-tipped applicator moistened with sterile water, then air dried and submitted as evidence. Swabs of the skin, vagina, mouth, and rectum may be obtained to test for the presence of sperm or semen.

2. A Pap test may also be useful to document the presence of sperm.

3. A sample of the vaginal secretions should be obtained for examination for motile sperm, semen, or pathogens. Motile sperm in the vagina indicate ejaculation occurred within 6 hours. Nonmotile sperm can be found in the cervical mucus for as long as 1 week. If ejaculation has occurred in the mouth, seminal fluid will be rapidly destroyed by salivary enzymes (108). If the survivor reports an anal assault, specimens can be obtained by washing the rectal vault with 10 mL of normal saline injected with a red rubber catheter. Allow the saline to stand for several minutes, then aspirate the rectal fluid and submit as evidence.
SECTION III Preventative and Primary Care

4. Vaginal secretions should also be collected for DNA fingerprinting and to test for the presence of seminal contents, including acid phosphatase, p30 protein (specific to the prostate), seminal vesicle-specific antigen, and ABO antigens (83).

5. The survivor’s pubic hair should be combed over a sheet of paper in an attempt to obtain pubic hair from the assailant. Both the comb and the pubic hair should be submitted as evidence.

6. Fingernail scrapings from the survivor should be collected and evaluated for evidence of trace fibers or the assailant’s blood, hair, or skin. This evidence may also be used for DNA fingerprinting.

7. Saliva should be collected from the survivor to document whether she is a secretor of major blood group antigens (80% of the population are secretors). If the patient is not a secretor and blood group antigens are found in vaginal washings, the antigens are probably from the semen of the assailant (83).

Treatment of sexual assault survivors should be directed to prevention of possible pregnancy and provision of prophylactic treatment for STDs (Table 11.8). About 5% of fertile rape survivors will become pregnant as a result of the rape (124). Options include awaiting the next expected menses, repeating the serum pregnancy test in 1 to 2 weeks, and using emergency (postcoital) contraception. If the patient desires emergency contraception, a preexisting pregnancy can usually be ruled out by performing a sensitive human chorionic gonadotropin assay. Pregnancy prophylaxis can be provided by several different regimens (125,126) (see also Chapter 10):

1. Administration of one tablet containing 0.75 mg of levonorgestrel followed by a second tablet 12 hours later (Plan B). A single 1.5-mg dose of levonorgestrel is just as effective as the two-dose regimen and is the preferred method of emergency contraception (126)

2. Immediate administration of two tablets of a combination oral contraceptive (each containing 50 µg of ethinyl estradiol and 0.5 mg norgestrel, i.e., Ovral birth control pills) followed by two more tablets 12 hours later (Yuzpe regimen)

3. Four tablets of a combination birth control pill containing 35 µg of ethinyl estradiol and a progesterone followed by four more tablets 12 hours later

4. Mifepristone as a single 10 mg dose (127)

5. Placement of a copper-containing intrauterine device

These regimens are highly effective if administered within 120 hours after the sexual assault (126,128). However, the sooner the medications are taken, the more effective they are. Most regimens have a failure (pregnancy) rate of about 1.5%. Some patients experience nausea and vomiting when given emergency contraception containing estrogen, which can be controlled with an antiemetic agent such as promethazine (12.5 mg every 4–6 hours). Single-dose levonorgestrel is more effective and is associated with fewer side effects than the Yuzpe regimen, and is the method of choice for emergency contraception. Emergency contraception has a small failure rate but poses little teratogenic risk if the pregnancy continues (129). Most women who take emergency contraception usually experience their next menstrual period within 3 days of the expected date. However, women using mifepristone for emergency contraception may experience delayed onset of the subsequent menstrual period (127). Emergency contraception may delay but not prevent ovulation; for this reason, patients receiving emergency contraception should be encouraged to use contraception if further coital episodes occur during the cycle.
The risk of acquiring an STD from a rape is difficult to assess because the prevalence of preexisting STDs is high (43%) in rape survivors (130–132). However, the risk is estimated as follows: gonorrhea, 6% to 12%; trichomonas, 12%; chlamydia, 2% to 12%; and syphilis, 5%.

1. Because it is difficult to differentiate between a preexisting STD and a newly contracted one attributable to a sexual assault, prophylaxis should be offered to all survivors. This is especially important because most sexual assault patients do not return for follow-up appointments (118). Prophylaxis should cover infections with *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, trichomonas, bacterial vaginosis, incubating syphilis, and HIV. Current recommendations include (131,133):
   a. *Ceftriaxone*, 125 mg intramuscularly for the treatment of gonorrhea (if the patient is allergic to cephalosporins, *spectinomycin*, 2 g intramuscularly, or *ciprofloxacin*, 500 mg orally, may be used), PLUS:
   b. A single dose of 1 g of *azithromycin* orally or 100 mg of *doxycycline* orally twice a day for 7 days for treatment of chlamydia (if the patient is pregnant at the time of the assault, *erythromycin* 500 mg orally four times a day for 7 days may be substituted for *doxycycline*), PLUS:
   c. A single dose of 2 g of *metronidazole* orally for the treatment of trichomoniasis and/or bacterial vaginosis.

2. Hepatitis B vaccination should be offered if the sexual assault survivor has experienced vaginal, oral, or anal penetration. Hepatitis B is 20 times more infectious than HIV during intercourse (83). Vaccination is recommended at the time of the initial evaluation. Subsequent doses are provided 1 month and 6 months after the first dose is administered. It is not necessary to treat the patient with hepatitis B immune globulin (133).

3. Tetanus prophylaxis (0.5 mL intramuscularly) should also be administered if indicated. Conversion of HIV through sexual assault, although reported, is low and similar to conversion from occupational exposure (0.1% to 0.3% per episode) (134). The probability of transmission depends on the type of assault, presence of trauma and bleeding, site of ejaculation, HIV viral load in the ejaculate, presence of a concomitant STD or ulcerative lesions in the assailant or survivor, and the community prevalence of HIV/acquired immune deficiency syndrome (120,134). Factors to consider when discussing HIV post-exposure prophylaxis with patients include the likelihood of exposure to the virus, the risks and benefits of treatment, the interval between the sexual assault and the initiation of therapy, and the patient’s desire to be treated. All survivors of unprotected vaginal or anal sexual assault presenting within 72 hours should be offered HIV prophylaxis unless the assailant is known to be HIV negative (135). Treatment should be initiated as soon as possible. The usual regimen is *Combivir* or its equivalent (300 mg *zidovudine* [AZT] and 150 mg *lamivudine* [3TC]) administered twice daily for 4 weeks). Administration of a protease inhibitor (*nelfinavir*, five 250 mg tablets twice a day for 28 days) should be considered for high-risk exposures, such as when the assailant is known to be HIV infected. Side effects of HIV prophylaxis include nausea, malaise, headache, and anorexia. About 33% of survivors who elect to take antiviral medication discontinue therapy prematurely (134). Patients should be aware that the efficacy of prophylactic treatment for HIV after sexual assault is unknown and they will have to be carefully monitored if they initiate treatment with antiretroviral medication.

5. If prophylactic treatment for gonorrhea, chlamydia, trichomonas, and bacterial vaginosis is not given, the survivor should return in 2 weeks for repeat testing for STDs and pregnancy. If the initial serologic test results were
negative, repeat serologic tests for syphilis, hepatitis B, and HIV should be performed at 6, 12, and 24 weeks after the assault.

6. **Ongoing supportive counseling for the patient should be arranged**, and the patient should be referred to a sexual assault center or a therapist who specializes in the treatment of sexual assault survivors.

Common Psychiatric Problems

Nada Logan Stotland

- Accurate diagnosis is the key to successful treatment.
- Most psychotropic medications appear to be relatively safe to use during pregnancy and lactation, but because studies are appearing at a rapid rate, it is essential to consult the latest literature before making clinical decisions. Withdrawal of successful psychotropic treatment is not indicated.
- Personality disorders and somatizing disorders can rarely be cured, but informed management can greatly decrease the suffering of the patient, the drain on the family, and the frustration of the health care team.
- Domestic violence and other unfortunate social circumstances are major risk factors for psychiatric illness.
- Some women are vulnerable to mood symptoms at times of hormonal change. However, menopausal hormone levels are not correlated with depression, and premenstrual syndrome should not be diagnosed without 2 months of prospective daily ratings.

Psychiatric problems are a central or complicating factor for many patients who seek care on an outpatient basis (1,2). Psychiatric diagnoses are extremely common and account for considerable morbidity and mortality in the general population (3). Despite their prevalence, however, psychiatric disorders are often undiagnosed or misdiagnosed (4–7). Clinical depression affects up to one fourth of women during their lives (8–10), but an estimated 80% of the cases are neither diagnosed nor treated (11). More than one half of the patients who commit suicide have seen a nonpsychiatric physician during the previous 3 months (12).

The Context of Psychiatric Conditions

Many gynecologists feel uncomfortable diagnosing and treating psychiatric illnesses for a number of reasons. The practice of gynecology is demanding. Patients with psychological problems can evoke negative reactions in physicians (Table 12.1). In the past, gynecologists have found it difficult to use psychiatric diagnostic systems because they were based on
theories of unconscious motivation and conflict. New systems for the diagnosis of psychiatric disorders are reliable and valid and can be systematically applied, and many psychiatric treatments are specific and effective. By incorporating these management strategies into practice, gynecologists can play a major role in improving the health and well-being of their patients.

### Psychiatric Assessment

In the past, the diagnosis of psychiatric disorders was based partially on hypotheses about a patient’s unconscious psychological conflicts, which cannot be verified (13). Current psychiatric diagnosis, as codified in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR), produced and published by the American Psychiatric Association, is based on empirical, valid, and reliable evidence. The DSM-IV yields reliability comparable to that of diagnostic systems used in other areas of medicine, and its diagnoses strongly correlate with response to treatment. The criteria in DSM-IV are the basis for the diagnostic entities described in this chapter (see also Chapter 1). The new edition, DSM-IV-TR, differs only in the explanations of some of the diagnoses and not in the diagnostic criteria themselves. The DSM-IV-PC is a special edition designed for the primary care provider. This volume is organized by initial signs and symptoms rather than psychiatric categories and uses algorithms and decision trees to facilitate the diagnostic process. Accurate diagnosis is absolutely critical to successful management, whether care is provided by a gynecologist or through referral to a mental health expert.

### Approach to the Patient

Although diagnostic criteria list signs and symptoms, the interaction with a patient should not be reduced to a series of rapid-fire questions and answers. A wealth of valuable information can be obtained from the patient’s spontaneous description of her concerns and from her responses to the physician’s open-ended questions (14). A patient who is encouraged to speak for several minutes before being asked to respond to specific questions will reveal information that is useful, even vital, to her care: a thought disorder, a predominant mood, abnormally high anxiety, a personality style or disorder, and attitudes toward her diagnosis and treatment. Such information may emerge only much later, or not at all, in a question-and-answer format (15,16). It is critical that the gynecologist neither jumps to diagnostic conclusions nor proceeds directly to therapeutic interventions.

One study revealed that many primary care physicians, feeling that they had too little time or training to assess psychological symptoms, tended to minimize verbal interactions with patients and to rely on the prescription of psychotropic medications (17). Allowing a few moments for open-ended discussion does not mean that the physician and the other patients awaiting care are to be held hostage by an overly talkative patient, however. The clinician can tell the patient with multiple, detailed symptoms how much time is available for the current appointment, invite her to focus on her most pressing problem, and offer a future appointment to continue the account.

**Psychiatric Referral**

Many gynecologists consider referral to a mental health professional, particularly a psychiatrist, to be a delicate matter. The first question is when to refer, followed by how to refer and to whom. Most mild psychiatric disorders are treated by nonpsychiatric physicians (18), who often prescribe antidepressants and anxiolytic medications. At the same time, however, psychiatric disorders often are overlooked, misdiagnosed, or mistreated in primary care practice. The following factors determine the decision to refer:

- The nature and severity of the patient’s disorder
- The expertise of the gynecologist
- The time available in the gynecologic practice
- The patient’s preference
- The gynecologist’s degree of comfort with the patient and the disorder
- The availability of mental health professionals

**Patients who are suicidal, homicidal, or acutely psychotic should be referred to a psychiatrist.** Patients also should be referred for psychiatric evaluation when the diagnosis is not clear or when the patient fails to respond to initial treatment by the primary provider. For many patients, the gynecologist can resume responsibility for ongoing care after an initial or periodic assessment by a psychiatrist.

**How to Refer?**

Some clinicians fear that patients will be insulted, alienated, or alarmed by a psychiatric referral. Following are techniques that decrease the discomfort of both the gynecologist and the patient and enhance the likelihood of a successful referral (19). The referral should be explained on the basis of the patient's own signs, symptoms, and level of distress. For a patient suffering from clinical depression, for example, this might be difficulty sleeping, loss of appetite, or lack of energy. For a patient with an anxiety disorder, it might be palpitations, shortness of breath, or nervousness. For a patient with mild Alzheimer's disease, it might be forgetfulness or frightening episodes in which she finds herself in a neighborhood she does not recognize. With the advent of treatments that may slow dementia, these referrals are easier and more meaningful because there is now some hope for effective intervention.

When a somatizing (psychosomatic) disorder is suspected, the gynecologist should emphasize the difficulty of living with symptoms in the absence of a definitive diagnosis and treatment rather than the hypothesis that the symptoms have a psychological basis:

1. “It is very stressful to be suffering while we can’t pinpoint the problem. I would like you to see one of our staff who specializes in helping people cope with these difficult situations.”

2. “It must be difficult to function when you have been so sickly all your life, have seen so many doctors, have had so many diagnostic tests and medical treatments, and still don’t have an answer or feel well.”
It is counterproductive to convey the idea that because the diagnostic process has not revealed a specific disorder, the problem must be “in the patient’s head.” It alienates the patient, and in any event, it is never possible to rule out an organic cause with absolute certainty.

Although suicidal and homicidal behaviors are absolute indications for referral, many physicians fear that questioning patients about these behaviors will provoke them. That is not the case (12). An open discussion of impulses to hurt oneself or someone else helps the patient to regain control, recognize the need for mental health care, or agree to emergency interventions such as psychiatric hospitalization, whereas avoiding the subject intensifies the patient’s feelings of isolation. The management of suicidal behavior is addressed later in this chapter in the section on mood disorders.

Likewise, the possibility of psychosis need not be avoided. Most patients with psychotic disorders have had previous experience with psychiatric referral. Their psychotic symptoms are often distressing, so treatment is an appealing option. They generally can discuss hallucinations and delusions quite matter-of-factly. The rare patient who comes to a gynecologist in the midst of a first episode of psychosis is likely to be frightened by her symptoms and willing to accept expert consultation.

Despite increasing public sophistication about mental illnesses and psychiatric care, some patients believe that any mention of mental health intervention implies either that they are “crazy” or that the referring physician is convinced that their physical symptoms are imaginary or feigned. The gynecologist may wish to state explicitly that this is not the case. Again, making the real reason for the referral clear and founded in signs and symptoms obvious to the patient will nearly always allay anxiety over a psychiatric referral.

It is not acceptable to refer a patient to a psychiatrist without informing and asking her in advance and obtaining her consent unless she is acutely psychotic, functionally incompetent, or in the throes of a suicidal or homicidal emergency. Even under those circumstances, it is highly preferable to be straightforward. A referral that begins with an unexpected clinical encounter with a psychiatrist is unfair to the psychiatrist and the patient and is unlikely to result in a satisfactory outcome.

To allay any concern a patient may have that a mental health referral is an indication of the gynecologist’s disdain or disinterest, and to promote good patient care in general, the referring gynecologist should make it clear to the patient that he or she will remain involved in her care. The mental health professional should be introduced as a member of the health care team, and the gynecologist should ask the patient to call after the mental health appointment to report on how it went. The patient should be given a follow-up appointment with the gynecologist at the time of the referral.

Where to Refer: Which Mental Health Professional?

Mental disorders are treated by social workers, psychologists, members of the clergy (often the first to be consulted), and various kinds of counselors as well as by psychiatrists. The distinctions between mental health professionals are neither generally well known nor understood by the lay public or even medical professionals. The criteria for membership in each profession can vary by region and institution. Social workers and psychologists can receive degrees at the bachelor, master, or doctoral level. In some states, licensure is required; generally, social workers require a master’s degree and psychologists receive a doctoral degree, in addition to supervised clinical experience, to qualify for licensure. The category of counselor includes a wide variety of practitioners, such as marriage counselors, pastoral counselors, school counselors, and family counselors. The training of social workers may focus on social policy, institutional care, psychosocial aspects of medical illness, or individual treatment.
Practitioners of all these disciplines may or may not be trained in psychotherapy. For a patient whose symptoms do not meet criteria for a major psychiatric disorder and who is able to eat, sleep, and carry out her regular duties, supportive psychotherapy provided by a trained mental health professional may suffice. Supportive psychotherapy calls on a patient’s existing coping mechanisms to combat a stressful situation. Doctoral-level psychologists and neuropsychologists also can perform testing that can be helpful in establishing a diagnosis. Such testing is especially useful in identifying and localizing brain pathology and in defining intelligence levels. Undiagnosed cognitive deficits may contribute to noncompliance with gynecologic care as well as other problems.

Trained social workers are often knowledgeable about community resources for patients and their families and about the impact of gynecologic diseases and treatments on them. Self-help or professionally led therapy groups can be helpful for patients reacting to gynecologic problems such as infertility or malignancy. Participation in a supportive group was said to lengthen the survival time and improve the quality of life for some patients with cancer (20–26), although there is some controversy about this assertion.

**Psychiatrists are the only medically trained mental health professionals.** They play a particularly important role in resolving diagnostic dilemmas, especially when questions arise about the psychological or behavioral manifestations of medical illness and pharmacologic treatment, and when a medical understanding of the gynecologic condition and treatment is essential to the care of the patient. Of all mental health professionals, only psychiatrists have been licensed to prescribe psychoactive medications and other biologic interventions as well as provide psychotherapy. Currently, the legislatures of New Mexico and Louisiana have conferred prescribing rights on doctoral-level psychologists with additional training but have not defined what the additional training or the limits of the prescribing authority, if any, will be. Psychiatrists continue to treat the most seriously ill patients and take ultimate responsibility for psychiatric emergencies.

In light of the frequent occurrence of psychiatric problems in gynecologic practice, it is worthwhile for the gynecologist to develop an ongoing relationship with one or more local mental health professionals. The state psychiatric society may have a list of subspecialists in “consultation liaison” psychiatry; this is a subspecialty recently accepted by the American Board of Psychiatry and Neurology. Many psychiatrists who have not had fellowship training offer consultative services. The availability of familiar and trusted resources enhances the likelihood that problems will be identified and addressed. An ongoing relationship with a mental health professional also allows the gynecologist to familiarize that professional with relevant developments in gynecology. **It is important to keep up-to-date information on local suicide prevention hotlines and other kinds of resources for battered women and for mothers who may pose a danger to their children.** Local laws may require that physicians report to the authorities their knowledge of mothers in this situation.

**Specific Disorders**

Whenever a patient’s thinking, emotions, or behaviors cause concern, the gynecologist should first consider a nonpsychiatric medical disorder or a reaction to prescribed or illicit drugs. Psychiatric disorders frequently coexist with these conditions.

**Manic-Depressive Disorders**

Mood is the emotional coloration of a person’s experience. **Mood may be pathologically elevated (mania) or lowered (depression) or may alternate between the two (bipolar or manic-depressive disorder)** (26). Mood disorders are different from, but frequently confused with, the inevitable ups and downs of everyday life, such as the reactions to...
difficult situations, including gynecologic conditions. In the English language, *depression* is used to describe both a transient mood and a psychiatric disorder. Because of this confusion, both patients and their loved ones become frustrated when well-meaning attempts to reason with them, distract them, or do thoughtful things for them fail to influence their protractedly disturbed moods.

**Mania is characterized by the following behavior:**

1. Elevated mood, with euphoria or without irritability
2. Grandiosity
3. Pressured, accelerated speech and physical activity
4. Increased energy
5. Decreased sleep
6. Reckless and potentially damaging behaviors, such as wild expenditures and promiscuity

Mania can be acute or subacute (hypomania). Hypomania can produce self-confidence, ebullience, energy, and productivity that are the envy of others, making the patient reluctant to relinquish this mood for treatment. It can therefore be particularly difficult to arrest the condition before it progresses to full-blown mania. Acute mania is a life-threatening condition; without treatment, patients fail to maintain essential sleep and nutrition levels and literally exhaust themselves with frantic activity.

**Depression**

The overall lifetime prevalence of affective disorders is 8.3%; the 6-month prevalence is 5.8%. During the reproductive years, depression is 2 to 3 times more common in women than in men (26–32). The highest incidence of depression is in the age group of 25 to 44 years, but depression occurs in every age group, from toddlers to the aged. Women have a lifetime risk of 10% to 25% and a point prevalence of 5% to 9% (33–36). Depression is the single most common reason for psychiatric hospitalization in the United States. As many as 15% of individuals with severe depressive disorders eventually commit suicide. Depression is a recurrent disorder; of those who experience a major depressive episode, 50% have a second one. Of these, 70% have a third, and the incidence continues to increase with each subsequent episode. It is difficult to know whether the incidence of depression has increased over recent years because diagnostic criteria in the past were vague.

Because women’s roles in society have changed a great deal over the last few decades, there is a temptation to attribute the higher rate of depression to women’s work outside the home. There is no evidence that employment outside the home increases women’s vulnerability to depression, although the need to carry out multiple roles in the absence of adequate social support can be stressful (37–39).

**Depression is characterized by the following behavior:**

1. Sad mood or irritability
2. Hopelessness
3. Helplessness
4. Decreased ability to concentrate
5. Decreased energy
6. Interference with sleep, generally with early awakening, inability to return to sleep, and failure to feel rested; atypically, with increased sleep
7. Decreased appetite and weight; atypically, increased food intake
8. Withdrawal from social relationships
9. Inability to enjoy previously gratifying activities
10. Loss of libido
11. Guilt
12. Retardation of psychomotor skills or agitation
13. Thoughts of death or suicide

The patient who has five or more of the signs and symptoms of depression for most of each day for 2 weeks or more fulfills the criteria for the diagnosis of clinical depression. Depression may be acute or chronic (dysthymic disorder), and it can be caused by genetic, neurophysiologic, and environmental factors. Trauma in early life plays a role. Serotonin is a major mediator. Depression can improve with effective treatment, whether pharmacologic or psychotherapeutic, or spontaneous recovery. The average duration of a major depressive episode is approximately 9 months.

Depression may be precipitated by an adverse life event such as an interpersonal loss, economic reversal, or serious illness (40,41). When there is an identifiable precipitant, there is a danger that the depression will be written off as the inevitable reaction to the event rather than considered properly as a complication, similar to infection or pneumonia that requires active treatment. When a patient’s symptoms meet criteria for the diagnosis, treating the depression will not only relieve symptoms, but also make her much more able to cope with the precipitating situation (42). Concomitant gynecologic or other medical illness can cause signs and symptoms similar to those of depression—loss of energy, sleep, and appetite—but does not cause guilt, hopelessness, or helplessness (43). These observations are helpful in differentiating depression from the malaise associated with other disease states.

Gynecologic Issues

The incidence of depression peaks, and the sex difference prevails, during the reproductive years (44). Connections between female reproductive functions and mood changes have been posited for centuries. When it first became possible to determine circulating hormone levels, researchers expected to find specific relationships between psychological and physiological changes. These expectations have been uniformly discounted. There is no serum hormone level associated with premenstrual dysphoria, postpartum depression, or depression at menopause (45). There is a subgroup of women who are vulnerable, not to absolute circulating hormone levels, but to hormonal changes (46–49). There is a correlation between the degree of hormonal change, pre- and postpartum, and the incidence of postpartum mood disorder. Women who are vulnerable to hormonal changes may experience severe premenstrual mood symptoms, postpartum depression, and, possibly, depression in association with hormonal influences such as hormonal contraceptive methods, menopause, and hormone treatments (50).
Premenstrual Syndrome

Depending on the methodology used to gather the data, most women report mood and behavioral changes associated with the menstrual cycle: premenstrual syndrome, or PMS. An estimated 3% to 5% of ovulating women suffer from symptoms so marked that they qualify for a diagnosis of premenstrual dysphoric disorder (PMDD) (51–53).

PMDD is described in DSM-IV-TR. Provisional diagnostic criteria are provided to standardize research:

In most cycles over the past year, the patient has had at least five of the following symptoms for most of the time during the premenstrual week, with symptoms remitting completely in the postmenstrual week:

- Depressed mood, hopelessness, self-deprecation
- Anxiety, tension
- Affective lability
- Anger, irritability, interpersonal conflict
- Decreased interest in usual activities
- Difficulty concentrating
- Decreased energy
- Appetite changes or cravings
- Changes in sleep
- Feeling overwhelmed or out of control
- Physical symptoms such as breast tenderness, headache, bloating

The symptoms markedly interfere with work, family, or academic responsibilities; are not only exacerbations of another existing disorder; and are corroborated by at least 2 months of prospective daily ratings.

Premenstrual syndrome has been characterized by more than 100 different physical and psychological signs and symptoms, making it difficult to define scientifically. Methodological problems further complicate the situation; in the United States, the prevalence of attitudes linking the menstrual cycle to adverse mood and behavioral changes is so high that it skews women’s perceptions, the way they report symptoms to researchers, and the factors to which they attribute negative feelings. No specific circulating hormone levels or markers are associated with premenstrual symptoms (54). When prospective daily ratings are obtained systematically, the symptoms of most women who seek care for PMS are not related to the menstrual cycle (55,56). Therefore, careful assessment is essential. Before the diagnosis of PMS or PMDD can be established, a woman must record symptom ratings daily for at least two full cycles. Records of emotions and behaviors should be kept separate from menstrual records to avoid confounding patients’ perceptions. At the same time, the patient must be screened for other psychiatric disorders, including depression and personality disorders, and for domestic abuse and other life circumstances that may contribute to her psychological state (57).

No treatment for PMS has been validated by empirical studies (58). However, a number of lifestyle changes and other benign interventions are effective for some patients with PMS (59):

- Elimination of caffeine from the diet
- Smoking cessation
• Regular exercise
• Regular meals and a nutritious diet
• Adequate sleep
• Stress reduction

Stress reduction can be accomplished by reducing or delegating responsibilities, insofar as that is possible, and devoting part of every day to relaxation techniques such as yoga. Still, many women experience stress factors over which they have no control.

Several selective serotonin reuptake inhibitors (SSRIs) have proved effective for treatment of PMDD in clinical trials (60–63). Although SSRIs and all other antidepressants require about 2 weeks of daily administration to achieve therapeutic effect, it appears that fluoxetine is effective for PMDD when taken in the usual daily doses for just the 1 to 2 weeks preceding menstruation. The medication has been packaged for this specific indication and dosage. It is thought that the mode of action of SSRIs when used in this fashion differs from that which alleviates major depression (63). Other medications for the treatment of PMS and PMDD are shown in Table 12.2. There has also been some interest in the role of oral contraceptives in management of PMDD (64).

Other Reproductive Events

Infertility is described by most women undergoing treatment as the most stressful event of their lives. Each unsuccessful treatment episode is experienced as the loss of a hoped-for pregnancy (65). The loss of a fetus or newborn also induces grief, with some of the same symptoms as depression. In general, depression is associated with guilt, whereas bereavement is not. However, women who lose pregnancies or infants often do feel guilty, regardless of whether these feelings are logically justified. Patients should not be pressed to “put the loss behind them” or expected to be “over it” within several months. Some feelings of sadness may persist for years. However, their sleep, appetite, and other vital functions and behaviors should begin to improve after a few weeks (66). Grief that not only persists, but interferes with normal functioning, is characterized as pathologic. Depression can complicate grief and should be treated (67).

There is no evidence that induced abortion causes clinical depression or any other negative psychiatric sequelae. Studies purporting to demonstrate negative sequelae fail to take into account the circumstances under which women often conceive unintended pregnancies and elect to terminate them—abuse, abandonment, poverty, rape, and incest—or the circumstances in which they occur—familial pressure or disapproval, clinic demonstrators (68).

Peripartum Psychiatric Disorders

The incidence of depression in women during their reproductive years is approximately 10%. The incidence of depression does not decrease during pregnancy; most postpartum depression is a continuation of antepartum depression (69–71). Although there are some cross-cultural variations currently under study, postpartum depression is found in around the globe (72). Risk factors include social isolation, lack of social supports, history of depression, and past or present victimization (73). Postpartum depression must be distinguished from the transitory, self-limited, and very common “baby blues,” which are associated with changes in hormone levels and are better characterized as mood intensity and lability rather than depression. Mild depression can be managed with psychotherapy (74). Moderate to severe cases often require antidepressant medications (75). Electroconvulsive treatment acts rapidly and effectively, appears to be safe during and after pregnancy, and can be a life-saving option for the most severe cases (76). Treatment with artificial light may alleviate milder symptoms (77).
## Table 12.2 Scientific Basis of Selected Medications Used to Treat PMS

<tbody>
<tr>
<td><strong>Alprazolam</strong></td>
<td>Several double-blind, placebo-controlled, randomized crossover studies. Results were mixed. Placebo was as effective as alprazolam in some studies.</td>
<td>Oral medication appears to be more effective in alleviating depression and anxiety symptoms than physical symptoms.</td>
<td>Potential for dependence; requires tapering; drowsiness reported by many subjects; long-term effects unknown; safety during pregnancy unknown.</td>
<td>The studies involved highly selective groups of women. There was a high dropout rate in one of the positive studies. In one study that found alprazolam effective, 87% of the women had a history of major depression or an anxiety disorder. Different doses were used in the studies (0.75–2.25 mg); the standard effective dosage is unknown.</td>
</tr>
<tr>
<td><strong>Fluoxetine (Prozac)</strong></td>
<td>Several double-blind, randomized, placebo-controlled, crossover trials. All found fluoxetine effective.</td>
<td>Well tolerated; single daily oral dose. Significant decrease in psychic and behavioral symptoms.</td>
<td>Long-term effects unknown. Safety during pregnancy unknown. Appears less effective in controlling physical symptoms.</td>
<td>Trials involved very small, highly select groups of women. Duration of treatment did not exceed 3 months. All trials used 20 mg orally daily.</td>
</tr>
<tr>
<td><strong>Gonadotropin-releasing hormone agonist</strong></td>
<td>Several small, double-blind, randomized, placebo-controlled, crossover trials. Most patients experienced improvement.</td>
<td>Rapidly reversible; many patients report being virtually symptom-free during therapy.</td>
<td>Produces pseudomenopause; expensive; risk for osteoporosis, hypoestrogenic symptoms. Usually given for only short periods of time.</td>
<td>An add-back regimen of estrogen-progestin in addition to gonadotropin-releasing hormone agonist has been reported. If replicated, it may have potential for an effective, long-term treatment for premenstrual syndrome.</td>
</tr>
<tr>
<td><strong>Spironolactone</strong></td>
<td>Several double-blind, randomized, placebo-controlled trials. Mixed results.</td>
<td>May alleviate bloating and improve symptoms related to mood. Oral medication taken once or twice a day. Nonaddictive.</td>
<td>Effectiveness not proven consistently across studies.</td>
<td>Spironolactone is the only diuretic that has shown effectiveness in treating premenstrual syndrome in controlled, randomized trials. Method of action may be antiandrogen properties.</td>
</tr>
<tr>
<td><strong>Vitamin B₆</strong></td>
<td>Ten randomized double-blind trials. About one third of the trials reported positive results, one third reported negative results, and one third reported ambiguous results.</td>
<td>No conclusive evidence that vitamin B₆ is more effective than placebo.</td>
<td>Doses ranged from 50 to 500 mg. Only one study involved more than 40 subjects. The large multicenter trial (N = 204) reported similar results for placebo and vitamin B₆.</td>

PMS: premenstrual syndrome.  

Although no agent can be declared perfectly safe for use during pregnancy and lactation, older SSRI agents have been well studied, yielding little or no evidence of adverse effects on the fetus or nursing infant (78–80). These agents also are used in the treatment of obsessive-compulsive disorder (81). Medication should not be stopped arbitrarily, nor should breastfeeding be prohibited. The withdrawal of antidepressant medication during
pregnancy is very likely to result in postpartum depression; both antenatal and postnatal depression have demonstrable, long-term ill effects for mother and child (82–88). Recently, there has been concern about withdrawal syndromes in neonates whose mothers had been taking SSRIs (89). These concerns arise from anecdotal reports and do not include data about the number of births from which the reports emerged, nor about confounding variables. Some observers have recommended that pregnant women be withdrawn from SSRIs some days or weeks before delivery. However, delivery dates are often uncertain; maternal withdrawal might subject the fetus, rather than the newborn, to withdrawal symptoms; and the likelihood of postpartum depression, with its effects on both mother and infant, would be greatly increased. Researchers are currently exploring ways to prevent postpartum depression, but thus far nothing has proved effective (90,91).

Schizophrenia affects approximately 1% of persons worldwide. Since the deinstitutionalization of persons with severe and persistent mental illnesses several decades ago, most affected individuals live in the community. Often health care and other services are inadequate, leaving these women vulnerable to sexual abuse and involuntary impregnation. Overall, the fertility of women with schizophrenia approximates that of matched populations. Schizophrenia is not an absolute contraindication to successful parenting, but there is considerable stigma against psychotic disorders, and patients may avoid prenatal care because they fear loss of custody (92,93). Older, atypical antipsychotic agents appear to be relatively safe for use during pregnancy (94). The care of these patients should be undertaken jointly by an obstetrician and a psychiatrist. The same is true of eating disorders and substance abuse, both of which pose substantial risks during pregnancy (95–97).

Decisions about the use of medications in pregnant and breastfeeding women should take into consideration the risks of untreated disease. Women whose partners or family members object to the use of medication should be encouraged to bring them to obstetric appointments to discuss the risks and benefits with professional health care providers so that the family is in agreement, if at all possible, and no one blames the mother later for future adverse events that are unlikely to be related to use of the medication.

Menopause

Although menopause was assumed for many years to be associated with an increased incidence of depression, this assumption has not been borne out in empirical studies. Whereas some patients are upset by their loss of fertility, others find menopause liberating (98,99). Patients who have suffered PMS or postpartum depression may, however, be vulnerable to a recurrence of depression at this new time of hormonal change. Patients with depression at the time of menopause should be assessed for psychosocial precipitants and domestic abuse. There are conflicting reports on the effectiveness of hormones for treatment of mood symptoms during menopause (100–105). Treatment with SSRIs may ameliorate hot flashes (106).

Depression in elderly patients can cause a pseudodementia, characterized by decreased activity and interest and what appears to be forgetfulness. Unlike patients with organically based dementia, these patients report memory loss rather than trying to compensate and cover up for it. The early stages of dementia also can precipitate depression as patients react to the loss of cognitive abilities.

Approach to the Patient

The severity of depression is determined by the patient’s emotional pain and the degree of interference with her normal functioning. Depression is an agonizingly painful and disabling, but readily diagnosable and treatable, disease. Nevertheless, it shares the stigma of all psychiatric disorders. Patients and their families often attribute the signs and symptoms of depression to life circumstances or to a medical condition, either diagnosed or undiagnosed. The persistence of symptoms in the face of a pleasant life situation or the
failure of the patient to respond to attempts at cheering, such as changes of scene, often exacerbate suffering by provoking guilt in the patient and frustration in her significant others. Patients are more likely to report low energy and general malaise than depressed mood. Physical symptoms are especially common in Asian and some other cultures. Some patients with severe depression continue to function and can appear not only normal but cheerful. The only way to rule out depression is by using the diagnostic criteria (107).

Management

Both antidepressant medication and psychotherapy are effective treatments for depression. There is evidence that a combination of the two produces the best outcomes (108–110). Reports about the efficacy of alternative treatments, the most common of which is St. Johns wort, are conflicting (111). Patients should be specifically questioned about their use of herbal and other preparations and encouraged to use those whose components are best standardized. Transcranial magnetic stimulation is a promising research intervention (112,113).

There are many forms of psychotherapy. Those that have been specifically studied for efficacy in the treatment of depression are cognitive-behavioral therapy and interpersonal therapy. These forms of therapy are focused on present thoughts, feelings, relationships, and behaviors. Therapy continues for a set number of sessions, usually no more than 16 weekly sessions, in a prescribed, predetermined progression (114). There is increasing evidence that supportive and psychodynamic psychotherapy may be of help.

It is especially important for the patient to have the opportunity to work out her feelings about having a psychiatric disorder, understand how it has affected her life, and feel comfortable about taking medication or undergoing psychotherapy. Patients often attribute depression to weakness, laziness, or immorality, and they often confuse antidepressants with stimulants, tranquilizers, and other psychoactive drugs. It is useful to provide the patient with written material about depression so that she can review it at her leisure and with her family and friends if they have difficulty understanding her condition.

The types and characteristics of antidepressants are in Table 12.3. All antidepressants have comparable therapeutic efficacy, and all require up to 2 to 4 weeks to take full effect. It is not yet possible to identify those patients who will respond best to certain medications, but there is early evidence that depression may be related to specific

eurotransmitters and responds differentially to medications affecting a given neurotransmitter. The response to treatment may differ with sex as well, but the data are not sufficient to derive clinical decisions (115).

It is sensible to use a more activating agent in a lethargic patient and a more sedating agent in an agitated patient. Nonetheless, responses vary on an individual basis, even within the
same class of medications. The choice of antidepressant, therefore, is based on side effects, dosage, cost, and the physician’s clinical experience (Table 12.4). Patients tend to respond to medications that have worked for them in the past and to those that have worked for depressed family members. It is essential to continue active management not only until the patient has responded but also has returned to her previous level of mood and function through the usual duration of a depressive episode: 9 to 12 months for major depression. If the patient does not recover completely, she should be referred to a psychiatrist (116).

### Tricyclic Antidepressants

Tricyclic antidepressants are the oldest antidepressants still in use and are available in generic preparations. They all have significant anticholinergic side effects that may be problematic in medically ill and elderly patients. They are associated with some slowing of intracardiac conduction; this side effect can be tolerated and managed in all but a few

patients, and it can be therapeutic for those with hyperconductibility. Tricyclic antidepressants should be taken in divided doses through the day, although bedtime dosing may help patients who have difficulty sleeping. Some tricyclic agents, such as nortriptyline, have “therapeutic windows”—blood levels above or below which they are not effective—that must be monitored. The average dose for tricyclic agents is 225 mg/day in divided doses. The most important drawback of tricyclic medications is their lethality in overdose, which is especially important because they are used with depressed patients who are already at risk for suicide. In the rare event that they must be used by a potentially suicidal patient, the patient must be given only a few pills at a time. Some medication plans, private or public, require that treatment begin with the least expensive generic medication, and that the patient fail first before a newer compound will be provided. The clinician may have to serve as advocate for the patient when this is not a clinically acceptable approach.

Monoamine Oxidase Inhibitors

Monoamine oxidase (MAO) inhibitors are especially effective for atypical depression, which is associated with abnormally increased sleep and appetite. They require dietary restrictions and can be used only in patients who are able to understand and comply with those restrictions to avoid hypertensive crises.

Selective Serotonin Reuptake Inhibitors

SSRIs pose few risks of medical or suicidal complications. Side effects include anxiety, tremor, headache, and gastrointestinal upset (either diarrhea or constipation), and usually abate within a few days of the onset of treatment. A more serious side effect is loss of libido and interference with orgasm (117). Patients may be reluctant to report sexual side effects, but they may discontinue treatment because of them. Some women are willing to accept SSRIs as an acceptable price to pay for recovery, especially considering that depression interferes with their sexual functioning. Female patients are frequently concerned about weight gain. In one study, it appeared that a weight gain of 5 to 7 pounds may be attributed to an SSRI; the return of normal appetite may also lead to weight gain. Concerned patients should be advised to watch their diets carefully while taking the medication. There is some evidence that bupropion causes less weight gain than SSRIs.

SSRIs are administered in a once-a-day regimen, with little need for dosage adjustments in most cases. It is important to continue treatment until the patient is fully recovered. SSRIs have long half-lives, so occasional missed doses do not constitute a problem. There is an SSRI withdrawal syndrome, generally characterized by flulike symptoms and sleep problems (118). Patients should be cautioned not to discontinue their medications without consulting the physician, and only then by gradually decreasing the dose. As with most medications, antidepressants were not initially tested in older women, but several are under consideration by the U.S. Food and Drug Administration for use in this age group (119).

Atypical Agents

Medications considered atypical include venlafaxine (120–122), lithium salts, and anti-convulsants, which are effective mood stabilizers used for bipolar disorders (123,124). Bupropion is another atypical agent used for depression as well as seizure disorders. Bupropion is now available in a once-a-day preparation. It lowers the seizure threshold slightly more than other antidepressants and should be avoided or used with caution in patients who have a history of head trauma. It is used, under a separate trade name, for smoking cessation, and thus is particularly useful for smokers who are depressed. Bupropion
Suicide seems to cause fewer sexual side effects than the SSRIs and may decrease these side effects when added to an SSRI regimen.

### Suicide

The most critical issue in the assessment and referral of depressed patients is the possibility of suicide. Following are the risk factors for suicide:

- Depression
- Recent losses
- Previous suicide attempts, even if seemingly not serious
- Impulsivity
- Concurrent alcohol or substance abuse
- Current or past physical or sexual abuse
- Family history of suicide
- A plan to commit suicide
- Access to the means to carry out the plan

Women attempt suicide more frequently than men, but men complete the act more frequently than women (125,126). This is probably because men use more drastic or irreversible means, such as firearms, whereas women tend to overdose and can be treated if discovered. Suicide can occur in the context of severe personality disorder and other conditions as well as a result of depression.

It would seem that someone who had repeatedly made suicidal gestures is more interested in the responses of others than in ending her life. However, past attempts or gestures increase the risk of completed suicide. Patients who have made a suicide attempt should be queried about the following risk factors: the intent to die (rather than escape, sleep, or make people understand her distress); increasing numbers or doses of drugs taken in a progression of attempts; and drug or alcohol misuse, especially if it, too, is increasing. Most people who commit suicide have consulted a nonpsychiatric physician within the prior month.

A possible link between SSRI use and suicidal and homicidal behavior has received a great deal of attention in the press. These reports generally fail to take into account the fact that many individuals who take antidepressants take them because they are suicidal. They also confuse suicidal ideation with suicide attempts and completed suicide.

**Inquiry about suicidal ideation and behavior is an inherent part of every mental status examination and is mandatory for every patient with past or current depression or evidence of self-destructive behavior.** The inquiry can follow from discussion of difficulties in the patient’s life or mood or be introduced with a comment that almost everyone has thoughts of death at one time or another. Nonsuicidal patients will immediately volunteer that they have had such thoughts and that they have no intention of acting on them. They will often add reasons such as they have too much to look forward to, it is against their religion, or it would hurt their family.

It is important to distinguish between the wish to be dead and the intention to kill oneself. A patient in a painful life situation—a chronic, painful, or terminal medical condition, the birth of a severely damaged child, or a grievous loss—may express a wish to die, and even refuse recommended medical care but emphatically and honestly disavow any intention of actively harming herself. It is only necessary to ask the patient.

If the patient has previously engaged impulsively in self-destructive behavior, without a plan or warning, it is wise to consult a psychiatrist. If a patient is actively contemplating suicide, she must see a psychiatrist immediately. Other mental health
professionals may be helpful but are less likely to have dealt extensively with and assumed responsibility for suicidal patients, to be able to determine whether the patient should be hospitalized, and to have admitting privileges. Until she is in the physical presence of a psychiatrist, or in a safe environment such as a hospital emergency room, a suicidal patient should be observed and protected at all times—every second—whether she is in the consulting room or the bathroom. The staff member assigned to remain with her may not leave to make a telephone call, go to the bathroom, or get a cup of coffee. Family members may offer to monitor the patient and can sometimes be effective, but the health care professional is responsible for ensuring that they understand these necessities.

**It is better to risk inconvenience and possible embarrassment to both the gynecologist and the patient than to risk a fatal outcome.** Once suicide is a possibility, only a psychiatrist can make the decision that a patient is safe. Psychiatric referral can also be useful in less dramatic cases: when the gynecologist lacks experience or is overloaded with patients, when a first trial of treatment is unsuccessful or there is uncertainty about the diagnosis, when domestic violence or substance abuse may be present, and when the depression is recurrent.

### Anxiety Disorders

**Diagnosis**

**Anxiety is a sense of dread without objective cause for fear accompanied by the usual physical concomitants of fear.** Although every human being has anxious feelings from time to time, anxiety disorders are diagnosed when anxiety becomes disabling or so painful as to interfere with an individual’s quality of life. The anxiety disorders include generalized anxiety disorder, panic disorder, agoraphobia, specific phobias, obsessive-compulsive disorder, and posttraumatic stress disorder (128,129).

**Generalized anxiety disorder is a condition in which anxiety pervades every aspect of a patient’s life.** She suffers from restlessness, easy fatigability, difficulty concentrating, irritability, muscle tension, and sleep disturbances. Whereas depressed patients fall asleep more or less normally and then awaken earlier than intended, anxious patients have difficulty falling asleep.

**Panic disorder is characterized by panic attacks:** acute periods, generally lasting about 15 minutes, with intense fear and at least four of the following symptoms:

- Diaphoresis
- Trembling
- Shortness of breath
- A choking sensation
- Chest discomfort
- Gastrointestinal distress
- Lightheadedness
- A sense of unreality
- Fear of going crazy or dying
- Paresthesias
- Chills or hot flushes

The attacks can recur with or without specific precipitating events (129). The patient is preoccupied with them and makes behavioral changes she hopes will avert future attacks: avoiding specific situations, assuring herself there is an escape route from certain situations, or refusing to be alone.

**The symptoms of panic attacks are often confused with the symptoms of cardiac or pulmonary disease.** They lead to many fruitless trips to the emergency department and to
costly, even invasive, medical investigations. A careful history can establish the correct diagnosis in most cases.

Agoraphobia

Agoraphobia is the avoidance of situations in which the patient fears she may be trapped, such as the center of a row in the theater or driving over a bridge. She fears that such a situation will trigger anxiety or a panic attack and therefore tends more and more to stay at home or limit her sphere of activity to a short list of venues. Agoraphobia and panic disorder can occur separately or together.

Specific Phobias

Specific phobias are irrational fears of certain objects or situations, although the patient recognizes that the object or situation poses no real danger. Of particular concern in gynecology are fear of needles and fear of vomiting. Social phobia causes the patient to fear and avoid situations in which the patient anticipates she will be observed by others in a humiliating light. Patients may alter their lives to avoid these anxieties, interfering with their interpersonal relationships and their ability to carry out their responsibilities, or they may manage to carry on despite considerable psychological pain.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder is characterized by obsessions: recurrent impulses, images, or thoughts that the patient recognizes as her own, dislikes, and cannot control; or compulsions: intrusive, repetitive behaviors that the patient feels she must perform to prevent some dire consequence. The disorder can be mild or totally crippling; in one half of the cases, it becomes chronic. This disorder is classified as an anxiety disorder because the obsessions are anxiety provoking, and the compulsions are performed to avoid overwhelming anxiety.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is the result of exposure to an event that threatens the life or bodily integrity of the patient or others. At the time of the trauma, the patient experiences horror, terror, or a sense of helplessness. Afterward, the patient may lose conscious memory of all or part of the event, avoid situations reminiscent of it, and become acutely distressed when she cannot avoid them. She feels numb and detached, without a sense of the future. She is hyperarousable and irritable and has difficulty sleeping and concentrating. She re-experiences the event in nightmares, flashbacks, and intrusive thoughts (130).

Epidemiology

Panic disorder without agoraphobia is twice as common in women as it is in men; panic disorder with agoraphobia is 3 times more common in women. Onset is generally in young adulthood, often following a stressful event. The lifetime prevalence is 1.5% to 3.5%; the 1-year prevalence is 1% to 2%. A substantial percentage of patients experience depressive episodes as well. Phobias are somewhat more common in women, depending on the object of the phobia. The 1-year prevalence is 9%, and the lifetime prevalence is 10% to 11%. Obsessive-compulsive disorder is equally common in women and men, with evidence of familial transmission. Prevalence is 2.5% for lifetime and 1.5% to 2.1% for 1 year. Posttraumatic stress disorder has a lifetime prevalence of 1% to 14%; victims of violence (including child abuse and wife battering) and war are at increased risk. Men and women differ in the types of violence to which they tend to be exposed. Rape, for example, poses a similarly high risk of PTSD in both men and women, but women are more often the victims of rape.
### Assessment

Given the relationship between anxiety disorders and traumatic experiences, the presence of signs and symptoms of anxiety disorders should trigger inquiries about abuse. It is important to know how long the patient has suffered from the disorder, what previous attempts have been made to diagnose and treat it, and the effect it has had on her psychological development, life choices, lifestyle, and relationships. In some cases, the entire family will have organized their schedules and activities around the patient’s symptoms and limitations; they may not volunteer this information.

### Management

Treatment should not be limited to antianxiety medications. Managing, even tolerating, patient anxiety is an anxiety-provoking process; anxiety is contagious and raises the specter of unlimited demands on the gynecologist’s time and energy. Prescribing medication is a familiar and comfortable, if not optimal, way to end a medical interview. The overprescription of benzodiazepines has become a cause for medical and media concern. It is useful to defer the administration of anxiolytic medications until the impact of the physician’s support and interest can be assessed (131). Treatment should address the effects on the patient’s life and family as well as the signs and symptoms of the specific disease (132).

**Benzodiazepines are most useful in acute situations.** Use can quickly become chronic, with escalating dosages, diminishing therapeutic effects, and increasing demands on the physician. Women taking benzodiazepines may forget to include them in their medical history. When admitted to the hospital, they may suffer unrecognized withdrawal symptoms, complicating their treatment, or may continue to take medications from a personal supply without informing the medical staff. For chronic anxiety and many cases of acute anxiety, there are more effective and safer medications than benzodiazepines.

**It is important to ascertain the source of anxiety or obsessive behavior.** Many patients and their families are anxious because of misinformation or misunderstanding about a medical problem or treatment. Few patients can absorb all the information about significant gynecologic conditions at a single visit, but most feel that asking questions will burden the physician or make them look stupid. Patients also suffer anxiety when there is disagreement among family members or medical staff about the diagnosis or recommended treatment. Many patients dread certain aspects of care, sometimes on the basis of past experience or outdated information. A simple explanation or alteration in procedure can alleviate the anxiety. For example, a reassuring family member or friend can be allowed to stay with the patient during a diagnostic test, sedation can be administered orally or by inhalation before an intravenous line is inserted, or the patient can be allowed control over her own analgesia.

**Behavioral interventions are extremely useful in managing anxiety without problematic side effects.** They include hypnosis, desensitization, and relaxation techniques (133–137). Whereas the use of prescribed medications fosters the patient’s dependence, these techniques provide her with tools to cope with her own anxiety. Specialists in behavioral medicine, usually psychologists, are expert in these techniques. Interested gynecologists can master some of them as well.

**It is easy to be trapped into a cat-and-mouse game with an anxious and needy patient who has an anxiety or personality disorder.** Faced with an obsessive or anxious, talkative, and needy patient in the midst of bedside rounds, clinic, or office hours, the clinician can develop a pattern of avoidance, sometimes alternating with overindulgence stemming from feelings of guilt. This kind of behavior results in sporadic, unpredictable reinforcement of the patient’s symptoms and demands for attention and is very likely to increase them. Attempting to escape by appearing distracted or harassed, or yielding with despair to the destruction of the day’s schedule and the care of other patients simply heightens the patient’s anxiety.
It is preferable to develop a prospective approach. Gynecologists tend to underrate the power of their personal interactions with patients and their own ability to structure and limit those interactions appropriately. A patient with a long list of symptoms can be informed at the beginning of the visit how much time is available and asked to focus on her most important problem, with other problems to be discussed at future, scheduled appointments. Instead of scheduling appointments and returning telephone calls grudgingly in response to patient demands, the gynecologist should inform the patient that her condition requires regular (brief) scheduled visits. If she has been contacting the office more often than visits can reasonably be scheduled, she should be asked to call between visits, at prearranged times, to advise the staff of her progress. There are useful self-help groups for patients with various psychiatric conditions and their families. Although groups focused only on victimization can validate patients’ experiences and pain and help them build new lives, they also interfere with their motivation to find other ways to identify themselves and obtain gratification.

Medication does have a place in the management of anxiety disorders (138–140). Table 12.5 describes many of these agents. SSRIs are effective for a variety of anxiety disorders, sometimes in different dosage regimens than those used for depression. Benzodiazepines are effective when taken for acute anxiety or during relatively brief, time-limited (several days) stressful situations. The specific agent should be chosen on the basis

of onset of action and half-life. The patient must be admonished to avoid concomitant use of alcohol and to exercise extreme care about driving or engaging in other activities requiring attention, concentration, and coordination.

Patients who fail to respond to a trial of office counseling or medication, who are unable to fulfill their responsibilities, who exhaust the patience and resources of significant others, who pose a diagnostic dilemma, who consume inordinate quantities of medical resources, or whose symptoms are becoming increasingly worse should be evaluated by a psychiatrist.

### Somatizing Disorders

**Definitions**

Somatizing disorders are those in which psychological conflicts are expressed in the form of physical symptoms. There is a spectrum of somatizing disorders based on the degree to which the patient is consciously aware of or responsible for the onset of the symptoms. The spectrum ranges from the deliberate malingeringer to the so-called hysteric, who is completely unaware of the link between her psyche and her physical symptom (141).

**Malingering**

Malingering is the deliberate mimicking of signs and symptoms of physical or mental illness to achieve a tangible personal gain, such as exemption from dangerous military duties or exoneration from criminal responsibility. Factitious disorder, or Munchausen syndrome, is a poorly understood condition in which the patient actively causes physical damage to herself or feigns somatic symptoms that result in repeated hospital admissions and painful, dangerous, invasive diagnostic and therapeutic procedures. These patients may introduce feces or purulent material into wounds or intravenous lines, inject themselves with insulin, or produce hemorrhages.

Given enough diagnostic and therapeutic interventions, significant iatrogenic conditions, such as adhesions from surgery or Cushing’s syndrome from the administration of steroids, may develop.

These patients are initially engaging but eventually frustrate the medical staff. Declaring that the patient “only wants attention” is not helpful. Most people want attention, but very few are willing to go to these lengths to get it. Confirming the diagnosis is a delicate process. When staff members become suspicious, they will be tempted to validate their suspicions by spying on the patient or sending her out of her hospital room on a pretext and then searching her belongings. The latter is generally illegal, and either action, followed by a confrontation, will certainly end the therapeutic relationship and provoke the patient to flee rather than addressing the problem. Unfortunately, calls for a psychiatric consultation usually provoke resentment in the patient and family as well. Patients soon reappear in another medical facility. As a result, there are little data about the etiology, incidence, and management of this condition. Often these patients are medically sophisticated because they or their family members have had some kind of medical training as well as knowledge gained during previous hospitalizations. Mothers may enact this disorder through their children by deliberately making them ill, a condition called Munchausen’s by proxy. Munchhausen’s by proxy has gained some popular notoriety, and it has resulted in accusations and loss of custody for some mothers whose children had serious, chronic diseases requiring multiple medical interventions. It will be interesting to see how managed care and shared electronic records affect the occurrence of these conditions.
Somatization Disorder

Somatization disorder consists of multiple physical symptoms for which adequate medical bases cannot be established, with these symptoms leading either to numerous medical visits or to impairment in the patient’s performance of her responsibilities. Symptoms must begin before age 30 and continue for many years thereafter. The diagnosis requires symptoms of pain related to at least four different anatomic sites or physiologic functions: two gastrointestinal symptoms, one sexual or reproductive symptom, and one pseudoneurologic symptom or deficit other than pain (seizures, paresis). The patient’s perception is that she is “sickly.” She responds accurately to questions about her past symptoms and treatments but may not volunteer information about them unless she is asked.

Conversion Disorder

Conversion disorder is the condition formerly called hysteria. The patient’s loss of a voluntary motor or sensory function cannot be explained by medical illness, is not deliberately produced by the patient, and appears to be related to psychological stress or conflict. The prognosis is directly related to the length of time from onset to diagnosis and treatment (142–145).

Other Somatizing Disorders

Pain disorder is a conversion condition with pain as the only symptom. Body dysmorphic disorder is preoccupation with a trivial or imagined defect in bodily appearance, a preoccupation that is not alleviated by the many medical and surgical treatments that the patient pursues. The gynecologist should hesitate to refer such a patient to a plastic or cosmetic surgeon, although specialists tend to be familiar with the condition and should hesitate to perform procedures on these patients.

Hypochondriasis is not a matter of a particular number or type of symptoms. It is a patient’s (nonpsychotic) conviction or fear that she suffers from a serious disease despite evidence and reassurance to the contrary. When one disease is ruled out, the patient is either convinced that the diagnosis has been overlooked, or switches her concerns to some other disease. This is the condition Woody Allen portrayed in his earlier movies.

Epidemiology

Somatization is believed to be among the most common and most difficult psychological conditions in office practice. It has been estimated that 60% to 80% of the general population experiences one or more somatic symptoms in a given week, providing an ample substrate for the patient preoccupied with her health. Somatization disorder occurs almost exclusively in women; menstrual symptoms may be an early sign. Lifetime prevalence in women is 0.2% to 2.0%. Conversion disorder occurs 2 to 10 times more frequently in women than in men (there is no sex difference in children), and it is more common in rural and disadvantaged populations with little medical sophistication. Conversion disorder may develop into somatization disorder. Reported rates of somatization disorder range from 11 to 300 per 100,000. Pain disorder is extremely common in both sexes. Hypochondriasis is equally distributed between men and women; prevalence in general medical practice is estimated to be 4% to 9%. There are few statistics about body dysmorphic disorder, but it seems to be equally distributed between men and women, with an average age of onset of about 30 years.

Assessment

Most somatizing disorders are chronic. The goal of treatment in primary care is not to eliminate all the somatic symptoms but to help the patient cope with them with as
little effect on her relationships and responsibilities as possible. Because patients often seek care simultaneously or sequentially from several physicians, it is crucial to ask about all past and current diagnostic procedures, diagnoses, treatments, and responses. Patients’ level of function over the years is also important; prognosis is inversely related to chronicity. Chronicity should not be an excuse for a failure to treat the patient; the impact on the lives of patients and their families can be mitigated even if the condition is not entirely eliminated. For these and most other patients, the gynecologist needs to know what the patient believes is wrong with her and what she believes she needs in the way of diagnostic and therapeutic interventions. When what the patient gets is not what she expects or desires, she is unlikely to comply with the recommended course of action, although she may accept it and pretend to be following it so as to avoid criticism from the physician.

Management

The management of somatizing disorders is focused on the avoidance of unnecessary medical interventions, iatrogenic medical or psychological complications, and disability. Unfortunately, it is never possible to definitively rule out all possible medical causes of a symptom. The literature is full of case presentations of patients with multiple sclerosis, brain tumors, and intermittently flaring infections that have been labeled for years as psychosomatic before the condition was diagnosed correctly. Organic pathology can befall patients with somatizing disorders. Patients who have had benign gastrointestinal symptoms for extended periods can get appendicitis.

Patients who have a somatizing disorder often approach each new clinician as the one who, “unlike the incompetent and insensitive physicians (she) has consulted in the past,” will finally get to the bottom of her troubles and cure her symptoms. The gynecologist must not get caught up in these expectations, but rather remind the patient that symptoms that have resisted diagnosis and treatment for many years are likely to be challenging ones. As with anxious patients, it is important to structure the doctor–patient relationship to avoid giving the patient attention inconsistently and only in response to escalating symptoms and demands. It is best to schedule frequent, brief office visits during which the clinician allots a small amount of time to listen to and sympathize with the patient’s somatic symptoms and spends the bulk of the time reinforcing the patient’s efforts to function despite her symptoms. Family members should be encouraged to facilitate functionality rather than invalidism.

Unmasking patently psychologically based symptoms by tricking the patient (shouting “Fire!” in the vicinity of a “paralyzed” patient), or documenting the patient’s behavior when she does not realize she is being observed, is momentarily gratifying for medical staff but humiliating for the patient. It may force her to relinquish a symptom, at least temporarily, but she will seek care elsewhere, exacerbating her dysfunction, distrust, and demands on the health care system.

Patients with conversion, somatization, and hypochondriacal disorders often benefit from prescriptive behavioral regimens aimed at saving face and improving function. It was once believed that a patient relieved of one symptom would soon substitute another, but this assumption has not been confirmed by empirical evidence. The behavioral regimen should consist of health-promoting activities relevant to the target symptoms, planned in a stepwise progression, and recommended with reasonable medical conviction and authority. For example, the patient with psychogenic difficulty swallowing could be advised to drink only clear liquids, at specified intervals, for a specified number of days, and then go on similarly to full liquids, purees, soft foods, and finally a regular diet. The patient with difficulties in the extremities can undertake an exercise regimen. The patient’s preoccupation with her symptoms can be channeled into documentation of her progress in a log that she brings to her medical appointments. The physician is not bound to peruse the entire document at each visit. If it is too long, the patient can be asked to prepare a summary. This process may enlighten both her and the physician to the relationships between her symptoms...
and her diet, relationships, or activities. She should be advised not to dwell on her symptoms apart from this important notation.

It is critical to remember that patients with somatic symptoms that are due to depression, posttraumatic stress disorder and other anxiety disorders, and domestic violence frequently seek care from gynecologists. In the case of domestic violence, the gynecologist is often the only human contact the abuser allows the patient outside the domestic situation (146–148). These possibilities must be ruled out before care is directed to symptom management.

There is considerable cross-cultural variation in the extent to which feelings and psychological conflicts are somatized. In many Asian cultures, for example, problems with feelings, behaviors, and interpersonal relationships are almost unheard of; these problems are expressed, diagnosed, and treated somatically. Conversely, some very sophisticated and psychologically informed patients in the West may dismiss serious somatic signs and symptoms as indications of psychological conflict.

**Referral**

Patients with somatizing disorders may resist mental health referral more adamantly than any other single class of patients. Focused as they are on physical symptoms, these patients can regard referral as a message that their symptoms are not being taken seriously and as a sign of contempt and rejection by the gynecologist. It is particularly useful with these patients to emphasize that distinctions between mind and body are artificial. The brain is part of the body. Our language expresses this synthesis; anxiety causes “butterflies in the stomach,” aggravation “gives us a headache,” and unwelcome news “gives us a heart attack.”

The referral should be framed as support for the patient’s suffering rather than as a statement that her problems are “all in her head.” The mental health professional should be introduced as a member of the medical team. Some medical institutions have dedicated psychiatric consultation, medical psychiatry, or behavioral medicine services offering expertise in the psychological complications of disease and in somatization disorders. Because so-called somatic and psychological symptoms often coexist and interact, the gynecologist should work in collaboration with the mental health professional. Patients should be given a return appointment with the primary physician, or a request for a telephone contact, at the time of the original mental health referral to reassure them that they are not being dismissed and to inform the primary physician of the results of the consultation.

**Personality Disorders**

Personality disorders are pervasive, lifelong, maladaptive patterns of perception and behavior. Patients with personality disorders do not consider themselves symptomatic, but rather as treated unfairly by circumstances and other people. They view their own behaviors, which can wreak havoc in the health care setting as well as in patients’ lives, as normal, expectable, inevitable reactions to these perceived circumstances. To make matters worse, their behaviors tend to provoke in others the very responses that confirm their expectations; for example, a patient who is convinced that people always abandon her clings desperately to others, eventually driving them away.

Personality disorders are organized into clusters in DSM-IV. Patients often manifest characteristics of several disorders within a cluster and between clusters.

*Cluster A*
- Paranoid personality disorder
- Schizoid personality disorder
- Schizotypal personality disorder
Cluster B
Narcissistic personality disorder
Histrionic personality disorder
Borderline personality disorder
Antisocial personality disorder

Cluster C
Avoidant personality disorder
Dependent personality disorder
Obsessive-compulsive personality disorder

Individuals with Cluster A disorders are isolated, suspicious, detached, and odd. Narcissistic patients are grandiose, arrogant, envious, and entitled. Histrionic individuals are flamboyant and provocative. Antisocial patients disregard laws and rules of common decency toward others. Borderline personality disorder causes patients to have difficulty controlling their impulses and maintaining stable moods and relationships. They also engage in self-destructive behaviors. They fluctuate between overvaluation and castigation of the same person or direct these feelings alternately between one person and another. When this happens on a gynecology service or in the office, it can precipitate significant tensions among the staff. Recent research reveals that many women who have been abused are diagnosed as borderline when posttraumatic stress disorder more accurately fits their symptoms. Posttraumatic stress disorder is a less stigmatizing and more treatable condition than borderline personality disorder.

Epidemiology

Lifetime prevalence of personality disorders as a group is 2.5%. Cluster A disorders are more common in men. Within Cluster B, 75% of cases are women; the prevalence in the general population is 2%. Personality disorders such as narcissistic personality are more common in the clinical population than in the general population. Among cluster C disorders, dependent personality is one of the most frequently diagnosed. Obsessive-compulsive personality is twice as common in men as in women. It is important to distinguish the personality disorder from the symptomatic obsessive-compulsive disorder. There is a strong association between personality disorders and a history of childhood abuse. The possibility of an ongoing abusive situation should be considered as well.

Assessment

The impact of personality disorders ranges widely. At one end of the spectrum, the disorder is an exaggerated personality style. At the other end of the spectrum, the individual suffers terrible emotional pain and is unable to function in work roles or relationships, spending significant periods of time in psychiatric hospitals. She characterizes her symptoms of despair as inevitable responses to abandonment or other mistreatment. As the definition implies, the patient will not seek treatment for the signs and symptoms listed in the diagnostic criteria but instead will have complaints about her treatment by others, their responses to her, and the unfairness and difficulties of life in general. Taking the history, the clinician should frame questions in those same terms: How long have these troubles gone on, and how much do they interfere with her ability to work and relate to others? Personality disorders do not bring patients to gynecologists’ offices directly, but they greatly complicate things once patients arrive there.

Management

It generally requires intense and lengthy psychotherapy to effect significant improvement in patients who have personality disorders. However, there is increasing evidence that expert, targeted therapeutic interventions can be successful and that the long-term prognosis is less dire than previously believed. The challenge in the gynecology setting is to minimize contention and drain on medical staff while maximizing the likelihood of effective diagnosis and treatment of the patient’s medical problems. The most helpful
single step is the identification of the personality disorder. Diagnosis enables the gynecologist to recognize the reasons for a patient’s problem behaviors, to avoid becoming entangled in fruitless interactions with the patient, and to set appropriate limits.

There is increasing evidence that psychotropic medications are useful adjuncts in the treatment of personality disorders. Treatment should be provided in consultation with a psychiatrist. The patient’s ability to use the medication can be compromised by impulsivity, self-destructive tendencies, and unstable relationships. Low doses of major tranquilizers are sometimes helpful, especially when the patient has brief psychotic episodes. Minor tranquilizers pose significant risk of overdose and physical and psychological habituation. They can be prescribed for temporary stresses, but only in a quantity sufficient for several days and with no refill allowed. At the same time, some patients’ anxiety, demands, and power struggles are eased when they are given control over their own use of medication. Such an approach requires enough familiarity with the patient to ensure her safety and should be managed by an expert. Because the patient with a personality disorder attributes her problems to others, her symptoms cannot be adduced as reasons for psychiatric referral, but her suffering can be. If a diagnosis of a personality disorder absolutely must be noted in the patient’s chart or on insurance forms, it is essential that she be so informed. It is useful to review the DSM-IV-TR criteria with her so that she understands the basis for the diagnosis. All psychiatric diagnoses, but particularly personality disorders, carry a significant stigma.

---

### Adjustment Disorders

#### Definitions

Adjustment disorders are temporary, self-limited responses to life stressors that are part of the normative range of human experience (unlike those that precipitate posttraumatic stress disorder). The patient has mood or anxiety symptoms that are sufficient to lead her to seek medical care but that do not meet criteria of sufficient quantity or quality to qualify for psychiatric diagnosis. The diagnosis requires an identifiable stressor, onset within 3 months after the stress begins, and spontaneous resolution within 6 months after the stressor ends. Obviously the latter cannot be determined until the symptoms resolve—but they do rule out the disorder if the symptoms persist beyond that time (149,150).

Adjustment disorders can be distinguished from normal grieving. Grieving produces symptoms similar to those of depression, although depression is somewhat more likely to cause guilt. Interference with function should not persist beyond several months, but some degree of sadness and preoccupation with the lost loved one often goes on for years. Patients with persistently disabling grief should be referred to a mental health professional.

#### Epidemiology

Adjustment disorders affect men and women equally. An estimated 5% to 20% of patients undergoing outpatient mental health treatment suffer from adjustment disorders. There is little literature on the subject; one study reported a prevalence of 2.3% among a sample of patients receiving care in a walk-in general health clinic.

#### Management

Patients with adjustment disorders can be treated effectively with brief counseling in the primary care setting. The counseling can be provided by the gynecologist or by a nurse clinician, social worker, or psychologist, preferably a member of the office or hospital staff who is familiar with the gynecologist and the practice. The medical setting is sometimes the only place where the patient can vent her feelings and think...
through her situation. Counseling is aimed at facilitating the patient’s own coping skills and helping her to make autonomous decisions about her situation. The gynecologist should follow the patient’s progress and facilitate referral to a psychiatrist if symptoms do not resolve.

Eating Disorders

Definitions

The etiology of eating disorders is neurobiological as well as psychosocial (151). Preoccupation with thinness, sometimes to the point of pathology, is a major problem for women in North America (152). Only a small number of women profess to be satisfied with their weights and body shapes. Nearly all admit to current or recent attempts to limit food intake. Physicians often share social prejudices against overweight patients and can easily exacerbate patients’ concerns by making chance comments. In some cases, such comments by the physician or others can precipitate, if not cause, an eating disorder.

Anorexia nervosa is characterized by severe restrictions on food intake, often accompanied by excessive physical exercise and the use of diuretics or laxatives. Clinical features include menstrual irregularities or amenorrhea, intense and irrational fear of becoming fat, preoccupation with body weight as an indicator of self-worth, and inability to acknowledge the realities and dangers of the condition. Some patients approach gynecologists for care of infertility (153).

Bulimia is characterized by eating binges followed by self-induced vomiting or purging. Patients’ weights may be normal or somewhat higher than normal. Patients have drastically low self-esteem, and the condition frequently coexists with depression (154).

Obesity is an increasingly frequent health problem, and there is little evidence that any nonsurgical approach is effective over time. Sensible eating should be encouraged, and fad or crash diets, which are rampant, are medically and psychologically counterproductive (155).

Epidemiology

More than 90% of cases of anorexia and bulimia occur in female patients. The prevalence is 0.5% to 1.0% in late adolescence and 1% to 3% in early adulthood. There is some evidence of familial transmission.

Assessment

The clinician treating the anorexic patient needs to know how much insight she has into her problem and to assess her mood, relationships, and general level of function. Anorexia poses significant risks of severe metabolic complications and death, often from cardiac consequences of electrolyte abnormalities. Thorough physical and laboratory examination is critical; immediate hospitalization may be necessary.

Management

Patients with anorexia or bulimia should be treated by mental health professionals, preferably those with subspecialization in this area. The conditions are highly refractory to treatment; patients can resort to elaborate subterfuges to conceal their failure to eat and gain weight. Up to 50% of cases will become chronic, and approximately 10% of those will ultimately die of the disease. Antidepressant medication is sometimes helpful. Amenorrheic patients should not be treated with ovulation induction. Evaluation for osteopenia and osteoporosis is necessary.
Psychotic Disorders

Definitions
Psychotic disorders are characterized by major distortions of thinking and behavior. They include schizophrenia, schizophreniform disorders, schizoaffective disorders, delusional disorders, and brief psychotic disorders. General medical and toxic conditions must be ruled out in determining the diagnosis. Distinctions between the disorders are based on symptoms, time course, severity, and associated affective symptoms. The hallmark of psychosis is the presence of delusions or hallucinations. Hallucinations are sensory perceptions in the absence of external sensory stimuli. Delusions are bizarre beliefs about the nature of motivation of external events. Because there is no reliable definition of “bizarre,” a physician working with a patient from an unfamiliar culture must determine whether a given belief is normal in that culture. Delusions and hallucinations are the positive symptoms of schizophrenia. The negative symptoms include apathy and loss of connection to others and to interests. The negative symptoms may be more disabling than the positive. There is increasing evidence that schizophrenia is associated with cognitive deficits.

Epidemiology
As mentioned previously, schizophrenia occurs in approximately 1% of the population worldwide (156). Onset is in the late teens to mid-30s. Women succumb later in life and have more prominent mood symptoms and a better prognosis than men. The risk is 10 times greater for first-degree biologic relatives and for individuals of low socioeconomic status. It is unclear whether indigent status is a precipitating stress or a result of psychotic illness, but, especially as extremely few individuals have private or public coverage for adequate treatment, most people with schizophrenia are indigent.

Assessment
There is wide variability in the functional impact of psychotic disorders. Patients must not be assumed to be incompetent to make medical decisions or lead independent lives, especially if they comply with treatment. Patients must be asked specifically about their living situations and coping skills. When psychotic women have responsibility for the care of children, their ability to do so should be assessed in consultation with a mental health expert. Motherhood and child custody are exceedingly sensitive matters for these vulnerable patients.

A relentlessly downhill course is not inevitable; remissions and recovery can occur. Therefore, the patient’s mental status must be examined carefully. Under the pressures of a busy medical setting, psychotic illnesses can be overlooked, only to erupt in the labor room, operating room, or recovery room. Patients who believe that conspiracies or aliens are responsible for their symptoms can answer yes-or-no medical questions without revealing their delusions. Open-ended questions (“Tell me about your symptoms.”) are more useful (157).

Sensationalized media accounts of violent crimes committed by psychotic patients exacerbate public misconceptions about these diseases. Statistically, individuals with psychoses are more likely to be victims than perpetrators of crime. Untreated patients, especially when under the influence of alcohol or other substances, are at somewhat increased risk of violent behavior; treated patients are no more violent than the public in general.

Management
Psychotic illnesses are nearly always managed by psychiatrists. However, a primary care practitioner can readily assume responsibility, in consultation with a psychiatrist, for a stable patient who complies with treatment. When a patient expresses delusions, the clinician may indicate that he or she does not share them, but should not debate with the
successful treatment (162). It is important to concentrate on the patient’s strengths. She can easily be humiliated by thoughtless epithets or behaviors that betray the expectation of violence or incompetence. Patients with severe cases must be treated with an integrated system of social services, family support, rehabilitation, general medical care, psychotherapy, and psychopharmacology. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of making a referral (159–161). It is important to concentrate on the patient’s strengths. She can easily be humiliated by thoughtless epithets or behaviors that betray the expectation of violence or incompetence. Patients with severe cases must be treated with an integrated system of social services, family support, rehabilitation, general medical care, psychotherapy, and psychopharmacology. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of successful treatment (162).

CHAPTER 12 Common Psychiatric Problems

SECTION III Preventative and Primary Care

CHAPTER 12 Common Psychiatric Problems

150. Fabrega H Jr, Mezzich JE, Mezzich AC. Adjustment disorder as a marginal or transitional illness category in DSM-III. Arch Gen Psychiatry 1987;44:567–572.

The spectrum of complementary and alternative approaches is broad and includes methods worthy of integration into our current practice, as well as ineffective or fraudulent practices that should be avoided.

A complete history should include the patient’s use of complementary and alternative medicine (CAM), particularly botanicals and supplements, as these can have actions ranging from estrogenic to anticoagulant.

The U.S. Food and Drug Administration (FDA) does not currently regulate botanicals and supplements, so extra steps must be taken to ensure quality of such products.

The management of many women’s health issues can be enhanced by the integration of selected CAM approaches.

Perceived congruency of values around life and health with CAM providers was predictive of use of these approaches; dissatisfaction with conventional medicine is not a predictor of use of CAM.

Acupuncture has been found to be of benefit in a variety of conditions, including pain, nausea and vomiting of pregnancy, and secondary to chemotherapy.

Mind–body approaches such as stress reduction, visualization, and hypnosis are gaining evidence as valuable adjuncts in a spectrum of women’s health concerns, from surgery to fertility.

The use of complementary and alternative medicine (CAM) for health maintenance and disease management is on a steady rise in the United States, and for more than 10 years, the number of visits to alternative care providers has exceeded the number of visits to primary care providers. Although evidence exists to support many of these approaches, some approaches are used in the absence of any documented benefit and can potentially be dangerous and even distributed fraudulently (1). The primary users are women, who are frequently making decisions regarding treatment options without the advice of their physicians. Obstetrician–gynecologists are in an excellent position to help guide patients in their treatment choices, counseling them about potentially dangerous alternative treatments and supporting their use of potentially beneficial ones. The most significant challenge is the
lack of training that most obstetrician–gynecologists have in this area; thus, this chapter reviews the domains of CAM as they apply to the practice of gynecology.

Definitions

The concept of complementary and alternative medicine is by definition a relative one. In a landmark publication, the CAM was defined as “medical interventions not taught widely at U.S. medical schools or generally available at U.S. hospitals” (2). As practices or therapies move in or out of the mainstream in this country, the definition of CAM will change. The spectrum of therapies, practitioners, and products that fall into this category are extremely broad and include everything from botanical medicine to “crystal gazing.” The five domains of CAM are listed in Table 13.1.

The amount of evidence on the use of these approaches varies widely. A significant number of randomized controlled trials, including those with sufficient quantity and quality to allow meta-analyses in some areas, have been done to assess the efficacy of acupuncture, botanical medicine, nutritional approaches, manual therapies, and mind–body medicine. Research in the other domains is much more limited. Many culturally based practices such as shamanism and curanderismo have virtually no research basis. A growing number of randomized controlled trials are being done in spiritual healing and homeopathy, but these techniques remain controversial based on the lack of plausible biophysical mechanisms to justify their efficacy.

Integrative medicine is a distinct entity separate from the practice of CAM. Integrative medicine neither blindly advocates CAM nor rejects conventional medicine. Integrative medicine is healing oriented and patient centered and adopts a whole-person approach to the treatment of disease and the maintenance of health. It draws on the best practices of medicine, regardless of system of origin. Typically, integrative medicine would include, in addition to conventional medicine, CAM techniques that may be of benefit, such as nutrition, movement and exercise, mind–body therapy, and spirituality. Integrative medicine allows the best practices of medicine to be offered to all patients, regardless of their system of origin.

Demographic Data

The first national survey assessing the use of CAM in the United States was done in 1990. This study revealed that 34% of the 1,539 individuals who responded to the survey had used...
CAM in the previous 12 months and that most of these users were women. When extrapolated, these results suggested 425 million visits to alternative care providers occurred that year, which exceeded the number of visits to primary care providers in the same year (388 million visits). An estimated $13.7 million was spent, $10.3 million of which was spent out of pocket. This expenditure is comparable to the $12.8 billion dollars spent out of pocket for all hospitalizations in the United States that same year. Only 28.5% of individuals disclosed this usage to their physician. Of note to conventional health care providers, 71.5% of individuals using these approaches did not inform their physicians of their use (2).

This national survey was repeated 7 years later and established the use of CAM in the United States as a significant and growing trend (N = 2,055). When compared with use in 1990, the use of CAM increased from 33.8% to 42.1%. Extrapolations suggest a 47.3% increase in total visits to alternative medicine providers, from 427 million in 1990 to 629 million visits in 1997, again exceeding visits to primary care providers. Not surprisingly, most of these users again were women, with 48.9% of women having used CAM that year, compared with 37.8% of men (1). There was no significant improvement in disclosure, with only 39.8% of users disclosing this information to their physicians. Most users were again found to be paying entirely out of pocket, with no significant change between 1990 (64%) and 1997 (58.3%).

Estimated expenditures for alternative medicine services increased 45.2%, and total 1997 out-of-pocket expenditures related to alternative therapies were conservatively estimated at $27 billion, which is comparable to the out-of-pocket expenditures for all physician services that year. A study of gynecologic oncology patients revealed that 56% were using CAM, and surveys of menopausal women have showed that 80% were using “nonprescriptive therapies” (3). The Study of Women’s Health Across the Nation (SWAN) found that approximately one half of women were actively using herbal, spiritual, or manipulative therapies (3). A study examining the use of CAM by women suffering from nausea and vomiting during pregnancy found that 61% reported using CAM therapies, with the most popular being ginger, vitamin B<sub>6</sub>, and acupressure (4). A study evaluating the use of CAM therapies by women with advanced-stage breast cancer revealed that 73% of patients used CAM, with relaxation or meditation techniques and botanicals being used most often (5). The reason most often given for the use of CAM was immune support, followed by the second treatment of cancer. A survey in Washington state exploring use of alternative therapies for menopause revealed that 76% of women were using alternative approaches, with 43% of these women using stress-reduction techniques, 37% using over-the-counter alternative approaches, 32% using chiropractic medicine, 30% massage therapy, 23% dietary soy, 10% acupuncture, 9% naturopathy or homeopathy, and 5% herbalists (6). Of these women, 89% to 100% found these approaches to be somewhat or very helpful. Current users of hormone therapy were 50% more likely to use CAM as those who had never used hormone therapy. Following the results of the Women’s Health Initiative indicating the risks associated with hormone therapy, interest in the use of CAM for management of menopausal symptoms has increased.

The Attraction

A national survey published in 1998 was the first to explore the very intriguing question of why so many patients were turning to CAM (7). Three hypotheses were proposed:

1. Dissatisfaction with conventional medicine
2. Personal control in their health care
3. Philosophical congruence of values around life, health, and wellness

Surprisingly, dissatisfaction with conventional medicine was not predictive of use of CAM. Patients turn to CAM because they are seeking greater congruency of values regarding life, health, and wellness (7). The message is, then, that people are happy to use conventional medicine when they have a diseased or injured body part, but when their...
goal is to improve their health or manage a chronic condition or lifestyle issue, they turn to alternative care providers. Establishing a partnership with patients can help them explore all of the options for maximizing their health.

The reluctance of patients to inform their physicians of their use of CAM creates barriers to the best practice of medicine. Included in the realm of CAM are potentially harmful practices and products as well as potential interactions between effective CAM and conventional approaches. In a 5-year prospective cohort study following women in San Francisco with newly diagnosed breast cancer, 72% were using at least one form of CAM in the management or treatment of their breast cancer. Of these women, 54% disclosed their use to their physician (much higher than the national average), whereas 94% discussed their conventional treatment with their CAM provider (8). Three reasons were given for the patients’ lack of disclosure:

1. Women anticipated physician disinterest, negative response, or unwillingness or inability to contribute useful information
2. Women believed their use of CAM to be irrelevant to their biomedical treatment
3. Women did not view disclosure as appropriate coordination of disparate healing strategies

This study highlighted the fact that the use of conventional approaches is well integrated into CAM patient visits, whereas the history of use of CAM is poorly integrated into the conventional medical encounter. Overall, patients’ disclosure to their physicians is very cautious, even when the physicians involved would welcome the discussion.

The Challenge

The demographics and trends associated with CAM use create challenges for physicians and dangers for patients. A huge market demand exists, and with it has come an opportunity for products and therapies that may be ineffective, dangerous, or fraudulently marketed. The development of the patient demand has preceded the incorporation of education regarding CAM for medical students, residents, and practicing physicians. As a result, patients make decisions regarding their care without the benefit of medical advice or the coordination of their care by one provider. The best practice of medicine necessitates the integration of all therapies that can benefit the patient and the exclusion of those that can cause harm. Integration of these techniques will require the collaborative, concerted effort of physicians, CAM providers, and patients.

Complementary and Alternative Medicine Techniques

The many types of CAM techniques can be organized by category. Each type is associated with some types of risk or complication. Licensing and certification requirements vary widely from state to state, but most techniques have some type of formal structure for training and accreditation (Table 13.2).

Biologically Based Therapies: Botanical Medicine

Botanical or herbal therapies use botanicals singly or in combination for therapeutic value. A botanical is a plant or plant part that contains chemical substances that act on the body. Botanical or herbal medicines have been studied extensively in Europe, and large multicenter trials are beginning to provide more robust evidence in this country.

(Continued)
Botanical medicine is the area of CAM most conceptually accessible to patients. Botanicals are the source of the active agents in approximately 25% of prescription drugs and 60% of over-the-counter drugs. In the United States, however, these products are often not perceived as active and are regulated as “dietary supplements,” not under the direction of the U.S. Food and Drug Administration (FDA). The most popular botanicals used in the United States are listed in Table 13.3.

### Complications and Risks

Botanical medicines are being used by an increasing number of patients, and they often do not advise their clinicians of this use. Certain patients are at risk for drug–botanical interactions or adverse reactions, and patients should be questioned about them (Tables 13.4, 13.5). Megadoses of vitamins and supplements also have associated risks and complications, and their use is increasing.
Because botanicals are regulated as dietary supplements, quality control is challenging. In 1994, the Dietary Supplement Health and Education Act (DSHEA) was enacted. This act makes it legal to refer to the supplement’s effect on the body’s structure or function or to a person’s well-being. Products within the jurisdiction of DSHEA are easily recognized by the following statement on their labels: “This product is not intended to diagnose, treat, cure, or prevent any disease.” Because the FDA does not regulate these products, the potential for lack of standardization of products, as well as adulteration or mislabeling, exists. Pharmacokinetic evaluation also is lacking.

Botanicals can cause toxicity in one of three ways: (i) the products can be adulterated; (ii) the labels can recommend dosages that exceed appropriate use and cause toxicity even when the product is safe in appropriate dosages; and (iii) Even when they are of good quality and taken in the correct dosage, these products can interact with other supplements and pharmaceutical agents. The Institute of Medicine has recommended the following measures: seed-to-shelf quality control, accuracy and comprehensiveness in labeling and other disclosure, enforcement against inaccurate and misleading claims, research into consumer use, incentives for privately funded research, and consumer protection against all potential hazards (9).

(Continued)
There is no national licensure for botanical or herbal medicine, and there is no national organization that regulates or accredits western and ayurvedic herbal medicine education. However, in 1996, the National Certification Commission for Acupuncture and Oriental Medicine developed a national certification written examination, which tests for entry-level capabilities in oriental herbal medicine. Passage of this examination allows practitioners to call themselves Diplomates of Chinese Herbology (Dipl CH). Currently, there are about 3,200 certified Diplomates in Chinese Herbology nationwide.

Chiropractic medicine focuses on the relationship between structure (primarily the spine) and function, and how that relationship affects the preservation and restoration of health. It uses manipulative therapy as an integral tool. Chiropractors can legally do more than manipulate and align the spine, including taking a medical history, performing a physical examination, and ordering lab tests and x-rays to determine a diagnosis. The spectrum of chiropractors varies in terms of the conditions treated with manipulation.

CNS, central nervous system; MAO, monoamine oxidase.
some practitioners limit their practice primarily to musculoskeletal problems, others claim
to offer effective treatment for virtually any medical condition. It should be noted that they
are referred to as doctors, which can be misleading to patients.

**Complications and Risks**

The most significant risk associated with chiropractic medicine is stroke. Vertebrobasilar
accidents occur mainly after a cervical manipulation with a rotatory component. Estimates
of vertebrobasilar accidents range from 1 per 20,000 patients to 1 per 1 million cervical
manipulations. The average age of patients with vertebrobasilar accidents is 38 years. The
second most common complication of spinal manipulation is cauda equina syndrome related
to progression of disk herniation. The incidence of cauda equina syndrome is estimated to be
less than 1 per 1 million treatments.

**Training and Licensure**

There is a national process for licensure for chiropractic medicine to which all 50 states
adhere. Chiropractors must have completed a 4-year chiropractic college program of study
accredited by the Council on Chiropractic Education (CCE).

---

**Massage Therapy and Bodywork**

Massage therapy involves manipulation of the soft tissues of the body to normalize
those tissues. A wide variety of approaches are available that include deep-tissue
massage, Swedish massage, reflexology, rolfing, and many others. A number of
randomized controlled trials have documented the value of massage therapy, particularly
in pediatric conditions such as childhood asthma.

Massage therapy and bodywork are used by a wide array of people seeking the benefits of
massage, which include physical relaxation, reduced anxiety, increased circulation, and
pain relief. Specific indications for massage include treatment of acute low-back pain and
lymphatic massage for patients with lymphedema from conditions such as postmastectomy
extremity edema. Massage is used by various practitioners, including physicians,
physical therapists, osteopathic physicians, chiropractors, acupuncturists, nurses, and
massage therapists.

**Complications and Risks**

Massage should not be used in the presence of bleeding disorders, phlebitis and
thrombophlebitis, edema that is due to heart or kidney failure, fever or infections
that can be spread by blood or lymph circulation, and leukemia or lymphoma.
Massage should not be performed on or near malignant tumors and bone metastases;
over bruises, unhealed scars, or open wounds; on or near recent fracture sites; or
over joints or other tissues that are acutely inflamed.

**Training and Licensure**

There is no national licensure in massage therapy, but licensure is offered in 30 states. One
fourth of the massage training schools are accredited by the American Massage Therapy
Association (AMTA). The National Certification Board for Therapeutic Massage and
Bodywork (NCBTMB) administers a certification examination, and 24 states use it for
licensure. The NCBTMB is an independent, private, nonprofit organization, founded in
1992, that fosters high standards for therapeutic massage and bodywork professionals.
Currently, there are more than 40,000 nationally certified massage therapists and body
workers in the United States. Certification by NCBTMB requires successful completion of
the examination as well as the completion of a minimum of 500 in-class hours of formal
education and training.
Mind-body Interventions

Clinical Hypnosis and Imagery

Hypnosis involves the induction of trance states and the use of therapeutic suggestions. Hypnosis has documented value for a variety of psychological conditions as well as pain control and recovery from surgery.

Complications and Risks

Hypnotized persons occasionally report unanticipated negative effects during and after hypnosis. The spectrum of reported effects has encompassed minor transient symptoms such as headaches, dizziness, or nausea in experimental situations to less frequent symptoms of anxiety or panic, unexpected reactions to an inadvertently given suggestion, and difficulties in awakening from hypnosis. More serious reactions following hypnosis have generally been attributed to the misapplication of hypnotic techniques, failure to prepare the participant, and preexisting psychopathology or personality factors. There have been no known deaths attributed to the use of hypnosis.

False memories of suggested events that did not occur in reality, particularly when legal and interpersonal battles are involved, can be viewed as an untoward reaction to psychotherapeutic procedures. In hypnotic as well as nonhypnotic situations, leading and suggestive overtures can produce false memories. Because hypnosis involves direct and indirect suggestions, some of which may be leading in nature, and because hypnosis can increase confidence of recalled events with little or no change in the level of accuracy, therapists must be vigilant to the problem of creating false memories.

Training and Licensure

There is no national or state licensure for hypnotherapists. The International Medical and Dental Hypnotherapy Association will certify hypnotherapists if they meet the minimum eligibility requirements and will provide referrals.

American Society of Clinical Hypnosis (ASCH) certification in clinical hypnosis is distinct from other certification programs in that it ensures that the certified individual is a health care professional who is licensed in his or her state or province to provide medical, dental, or psychotherapeutic services. Certification by ASCH distinguishes the professional practitioner from the lay hypnotist. There are two levels of certification, each of which is simply called certification, and requires, among other things, a minimum of 40 hours of ASCH-approved workshop training, 20 hours of individualized training, and a minimum of 2 years of independent practice using clinical hypnosis. An advanced level, called approved consultant, recognizes individuals who have obtained advanced training in clinical hypnosis and who have extensive experience in using hypnosis within their professional practices. Certification at this level requires a minimum of 60 additional hours of ASCH-approved workshop training and 5 years of independent practice using clinical hypnosis.

Meditation and Stress Reduction

Meditation is a self-directed practice for relaxing the body and calming the mind. Most meditative techniques have come to the West from religious practices in the East, particularly India, China, and Japan, but it can be found in all cultures of the world. A National Institutes of Health Consensus Panel in 1996 concluded that mind–body and behavioral techniques were effective in the treatment of stress-related conditions and insomnia. Mindfulness-based stress reduction (MBSR), based on Vipassana meditation from India, has been promoted in this country. This technique is based on the cultivation of mindfulness, an intentional, focused awareness of nonjudgmental attentiveness to experiences in the present moment. Vipassana meditation, one of India’s most ancient techniques of meditation, was taught more than 2,500 years ago as a remedy for universal ills.
Transcendental meditation (TM) is a simple, natural, effortless procedure practiced for 15 to 20 minutes in the morning and evening while sitting comfortably with the eyes closed. During this technique, the individual experiences a unique state of restful alertness. Transcendental meditation has been shown to be useful in the treatment of hypertension. The relaxation response is a physical state of deep rest that changes the physical and emotional responses to stress (e.g., decrease in heart rate, blood pressure, and muscle tension). If practiced regularly, it can have lasting effects when encountering stress throughout the day.

Complications and Risks

Meditation rarely may lead to a “spiritual emergency,” defined as a crisis during which the process of growth and change becomes chaotic and overwhelming as individuals enter new realms of spiritual experience. It is included in the DSM-IV diagnostic category “religious or spiritual problem.” Types of spiritual emergency include but are not limited to various categories: loss or change of faith, existential or spiritual crisis, experience of unitive consciousness or altered states, psychic openings, possession, near-death experience, kundalini, shamanic journey, or difficulties with a meditation practice.

Training and Licensure in Meditation and Stress Reduction

There is no nationally recognized licensing or certification procedure for teachers of meditation.

Energy Therapies

Energy therapies involve the use of energy fields. They are of two categories:

1. **Biofield therapies** are intended to affect energy fields that purportedly surround and penetrate the human body. Some forms of energy therapy attempt to manipulate biofields by applying pressure or manipulating the body by placing the hands in, or through, these fields. Examples include qi gong, Reiki, and therapeutic touch.

2. **Bioelectromagnetic-based therapies** involve the unconventional use of electromagnetic fields, such as pulsed fields, magnetic fields, or alternating current or direct current fields.

Complications and Risks

Energy-based therapies are the least well researched and the most diverse of all CAM modalities. It is, therefore, not possible to address potential complications and risks.

Training and Licensure in Energy-based Therapies

Given the wide array of therapies that fall under this category, the levels of training vary tremendously from modality to modality.

Alternative Medical Systems

**Oriental Medicine and Acupuncture**

Acupuncture is a therapeutic intervention that is used in many Asian systems of medicine. It is based on the theory that there are energy channels called meridians that run throughout the body and that disease results from blockages of this energy. Acupuncture
is used as one approach to release these blockages. It involves stimulating specific anatomic points in the body along these meridians by puncturing the skin with a very fine needle (32 gauge or smaller). There are many distinct styles of acupuncture, which include traditional oriental medicine, Japanese manaka style, Korean hand acupuncture, and the Worsley five-element method.

Given the western, biomedical model, acupuncture is difficult to comprehend. There is, however, an intriguing and growing body of research on this technique. In one study involving stimulation of an acupuncture point that corresponds to the visual cortex and is located on the lateral aspect of the foot, magnetic resonance imaging detected activity of the visual cortex of the brain equivalent to the activity seen when a light is shone in the eye. No activity was seen when an acupuncture needle was placed one centimeter away from the designated acupuncture point (10). Many of the CAM approaches that claim to have an effect and yet seem to be inconsistent with the biomedical model may deserve further investigation.

A 1997 National Institutes of Health Consensus Panel established that there was convincing evidence for the use of acupuncture in the treatment of postoperative dental pain as well as nausea and vomiting. Other indications that were considered promising and worthy of more research included headache, low-back pain, stroke, addiction, asthma, premenstrual syndrome, osteoarthritis, carpal tunnel syndrome, and tennis elbow. There is an extensive body of animal research supporting the neurophysiologic effects of acupuncture on the endorphin system.

Complications and Risks

Bruising and minor bleeding is the most common complication of acupuncture and occurs in about 2% of all needles placed. It rarely requires treatment other than local pressure to the needle site. The most significant risk of acupuncture is infection, and 126 cases of hepatitis have been documented. The only reported cases of infection from acupuncture occurred in instances in which needles were reused. The risk of transmissible infection is eliminated by one-time use of disposable needles, which is now standard practice in the United States. Pneumothorax is the second most significant risk of acupuncture with 66 reported cases. The needles are 32 gauge or smaller; therefore, a chest tube usually is not required for treatment. Five deaths related to acupuncture have been reported. Two deaths were caused by staphylococcal septicemia, two resulted from pericardial tamponade, and one patient died during treatment for acute asthma.

Training and Licensure

Currently there is no national licensure for acupuncture. Educational requirements for state licensure for acupuncture vary. Forty states either license or register acupuncturists as doctors of oriental medicine or acupuncture physicians. About two thirds of these states grant licenses. To get licensed in most states, the practitioner must provide proof that he or she has attended and graduated from an accredited school or from a school that is in the process of being accredited by the Accreditation Commission for Acupuncture and Oriental Medicine (ACAOM). These schools provide 3- or 4-year training programs in oriental medicine that consist of about 2,500 to 3,200 hours.

The National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM) administers a standardized examination to test entry-level capabilities in acupuncture that consists of a comprehensive written examination, point location examination, and demonstration of clean needle technique. An acupuncturist must pass this examination and meet continuing education requirements every 4 years to retain certification and licensure. In the United States, there are about 17,000 practitioners currently
certified in acupuncture by the NCCAOM, and many states have adopted this examination as the basis for licensure.

Medical doctors can practice acupuncture, though physician acupuncture practitioners are seldom as fully trained in the art as nonphysician licensed acupuncturists. To be certified by the American Board of Medical Acupuncture, physicians must take a minimum 300 hours in training.

**Homeopathy**

*Homeopathic medicine* is a CAM alternative medical system based on the work of the German physician and chemist Samuel Hahnemann approximately 200 years ago. In *homeopathic medicine*, there is a belief in “the law of infinitesimals” and that “like cures like.” Thus, small, highly diluted quantities of medicinal substances are given to cure symptoms when the same substances given at higher or more concentrated doses would actually cause those symptoms.

**Naturopathic Medicine**

Unlike oriental medicine or homeopathy, naturopathy does not have a long history of traditional use, nor is it based in a comprehensive system. *Naturopathy views disease as a manifestation of alterations in the processes by which the body naturally heals itself and emphasizes health restoration rather than disease treatment.* Naturopathic physicians employ an array of healing practices, including diet and clinical nutrition; homeopathy; acupuncture; herbal medicine; hydrotherapy (the use of water in a range of temperatures and methods of applications); spinal and soft-tissue manipulation; physical therapies involving electric currents, ultrasonography, and light therapy; therapeutic counseling; and pharmacology.

**Training and Licensure**

There is no national licensure for naturopathy, and licensure at the state level is inconsistent. Currently only 16 states have licensing laws, and they differ considerably. Four 4-year naturopathic medical schools are accredited by the Council on Naturopathic Medical Education.

**Patient Care Issues**

**The Placebo Effect**

Only with more rigorous scientific research will the role of the placebo effect in various CAM approaches be further elucidated. Just as with conventional medicine, the effects of certain approaches are more likely than others to be associated with a placebo response. After exposure to a stimulus believed by both the patient and the practitioner to be an active intervention, the body responds physiologically in an equivalent manner. **Approximately one third of patients in placebo-controlled trials of conventional methods experience a placebo response.** It would be of great value to medicine if the placebo response were better understood and could be activated more reliably in patients. There is, however, no evidence that the placebo response is more active in CAM than in conventional approaches.

**Quality Control**

Quality control issues in CAM are very challenging for several reasons. First, the market demand is huge and is far ahead of the health care system’s ability to address issues of regulation, education, or research. Because CAM, by definition, is inclusive of everything that conventional medicine is not, issues of quality control are extremely difficult. The Federation of State Medical Boards has recently developed “Model Guidelines for the Use
of Complementary and Alternative Therapies in Medical Practice,” which were approved by the House Delegates of the Federation of State Medical Boards of the United States, Inc., as policy in April 2002. The intention of this initiative was to provide guidelines that are clinically responsible, ethically appropriate, and consistent with what state medical boards generally consider to be within the boundaries of professional practice and accepted standard of care.

Potential Misuse

In addition to physical risks, patients and physicians alike should be aware of other areas of potential misuse. Two areas are of particular concern. First, given that the dollars being spent out of pocket are so significant, there are some products and some providers whose primary motivation is monetary. Patients can spend significant dollars based on false promises or claims. Second, patients can postpone effective therapy or treatment by turning to CAM modalities exclusive of conventional approaches. This time can be significant in the treatment of many patients’ diseases. Factors that should increase suspicion for potential misuse are listed in Table 13.6.

The Potential Benefits: Therapeutic Opportunities

Given all of the risks and uncertainties, it is appropriate to ask the question: Why should physicians educate themselves regarding CAM? The most basic answer is commitment to the best practice of medicine. If patients are using therapies that are potentially dangerous in their action or in their interaction, physicians should be aware of this possibility and counsel them accordingly. Physicians also have a commitment to offer their patients the best treatment options, regardless of their system of origin. If there are CAM therapies that can benefit patients, they should be informed of them.

In addition to this most fundamental of reasons, there are additional therapeutic opportunities offered by CAM, as shown by the following examples:

- Decreased harm of interventions: Chiropractic medicine to treat acute low-back pain and potentially avoid surgery; mind–body approaches to decrease anxiety and need for medical management
- Treatment of conditions when conventional approaches fail: Treatment of nausea and vomiting of pregnancy with acupuncture, vitamin B<sub>6</sub>, and ginger
- Prevention: Increased intake of isoflavones to potentially decrease the risk of breast cancer
- Improved outcomes: Successful management of menopausal symptoms in patients at risk for breast cancer

Doctor–Patient Interaction

One of the greatest barriers regarding issues of CAM is a lack of communication. As multiple studies have shown, most patients do not tell their physicians of their use of CAM. Often, this is the case even when the physicians are receptive to the topic. Given the prevalence of use and the potential for interactions with conventional approaches, it is imperative that questions regarding CAM be integrated into the patient history. Many patients simply do not think of sharing this information with their physicians, so direct and specific inquiry is necessary. Many practices incorporate this information in a separate sheet for patients to fill out and for physicians to review and add to the chart. It is useful to know all CAM therapies that patients have used in the past or are using presently, particularly anything ingestible. If a patient is seeing a CAM practitioner, it is best to specifically ask if they have recommended any supplements or botanicals. Oriental medicine practitioners or acupuncturists, for example, often treat with botanical products or herbal teas. Naturopaths and chiropractors often recommend vitamins and supplements. When patients are asked this history directly in an atmosphere of respect, they usually are very forthcoming, and the most significant barrier has been broken.

Three factors contribute to an interesting dynamic that often arises when discussing issues of CAM with patients. This is an area in which (i) very few physicians have received any formal training, (ii) there is little (albeit increasing) research in the mainstream medical journals, and (iii) there is a tremendous amount of information, of variable quality, in the lay press. All of these factors contribute to a circumstance that often is uncomfortable for physicians. This discomfort is important to recognize because it can contribute to avoidance of the topic altogether. The development of CAM therapies and their integration into the treatment plans is a new and evolving area. It is appropriate to begin the conversation with a patient by explaining that this is new territory in conventional medicine and that you are not an expert. Most patients have already assumed this to be the case, appreciate the honesty, and value the opportunity to discuss these dilemmas. This is a significant step in building a trusting and therapeutic relationship with patients interested in CAM.

It is useful to share the following decision tree with patients when making decisions regarding the use of CAM (Fig. 13.1).

**Step One: Assess Potential Harm**

Although research regarding CAM approaches is often less than optimal, the potential for any therapy to do harm should be thoroughly evaluated (to the best of available knowledge). It is necessary to evaluate the potential to cause both direct harm and indirect harm.

*Potential for Direct Harm* This should include any evidence regarding potential harm directly from the therapy or potential interactions. When lacking good evidence, assessment of the invasiveness of the therapy is a strong predictor of risk.

*Potential for Indirect Harm* This should include an assessment of potential harm caused by postponing effective treatments, as well as by financial exploitation. Many CAM approaches are costly, and the patient usually assumes all of the cost. Marketing can prey on vulnerable patients and result in significant and unnecessary expenditures.

**Step Two: Assess Potential Benefits**

The potential for any approach to be of benefit should be assessed on several levels.
SECTION III  Preventative and Primary Care

1. Assess potential harm

   What is the potential for direct harm?
   (from the treatment itself; e.g., toxicity, injury)

   High  Low

   DO NOT RECOMMEND

   What is the potential for indirect harm?
   (e.g., postponing other treatments, financial exploitation)

   High  Low

   DO NOT RECOMMEND

2. Assess potential benefit

   Are there data on efficacy?

   Evidence shows no efficacy  Evidence shows efficacy  Indeterminant

   DO NOT RECOMMEND

   Is there cultural evidence?

   Yes  No

   DO NOT RECOMMEND

   Is there strong patient belief?

   Yes  No

   Evidence shows no efficacy

   Evidence shows efficacy

   Indeterminant

   DO NOT RECOMMEND

3. Assess the quality of product or provider
   (e.g., independent product assessment, licensing body, patient experience)

   Unacceptable  Acceptable

   DO NOT RECOMMEND

4. Assess the integration with the conventional treatment plan

   Can the approach be integrated?
   (e.g., no significant interactions or contraindications with conventional treatments)

   No  Yes

   DO NOT RECOMMEND

   Can the provider be integrated?
   (e.g., desires collaboration, supports integration of conventional and CAM approaches)

   No  Yes

   RECOMMEND
   (informing patient of rationale for recommendation and level of evidence for the approach)

Figure 13.1  Decision Tree for Integrating CAM Approaches.
Scientific Evidence  A review of the peer-reviewed literature should certainly be conducted for evidence of the effectiveness of the approach under consideration.

Cultural Evidence  Another form of useful information is the historic or cultural use of the approach. For example, it is valuable to consider whether a therapy has a long history of use within a given culture. If, on the other hand, the approach has no historic use, this too is important to recognize. Examples include the use of black cohosh for menopausal symptoms, which has been used for centuries with reported safety and effectiveness, compared with red clover, which has no historic use or track record. Another example would be acupuncture, with thousands of years of use, compared with chelation, which has been in use for a relatively short time and is associated with considerable debate regarding its benefit.

Personal Belief  Another part of the assessment of benefit is to recognize the patient’s belief system as it pertains to the approach. If the patient has a strong belief in the approach, and there is no evidence of potential harm, it is often reasonable to support its use. Activating a healing response or a placebo effect can often be very therapeutic.

Step Three: Assess the “Delivery System”

When assessing the delivery system, both products and providers must be considered.

Product  Assessing the history of the manufacturing company and understanding its process of quality assurance can be useful. Referral to independent sources for determining the quality of product and accuracy of labeling also may be useful.

Provider  It can be difficult to assess the skill level of CAM providers. Inquiring about the education of a given provider as well as his or her licensing status (if there is a licensing body for the field) is an important place to start. It also is useful to talk to other patients who have used these services. Finally, one’s own sense of a provider is extremely important.

Step Four: Assess the Integration

Although the individual CAM therapy may have no evidence of harm and be of potential benefit, the way in which it is integrated into the patient’s overall treatment plan is important. The same is true for CAM providers.

Approaches  The therapy or approach should be integrated into the overall treatment plan. For example, large doses of antioxidant vitamins should not be used in patients undergoing radiation therapy, as they may counteract the action of the radiation. Likewise, patients with Down’s syndrome should not undergo chiropractic manipulation.

Providers  Perhaps most importantly, the potential for integration of the providers is essential to assess. If the intention is to offer the patient the best possible care, all providers, conventional and CAM alike, should be assessed for their willingness to integrate their care for the benefit of their patients. If any providers are unsupportive of conventional medicine, it is critical to recognize this and look for a provider who supports integration of care.

It is useful for each physician to recognize his or her own biases about CAM and willingness to learn about the techniques. At a minimum, physicians should know the basics about which CAM approaches may be of benefit to patients and which may be of harm. Familiarity with resources in the community that are more focused on these areas can serve physician and patient alike.
Specific Gynecologic Issues

Menstrual Disorders

Biologically Based Therapies: Supplements and Botanicals

Premenstrual Symptoms

In a review of randomized controlled trials of CAM approaches in reproductive-age women, the authors concluded that data clearly supported the use of calcium for premenstrual syndrome (PMS) and that initial studies were promising for magnesium, Vitamin B₆, and chasteberry, as well as fish-oil supplementation for dysmenorrhea (11).

Calcium

Multiple studies have shown that calcium, 900 to 1,200 mg/day in divided doses, has at least some effect on symptoms of PMS and premenstrual dysphoric disorder (PMDD), including negative mood, water retention, and food cravings (12). One of the largest studies to date examined the effect of 1,200 mg of calcium per day and reported a 48% decrease in PMS symptoms. In this study, the placebo group also had a 30% reduction in symptoms (12). Although the difference between the groups was statistically significant, it is interesting to note that there tends to be a large placebo effect in these studies.

Magnesium

As a sole agent, there is less evidence on magnesium than calcium, although low magnesium levels have been reported in women suffering from PMS. However, several studies show a significant decrease in PMS symptoms with magnesium supplementation (13,14). Magnesium can be taken 200 to 400 mg/day, in divided doses, either cyclically during the luteal phase or continuously. It also helps to counteract the constipating effects of calcium supplementation.

Vitamin B₆

Vitamin B₆ binds to estrogen and progesterone receptors and has been the subject of most of the randomized controlled trials regarding CAM and PMS. Most controlled studies on vitamin B₆ in the treatment of PMS have limited numbers of patients; therefore, the evidence of positive effects is fairly weak (15). This is a benign therapy in doses of 100 mg or less, however. A systematic review of nine trials indicated significant benefit over placebo for the symptoms of mastalgia, swollen breasts, pain, and depression (16). A recent review of these trials has shown that most of them have shown some benefit (11). It is important to note that peripheral neuropathies can occur with doses of 200 mg/day or higher and that vitamin B₆ may interact with other medications, specifically those used to treat Parkinson’s disease. The recommended starting dose is 50 mg/day with meals, daily.

Vitamin E

Studies performed in the 1940s suggested that vitamin E might be effective in the treatment of menstrual disorders such as PMS. Recent studies have failed to reproduce these results. One study that evaluated vitamin E (in d-alpha tocopherol form) for the treatment of PMS symptoms showed an improvement over placebo (17).

Omega-3 Fatty Acids

There are two major types of omega-3 fatty acids: eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Omega-3 fatty acids act as anti-inflammatory agents in that they shift arachidonic acid metabolism away from PGF₂α and increase levels of the less inflammatory PGE₁. Omega-3 fatty acids are essential foods, and levels are extremely low in the average diet of individuals in the United States. They can be increased through dietary means as well as supplements (Table 13.7). One study looked at EFA and PMS and showed no effect. There are, however, some positive studies looking at the effectiveness of omega-3 fatty acids in treating mild depression with fish oils.

(Continued)
may be a reasonable approach to try if one of the patient’s primary symptoms is mood depression (3 grams, divided with meals) (18). Side effects are rare, but occasionally patients will experience nausea, diarrhea, belching, or an unpleasant taste in the mouth. Omega-3 fatty acids have an anticoagulant effect and are relatively high in calories.

Chasteberry  

Chasteberry (*Vitex agnus castus*) is a botanical with a long history of use for “menstrual disorders.” Many small studies have shown promising results, and one larger study examined the effectiveness of chasteberry on PMDD (19–21). In this randomized controlled trial, the active arm received 20 mg of chasteberry daily. Compared with placebo, the patients receiving chasteberry had a significant improvement in the combined symptom score (21). A multicenter noninterventional trial examined the experience and tolerance of chasteberry in 1,634 patients. After use in three cycles, 93% of women reported a decrease in or cessation of symptoms, and 94% of patients reported good or very good tolerance to this botanical. Adverse drug reactions were suspected by physicians in 1.2% of patients, but there were no serious adverse reactions (22). A randomized, single-blind trial comparing *Vitex* and *fluoxetine* showed equal symptom reduction at 2 months (58% and 68%, respectively) (23). Because chasteberry contains iridoids and flavonoids, the mechanism of action is believed to be stimulation of dopamine D2 receptors, which decrease prolactin levels. *In vitro*, it also inhibits opioid, mu, and kappa receptors. It has no effect on luteinizing hormone or follicle-stimulating hormone levels (24). *Vitex* has also been shown to restore progesterone levels and in Germany is used to treat menstrual irregularities as well as undiagnosed infertility. No significant toxicities have been reported with *Vitex* extracts when used in appropriate dosages.

St. John’s Wort  

St. John’s wort (*Hypericum perforatum*) is recognized as an effective antidepressant for the treatment of mild to moderate depression. One open trial of 19 women found that this compound, when used at a dose of 300 mg per day of a 0.3% hypericin standardized extract, showed a 51% improvement in mood disturbances in PMS/PMDD (25). This dose is one third of that typically used for depression. Although adverse reac-

*For general health, aim for 7 to 10 g of omega-3s weekly.*

EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

tions occur less frequently than with prescription antidepressants, care must be exercised with the use of this product. Most common side effects include gastrointestinal upset, headache, and agitation. Rare but severe phototoxicity also has been reported. Because St. John’s wort induces the cytochrome P450 complex, significant drug interactions can occur. Specifically, reduced levels of birth control pills, theophylline, cyclosporine, and antiretroviral drugs have been reported. Interactions have also been described with buspirone, statins, calcium channel blockers, digoxin, and carbamazepine. There are no apparent significant interactions with Coumadin. The mechanism of action for its efficacy in the treatment of PMS has not been elucidated. There have been two isolated reports of pregnancy occurring in women who were taking oral contraceptives in conjunction with St. John’s wort. If patients choose to take St. John’s wort, they may want to use a backup method of birth control or change to a different method.

**Ginkgo**  
Ginkgo (*Ginkgo biloba*) has traditionally been used to relieve breast tenderness and discomfort, improve concentration, and enhance sexual function. Its vascular effects, particularly with regard to dementia and peripheral vascular disease, also have been studied. One large study examined the effectiveness of ginkgo in the treatment of women with PMS and found that after two cycles with treatment, breast symptoms were significantly improved in the ginkgo group. The effectiveness in terms of concentration or libido was not examined (26). In doses ranging from 60 to 240 mg of standardized extract per day, ginkgo has shown clinical efficacy in the treatment of breast pain, tenderness, and fluid retention. In at least one study, ginkgo has also been found to be effective in the relief of symptoms related to emotional distress (27). Ginkgo has been promoted as an agent that can increase libido, but the methodology of these studies has been criticized, and further studies are required to better define the botanical’s role in these areas. Side effects include gastrointestinal upset and headache. High doses can cause nausea, vomiting, diarrhea, restlessness, or insomnia. Ginkgo also has anticoagulant activity, and care must be taken when used with anti-inflammatory drugs as well as with warfarin. The underlying mechanism of action is believed to be dilation of vessels and increased blood flow.

Other products that are used to treat symptoms of PMS and PMDD but are not recommended are listed in Table 13.8.

**Table 13.8 Other Products Often Used to Treat Symptoms of PMS And PMDD (Not Recommended)**

- **Tryptophan**, an amino acid that is a precursor of serotonin, has been shown in several trials to improve the symptoms of PMS and PMDD. Impurities in one product made in Japan have been associated with the development of eosinophilia–myalgia syndrome (EMS), which can be fatal. It is unclear if all the cases were related to impurities or if some were related simply to the active ingredients. Until this is clearly understood, tryptophan should be avoided.

- **Dehydroepiandrosterone (DHEA)**, a hormone secreted by the adrenal glands and often used for depression, has not been shown to be of benefit in PMS/PMDD.

- **Melatonin**, a hormone that regulates sleep–wake cycles and often is used to prevent jet lag, has been used for the treatment of PMS. There is no evidence of efficacy, and it can worsen depression in some patients.

- **Black cohosh (*Cimicifuga racemosa*)** has been well studied in the treatment of menopausal symptoms, but it has not been studied in the treatment of PMS/PMDD. Although it may prove to be beneficial, data are needed.

- **Evening primrose oil** is frequently used for PMS, but with the exception of cyclic mastalgia, research has failed to show benefit beyond placebo.

- **Dong quai** is an oriental herb often used in combination with other herbs for the treatment of menstrual disorders and menopausal symptoms. Its effectiveness has not been researched.

- **Kava** has been used to treat anxiety and irritability, and several studies have documented its effectiveness. It has, however, been associated with hepatotoxicity, even necessitating liver transplant. It is unclear whether this effect was related to drug or alcohol interactions, contaminants, or the kava itself.

PMS, premenstrual syndrome; PMDD, premenstrual dysphoric disorder.
Dysmenorrhea

Although dysmenorrhea is in general managed more effectively than PMS and PMDD with conventional approaches, treatment still has a failure rate of approximately 20% to 25%, and many patients seek alternatives. Table 13.9 lists findings by a Cochrane review study on alternative treatments. The review concluded that vitamin B1 is effective in the treatment of dysmenorrhea when taken at 100 mg daily, although this finding is based on only one large randomized controlled trial (28). The results further suggested that magnesium is a promising treatment, but it is unclear what dose or treatment regimen should be used (28). The addition of fish oils has shown promising results.

Manipulative and Body-based Methods

Table 13.9 Findings on Alternative Treatments

- **Magnesium** Three small trials were included that compared magnesium with placebo. Overall, magnesium was more effective than placebo for pain relief, and the need for additional medication was lessened. There was no significant difference in the number of adverse effects experienced.
- **Vitamin B6** One small trial showed vitamin B6 to be more effective at reducing pain than both placebo and a combination of magnesium and vitamin B6.
- **Vitamin B1** One large trial showed that vitamin B1 was more effective than placebo in reducing pain.
- **Vitamin E** One small trial comparing daily vitamin E with ibuprofen taken during menses showed no difference in pain relief.
- **Omega-3 fatty acids** One small trial showed fish oil to be more effective than placebo in pain relief. A number of studies have found that the intake of marine origin omega-3 fatty acids (such as salmon and sardines) decrease symptoms of dysmenorrhea. Given the established benefits of omega-3 fatty acids in other conditions such as heart disease, high intake of these compounds can be recommended throughout the cycle.

Dysmenorrhea

Although dysmenorrhea is in general managed more effectively than PMS and PMDD with conventional approaches, treatment still has a failure rate of approximately 20% to 25%, and many patients seek alternatives. Table 13.9 lists findings by a Cochrane review study on alternative treatments. The review concluded that vitamin B1 is effective in the treatment of dysmenorrhea when taken at 100 mg daily, although this finding is based on only one large randomized controlled trial (28). The results further suggested that magnesium is a promising treatment, but it is unclear what dose or treatment regimen should be used (28). The addition of fish oils has shown promising results.

**Premenstrual Symptoms**

Massage has been shown to relieve anxiety, sadness, and pain immediately after the therapy, but it has not been shown to reduce symptoms of PMS/PMDD overall.

Chiropractic manipulation has not been shown to be of benefit for women with PMS/PMDD. One small (N = 25) placebo-controlled crossover study showed the group receiving chiropractic treatment had a significant improvement in symptoms, but the group that received placebo first improved over baseline with the placebo but experienced no further improvement when they received the active treatment (29).

**Dysmenorrhea**

A Cochrane review of the use of spinal manipulation for primary and secondary dysmenorrhea concluded that overall there is no evidence to suggest that spinal manipulation is effective in the treatment of primary or secondary dysmenorrhea. In four trials, high-velocity, low-amplitude manipulation was no more effective than sham manipulation, although it was possibly better than no treatment (30). Three of the smaller trials indicated a difference in favor of the manipulation; however, the one trial with sufficient sample size found no difference. There was also no difference in adverse effects between the two groups (30).
Mind-body Interventions

Relaxation techniques have shown some very promising results for women with PMS/PMDD. One study examined the effect of the relaxation response for 15 minutes, twice a day, for 3 months, compared with women who read for the same amount of time, and women who charted their symptoms. Of women in the relaxation response group, 58% experienced improvement in their symptoms, compared with 27% for the reading group, and 17% for the charting group (31). Given that there are many other health benefits to the relaxation response, with no cost and no risk, it is a good technique to recommend to patients.

Alternative Medical Systems

Oriental Medicine and Acupuncture

Oriental medicine and acupuncture have been used traditionally for thousands of years for a myriad of menstrual symptoms, PMS and PMDD among them. The effectiveness in this domain has not been studied to date. There have been studies showing the effectiveness of acupuncture in the treatment of mild depression and generalized anxiety, although not all results have been positive. In general, if the patient has access to a qualified acupuncturist and has a belief or interest in pursuing this therapy, it is generally safe and may be effective. She should be informed, however, of the lack of research in this domain.

There has been one small but methodologically sound trial of acupuncture in the treatment of primary dysmenorrhea. This trial followed 43 women for 1 year and showed significant effectiveness of acupuncture when compared with placebo (91% of women showed improvement, compared with 10% to 36%, 18%, and 10% in the other groups) (28). Clearly more research is needed, but this is a promising and safe modality.

Homeopathy

The use of homeopathy in the treatment of PMS and PMDD has not been well studied, nor has its effectiveness in the treatment of related disorders such as depression or anxiety. One study did claim positive results but was fairly weak in design as well as in showing improvement (31).

Infertility

Mind-body Interventions

Mind–body approaches are of particular interest in the infertility patient. Not only are the treatments for infertility stress inducing, but increased stress is associated with decreased fertility (as well as increased risk of such things as gestational diabetes, preterm labor and delivery, and prolonged labor).

In a study of infertility patients, two group psychological interventions were compared with routine care. The two groups who received group support and cognitive behavioral therapy had fertility rates of 54% and 55%, respectively, compared with the control group, which had a pregnancy rate of 20%. There were, however, large and disparate dropout rates, which complicate the interpretation of these results (32). Intercessory prayer has been explored in a double-blind, randomized controlled trial. Patients undergoing in vitro fertilization in Korea (N = 219) were randomized to receive prayer-by-prayer groups in the United States, Canada, and Australia. The group that received the intervention had a pregnancy rate of 50% compared with the control group rate of 26% (p = 0.0013) (33).

In general, mind–body therapies, such as relaxation techniques and hypnosis, are reasonable to recommend to relieve a wide variety of issues that can arise with infertility patients.
Alternative Medical Systems

The use of acupuncture has also been studied in the treatment of infertility. Auricular acupuncture was studied as an alternative therapy for female infertility secondary to oligomenorrhea or luteal insufficiency, and the authors concluded it was a valuable therapy (34). Another study used electroacupuncture in anovulatory women with PCOS and found that regular ovulation was induced in more than one third of the women. In a randomized controlled trial comparing usual care to usual care plus 25 minutes of a standard acupuncture treatment pre- and postembryo transfer, the pregnancy rates were 43% in the intervention arm as opposed to 26% in the control arm. The acupuncture protocol was designed to promote sedation, uterine relaxation, and increased uterine blood flow (35). It is interesting to note that blood flow impedance in uterine arteries, measured as the pulsatility index, has been considered useful in assessing endometrial receptivity to embryo transfer. A study was performed assessing the effect of electroacupuncture on the pulsatility index of infertile women. After treatment twice a week for 4 weeks, the mean pulsatility index was significantly reduced both shortly after the last treatment and also 10 to 14 days after the treatments. The skin temperature of the forehead also was increased significantly, suggesting a central inhibition of sympathetic activity (36).

Menopause

Before the release of the results of the Women’s Health Initiative, 80% of women in the United States were using “nonprescriptive therapies” to help manage their menopausal symptoms, and many of these therapies were CAM approaches. In a study exploring women’s beliefs about “natural hormones,” women using compounding pharmacies believed that compared with standard hormones, natural hormones are safer, cause fewer side effects, and are equally or more effective for symptom relief. Many women believed natural hormone therapy was equally or more effective for long-term protection of bones and lipid levels (37). It is reasonable to assume that women are now exploring and choosing such therapies in ever increasing numbers, often without being accurately or fully informed. This expanded market generates more products and promotion of alternatives. It is imperative that physicians be informed about these options so they can help patients make medically sound choices.

Biologically Based Therapies

The list of botanicals promoted and used for the treatment of menopausal symptoms is extensive. Following is a review of the products most commonly used and recommended based on research evidence.

Vitamin E

Since the 1940s, vitamin E has been studied for the treatment of hot flashes. Although some early studies showed promising results, more recent studies evaluating 200- to 600-IU doses have failed to show an effect. Up to 1,200 IU may be needed to see an effect. Vitamin E is an anticoagulant, and spontaneous subarachnoid hemorrhages have been reported. One study examining vitamin E in menopausal patients with breast cancer found that after 4 weeks of 800 IU daily, the patients in the treatment arm had on average one less hot flash per day. Although this finding was statistically significant, it was not significant clinically (38).

Black Cohosh

Black cohosh (Cimicifuga racemosa) has traditionally been used for relief of both PMS and menopause symptoms. It has been used in the Native American population for centuries and in Germany since 1950. Its most studied form is a brand called Remifemin, which is standardized to 1 mg of deoxyactein and is administered in a dose of 40 mg two times daily. Most early studies had been uncontrolled,
but recent studies have been more methodologically sound. Initially, it was felt that black cohosh was estrogenic. Subsequently, it has been shown that it does not contain phytoestrogens and that it does not have an estrogenic effect on vaginal cytology. Additionally, there are no changes in hormone levels in women taking black cohosh. Studies confirmed that black cohosh inhibited luteinizing hormone in ovariectomized rats, as well as in women. Animal studies showed no uterotrophic or vaginotropic activity. Luteinizing hormone, therefore, is most likely being decreased via neurotransmitters. In laboratory studies, black cohosh actually suppresses rather than stimulates breast cells (39). One of the first randomized controlled trials on black cohosh was done in 1987. It included 80 women who were randomized to 0.625 mg of Premarin versus 8 mg of black cohosh versus placebo for 12 weeks. The group taking black cohosh showed significant improvement in menopausal symptoms, anxiety, and vaginal dryness, and it was well tolerated (40). Another study done in 1987 compared estrogen injections with black cohosh. In this study, 82% of women reported good to very good relief of their symptoms, with no side effects noted (41). In 1988, another study compared conjugated estrogens, estrogen–gestogen sequential therapy, estriol, and black cohosh. The results with black cohosh were comparable to those of the hormonal therapies (42). In a study of 629 women who underwent 6 to 8 weeks of treatment with black cohosh, 80% of women had improvements in hot flashes, fatigue, irritability, and vaginal dryness. At 8 weeks, 50% of women were symptom free (43). Another randomized controlled trial of black cohosh compared 40 mg with 127 mg a day for 6 months. Luteinizing hormone, follicle-stimulating hormone, sex hormone–binding globulin, prolactin, estradiol, and vaginal dryness were not affected. Both dosages had similar effectiveness and safety (44). In a recent double-blind, placebo-controlled trial, black cohosh (40 mg) was compared with conjugated estrogen (0.6 mg) and placebo in 62 women for 3 months (45). Black cohosh was found to be equally potent to conjugated estrogen and superior to placebo in decreasing symptoms. Both black cohosh and conjugated estrogen had beneficial effects on bone metabolism, as evidenced by bone-specific alkaline phosphatase. Black cohosh had no effect on endometrial thickening, as measured by vaginal ultrasonography, unlike conjugated estrogen, which caused a significant increase in endometrial thickening. Additionally, an increase in vaginal superficial cells occurred with both black cohosh and conjugated estrogen. The authors proposed that black cohosh contains selective estrogen receptor modulator activity. In a randomized double-blind trial comparing the efficacy of black cohosh to placebo, black cohosh was found to be effective in reducing symptoms of menopause. The effect was similar to that of hormone therapy and was most significant in women in the early stages of menopause (46).

Although many of the studies of black cohosh have design weaknesses, it appears to be safe and efficacious for the treatment of menopausal symptoms. Therapy should begin at 20 to 40 mg two times daily, standardized to 2.5 triterpenes. Others have recommended a dose of 40 to 200 mg daily. Patients should be informed that it might take 4 to 8 weeks to see an effect. Side effects are rare and include gastrointestinal upset, headache, weight gain, and dizziness. Some recommend using black cohosh for no longer than 6 months (47). There is no indication that longer use is unsafe, and studies following patients for 2 years are ongoing.

**Breast Cancer**  Multiple studies have shown that black cohosh has an inhibitory effect on estrogen receptor breast cancer cells. One study showed augmentation of the antiproliferative effects of tamoxifen. In a study that looked at the effectiveness of black cohosh in reducing menopausal symptoms for breast cancer patients, both the placebo group and the group receiving black cohosh had a 27% reduction in the number and intensity of hot flashes. Only sweating was significantly more improved in the black cohosh arm (47). In another study, 136 breast cancer survivors were randomized either to tamoxifen alone or tamoxifen plus black cohosh. At 6 months, there were no significant differences, but at 1 year, 47% of women in the intervention arm versus none in the control group were free of hot flash. Severe hot flashes were also reduced in the intervention arm (24%) compared with the tamoxifen-alone arm (74%) (48). Although it is useful to know that
black cohosh is not estrogenic, its efficacy in this group of patients has not yet been established.

**Ginseng**

Many different botanicals use the name *ginseng*. The two most common are Siberian ginseng (*Eleuthero*) and oriental or Korean ginseng (*Panax*). Both of these agents are extracted from the root of their respective plants, and both are used to combat fatigue or to restore “vital force” for performance enhancement.

Panax ginseng is a small perennial that grows in northeast Asia. One study of 12 patients examined its effect on menopausal women, both with and without the symptoms of fatigue, insomnia, and depression. At baseline, the patients with symptoms had significantly higher anxiety states. The dehydroepiandrosterone-sulfate was one half that of those in the control group, and the cortisol/dehydroepiandrosterone-sulfate ratio was significantly higher in the symptomatic patients. After treatment, the anxiety state decreased to that of the controls, and the cortisol/dehydroepiandrosterone-sulfate ratio decreased significantly although not to the level of the control group (49).

In terms of the physiologic symptoms, a randomized, multicenter, double-blind parallel group study compared a standard ginseng extract with placebo. Quality of life and physiologic parameters were assessed at baseline and after 16 weeks of treatment. There was no significant difference in symptom relief and no significant difference in the physiologic parameters of follicle-stimulating hormone, estradiol, endometrial thickening, maturity index, or vaginal pH. Patients did, however, experience significant improvement in depression, sense of well-being, and health (50).

There is no evidence to support the use of ginseng for relief of physiologic symptoms. If patients are suffering from psychological symptoms of menopause, they potentially may benefit from *Panax* ginseng. Although its mechanism of action is not clear, *Panax* ginseng does not appear to be estrogenic. Use of *Panax* ginseng should be avoided with stimulants, and it may cause headaches, breast pain, diarrhea, or bleeding. The recommended dose is 100 mg of a standardized extract two times daily for 3 of 4 weeks.

The estrogenic effect of black cohosh, dong quai, ginseng, and licorice root has been evaluated by (i) an examination of the effect on cell proliferation of MCF-7 cells (a human breast cancer cell line), (ii) transient gene expression assay, and (iii) a bioassay in mice. The authors concluded that dong quai and ginseng stimulate growth of MCF-7 cells independent of estrogenic activity, and that black cohosh and licorice root neither have estrogenic activity nor stimulate the breast cell line (39).

**Red Clover**

Red clover (*Trifolium pratense*) is a member of the legume family, with brand names including *Promensil* and *Rimostil*. It contains at least four estrogenic isoflavones and, therefore, is promoted as a source of phytoestrogens. Red clover is a medicinal herb with no traditional long-term use in menopause. Its estrogenic effects were first discovered by observing its effects on sheep. The term Clover syndrome is used to describe the symptoms frequently seen in sheep that consume large amounts of red clover. This syndrome is characterized by reproductive complications, including infertility. Despite its estrogenic activity, several studies, including two double-blind placebo-controlled trials, have failed to show an effect over placebo in the treatment of menopausal symptoms (51). A randomized controlled trial of 30 women compared the effect of red clover versus placebo on hot-flash frequency. All patients received placebo for 4 weeks and then were randomized to 80 mg of red clover versus placebo for 12 weeks. In the first 4 weeks, hot flashes were reduced by 16% and subsequently further reduced by 44% in the red clover group.
compared with no further reduction in the placebo group ($P < 0.01$) (52). In a much larger trial involving 252 women, two different red clover supplements were compared with placebo over 12 weeks (Promensil, containing 82 mg isoflavones, and Rimostil, containing 57 mg isoflavones). Although Promensil did reduce hot flashes more quickly than Rimostil or placebo, all three groups experienced the same level of reduction in hot flashes at the end of 12 weeks. This study does supply some evidence for a biological effect of Promensil, but neither of the red clover supplements had a clinically significant effect when compared with placebo (53). In one randomized controlled pilot study examining the effect of red clover on the endometrium, an antiproliferative effect was not observed (54). The effect of red clover on the endometrium must be further delineated.

Other trials have examined the efficacy of red clover in moderating cardiovascular risk factors. Of five trials examining the effect of red clover on lipid levels, three showed no effect, and one had insufficient data to interpret. Another trial examined the effects of red clover on arterial compliance and showed significant improvement (23%) when compared with placebo. There was no effect on lipids. One intervention-only trial using a preparation of Rimostil found a significant increase in high-density lipoprotein, a decrease in apolipoprotein B, and an increase in cortical bone in the radius and ulnar after 6 months of treatment (55, 56).

Red clover has no traditional long-term history of use in menopause. It has no clear demonstrable effect on symptoms of menopause, it is estrogenic, and its effects on breast and endometrium have not been adequately studied. Coumarin is present in some clover species. Unfortunately, brands of red clover such as Promensil are being marketed directly to patients. For the reasons stated, red clover is not recommended.

**Dong Quai**

Dong quai (Angelica sinensis) has a long history of traditional use in menopause and in the treatment of menstrual problems. Traditionally, in the oriental system of medicine, it is used in combination with other botanicals. Several studies of the effectiveness of dong quai in treating the symptoms of menopause have failed to show its effectiveness (57). No evidence exists to support the use of dong quai as a single agent in the treatment of menopausal symptoms. The use of dong quai in combination with other herbs, as has been done traditionally, has not been well studied. It is important to note that dong quai also contains coumarin derivatives.

**Kava**

Kava (Piper methysticum) is native to the South Pacific, and one of its traditional uses is to reduce anxiety. It is often recommended for menopausal symptoms, particularly irritability, insomnia, and anxiety. Studies have shown that 100 to 200 mg, three times daily, standardized to 30% kavalactones, decreases irritability and insomnia associated with menopause. It is often used in combination with other components, such as black cohosh and valerian, for the management of menopausal symptoms. One study that examined the use of kava in addition to hormone therapy for the treatment of anxiety showed that the combined use resulted in a significant decrease in anxiety when compared with hormone therapy alone.

Kava, however, has the potential for significant, albeit rare, side effects. Cases of hepatotoxicity severe enough to require transplant have been reported. Other side effects include dermatitis, as well as a movement disorder similar to Parkinson’s disease but reversible. The use of kava is not recommended, but if patients are using this botanical (which is available over the counter), they should be informed of the risks, as well as advised to avoid taking kava in conjunction with other anxiety-reducing agents or with alcohol.
**St. John's Wort (Hypericum perforatum)**

The leaves and the tips of the flowers of the plant St. John's wort (Hypericum perforatum) have been used medicinally, primarily as an antidepressant. It is also used for anxiety, and in Germany, it is used to treat menopausal mood swings.

Although its mechanism of action is unclear, St. John's wort does appear to be beneficial in relieving mild to moderate depression, with 60% improvement in mood, energy, and sleep with a dose of 300 mg three times daily. Standardization is controversial because the active ingredients have not been identified, but most research has been done on products standardized to 0.3% hypericin. The first trial to examine its use for menopausal symptoms was done in 1999. Patients not taking hormone therapy were given 300 mg of St. John’s wort three times daily, and symptoms were evaluated at baseline and 5, 8, and 12 weeks by both patients and physicians. At baseline, 80% to 90% of all symptoms were moderate to marked in severity. By 12 weeks, 20% to 30% remained at this level, whereas most patients had only slight symptoms or were symptom free. There was no change in vasomotor symptoms; however, 80% of patients reported that their sexuality was substantially enhanced. Of 106 patients, 4 reported adverse effects. These effects included skin rash with sun exposure, gastrointestinal upset, headache, and fatigue (58). St. John’s wort induces the cytochrome P450 complex. Specifically, lower levels of oral contraceptives, theophylline, cyclosporine, and antiretroviral drugs have been reported. Interactions have also been described with buspirone, statins, calcium channel blockers, digoxin, and carbamazepine. There are no apparent significant interactions with Coumadin.

**Chasteberry**

Chasteberry (Vitex agnes) has a long history of uses by civilizations ranging from Greeks to the monks of middle ages. Among the uses is treatment of menopausal symptoms. Although its use has been recommended for this indication, the efficacy of chasteberry in menopause has not yet been demonstrated.

**Ginkgo Biloba**

Ginkgo biloba is often promoted for the improvement of libido in menopausal women. Muira puama plus ginkgo had a significant effect in 65% of the patients in one study (59). Side effects include gastrointestinal upset and headaches, and drug interactions can occur with estrogens, statins, and calcium channel blockers. Ginkgo also has an anticoagulant effect.

**Mind-body Interventions**

Mind–body therapies for the treatment of menopausal symptoms have been studied in several domains. In one randomized controlled trial, symptomatic menopausal patients who had at least five hot flashes per 24 hours were randomized to either the relaxation response, to reading, or to a control group. The relaxation response group had significant reductions in hot-flash intensity, tension–anxiety levels, and depression compared with the control group, which had no significant changes (60). In another randomized controlled trial of symptomatic menopausal patients, women with frequent hot flashes were randomized to paced respiration, muscle relaxation, and alpha-wave feedback. In the paced respiration group, there was significant reduction in the hot-flash frequency, whereas muscle relaxation and biofeedback showed no differences. The proposed mechanism of action is decreased central sympathetic activity (61).

Insomnia, which is another frequent symptom of menopause, is a complex, multifactorial problem. Optimal treatment has been described as incorporating the following components: stress management, coping strategies, enhancement of relationships, as well as lifestyle changes that facilitate sleep (62).
Overall, mind–body techniques are a low- or no-cost, low-risk intervention that can decrease central nervous system adrenergic tone. These techniques have been reported to decrease hot flashes and other menopausal symptoms significantly.

**Alternative Medical Systems**

Oriental medicine has been used for more than 2,500 years and includes treatment with acupuncture, herbs, and movement. Although diagnosis and treatment is highly individualized, from the perspective of oriental medicine, menopause is often associated with deficiencies in qi, blood, and jing. Acupuncture is one of the best-studied CAM modalities, but more studies of higher quality are needed regarding its application to the menopausal patient. One uncontrolled study, which explored the experience of more than 300 women, found that 97% of women reported that acupuncture improved their symptoms, and 51% reported being symptom free (63). In a pilot study looking at the use of acupuncture in patients being treated with tamoxifen, 15 patients were followed for 6 months. Patients were evaluated before and after 1, 3, and 6 months of treatment. There was significant improvement in anxiety, depression, and somatic and vasomotor symptoms. Libido was not affected. This is a promising area for those patients whose options for treatment of these symptoms are limited.

In the hands of a competent practitioner, acupuncture is a safe CAM modality. If menopausal patients are interested in exploring this technique as part of their plan for managing symptoms and understand the lack of comprehensive studies, it is reasonable to support a trial of acupuncture with a qualified practitioner. Because many of the herbal treatments in oriental medicine can be estrogenic, it is best to avoid them if the patient is taking any form of hormonal therapy.

**“Natural” Hormones**

There is increasing confusion around the myriad hormonal options for patients. Because many hormonally active compounds are available over the counter, physician awareness about these issues is essential, especially in light of the findings of the Women’s Health Initiative.

**Natural Versus Bioidentical Hormones**

There is a dominant belief in the culture that natural is “good” and synthetic is “bad.” A natural product is any product with principle ingredients that are of animal, mineral, or vegetable origins. Natural products may have no resemblance to the ingredients in their natural state. For example, conjugated equine estrogens are natural products. They do not, however, resemble anything natural or native to the human body. It is useful to make this distinction with patients. Very often patients requesting “natural hormones” are uncertain about what they are actually requesting. Most patients, when using this term, are looking for bioidentical hormones, or hormones that are molecularly identical to the hormones their ovaries produce.

The ovaries produce three types of estrogen: 17 beta-estradiol, estrone, and estriol. Premenopausally, the predominant estrogen produced by the ovary is 17-beta estradiol, or E₂. It is converted back and forth to estrone, E₁, which also is made in the fat and, therefore, is the predominant estrogen postmenopausally. All of the patches, as well as several oral formulations such as Estrace, are E₂. When E₁ is taken orally, much of it is converted to E₃ in the gut. E₁ and E₃ essentially are equivalent in their level of estrogenic activity. Estriol, E₃, is the weakest of the three estrogens and is predominantly made in the placenta during pregnancy. It has not been conventionally prescribed and currently is available only through compounding pharmacies. Estriol is the predominant form of estrogen in Tri-Est and Bi-Est. Estriol, Tri-est, and Bi-est are frequently used and recommended by the alternative medicine community.

Conjugated equine estrogens are composed of more than 10 different molecules extracted from the urine of pregnant mares. This is a natural product but is not bioidentical or native.
In addition to animal conjugated equine estrogen, a synthetic version, such as Cenestin, is available. It is difficult to draw conclusions regarding options for the use of these hormones. The reasons for this are listed in Table 13.10.

### Table 13.10 Reasons for Difficulty in Drawing Conclusions Regarding Use of Hormones

Drawing conclusions regarding options for the use of these hormones is challenging for a variety of reasons:

1. **It is essential to reinforce to patients that all hormones are not created equal.** Different hormones have different effects. For example, estriol is often promoted as a hormone that does everything that conjugated equine estrogen does but with none of the risks. Given that it is a significantly weaker estrogen than conjugated equine estrogen, this is dubious and is not based in scientific evidence.

2. **Native or bioidentical hormones are rarely included in research protocols.** The Women’s Health Initiative studied only conjugated equine estrogen (Premarin) and MPA (Provera). The Postmenopausal Estrogen-Progestin Intervention (PEPI) used only conjugated equine estrogen, but did compare it with micronized progesterone (and showed micronized progesterone to be as effective as medroxyprogesterone acetate at protecting the endometrium and better than medroxyprogesterone acetate at protecting the lipid benefits of estrogen).

3. **All forms of hormone therapy frequently are clumped together as one entity.** The distinctions between the types of hormones studied are rarely made in the media and often not clear even in the medical literature. The coverage of the Women’s Health Initiative is a perfect example, as the media generalized its findings to hormone therapy, and even most information released by and for doctors did not clarify that the findings were regarding one specific form of estrogen combined with one specific form of progestin.

In addition to animal conjugated equine estrogen, a synthetic version, such as Cenestin, is available.

It is difficult to draw conclusions regarding options for the use of these hormones. The reasons for this are listed in Table 13.10.

### Bioidentical Hormones

**Progestins**  Bioidentical progesterone is available either through compounding pharmacies or through retail pharmacies as micronized progesterone, natural progesterone, or progesterone USP (brand name Progesterone). Medroxyprogesterone acetate is a nonbioidentical progestin (i.e., its molecular structure is foreign to the body).

**Bioidential Estrogens**  E₂ or 17 beta-estradiol, often has been used interchangeably with conjugated equine estrogen. It is effective in relieving vasomotor symptoms, helps maintain bone, and has been shown to improve the lipid profile. It is most bioidentical when delivered in the form of the patch because its oral form is converted to estrone in the gut. (The patch also bypasses the liver and is not as beneficial in its effects on high-density lipoprotein and low-density lipoprotein, but it increases triglycerides to a lesser extent.) No comprehensive long-term data regarding its use are available.

Estriol, or E₃, the weakest of the estrogens that occurs naturally only in high circulating levels during pregnancy, is very popular in the alternative community. Unfortunately, it is often promoted as the ideal estrogen, a natural alternative providing all of the benefits of hormone therapy with none of the risks. This assumption is not supported by the literature, as the research to date on estriol is limited. In one study examining the use of estriol over 12 months, 53 women were given 2 mg daily. They reported good symptom relief and satisfaction, and histologic evaluation of the endometrium revealed no hyperplasia or atypia. Bone mineral density showed no change (64). In another study examining the effect of estriol, 64 women were followed for 24 months. There were four treatment arms: 2.0 mg E₁ plus 2.5 mg medroxyprogesterone acetate, 0.625 mg of conjugated estrogen plus 2.5 mg medroxyprogesterone acetate, 1 μg of 1-alpha hydroxy vitamin D₃, and 1.8 g calcium lactate containing 250 mg of elemental calcium. Outcome measures were taken at baseline, 6, 12, 18, and 24 months, and included the following assessments: bone mineral density at third lumbar vertebrae, serum levels of osteocalcin, total alkaline phosphatase, and urinary ratios of calcium/creatinine and hydroxyproline/creatinine. The findings
CHAPTER 13 Complementary Therapy

revealed decreased bone mineral density in the vitamin D and calcium groups and no decrease in the conjugated estrogen and E_3 groups. Osteocalcin and alkaline phosphate was decreased or without change in the conjugated estrogen and E_3 groups, and was increased in the vitamin D_3 and calcium groups. Urinary calcium/creatinine ratios were decreased with E_3 and conjugated estrogen, and there was no decrease with the use of vitamin D_3 and calcium. Urinary hydroxyproline/creatinine ratios were decreased in the conjugated estrogen group, unchanged in the E_3 and vitamin D_3 groups, and increased in the calcium group. Uterine bleeding was significantly less in the E_3 group compared with the conjugated estrogen group, with 2.4 days compared with 13 days per person. In conclusion, the study supported the finding that a bone-preserving effect occurred with E_3 when compared with conjugated estrogen (65).

It has been proposed that estriol may have anticarcinogenic activity. Unlike estradiol, estriol is not carcinogenic in rodent models, reduces uterine growth, and enhances phagocytic activity. After one or more pregnancy, estriol excretion significantly increases in comparison with nulliparous women. This may or may not be linked to the increased risk of breast and ovarian cancer in nulliparous women.

In preliminary studies, oral estriol appears to provide symptom relief and to stimulate breast and endometrial tissue less than estradiol. It also may prove to have mildly beneficial effects on bone. It appears to exert estrogenic effects on the endometrium and to have no effect or mild effects on lipids. No clinical interventional trials exist on the effect of oral estriol use on the breast.

Tri-est and Bi-est  Tri-est and Bi-est are formulations in which the predominant estrogen is estriol. The typical formulations contain 80% estriol. Typically Tri-est contains 2 mg of estriol, 0.25 mg of estradiol, and 0.25 mg of estrone, and Bi-est contains 2 mg of estriol and 0.5 mg of estradiol (66). It should be noted, however, that these names refer only to the types of estrogen used, and the specific amounts of each can vary. These particular formulations are often marketed as the most “natural” form of estrogen therapy because they contain either two or all three forms of naturally occurring estrogens. The following factors should be noted:

- Tri-est and Bi-est are not formulated in naturally occurring ratios or quantities.
- Although Tri-est and Bi-est are only 20% E_2 or E_1 plus E_3, the dose is still significant (i.e., 0.5 mg).
- Although a certain combination of E_1/E_2/E_3 may prove to have benefits over other forms of hormone therapy and should be explored, this research currently does not exist.

Estriol Vaginal Cream  Estriol vaginal cream has been studied in women who have had recurrent urinary tract infections. This randomized controlled trial compared vaginal estriol cream with placebo for 8 months of treatment and showed a significant reduction in urinary tract infections (0.5 versus 5.9 per patient year). In the treatment arm, there was a reduction in vaginal pH from 5.5 to 3.8 compared with no decline in the placebo group (67).

The effect of vaginal estriol cream on the endometrium was evaluated in a study examining long-term use for urogenital atrophy. Patients were given 0.5 mg of estriol cream vaginally for 21 days, then twice weekly for 12 months. Hysteroscopic and histologic examinations were performed at baseline, 6 months, and 12 months. Complete endometrial atrophy occurred in all patients (N = 23) (68). This pilot study needs to be performed in a larger patient population, but its findings are promising.

Bioidentical Progestins  The Postmenopausal Estrogen-Progestin Intervention (PEPI) trials provided a multicentered, randomized controlled trial that, among other things,
compared conjugated equine estrogen plus medroxyprogesterone acetate with conjugated equine estrogen plus natural or micronized progesterone (69,70). The trial compared 12 days of 10 mg of medroxyprogesterone acetate with 200 mg of micronized progesterone. The micronized progesterone provided equal protection of the endometrium and actually was better at protecting the beneficial effects of the conjugated equine estrogen on the lipid profile. Patients reported that micronized progesterone had significantly fewer side effects than medroxyprogesterone acetate. Given these data, there is no reason to not prescribe micronized progesterone. Interestingly, the arm of the Women’s Health Initiative that was prematurely discontinued was the conjugated equine estrogen/medroxyprogesterone acetate arm. The conjugated equine estrogen–alone arm was continued. The role and the effect of medroxyprogesterone acetate should be closely examined. In ovariectomized rhesus monkeys, E₂ plus medroxyprogesterone acetate interfered with ovarian estrogen protection against coronary vasospasm. E₂ plus micronized progesterone protected against coronary vasospasm. Given the increased cardiovascular risks in women taking conjugated equine estrogen and medroxyprogesterone, combined with the positive data from PEPI, micronized progesterone is an excellent choice for patients who are taking systemic estrogen and have a uterus.

Natural progesterone has also been used as a single agent in the treatment of menopausal symptoms. The typical dose is 100 mg per day. More research is needed to demonstrate efficacy.

**Yam Creams, Progesterone Creams** Yam creams and progesterone creams, which are both sold over the counter, are distinctly different products. Yam creams should, by definition, not contain progesterone, but rather should contain phytoprogesterones, plant products that are progesterone-like (Table 13.11). Progesterone creams, by contrast, should contain progesterone. Part of the challenge is that there is a large media presence asserting that progesterone creams can solve all that ails menopausal women. These creams are not regulated by the FDA. Their content is highly variable, ranging from 700 mg progesterone/ounce to less than 2 mg/ounce in products whose names imply that they are progesterone creams, not yam creams. The absorption of these products also is highly variable.

Wild yam creams (which refer to the genus name *Dioscorea villosa*, rather than the fact that they are grown in the wild) are applied topically. They contain steroidal saponins, including diosgenin, and claim to affect estrogen steroidogenesis. Although these are interesting products, studies of their safety and efficacy are needed. In one double-blind, placebo-controlled crossover study, after a 4-week baseline period, patients received 3 months of active treatment and 3 months of placebo. Symptom diaries were maintained at baseline and then for 1 week of each month. Blood and salivary hormone levels as well as serum lipids were assessed at baseline, 3 months, and 6 months. At 3 months there were no significant side effects and no change in levels of blood pressure, weight, lipid levels, follicle-stimulating hormone, glucose, estradiol, or progesterone. In terms of symptom relief, the placebo and yam cream had a minor effect on the number and severity of flushes. Although wild yam creams appear to be free of side effects, they also appear to have little effect on menopausal symptoms (71).

In terms of progesterone creams, a randomized controlled trial was performed comparing transdermal progesterone with placebo. One quarter teaspoon of 20 mg of progesterone was used daily for 12 months. In addition, all patients took a multivitamin plus 1,200 mg of calcium. Outcomes evaluated included DEXA results, serum thyroid-stimulating hormone, follicle-stimulating hormone, lipids, chemistry, and symptom diary. The group that received the progesterone cream reported 83% improvement in hot flashes compared with 19% improvement in the placebo group. There was no difference in bone density (72).

Given the data currently available, progesterone or yam creams should not be considered adequate to protect the uterus in a woman taking systemic estrogen. Progesterone cream may be useful for symptom relief in women not taking systemic hormone therapy, and it may prove to have other benefits and risks.

**Counseling Patients**

It’s important to communicate to patients what is known regarding hormone therapy as well as what is not known. Some of the unknown aspects of hormone therapy are listed in Table 13.12.

Given the present state of the medical knowledge, the need to individualize treatment plans in menopausal women cannot be overemphasized. It is essential to clarify patient goals, as well as individual health risks, history of hormonal exposure (both length and time), family history, and personal preferences.

Surgery and CAM

There are special considerations regarding CAM and the surgical patient. These issues primarily fall into two domains:

1. Supplements that, when used perioperatively, may affect the patient’s course
2. CAM approaches that may be of benefit to the surgical patient

When examining what patients are using that may affect their surgical course, the greatest concern and awareness needs to be in the domain of biologically based therapies. A survey of 2,560 surgical patients in five California hospitals revealed that 68% of patients were using botanicals, 44% of them did not consult their physician, 56% did not inform their anesthesiologists, and 47% did not stop them before their surgery. Variables that were associated with use included female sex, age 35 to 49 years, higher income, Caucasian race, higher education, and problems with sleep, joints, back, allergies, and addiction (73).

A survey based in a tertiary care center examined the use of botanicals and vitamins in patients preoperatively (N = 3,106). Of the patients studied, 22% were using botanicals and 51% were using vitamins. The typical users were women and in the age range of 40 to 60 years. The most commonly used compounds were echinacea, ginkgo biloba, St. John’s wort, garlic, and ginseng (74). In another study based in a university medical center that surveyed patients undergoing outpatient surgery, 64% of patients were using supplements: 90% of them were using vitamins, 43% were using garlic extracts, 32% ginkgo biloba, 30% St. John’s wort, 18% ma huang, 12% echinacea, and others were using aloe, cascara, and licorice (75).

Effects on Surgery

Many of the most commonly used substances have effects of which surgeons and anesthesiologists should be aware. Botanicals used with anesthesia can lead to the following complications:

- Prolongation of anesthetic agents
- Coagulations disorders
- Cardiovascular effects
- Electrolyte disturbances
- Hepatotoxicity
- Endocrine effects

Prolongation of Anesthetic Agents

Valerian, kava, and St. John’s wort are among the more commonly used botanicals that can prolong the effects of anesthetic agents. Valerian has sedative effects that are believed to be mediated by benzodiazepine and GABA receptors. For patients who use valerian on a daily basis, it is suggested that it be tapered off over the weeks preceding the surgery. Kava is mediated by GABA receptors and potentiates the sedative effects of anesthetics. The general recommendation is to discontinue its use 24 hours before surgery. St. John’s wort induces cytochrome P450 enzymes (cyclosporin, indinavir, and warfarin). It modulates the GABA receptor and inhibits the reuptake of serotonin, dopamine, and noradrenaline. The recommendation is to discontinue it 5 days preoperatively.

Coagulation Effects

Some of the more commonly used supplements and botanicals that have been reported to have anticoagulative properties include fish oil, ginseng (Asian and American), ginkgo, garlic, vitamin E, ginger, feverfew, dong quai, and chondroitin.
Cardiovascular Effects  Licorice root contains glycyrrhizic acid, which has an aldosteronelike effect and can result in hypertension, hyperkalemia, and edema. Ma huang (ephedra) has been associated with arrhythmias and hypertension, and ginseng also has been associated with hypertension.

Electrolyte Disturbances  Licorice root has been associated with hypernatremia and hypokalemia. Goldenseal can reduce the effect of antihypertensives.

Hepatotoxicity and Endocrine Effects  The following botanicals have been associated with hepatotoxicity: kava, red yeast rice (which contains lovastatin), chaparral, valerian, and echinacea. In terms of endocrinologic effects, both chromium and ginseng can cause hypoglycemia. Table 13.13 highlights

<th>CAM Approaches that May Benefit the Surgical Patient</th>
</tr>
</thead>
<tbody>
<tr>
<td>The two domains in which there is the most research and the most promise with regard to surgical patients are mind–body-based therapies and approaches based in complete systems, specifically oriental medicine and acupuncture.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Oriental Medicine and Acupuncture</th>
</tr>
</thead>
<tbody>
<tr>
<td>A review of the use of acupuncture as the sole source of anesthesia for patients undergoing cesarean delivery in China reviewed 12 years of experience with success rates of 92% to 99%. Blood pressure, heart rate and respiratory rate remained stable throughout the surgery, which is a significant advantage over pharmaceutical anesthesia (76). Although it is unlikely that acupuncture will readily be used as the only source of anesthesia in this country, it does demonstrate the effectiveness of this approach and encourage its consideration as an adjunct. In one randomized controlled trial in patients undergoing upper- and lower-abdominal (gastrointestinal) surgery, acupuncture was given 2.5 cm lateral to the spine before induction. Postoperatively, patients who received the acupuncture had decreased postoperative pain, nausea and vomiting, analgesic requirement, and sympathoadrenal responses. Supplemental morphine use dropped by 50%, and postoperative nausea was reduced by 30%. Cortisol and epinephrine levels were reduced 30% to 50% during the recovery phase and the first postoperative day (77).</td>
</tr>
</tbody>
</table>

In a sham-controlled trial, the intensity of transcutaneous acupoint electrical stimulation (TAES) was studied in women undergoing lower-abdominal surgery. In patients receiving high-intensity TAES (9–12 mA), there was a 65% decrease in analgesia requirement, decreased duration in patient-controlled anesthesia therapy, and decrease in nausea, vomiting, and pruritus (78). |

In Germany, auricular electrically stimulated anesthesia is frequently used. Review of one randomized controlled trial in patients anesthetized with desflurane with and without auricular acupuncture revealed significantly reduced anesthetic requirement (the amount of anesthesia required to prevent purposeful movements) (79). |

Acupuncture warrants further investigation as an adjunct to anesthesia in gynecologic patients. Even simple adjuncts, such as the use of acupressure bands or electroacupressure bands, are reasonable to support as they are safe and have shown some efficacy in decreasing nausea and vomiting postoperatively. |

<table>
<thead>
<tr>
<th>Mind-body Interventions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mental preparation for surgery results in psychological, physiologic, and economic benefit. Higher levels of anxiety are associated with a greater risk of complications, depression, increased need for anesthesia, decreased immune function, and a longer time to heal. Many different physiologic aspects are affected, including decreased chemotaxis and phagocytosis and decreased inflammatory factors such as cytokines. One study examining wound healing took healthy dental students and made a standardized scalpel incision in the palate at two times: one right before exams and one during summer vacation. The incisions in these healthy students took 3 days (40%) longer to heal during times of stress versus times of decreased stress (80). The power of the spoken word was explored as long ago as 1964, when a study randomized patients to a preoperative visit characterized by sympathetic, caring, and informative communication versus an interchange characterized by cursory remarks. The patients receiving the sympathetic preoperative visit required one half the pain medicine and had a two- and one-half day decreased hospital stay (81).</td>
</tr>
</tbody>
</table>
A meta-analysis of mind–body interventions and surgery included 191 studies and more than 8,600 patients. The use of mind–body approaches, including such interventions as hypnosis, imagery, and relaxation, was associated with reduced blood loss, decreased pain, decreased medication use, increased return of bowel function, decreased psychological stress, and decreased hospital stay by 1.5 days. In a study designed to examine the impact of preoperative instructions, patients undergoing spinal procedures involving fusions or instrumentation (surgeries associated with significant blood loss) were enrolled. All subjects received a 15-minute interaction with a psychologist. The subjects were randomized into one of three groups receiving either direct simple information alone, information plus instruction in muscle relaxation, or information plus instruction in visualizing the blood moving away from the surgical site during surgery. Controlling for the length of surgery and incision length, the estimated blood loss in the first two groups averaged 900 mL and in the third group was 500 mL (82).

In a study of ambulatory surgery patients receiving spinal anesthesia, patients who were randomized to listening to soothing music had decreased sedative requirements both during the surgery and in the perioperative period (83). Patients undergoing cataract surgery were randomized to receive a 5-minute hand massage preoperatively or to the control group. When compared with the control group, the intervention group had significantly decreased levels of anxiety, systolic blood pressure, diastolic blood pressure, heart rate, and epinephrine and norepinephrine (84).

In a study of women undergoing hysterectomy, patients received standardized anesthesia and were randomized to music during surgery, music plus positive suggestions, or the sounds of the operating room. On the day of surgery, both the music group and the music-plus-suggestion groups received significantly less rescue anesthesia. On postoperative day 1, the patients who had received music had more effective analgesia and early mobilization. At the time of discharge, both intervention groups had less fatigue. There was no change in nausea and vomiting, bowel function, or length of stay (85).

In another study with patients undergoing abdominal hysterectomy, patients were randomized to listen intraoperatively to one of four tapes: positive suggestions regarding pain, or nausea and vomiting, or both, or white noise. The positive suggestions had no beneficial effects in reducing nausea and vomiting or the consumption of analgesics or antiemetics (86). In another randomized controlled trial in patients undergoing thyroidectomy under general anesthesia, patients were randomized to listen to taped positive suggestions during surgery versus a blank tape. The group receiving the suggestions had less nausea and vomiting (47% versus 85%), and less antiemetic treatment (30% versus 68%) (87). In a study exploring the timing of listening to taped suggestions, patients who received the suggestions preoperatively had a 30% decrease in estimated blood loss. Patients receiving the suggestions both pre- and perioperatively had a 26% decrease in blood loss, and in the group listening to the suggestions only intraoperatively, there was a 9% decrease in blood loss. The authors suggest that the preoperative suggestions may be the critical factor (88).

In a retrospective study examining the use of hypnosis plus conscious sedation for plastic surgery, the patients who received hypnosis had better pain and anxiety relief, decreased nausea and vomiting, a significant reduction in midazolam and alfentanil requirements, and patient satisfaction was significantly increased (89).

Although the studies and interventions in mind–body approaches in the surgical patient are varied, these interventions are low cost and low risk and may offer very real benefits for the patient, as well as a greater sense of empowerment.
SECTION III Preventative and Primary Care

Conclusion

As physicians driven by our desire and commitment to provide the best possible care, we have a responsibility to inform our patients of all therapies that can be of benefit, regardless of their system of origin. In practice this is challenging, because not only are there many unanswered questions in the use of complementary and alternative modalities, there is no established standard of care. Each physician, together with his or her patient, needs to form his or her own opinions regarding the appropriate integration of CAM therapies. Many patients will want conclusive evidence of any therapy before using it. Others, assured of the relative safety of a therapy, may require less conclusive evidence. Illustrating this dilemma, in a systematic review of randomized trials regarding CAM approaches to PMS, the authors concluded that “despite some positive findings, the evidence was not compelling for any of these therapies, with most trials suffering from various methodological limitations. On the basis of current evidence, no complementary or alternative therapy can be recommended as a treatment for premenstrual syndrome (90).” Although this concept certainly is appealing in its simplicity, it may not be in the best interest of patients. We need to be consistent in our requirement of evidence, using the same levels of evidence for incorporating interventions from CAM as from conventional approaches. As with many clinical decisions we are forced to make with incomplete data, many factors must be considered. The potential risks and benefits must be weighed carefully, and primum non nocere must certainly be our guide.

In many regards, we are in the most challenging time as it relates to integrating appropriate CAM approaches into the practice of gynecology. In the future, as more research is done and as medical schools and residency programs incorporate education about these approaches, the gap between our patients’ desires and our standard practices will continue to lessen as appropriate therapies are seamlessly incorporated and ineffective and fraudulent ones are discarded.

References

SECTION III Preventative and Primary Care

The causes of abnormal bleeding vary by age, with anovulatory bleeding most likely in adolescents and perimenopausal women.

Pelvic masses in adolescents are most commonly functional or benign neoplastic ovarian masses, whereas the risks of malignant ovarian tumors increases with age.

Although pelvic ultrasonography is an excellent technique for imaging pelvic masses, and ultrasonographic characteristics may suggest reassuring characteristics of an ovarian mass, the possibility of malignancy must be kept in mind.

Vulvovaginal symptoms of any sort in a young child should prompt the consideration of possible sexual abuse.

Most uterine leiomyomas are asymptomatic, although bleeding, pressure symptoms, or pain may necessitate medical or surgical management.

Benign gynecologic conditions can present with a variety of signs and symptoms that vary by age. In this chapter, the most likely causes of specific signs and symptoms, as well as diagnosis and management, are described for each age group: prepubertal, adolescent, reproductive age, and postmenopausal women. The common gynecologic problems include those that cause pain, bleeding, pelvic masses (which may be symptomatic or asymptomatic), as well as vulvar and vaginal symptoms. Benign conditions of the female genital tract include anatomic lesions of the uterine corpus and cervix, ovaries, fallopian tubes, vagina, and vulva. A classification of benign lesions of the vulva, vagina, and cervix appears in Table 14.1. Leiomyoma, polyps, and hyperplasia are the most common benign conditions of the uterus in adult women. Benign tumors of the ovaries are listed in Table 14.2. Malignant diseases are presented in Chapters 33 through 38.
### Table 14.1 Classification of Benign Conditions of the Vulva, Vagina, and Cervix

#### Vulva
- Skin conditions
- Pigmented lesions
- Tumors and cysts
- Ulcers
- Nonneoplastic epithelial disorders

#### Vagina
- Embryonic origin
  - Mesonephric, paramesonephric, and urogenital sinus cysts
  - Adenosis (related to diethylstilbestrol)
  - Vaginal septa or duplications
- Disorders of pelvic support
  - Anterior vaginal prolapse
  - Cystourethrocele
  - Cystocele
  - Apical vaginal prolapse
  - Uterovaginal
  - Vaginal vault
  - Posterior vaginal prolapse
  - Enterocele
  - Rectocele
- Other
  - Condyloma
  - Urethral diverticula
  - Fibroepithelial polyp
  - Vaginal endometriosis

#### Cervix
- Infectious
  - Condyloma
  - Herpes simplex virus ulceration
  - Chlamydial cervicitis
  - Other cervicitis
- Other
  - Endocervical polyps
  - Nabothian cysts
  - Columnar epithelium eversion
Prepubertal Age Group

Bleeding

Before menarche, occurring no younger than age 9 years, any bleeding requires evaluation. To appropriately evaluate a young girl with vaginal bleeding, a practitioner should understand the events of puberty (1–3). The hormonal changes that control the cyclic functioning of the hypothalamic–pituitary-ovarian axis are described in Chapter 7. An understanding of the normal sequence and timing of these events is critical to an appropriate assessment of a girl at the onset of bleeding (see Chapter 26). Menarche typically occurs when an adolescent has reached Tanner stage 3–4 of breast development (Fig. 14.1).

Differential Diagnosis

Slight vaginal bleeding can occur within the first few days of life because of withdrawal from exposure to high levels of maternal estrogen. New mothers of female infants should be informed of this possibility to preclude unnecessary anxiety. After the neonatal period, a number of causes of bleeding should be considered in this age group (Table 14.3). Menses rarely occurs before breast budding (4,5). Vaginal bleeding in the absence of secondary sexual characteristics should be evaluated carefully.

The causes of bleeding in this age group range from the medically mundane to malignancies that may be life threatening. The source of the bleeding is sometimes difficult to identify, and parents who observe blood in a child’s diapers or panties may be unsure of the source. Pediatricians usually will look for urinary causes of bleeding, and gastrointestinal factors should also be considered. The possibility of abuse should always be considered in girls with any vulvovaginal symptoms, particularly

if bleeding is present. Failure to diagnose sexual abuse may leave a child in significant danger.

**Vulvar Lesions**  Vulvar irritation can lead to pruritus with excoriation, maceration of the vulvar skin, or fissures that can bleed. Other visible external causes of bleeding in this age group include urethral prolapse, condylomas, lichen sclerosus, or molluscum contagiosum. **Urethral prolapse** can present acutely with a tender mass that may be friable or bleed slightly; it is most common in African–American girls and may be confused with a vaginal mass (Fig. 14.2). The classic presentation is a mass symmetrically surrounding the urethra. This condition can be managed medically with the topical application of estrogens (6). The presence of condyloma should prompt questioning about abuse, although it has been suggested that **condyloma that appears during the first 2 to 3 years of life may have been acquired perinatally from maternal infection with human papillomavirus** (7,8) (Fig. 14.3). Excoriation and hemorrhage into the skin can cause external bleeding in the presence of prepubertal lichen sclerosus; this finding may mistakenly be identified as abuse, although the conditions are not mutually exclusive (9) (Fig. 14.4). Although most gynecologists recognize the appearance of lichen sclerosus in postmenopausal women, the condition also occurs in prepubertal girls and may not be recognized by clinicians who are familiar with this condition. As with adults, the cause of lichen sclerosus remains uncertain; a familial incidence has been identified (10).

**Foreign Body**  A foreign body in the vagina is a common cause of vaginal discharge, which may appear purulent or bloody. Young children explore all orifices and may

place all varieties of small objects inside their vaginas (Fig. 14.5). An object, such as a small plastic toy, can sometimes be palpated on rectal examination. The most common foreign bodies found in the vagina are small pieces of toilet paper (11). One study suggests that the presence of vaginal foreign bodies may be a marker for sexual abuse; although this is by no means always the case, the possibility of abuse should be considered (12).

Precocious Puberty Vaginal bleeding in the absence of other secondary sexual characteristics may result from precocious puberty (see Chapter 26), although the onset of breast budding or pubic hair growth are more likely to occur before vaginal bleeding. A large observational study suggests that the onset of pubertal changes—breast budding and pubic hair—may occur earlier than had originally been thought (2). Previously, evaluation for precocious puberty was recommended for girls with pubertal development younger than age 8 years. New guidelines from the Pediatric Endocrine Society propose evaluation of white girls younger than age 7 years and African–American girls younger than age 6 years who have either breast development or pubic hair (13).

Trauma Trauma can be a cause of genital bleeding. A careful history should be obtained from one or both parents or caretakers and the child herself, because trauma caused by sexual abuse often is not recognized. Physical findings that are inconsistent with the description of the alleged accident should prompt consideration of abuse and appropriate consultation or referral to an experienced social worker or sexual abuse team. All states impose a mandatory legal obligation to report suspected child physical abuse; most states specifically require reporting child sexual abuse as well, but even in those that do not, the laws are broad enough to encompass sexual abuse implicitly (14). Notification is required even with the suspicion of sexual abuse. In general, straddle injuries affect the anterior and lateral vulvar area (Fig. 14.6), whereas penetrating injuries with lesions of the fourchette or lesions that extend through the hymenal ring are less likely to occur as a result of accidental trauma (15,16).

Abuse The medical evaluation of suspected child sexual abuse is best managed by individuals who have experience in assessing the physical findings, laboratory results,
and the children’s statements and behaviors. Genital findings have been described as follows (17):

1. Normal or unrelated to abuse
2. Nonspecific for abuse
3. Concerning for abuse
4. Clear evidence of blunt force or penetrating trauma.

The overall classification of the likelihood for abuse can be categorized as follows (17):

1. No evidence of abuse
2. Possible abuse
3. Probable abuse
4. Definitive evidence of abuse or penetrating trauma.

Most cases of child sexual abuse do not come to light with an acute injury and instead are associated with normal or nonspecific genital findings (18–20). Forms of abuse such as fondling or digital penetration may not result in visible genital lesions.

Other Causes  Other serious but rare causes of vaginal bleeding include vaginal tumors. The most common tumor in the prepubertal age group is a rhabdomyosarcoma.
Diagnosis

**Examination**  A careful examination is indicated when a child has genital symptoms. The technique of examining the prepubertal child is described in Chapter 1. If no obvious cause of bleeding is visible externally or within the distal vagina, an examination can be performed using anesthesia and an endoscope to completely visualize the vagina and cervix. This examination is best performed by a clinician with experience in pediatric and adolescent gynecology.

**Imaging**  If an ovarian or vaginal mass is suspected, a pelvic ultrasonographic examination can provide useful information. The appearance of the ovaries (normal prepubertal size and volume, follicular development, cystic, or solid) can be noted, as well as the size and configuration of the uterus. The prepubertal uterus has a distinctive appearance, with equal proportions of cervix and fundus and a size of approximately 2 to 3.5 cm in length and 0.5 to 1 cm in width (Fig. 14.7). The uterine fundus enlarges with estrogen stimulation, resulting in the postmenarchal appearance in which the uterine fundus is larger than the cervix (21). An ultrasonographic examination should be the first imaging

study performed; more sophisticated imaging techniques, such as magnetic resonance imaging (MRI) or computed tomography (CT) scanning, add unnecessary expense and are rarely indicated as initial diagnostic modalities.

Management

The management of bleeding in the prepubertal-age girls is directed toward the cause of bleeding. If bloody discharge believed to be due to nonspecific vulvovaginitis persists despite therapy, further evaluation may be necessary to rule out the presence of a foreign body. Skin lesions (chronic irritation) and lichen sclerosus may be difficult to manage but can be treated with a course of topical steroids; lichen sclerosus often requires the use of high-potency topical steroids and ongoing maintenance therapy. **Vaginal and ovarian tumors should be managed in consultation with a gynecologic oncologist.**

Pelvic Masses

Presentation

The probable causes of a pelvic mass found on physical examination or through radiologic studies are vastly different in prepubertal children than they are in adolescents or postmenopausal women (Table 14.4). A pelvic mass may be gynecologic in origin,

or it may arise from the urinary tract or bowel. The gynecologic causes of a pelvic mass may be uterine, adnexal, or more specifically ovarian. Because of the small pelvic capacity of a prepubertal child, a pelvic mass very quickly becomes abdominal in location as it enlarges and may be palpable on examination. Ovarian masses in this age group may be asymptomatic, associated with chronic pressure-related bowel or bladder symptoms, or may present with acute pain caused by rupture or torsion. Abdominal or pelvic pain is one of the most frequent initial symptoms. The diagnosis of ovarian masses in prepubertal girls is difficult because the condition is rare in this age group and, consequently, there is a low index of suspicion. Many symptoms are nonspecific, and acute symptoms are more likely to be attributed to more common entities such as appendicitis. Abdominal palpation and bimanual rectoabdominal examination are important in any child who has nonspecific abdominal or pelvic symptoms. An ovarian mass that is abdominal in location can be confused with other abdominal masses occurring in children, such as Wilms’ tumor or neuroblastoma. Acute pain is often associated with torsion. The ovarian ligament becomes elongated as a result of the abdominal location of these tumors, thus creating a predisposition to torsion.

**Diagnosis**

Ultrasonography has become a valuable tool for diagnosing ovarian masses. The characteristics of a pelvic mass can be determined. Whereas both unilocular and multilocular cysts frequently resolve with observation, the finding of a solid component mandates surgical assessment because of the high risk of a germ cell tumor (22). Additional imaging studies, such as CT scanning, MRI, or Doppler flow studies, may be helpful in establishing the diagnosis (23).

**Differential Diagnosis**

Fewer than 2% of ovarian malignancies occur in children and adolescents (24). Ovarian tumors account for approximately 1% of all malignant tumors in these age groups. Germ cell tumors make up one half to two thirds of ovarian neoplasms in individuals younger than 20 years of age. A review of studies conducted from 1940 until 1975 concluded that 35% of all ovarian neoplasms occurring during childhood and adolescence were malignant (25). In girls younger than 9 years of age, approximately 80% of the ovarian neoplasms were found to be malignant (26,27). Germ cell tumors account for approximately 60% of ovarian neoplasms in children and adolescents compared with 20% of these tumors in adults (25). Epithelial neoplasms are rare in the prepubertal age group; thus, data usually are reported from referral centers. However, some reports include only neoplastic masses, whereas others include nonneoplastic masses; some series combine data from prepubertal and adolescent girls. However, one community survey of ovarian masses revealed that the frequency of malignancy was much lower than previously reported; of all ovarian masses confirmed surgically in childhood and adolescence, only 6% of patients with ovarian enlargement had malignant neoplasms, and only 10% of neoplasms were malignant (28). Surgical decision making clearly influences the statistics on incidence; the surgical excision of functional masses that would resolve in time inflates the percentage of benign masses. In one series, nonneoplastic masses in young women and girls younger than 20 years of age constituted two thirds of the total (29). Even in girls younger than 10 years of age, 60% of the masses were nonneoplastic, and two thirds of the neoplastic masses were benign. Functional, follicular cysts can occur in fetuses, newborns, and prepubertal children (30). Rarely, they may be associated with sexual precocity.

**Management**

A plan for the management of pelvic masses in prepubertal age girls is shown in Figure 14.8. Unilocular cysts are virtually always benign, even in this age group, and will regress in 3 to 6 months; thus, they do not require surgical management with oophorectomy or oophorectomy. Close observation is recommended, although there is a risk of ovarian torsion that must be discussed with the child’s parents (31). Recurrence rates after cyst aspiration (either ultrasonographically guided or with laparoscopy) may be as high as 50%. Attention should be directed to long-term effects on endocrine function as well as
future fertility; preservation of ovarian tissue is a priority for patients with benign tumors. **Premature surgical therapy for a functional ovarian mass can result in ovarian and tubal adhesions that can adversely affect future fertility.** Solid masses, those larger than approximately 8 cm, and enlarging masses require surgical intervention.

**Vulvar Conditions**

**Neonatal Vulvar Conditions**

Various developmental and congenital vulvovaginal abnormalities occur in the neonatal age group. Whereas an extensive discussion of these abnormalities is beyond the scope of this text, obstetrician–gynecologists will recognize that they must be prepared to deal with
the parents and family when an infant is born with ambiguous genitalia. The etiology of these problems, as well as intersex disorders that may be discovered in an older child, can be complex. Chromosomal abnormalities, enzyme deficiencies (including 17- or 21-hydroxylase deficiency as causes of congenital adrenal hyperplasia), or prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposure can all result in genital abnormalities that are noted at birth. These abnormalities are described in Chapter 26.

Ambiguous genitalia represent a social and potential medical urgency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists. The first questions parents ask after a baby is born include, “Is it a boy or a girl?” In the case of ambiguous genitalia, the parents should be informed that the baby’s genitals are not fully developed and, therefore, a simple examination of the external genitalia cannot determine the actual sex. The parents should be told that data will be collected but that it may take several days or longer to determine the baby’s intended sex. In some situations, it may be best to state simply that the baby has some serious medical complications. The issues of sex assignment and timing of surgical therapy are controversial and should be managed by clinicians with extensive experience in this area (32–34).

Other genital abnormalities may be noted at birth, although few obstetricians or pediatricians carefully examine the external genitalia of female neonates. It has been argued that careful inspection of the external genitalia of all female infants should be performed, with gentle probing of the introitus and anus to determine the patency of the hymen or a possible imperforate anus. If patency is in doubt, a rectal thermometer may be used to gently test the patency. It has been suggested that this examination should be performed on all female infants in the delivery room (35,36). Various types of hymenal configurations in the newborn have been described, ranging from imperforate to microperforate, to cribriform, to hymenal bands, and to hymens with central anterior, posterior, or eccentric orifices (37). An examination during the neonatal period would prevent the discovery of an imperforate hymen or vaginal septum after a young woman experiences periodic pelvic and abdominal pain with the development of a large hematometra or hematocolpos (38).

Congenital vulvar tumors may include strawberry hemangiomas, which are relatively superficial vascular lesions, and large cavernous hemangiomas. Treatment is controversial; many lesions will spontaneously regress. Some clinicians have advocated cryotherapy, argon laser therapy, or sclerosing solutions (39).

**Childhood Vulvar Conditions**

Vulvar and vaginal symptoms, such as burning, dysuria, itching, or a rash, are a common initial symptom reported to gynecologists among children. It may be difficult for a young child to describe vulvar sensations. Parents may notice the child crying during urination, scratching herself repeatedly, or complaining of vague symptoms. Often, the child’s pediatrician will have evaluated the child for urinary tract infection. Evaluation for pinworms is also warranted, because pinworms can cause severe itching in the vulvar as well as perianal area. **Vulvovaginitis is the most common gynecologic problem of childhood.**

Prepubertally, the vulva, vestibule, and vagina are anatomically and histologically vulnerable to infection, with the bacteria typically present in the perianal area. The physical proximity of the vagina and vestibule to the anus can result in overgrowth of bacteria that can cause primary vulvitis and secondary vaginitis. Yeast infections are uncommon in prepubertal children who are toilet trained (40).

The clinician should be familiar with normal prepubertal genital anatomy and hymenal configuration (41,42). **The unestrogenized vulvar vestibule is mildly erythematous and can be confused with infection. In addition, smegma around and beneath the prepuce**
may resemble patches of candida vulvitis. In prepubertal girls, the vulvar area is quite susceptible to chemical irritants.

Chronic skin conditions such as lichen sclerosus, psoriasis, seborrheic dermatitis, and atopic vulvitis may occur in children (43). Lichen sclerosus, the cause of which is not well established, has a characteristic “cigarette paper” appearance in a keyhole distribution (around the vulva and anus) (Fig. 14.4). Lichen sclerosus should be treated in pediatric patients as it is in adults; there is some evidence that the condition may regress as the child progresses through adrenarche and menarche. The use of ultrapotent steroids topically has been successful in children as well as adults (44).

Labial agglutination or adhesions may occur as a result of chronic vulvar inflammation from any cause (Fig. 14.9A). The treatment of labial adhesions consists of a brief course (2 to 6 weeks) of externally applied estrogen cream. The area of agglutination (adhesion) will become thin as a result, and separation can usually be performed in the office with the use of a topical anesthetic (e.g., lidocaine jelly) (Fig. 14.9B). Manual separation in the office without pretreatment with topical estrogen and without anesthesia is discouraged, as this practice may be so traumatic to the child that she will not allow subsequent examination. In the absence of a previously traumatic examination or previous surgical separation with recurrence, surgical separation frequently is not required (45). Treatment with a topical emollient (such as petrolatum) is indicated to prevent recurrent adhesions. Urethral prolapse may cause acute pain or bleeding, or the presence of a mass may be noted (Fig. 14.2).

**Vulvovaginal symptoms of any sort in a young child should prompt the consideration of possible sexual abuse.** Sexually transmitted infections may occur in prepubertal children (46). Although vulvar condyloma presenting before age 2 to 3 years can be transmitted during vaginal delivery from the mother or from warts on caretakers’ hands, the possibility of abuse should be considered in all children with genital warts (47). Sensitive but direct questioning of the parent or caretaker and the child should be a part of the

**Figure 14.9** A: Labial adhesions. B: Cotton-tipped applicator placed inside the labial agglutination shown in (A).
evaluation; if sexual abuse is suspected, the incident must be reported to the appropriate social services agency.

Nonsexually transmitted vulvar ulcers can occur in peripubertal and adolescent girls, often in association with systemic symptoms suggestive of a viral illness (48) (Fig. 14.10). Herpes simplex virus, syphilis, and Behçet’s disease can cause vulvar ulcers, but they also may occur as a form of genital aphthosis.

**Vaginal Conditions**

**Vaginal Discharge**

The symptom of vaginal discharge in the prepubertal age group is almost always caused by inflammation and irritation. In prepubertal girls, the primary site typically is the vulva, with vaginitis following secondarily, whereas in adolescents and adults, vaginitis typically is the primary finding with vulvitis occurring secondarily. **Sexual abuse should always be considered in prepubertal children with vaginal discharge or a foreign body** (12). Although the routine use of cultures to detect sexually transmitted diseases (STDs) in girls with a history of sexual abuse has been questioned, vaginal culture for gonorrhea and chlamydia should be performed in girls who have vaginal discharge (49). In prepubertal girls, vulvovaginitis is usually caused by multiple organisms that are present in the perineal area, although a single organism such as *Streptococcus*, or even rarely *Shigella*, may be causative (50). When the cause is related to poor perineal hygiene, cultures often reveal a mixture of bacterial organisms. In this situation, the typical history is intermittent symptoms of irritation, itching, discharge, and odor over many months to years. Treatment should be initiated with a focus on hygiene and cleansing measures (51). A short-term (less than 4 weeks) course of treatment with topical estrogens and broad-spectrum antibiotics may be necessary. The problem is frequently recurrent. In girls who have a relatively acute onset of vaginal
discharge and vulvovaginal symptoms, a single bacterial organism is more likely to be the cause of their symptoms.

Pokorny and Stormer has described a technique for obtaining vaginal cultures and for performing vaginal irrigation (52). A catheter within a catheter can be fashioned using the tubing from an intravenous butterfly setup within a sterile urethral catheter. Nonbacteriostatic saline (1–3 mL) can be injected, aspirated, and sent for culture. Cultures taken in this manner are almost always better tolerated than cultures obtained using a cotton-tipped applicator. A larger quantity of saline can then be used to irrigate the vagina while the catheter is still within the vagina. Small foreign bodies can often be flushed from the vagina in this manner. The most common foreign body is a small piece of toilet paper, although children will place other objects (toys, beans, coins) within their vaginas (Fig. 14.5). A persistent vaginal discharge after treatment, or a discharge that is bloody or brown in color without other obvious external lesions, should prompt vaginal irrigation or vaginoscopy to rule out a foreign body (53).

Adolescent Age Group

The adolescent’s experience and expression of illness and pain should be viewed within the context of her life experiences. Most adolescents have had limited life experiences with problems such as pain, discomfort, or bleeding. An adolescent may state that she is experiencing the “worst pain of her life” and yet may appear to be reasonably comfortable. She may well be stating the truth about this experience, which the clinician must still interpret differently from the symptoms of an adult woman who, for instance, may be in active labor. It should be remembered that an individual’s responses to illness and pain are to some extent learned behaviors.

Abnormal Bleeding

Normal Menses

To assess vaginal bleeding during adolescence, it is necessary to have an understanding of the range of normal menstrual cycles (see Chapter 7). During the first 2 years after menarche, most cycles are anovulatory. Despite this, they are somewhat regular, within a range of approximately 21 to 42 days (54–57), in contrast to adult women, whose cycles typically range between 21 and 35 days. In more than one fourth of girls, a pattern of plus or minus 10 days and a cycle length of 21 to approximately 42 days are established within the first three cycles; in one half of girls, the pattern is established by the seventh cycle; and in two thirds of girls, such a pattern is established within 2 years of menarche (56).

The mean duration of menses is 4.7 days; 89% of cycles last 7 days. The average blood loss per cycle is 35 mL (58), and the major component of menstrual discharge is endometrial tissue. Recurrent bleeding in excess of 80 mL/cycle results in anemia.

Quantitative information about the volume of menstrual blood loss is of little clinical use. The common clinical practice of asking how many pads or tampons are soaked on a heavy day or per cycle can give a rough approximation of blood loss (3 to 5 pads per day is typical). Individual variations in fastidiousness, lack of familiarity with the volume of blood loss other than one’s own, and errors in estimation or recollection result in inaccuracies in estimations of menstrual volume. One study found that one third of individuals who estimated their cycles to be moderate or light had bleeding in excess of 80 mL/cycle, whereas nearly one half of those who described the bleeding as heavy had flow less than 80 mL/cycle (59). In addition, the amount of menstrual blood
contained in each tampon or pad may vary both within brands as well as from one brand to another (60).

The transition from anovulatory to ovulatory cycles takes place during the first several years after menarche. It results from the so-called maturation of the hypothalamic-pituitary-ovarian axis, characterized by positive feedback mechanisms in which a rising estrogen level triggers a surge of luteinizing hormone and ovulation. Most adolescents have ovulatory cycles by the end of their second year of menstruation, although most cycles (even anovulatory ones) remain within a rather narrow range of approximately 21 to 42 days.

Differential Diagnosis

Cycles that are longer than 42 days, cycles that are shorter than 21 days, and bleeding that lasts more than 7 days should be considered abnormal, particularly after the first 2 years from the onset of menarche. The variability in cycle length is greater during adolescence than adulthood; thus, greater irregularity is acceptable if neither significant anemia nor hemorrhage is present. However, consideration should be given to an evaluation of possible causes of abnormal menses (particularly underlying causes of anovulation such as androgen excess syndromes or causes of oligomenorrhea such as eating disorders) for girls whose cycles are consistently outside normal ranges (61) or whose cycles were previously regular and become irregular (57). Conditions that are associated with abnormal bleeding are listed in Table 14.5 and more fully discussed in Chapters 26, 27, and 28.

Anovulation

Anovulatory bleeding can be too frequent, prolonged, or heavy, particularly after a long interval of amenorrhea. The physiology of this phenomenon relates to a failure of the feedback mechanism in which rising estrogen levels result in a decline in follicle-stimulating hormone (FSH) with subsequent decline of estrogen levels. In anovulatory cycles, estrogen secretion continues, resulting in endometrial proliferation with subsequent unstable growth and incomplete shedding. The clinical result is irregular, prolonged, and heavy bleeding.

Studies of adolescent menses show differences in rates of ovulation based on the number of months or years postmenarche. The younger the age at menarche, the sooner regular ovulation is established. In one study, the time from menarche until 50% of the cycles were ovulatory was 1 year for girls whose menarche occurred when they were younger

than 12 years of age, 3 years for girls whose menarche occurred between 12 and 12.9 years of age, and 4.5 years for girls whose menarche occurred at 13 years of age or older (22,62).

Pregnancy-related Bleeding  The possibility of pregnancy must be considered when an adolescent seeks treatment for abnormal bleeding. Bleeding in pregnancy can be associated with a spontaneous abortion, ectopic pregnancy, or other pregnancy-related complications, such as a molar pregnancy. In the United States, 31% of 15- to 17-year-old adolescent girls have had sexual intercourse, as have 69% of those 18 to 19 years old (63). Issues of confidentiality for adolescent health care are critical to an adolescent’s willingness to seek appropriate reproductive health care (see Chapter 1).

Exogenous Hormones  The cause of abnormal bleeding that is experienced while an individual is taking exogenous hormones usually is very different from bleeding that occurs without hormonal manipulation (64). Oral contraceptive use is associated with breakthrough bleeding, which occurs in as many as 30% to 40% of individuals during the first cycle of combination pill use. In addition, irregular bleeding can result from missed pills (65,66). Strict compliance with correct and consistent pill taking is difficult for many individuals who take oral contraceptives; one study reported that only 40% of women took a pill every day (67). Other studies suggest that adolescents have an even more difficult time taking oral contraceptives, missing an average of three pills per month (68). With this many missed pills, it is not surprising that some individuals experience irregular bleeding. The solution is to emphasize consistent pill taking; if the individual is unable to comply with daily pill use, an alternative contraceptive method may be preferable.

All forms of hormonal contraception, from combination and progestin-only minipills, to contraceptive patches, rings, intrauterine devices, and injectable and implantable contraception, can be associated with abnormal bleeding (69,70). Irregular bleeding occurs frequently in users of depomedroxyprogesterone acetate (DMPA), although at the end of 1 year, more than 50% of users will be amenorrheic (71). Although the mechanism of bleeding associated with these hormonal methods is not well established, an atrophic endometrium or factors related to angiogenesis may be involved, suggesting options for therapy (64,72). However, it should not be assumed that any bleeding occurring while an individual is using a hormonal method of contraception is caused by that method. Other local causes of bleeding, such as cervicitis or endometritis, also can occur during use of hormone therapy (73,74).

Hematologic Abnormalities  In the adolescent age group, the possibility of a hematologic cause of abnormal bleeding must be considered. One classic study reviewed all visits by adolescent patients to an emergency room with the symptom of excessive or abnormal bleeding (Fig. 14.11) (75). The most common coagulation abnormality diagnosed was idiopathic thrombocytopenic purpura, followed by von Willebrand’s disease. Von Willebrand disease occurs in approximately 1% of women in the United States and, in its mildest form, menorrhagia may be the only symptom (76). Adolescents who have severe menorrhagia, especially at menarche, should be screened for coagulation abnormalities, including von Willebrand’s disease.

Infections  Irregular or postcoital bleeding can be associated with chlamydial cervicitis. Adolescents have the highest rates of chlamydial infections of any age group, and sexually active teens should be screened routinely for Chlamydia (77). Menorrhagia can be the initial sign in patients infected with sexually transmissible organisms. Adolescents have the highest rates of pelvic inflammatory disease (PID) of any age group of sexually experienced individuals (78) (see Chapter 16).

Other Endocrine or Systemic Problems  Abnormal bleeding can be associated with thyroid dysfunction. Signs and symptoms of thyroid disease can be somewhat subtle in
teens (see Chapter 28). Hepatic dysfunction should be considered because it can lead to abnormalities in clotting factor production. Hyperprolactinemia can cause amenorrhea or irregular bleeding.

Polycystic ovary syndrome (PCOS) can occur during adolescence, and manifestations of excess androgen (hirsutism, acne) should prompt evaluation (79). Androgen disorders occur in about 5% to 10% of women, making them the most common endocrine disorders in women (see Chapter 28). Classic PCOS, functional ovarian hyperandrogenism, or partial late-onset congenital adrenal hyperplasia all can occur in adolescence (80). These disorders often are overlooked, unrecognized, or untreated. Women with even mild disorders are candidates for intervention. These disorders may be a harbinger of type 2 diabetes, endometrial cancer, and cerebrovascular disease. Acne, hirsutism, and menstrual irregularities are often dismissed as normal during adolescence but may be manifestations of hyperandrogenism (81,82). If an androgen abnormality is not treated, it is likely to persist beyond adolescence. Obesity, hirsutism, and acne should be evaluated to minimize the significant psychosocial costs (83). Androgenic changes are partially reversible if detected early and managed appropriately. Behavioral changes (diet and exercise) should be strongly encouraged but are often difficult to achieve. Signs of insulin resistance (acanthosis nigricans) should also be evaluated and managed appropriately (84).

Figure 14.11 Etiology of menorrhagia in adolescents. (From Classens AE, Cowell CA. Acute adolescent menorrhagia. Am J Obstet Gynecol 1981;139:277–280, with permission.)
Anatomic Causes  Obstructive or partially obstructive genital anomalies typically present during adolescence. Complex müllerian abnormalities, such as obstructing longitudinal vaginal septa or uterus didelphys, can cause hematoccolpos or hematometra. If these obstructing anomalies have or develop a small outlet, persistent dark-brownish discharge (old blood) may appear instead of or in addition to a pelvic mass. Many varieties of uterine and vaginal anomalies exist, and clinicians who have expertise with these anomalies should be involved in their management. Fig. 14.12 illustrates situations in which abnormal bleeding can occur as a result of obstructing septa.

Diagnosis

Examination  A careful general physical examination can reveal signs of androgen excess such as acanthosis nigricans or facial, chest/periareolar, or abdominal terminal hair growth. Because body hair is felt by many to be culturally unacceptable in women and girls, sensitive questioning about hair removal techniques (bleaching, waxing, use of depilatories, shaving, plucking) is warranted during an examination. A complete pelvic examination is appropriate in patients who have been sexually active, are having severe pain, or may have an anatomic anomaly. Testing for gonorrhea and C. trachomatis infection are appropriate during a speculum examination if the patient has been sexually active. Some young teens who have a history that is classic for anovulation, who deny sexual activity, and who agree to return for follow-up evaluation may be managed with a limited gynecologic examination supplemented with pelvic ultrasonography.

Laboratory Testing  Any adolescent with abnormal bleeding should undergo sensitive pregnancy testing, regardless of whether she states that she has had intercourse. The medical consequences of failing to diagnose a pregnancy are too severe to risk missing the diagnosis. Complications of pregnancy should then be managed accordingly. In addition to a pregnancy test, laboratory testing should include a complete blood count with platelet count and screening tests for coagulopathies and platelet dysfunction (85). Thyroid studies also may be appropriate. Testing for STDs may be performed as appropriate on either a cervical or a urine specimen using DNA amplification techniques. Cervical cytology testing is generally not appropriate at an emergency or urgent visit for excessive bleeding.
Imaging Studies  If the pregnancy test results are positive, pelvic imaging using ultrasoundography may be necessary to confirm a viable intrauterine pregnancy and rule out a spontaneous abortion or ectopic pregnancy. If a pelvic mass is suspected on examination, or if the examination is inadequate (more likely to be the case in an adolescent than an older woman) and additional information is required, pelvic ultrasonography may be helpful. Although transvaginal ultrasonographic examination can be more helpful than transabdominal ultrasonography in ascertaining details of pelvic anatomy, the use of the vaginal probe may not be possible in a young girl or one who has not used tampons or had intercourse. Direct communication between the clinician and the radiologist can be helpful in identifying candidates for transvaginal ultrasonographic examination.

Other imaging studies are not indicated as initial testing but may be helpful in selected instances. If a pelvic ultrasonographic examination does not lead to clarification of the anatomy when vaginal septa, uterine septa, uterine duplication, or vaginal agenesis is suspected, MRI can be helpful in delineating anatomic abnormalities. This imaging technique is useful in the evaluation of uterine and vaginal developmental anomalies, although laparoscopy can still play a role in the clarification of abnormal anatomy (86,87). Computed tomography scanning may be helpful in detecting nongenital intraabdominal abnormalities.

Management  Management of bleeding abnormalities related to pregnancy, thyroid dysfunction, hepatic abnormalities, hematologic abnormalities, or androgen excess syndromes should be directed to treating the underlying condition. Oral contraceptives can be extremely helpful in managing androgen excess syndromes and other causes of anovulation (88).

Treatment with *mefenamic acid* and other nonsteroidal anti-inflammatory agents (NSAIDs) has been shown to result in decreased menstrual bleeding when compared with placebo (89). *Tranexamic acid*, an antifibrinolytic agent, has been shown to be more effective than NSAIDs, although it is not frequently used for menorrhagia in the United States. After specific diagnoses have been ruled out by appropriate laboratory testing, anovulation or dysfunctional bleeding becomes the diagnosis of exclusion. This condition can be managed either expectantly or with hormone therapy, depending on the clinical presentation and other factors, such as the need for contraception.

Anovulation: Mild Bleeding  Adolescents who have mildly abnormal bleeding, as defined by adequate hemoglobin levels and minimal disruption of daily activities, are best managed with prospective menstrual charting, frequent reassurance, close follow-up, and supplemental iron. If the patient has been bleeding heavily or for a prolonged interval, however, an apparent decrease in the bleeding does not necessarily mean that therapy is not required. This type of intermittent bleeding characterizes anovulatory bleeding and is likely to continue in the absence of therapy.

A patient who is mildly anemic will benefit from hormone therapy. If the patient is not bleeding at the time of evaluation and has no contraindications to the use of estrogen, a combination low-dose oral contraceptive can be prescribed for use in the manner in which it is used for contraception (21 days of hormonally active pills, followed by 7 days of placebo, during which time withdrawal bleeding is expected). If the patient is not sexually active, she should be reevaluated after three to six cycles to determine if she desires to continue this regimen. Parents may sometimes object to the use of oral contraceptives if their daughter is not sexually active (or if they believe her not to be or even if they would like her not to be). These objections are frequently based on misconceptions about the potential risks of the pill and can be overcome by careful explanation of the pill’s
role as medical therapy. If the medication is discontinued when the young woman is not sexually active and she subsequently becomes sexually active and requires contraception, it may be difficult to explain the reinstitution of oral contraceptives to the parents. If there is no significant medical or family history that would preclude their use, combination oral contraceptives are especially appropriate for the management of abnormal bleeding in adolescents for a number of reasons:

1. Approximately 50% of 17-year-old adolescent girls in the United States are sexually experienced (63).

2. Adolescents typically wait 12 or more months after initiating sexual activity to seek medical contraception (90).

3. At least 75% of adolescent pregnancies are unintended (91).

4. Approximately one half of adolescent pregnancies end in abortion (92).

5. Approximately one in three young women will experience a pregnancy before age 20 (93).

Thus, consideration should certainly be given to continuing the oral contraception use, and parents should be reassured that the medical risks are small in otherwise healthy adolescents and that there are no significant risks associated with prolonged use. Individuals may choose to continue oral contraceptives for contraception or their noncontraceptive benefits (improvement of acne, decreased dysmenorrhea, and lighter, more regular menstrual flow).

Sometimes, providing parents with accurate information about the safety of oral contraceptives, emphasizing that currently available oral contraceptive preparations contain lower doses of estrogens and progestins than those used in the 1960s and 1970s, and emphasizing the hormonal rather than contraceptive function, may not be persuasive. In such cases, cyclic progestins are an alternative. A systematic review of the use of combination hormonal therapy versus progestins alone for the treatment of anovulatory bleeding found a paucity of evidence supporting the efficacy of one management regimen over the other (94). Medroxyprogesterone acetate, 5 to 10 mg/day for 10 to 13 days every 1 to 2 months, prevents excessive endometrial buildup and irregular shedding caused by unopposed estrogen stimulation. This therapy also should be reevaluated regularly and accompanied by oral administration of iron. Eventual maturation of the hypothalamic–pituitary–ovarian axis usually will result in the establishment of regular menses unless there are underlying conditions such as hyperandrogenism.

**Acute Bleeding**

*Moderate* Patients who are bleeding acutely but in a stable condition and do not require hospital admission will require doses of hormones that are higher than those in oral contraceptives to effectively stop anovulatory bleeding. An effective regimen is the use of combination monophasic oral contraceptives (every 6 hours for 4 to 7 days). After that time, the dose should be tapered or stopped to allow withdrawal flow. With this therapy, the patient and her parents should be given specific written and oral instructions warning them about the potential side effects of high-dose hormone therapy—nausea, breast tenderness, and breakthrough bleeding. The patient should be instructed to call with any concerns rather than discontinue the pills, and she must understand that stopping the prescribed regimen may result in a recurrence of heavy bleeding. Both the patient and her mother should be warned to expect heavy withdrawal flow for the first period. It will be controlled by the institution of combination low-dose oral contraceptive therapy given once daily and continued for three to six cycles to allow regular withdrawal flow. If
the patient is not sexually active, the pill may be discontinued and the menstrual cycles may be reassessed.

**Emergency Management** The decision to hospitalize a patient depends on the rate of current bleeding and the severity of any existing anemia. The actual acute blood loss may not adequately be reflected in the initial blood count but will be revealed with serial hemoglobin assessments. The cause of acute menorrhagia may be a primary coagulation disorder (75); thus, measurements of coagulation and hemostasis, including screening for coagulopathy, should be performed for any adolescent patients with acute menorrhagia. The method of screening depends on the laboratory tests that are available; the use of a platelet function analyzer has been described as a reasonable screening tool (95). Von Willebrand’s disease, platelet disorders, or hematologic malignancies can cause menorrhagia in adolescents. Depending on the patient’s level of hemodynamic stability or compromise, a blood sample can be analyzed for type and screen. The decision to transfuse must be considered carefully, and the benefits and risks should be discussed with the adolescent and her parents. Generally, there is no need for transfusion unless the patient is hemodynamically unstable.

In patients who, by exclusion, have been diagnosed as having dysfunctional bleeding, hormone therapy usually makes it possible to avoid surgical intervention (dilation and curettage [D & C], operative hysteroscopy, or laparoscopy). A patient who has been hospitalized for severe bleeding requires aggressive management as follows:

1. After stabilization, when appropriate laboratory assessment and an examination have established a working diagnosis of anovulation, hormonal management will usually control bleeding.

2. *Conjugated estrogens*, either 25 to 40 mg given intravenously every 6 hours or 2.5 mg given orally every 6 hours, will usually be effective.

3. If estrogens are not effective, the patient should be reevaluated and the diagnosis should be reassessed. The failure of hormonal management suggests that a local cause of bleeding is more likely. In this event, consideration should be given to a pelvic ultrasonographic examination to determine any unusual causes of bleeding (such as uterine leiomyomas or endometrial hyperplasia) and to assess the presence of intrauterine clots that may impair uterine contractility and prolong the bleeding episode.

4. If intrauterine clots are detected, evacuation of the clots (suction curettage or D & C) is indicated. Although a D & C will provide effective immediate control of the bleeding, it is unusual to reach this step in adolescents.

More drastic forms of treatment other than a D & C (such as ablation of the endometrium by laser or cryotherapy) are considered inappropriate for adolescents because of concerns about future fertility.

If intravenous or oral administration of estrogen controls the bleeding, oral progesterin therapy should be instituted and continued for several days to stabilize the endometrium. This therapy can be accomplished by using a combination oral contraceptive, usually one with 30 to 35 mg of estrogen, or by using the tapering regimen previously described. The medication can be tapered and ultimately stopped to allow withdrawal bleeding. Low-dose combination oral contraception should be continued for three to six cycles, or longer if desired, to provide normal menstrual cycles.

In general, the prognosis for regular ovulatory cycles and subsequent normal fertility in young women who experience an episode of abnormal bleeding is good, particularly for
patients who develop abnormal bleeding as a result of anovulation within the first years after menarche and in whom there are no signs of other specific conditions. Some girls, including those in whom there is an underlying medical cause, such as PCOS, will continue to have abnormal bleeding into middle and late adolescence and adulthood and will benefit from the ongoing use of oral contraceptives to manage hirsutism, acne, and irregular periods. Ovulation induction may be necessary to achieve fertility in these individuals. Girls with coagulopathies also may benefit from ongoing oral contraceptive use.

**Long-term Menstrual Suppression**

For patients with underlying medical conditions, such as coagulopathies or a malignancy requiring chemotherapy, long-term therapeutic amenorrhea with menstrual suppression using the following regimens may be necessary:

1. Progestins such as oral norethindrone, norethindrone acetate, or medroxyprogesterone acetate on a continuous daily basis
2. Continuous (noncyclic) combination regimens of oral estrogen and progestins (birth control pills) that do not include a withdrawal bleeding–placebo week
3. Depot formulations of progestins (DMPA), with or without concurrent estrogens
4. Gonadotropin-releasing hormone (GnRH) analogs with or without estrogen add-back therapy
5. Levonorgestrel intrauterine system (IUS)

The choice of regimen depends on the presence of any contraindications (such as active liver disease precluding the use of estrogens) and the clinician’s experience. Although the goal of these long-term suppressive therapies is amenorrhea, all of these regimens may be accompanied by breakthrough bleeding. At 1 year, rates of amenorrhea approach 90% with extended cycle combination oral contraceptives, 50% with DMPA, and 50% with the levonorgestrel IUS (96–98). Because both DMPA and GnRH analogs have been associated with disadvantageous effects on bone mineral density, the potential risks must be weighed against their medical benefits (99,100). Regular follow-up visits and continued patient encouragement are required with all of these options. Occasional episodes of spotting and mild breakthrough bleeding that do not result in a lowered hemoglobin level may be managed expectantly. When breakthrough bleeding affects the hemoglobin level, it should be evaluated with respect to the underlying disease. For example, in a patient with underlying platelet dysfunction, breakthrough bleeding may reflect a lowered platelet count. Bleeding in a patient with hepatic disease may reflect worsening hepatic function. Supplemental low-dose estrogen can be helpful in the management of excessive breakthrough bleeding that has no specific cause other than the hormone therapy.

**Pelvic Masses**

**Presentation**

Adolescents with pelvic masses may be asymptomatic or may have chronic or acute symptoms. An ovarian mass may be discovered incidentally when an ultrasonographic examination is performed to evaluate the urinary system or when imaging is performed to evaluate pelvic pain. The mere presence of a mass on imaging studies does not always indicate that the mass is the cause of pelvic pain. A “ruptured ovarian cyst” is a classic diagnosis when an adolescent presents with pelvic pain, even if ultrasonography findings suggest only a simple cystic follicle and a physiologic amount of pelvic fluid that are unlikely to cause pain. Alternatively, ovarian masses can cause severe acute or
intermittent symptoms caused by torsion (Fig. 14.13), intraperitoneal rupture, or bleeding into the ovarian tissue. These conditions can represent a true surgical emergency or urgency, and their diagnosis can be challenging. The pressure of an enlarging ovarian mass can cause bowel-related symptoms such as constipation, vague discomfort, and early satiety; urinary frequency; or even ureteral or bladder neck obstruction.

**Diagnosis**

The history and pelvic examination are critical in the diagnosis of a pelvic mass. Considerations in adolescents include the anxiety associated with a first pelvic examination, as well as issues of confidentiality related to questions about sexual activity. Techniques for history taking and the performance of the first examination are discussed in Chapter 1.

Laboratory studies should always include a pregnancy test (regardless of stated sexual activity), and a complete blood count may be helpful in diagnosing inflammatory masses. Tumor markers, including α-fetoprotein and human chorionic gonadotropin (hCG), may be elaborated by germ cell tumors and can be useful in preoperative diagnosis as well as follow-up (see Chapter 32).

As in all age groups, the primary diagnostic technique for evaluating pelvic masses in adolescents is ultrasonography. Although transvaginal ultrasonographic examinations may provide more detail than transabdominal ultrasonography, particularly with inflammatory masses, a transvaginal examination may not be well tolerated by adolescents (101). Ultrasonography usually is the most helpful imaging technique for assessing ovarian masses. For cases in which the suspected diagnosis is appendicitis or another nongynecologic condition, or if the results of the ultrasonographic examination are inconclusive, CT or MRI may be helpful. An accurate preoperative assessment of anatomy is critical, particularly in cases of uterovaginal malformations. Magnetic resonance imaging can be useful for evaluating this group of rare anomalies (102,103). Adolescents who present with abdominal pain should be evaluated with some type of imaging procedure.
because an unexpected finding of a complex uterine or vaginal anomaly requires careful surgical planning and management.

**Differential Diagnosis**

**Ovarian Masses** Many studies of ovarian tumors in the pediatric and adolescent age group do not distinguish between prepubertal/premenarchal girls and menarchal adolescents. The findings of some reports are based on age group, although this is less helpful than a distinction by pubertal development. In evaluating a pelvic or abdominal mass, the clinician must take into consideration the patient’s pubertal status because the likelihood of functional masses increases after menarche. **The risk of malignant neoplasms is lower among adolescents than among younger children.** Epithelial neoplasms occur with increasing frequency with age. Germ cell tumors are the most common tumors of the first decade of life but occur less frequently during adolescence (see Chapter 35). Mature cystic teratoma is the most frequent neoplastic tumor of children and adolescents, accounting for more than one half of ovarian neoplasms in women younger than 20 years of age (104).

It is well established that neoplasia can arise in dysgenetic gonads. Malignant tumors have been found in about 25% of dysgenetic gonads of patients with a Y chromosome (105). Gonadectomy is recommended during adolescence after the attainment of pubertal development for patients with XY gonadal dysgenesis or its mosaic variations (106).

**Functional ovarian cysts occur frequently in adolescence.** They may be an incidental finding on examination or may be associated with pain caused by torsion, leakage, or rupture. Paratubal cysts represent embryologic remnants that may be confused with an ovarian mass (Fig. 14.14); they are typically asymptomatic, but can be associated with adnexal torsion. Endometriosis is less common during adolescence than in adulthood, although it can occur during adolescence. In one study of adolescents referred with chronic pain, 50% to 65% were found to have endometriosis (107). Although endometriosis can occur in young women with
obstructive genital anomalies (presumably as a result of retrograde menstruation), most adolescents with endometriosis do not have associated obstructive anomalies (108). In young women, endometriosis may have an atypical appearance characterized by nonpigmented or vesicular lesions, peritoneal windows, and puckering (109).

Uterine Masses

Other causes of pelvic masses, such as uterine abnormalities, are rare in adolescence. Uterine leiomyomas are not often seen in this age group. Obstructive uterovaginal anomalies occur during adolescence, at the time of menarche, or shortly thereafter. The diagnosis is frequently is either not suspected or delayed (110). A wide range of anomalies can occur, from imperforate hymen to transverse vaginal septa, to vaginal agenesis with a normal uterus and functional endometrium, vaginal duplications with obstructing longitudinal septa, and obstructed uterine horns (Fig. 14.12). Patients may seek treatment for cyclic pain; amenorrhea; vaginal discharge; or an abdominal, pelvic, or vaginal mass. A hematocolpos, hematometra, or both frequently will be present, and the resulting mass can be quite large (111).

Inflammatory Masses

Of all age groups of sexually active women, adolescents have the highest rates of PID (78). Thus, an adolescent who has pelvic pain may be found to have an inflammatory mass. Such masses may consist of a tubo-ovarian complex (a mass of matted bowel, tube, and ovary), tubo-ovarian abscess (a mass consisting primarily of an abscess cavity within an anatomically defined structure such as the ovary), pyosalpinx, or, chronically, hydrosalpinx.

The diagnosis of PID is primarily a clinical one based on the presence of lower abdominal, pelvic, and adnexal tenderness; cervical motion tenderness; a mucopurulent discharge; and elevated temperature, white blood cell count, or sedimentation rate (see Chapter 16). The risk of PID is clearly associated with that of acquiring STDs, and methods of contraception may either decrease the risk (oral contraceptives, male latex condoms) or increase it (the intrauterine device in the interval immediately after insertion) (112–114).

Pregnancy

In adolescents, pregnancy should always be considered as a cause of a pelvic mass. In the United States, approximately 50% of adolescent young women have experienced sexual intercourse (63). Most pregnancies in adolescents are unintended; 82% of pregnancies in adolescents younger than age 15, 83% in women aged 15 to 17, and 75% in women aged 18 to 19 are unintended (91). Adolescents may be more likely than adults to deny the possibility of pregnancy because of wishful thinking, anxiety about discovery by parents or peers, or unfamiliarity with menstrual cycles and information about fertility. Ectopic pregnancies may cause pelvic pain and an adnexal mass. With the availability of quantitative measurements of \( \beta \)-hCG, more ectopic pregnancies are being discovered before rupture, allowing conservative management with laparoscopic surgery or medical therapy with methotrexate (see Chapter 18). The risk of ectopic pregnancy varies by method of contraception; users of no contraception have the highest risk, whereas oral contraceptive users have the lowest risk (115). As with older patients, paraovarian cysts and nongynecologic masses can appear as a pelvic or abdominal mass in adolescents.

Management

The management of masses in adolescents depends on the suspected diagnosis as well as the initial symptom. Figure 14.8 outlines a plan of management for pelvic masses in adolescents. Asymptomatic unilocular cystic masses are best managed conservatively because the likelihood of malignancy is low. If surgical management is required based on symptoms or uncertainty of diagnosis, attention should be directed to minimizing the risks of
subsequent infertility resulting from pelvic adhesions. In addition, every effort should be made to conserve ovarian tissue. In the presence of a malignant unilateral ovarian mass, management may include unilateral oophorectomy rather than more radical surgery, even if the ovarian tumor has metastasized (see Chapter 35). Analysis of frozen sections may not be reliable. In general, conservative surgery is appropriate; further surgery can be performed, if necessary, after an adequate histologic evaluation of the ovarian tumor.

Some surgeons advocate the use of laparoscopy in the management of suspected acute PID to confirm the diagnosis and to perform irrigation, lysis of adhesions, drainage and irrigation of unilateral or bilateral pyosalpinx or tubo-ovarian abscess, or extirpation of significant disease (Fig. 14.15) (116,117). When symptoms persist in a patient with the clinical diagnosis of PID or tubo-ovarian abscess, laparoscopy should be considered to confirm the diagnosis. A clinical diagnosis may be incorrect in as many as one third of patients (118). The surgical management of inflammatory masses is rarely necessary in adolescents, except to treat rupture of tubo-ovarian abscess or failure of medical management with broad-spectrum antibiotics (see Chapter 16). Conservative, unilateral adnexectomy usually can be performed in these situations, rather than a pelvic clean-out, maintaining reproductive potential. Percutaneous drainage, transvaginal ultrasonographic drainage, and laparoscopic management of tubo-ovarian abscesses are being done more often. As with the laparoscopic management of ovarian masses, the surgeon’s skill and experience with this procedure are critical, and prospective studies on its effectiveness are lacking (119). Laparoscopic management has been associated with a risk of major complications, including bowel obstruction and bowel or vessel injury (120).

**Vulvar Conditions**

Adolescents with gonadal dysgenesis or androgen insensitivity may have abnormal pubertal development and primary amenorrhea (see Chapter 27). Various developmental abnormalities—vaginal agenesis, imperforate hymen, transverse and longitudinal
vaginal septa, vaginal and uterine duplications, hymenal bands, and septa—most often occur in early adolescents with amenorrhea (for the obstructing abnormalities) or with concerns such as inability to use tampons (for hymenal and vaginal bands and septa). These developmental abnormalities must be evaluated carefully to determine both external and internal anatomy.

A tight hymenal ring may be discovered when the patient seeks care because of concerns about the inability to use tampons or have intercourse. Both manual dilation and small relaxing incisions at 6 o’clock and 8 o’clock in the hymenal ring can be effective. This procedure can sometimes be done in the office using local anesthesia but may require conduction or general anesthesia in the operating room. Hymenal bands are not rare and also lead to difficulty in using tampons; they usually can be incised in the office using local anesthetic. Hypertrophy of the labia minora is a developmental abnormality that can be corrected surgically (121). This condition is more appropriately considered a variant of normal, and reassurance rather than a cosmetic surgical reduction is appropriate as the primary therapy. Genital ulcerations may occur in girls with leukemia or other cancers requiring chemotherapy (122). The possibility of sexual abuse, incest, or involuntary intercourse should be considered for young adolescents with vulvovaginal symptoms, STDs, or pregnancy.

The presence of vulvar symptoms such as itching or burning may prompt a patient to seek care; however, this anatomic site is not one that is easily inspected by the patient. Thus, vulvar lesions may be found on examination and may not have been noticed by the patient. **Vulvar self-examination should be encouraged and could potentially result in the earlier diagnosis of vulvar lesions such as melanoma** (123). Adolescents presenting with vulvar itching may have lichen sclerosus; this condition can also be relatively asymptomatic, even when an examination reveals loss of anatomic structures and scarring (10).

Adolescents as well as adults often incorrectly self-diagnose vulvovaginal candidiasis; in one study, only one third of women with self-diagnosed yeast vaginitis were found to have this infection (124) (see Chapter 16). A clinical examination and appropriate testing can be performed even on young adolescents using a cotton swab to obtain vaginal secretions for pH testing and microscopic examination.

**Vulvar condylomata are an extremely common cause of vulvar lesions in adolescents** (see Chapter 16). Genital warts can affect the vulva, perineum, and perianal skin, as well as the vagina, urethra, and anus (Fig. 14.16). They may be asymptomatic or cause symptoms of itching, irritation, or bleeding. Symptomatic, enlarging, or extensive vulvar condylomata can be managed with topical medication applied by the patient or clinician (77). The choice of treatment should be guided by patient preference, available resources, and the clinician’s experience; no one treatment has been found to be superior to the others (77).

**Vaginal Conditions**

Vulvovaginal symptoms in adolescents may be caused by a variety of conditions, ranging from vulvar lichen sclerosus to urinary tract infection to *Chlamydia trachomatis* to non-STD-related vaginitis. Urinary or vaginal symptoms do not differentiate well between urinary tract infections (UTIs) and vaginitis. Adolescent girls who are screened for both *Chlamydia trachomatis* and UTI have high rates of concurrent disease (125). Because clinical diagnosis based on symptoms is imprecise, female adolescent with vaginal or urinary symptoms should be tested for both *Chlamydia trachomatis* and UTI. Testing with DNA-based procedures may be performed on samples obtained from the cervix, from swabs of vaginal secretions (either clinician or patient obtained), and from urine specimens. Testing that does not involve a speculum examination may be particularly helpful for adolescents; a recent rigorous review concluded that noninvasive *Chlamydia* testing was comparable to cervical or urethral screening, although this was not the case with testing for gonorrhea (126).
Discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis may cause vaginal discharge in adolescents. Infectious vaginal conditions are described in more detail in Chapter 16. The risks of self-diagnosis of vaginal discharge in adolescents may be greater than in adult women, as infection with STDs—including Neisseria gonorrhoea, Trichomonas vaginalis, Chlamydia trachomatis, herpes simplex, and condyloma acuminata—are common in adolescents and may be less likely to be recognized as such.

Use of vaginal tampons has been associated with both microscopic and macroscopic ulcerations. Healing of the macroscopic ulcerations occurs within several weeks without specific therapy if tampon use is suspended. A follow-up examination to demonstrate healing is appropriate, with biopsy of any persistent ulcerations to rule out other lesions.

Toxic shock syndrome (TSS) has been associated with tampon use and vaginal exotoxins produced by Staphylococcus aureus. This syndrome consists of fever, hypotension, a diffuse erythroderma with desquamation of the palms and soles, plus involvement of at least three major organ systems (127). Vaginal involvement includes mucous membrane inflammation. The frequency of TSS appears to be declining, and an increasing percentage of cases are not associated with menses (128). Currently, approximately one half of all cases of TSS are menstrual related (128). Epidemiologic studies have suggested that adolescents are at greater risk of menstrual TSS than older women; however, this finding does not appear to be explained by differences in the detection of antibodies to the TSST-1 toxin-producing strain of S. Aureus or in S. Aureus vaginal colonization rates (129).

Abscesses of Bartholin and Skene's glands are related to both aerobic and anaerobic organisms, with mixed infections accounting for approximately 60% of these and other vulvar and labial abscesses (130). Therapy consists of surgical drainage, with use of antibiotics a secondary measure. In younger adolescents, incision and drainage with insertion of a Word indwelling catheter may require general anesthesia.
Reproductive Age Group

Abnormal Bleeding

Normal Menses

After adolescence, menstrual cycles generally conform to a cycle length of 21 to 35 days, with a duration of fewer than 7 days of menstrual flow. As a woman approaches menopause, cycle length becomes more irregular as fewer cycles are ovulatory (54). The most frequent cause of irregular bleeding in the reproductive age group is hormonal, although other causes such as pregnancy-related bleeding (spontaneous abortion, ectopic pregnancy) should always be considered. Although a variety of terms have been used to describe abnormal menses (Table 14.6), accurate characterization of the bleeding based on records (preferably charted prospectively) may be more important than the use of specific terms. The mean duration of menses is 4.7 days; 89% of cycles last 7 days or longer. The average blood loss per cycle is 35 mL (58). Menses is a suspension of blood- and tissue-derived solids within a mixture of serum and cervicovaginal fluid; the blood content of menses varies over the days of bleeding, but on average is close to 50% (131). Recurrent bleeding in excess of 80 mL/cycle results in anemia.

Differential Diagnosis

**Dysfunctional Uterine Bleeding**  The term dysfunctional uterine bleeding has been used to describe abnormal bleeding for which no specific cause has been found. It most often implies a mechanism of anovulation, although not all bleeding that is outside the normal range (in either cycle length or duration) is anovulatory. The term is a diagnosis of exclusion, which is probably more confusing than enlightening. Other terms that are commonly used to describe bleeding abnormalities include anovulatory uterine bleeding and abnormal uterine bleeding (132).

Most anovulatory bleeding is a result of what has been termed estrogen breakthrough. In the absence of ovulation and the production of progesterone, the endometrium responds to estrogen stimulation with proliferation. This endometrial growth without periodic shedding results in eventual breakdown of the fragile endometrial tissue. Healing within the endometrium is irregular and dyssynchronous. Relatively low levels of estrogen stimulation will result in irregular and prolonged bleeding, whereas higher sustained levels result in episodes of amenorrhea followed by acute, heavy bleeding.

**Pregnancy-related Bleeding**  Spontaneous abortion can be associated with excessive or prolonged bleeding. A woman may be unaware that she has conceived and may seek care because of abnormal bleeding. In the United States, more than 50% of pregnancies are

unintended (91), and 10% of women are at risk for unintended pregnancy but use no method of contraception. These women may be at particular risk for bleeding related to an unsuspected pregnancy. About one half of unintended pregnancies are a result of nonuse of contraception; however, the other one half are contraceptive failures (90). **Unintended pregnancies are most likely to occur among adolescents and women older than 40 years of age** (see Chapter 10). If an ectopic pregnancy is ruled out, the management of spontaneous abortion may include either observation, if the bleeding is not excessive, medical or pharmacologic uterine evacuation, or surgical management with suction curettage or D & C, depending on the clinician’s judgment and the patient’s preference (133–135). Surgical management appears to be the most likely to result in complete evacuation; lower rates of success are seen with both medical and expectant management, although the type of miscarriage and gestational age affect these rates (136) (see Chapter 18).

**Exogenous Hormones** Irregular bleeding that occurs while a woman is using contraceptive hormones should be considered in a different context than bleeding that occurs in the absence of exogenous hormone use. Breakthrough bleeding during the first 1 to 3 months of oral contraceptive use occurs in as many as 30% to 40% of users; it should almost always be managed expectantly with reassurance because the frequency of breakthrough bleeding decreases with each subsequent month of use (65). Irregular bleeding can also result from inconsistent use (137–139). Other estrogen–progestin delivery systems, including the contraceptive patch, vaginal ring, and intramuscular regimens, also are associated with irregular breakthrough bleeding (140). These nondaily contraceptive regimens may promote successful compliance, making irregular bleeding a less important factor for some women in assessing the balance of risks versus benefits (141) (see Chapter 10).

Use of progestin-only methods—including DMPA, progestin-only pills, the contraceptive implant, and the **levonorgestrel IUS**—is associated with relatively high rates of initial irregular and unpredictable bleeding; rates of amenorrhea vary over time and by method (142). Because irregular bleeding is so often present with these two methods of contraception, counseling before their use is imperative. Women who do not believe that they can cope with irregular, unpredictable bleeding may not be good candidates for these methods. **The management of irregular bleeding with hormonal contraceptive use can range from reassurance and expectant management initially to recommendations for a change in the hormonal delivery system or regimen.** The use of additional oral estrogen has been reported to improve bleeding with both DMPA and the subdermal levonorgestrel (71,143,144). The use of NSAIDs has also been shown to result in decreased breakthrough bleeding (143). The development of a better understanding of the mechanisms causing irregular bleeding will likely result in more effective and acceptable management strategies (145).

Not all bleeding that occurs while an individual is using hormonal contraception is a consequence of hormonal factors. In one study, women who experienced irregular bleeding while taking oral contraceptives were found to have a higher frequency of *C. trachomatis* infection (73). Thus, screening should be considered in women presenting with irregular bleeding while using hormonal contraception.

**Endocrine Causes** Both hypothyroidism and hyperthyroidism can be associated with abnormal bleeding. With hypothyroidism, menstrual abnormalities, including **menorrhagia**, are common (see Chapter 28). The most common cause of thyroid hyperfunctioning in premenopausal women is Graves’ disease, which occurs four to five times more often in women than men. Hyperthyroidism can result in oligomenorrhea or amenorrhea, and it also can lead to elevated levels of plasma estrogen (146). Other causes of anovulation include hypothalamic dysfunction, hyperprolactinemia, premature ovarian failure, and primary pituitary disease (132). Although these conditions often are considered as causes of amenorrhea (see Chapter 27), irregular bleeding also may result in their presence.
The rare and unusual causes of abnormal bleeding should not be overlooked. Women with premature ovarian failure frequently see several clinicians, and the diagnosis is often delayed during waning ovarian function and insufficiency (147,148). For this reason, some clinicians have urged that women be encouraged to track their menstrual cyclicity and to consider that the menstrual cycle can be a “vital sign” that reflects overall health.

Diabetes mellitus can be associated with anovulation, obesity, insulin resistance, and androgen excess. Androgen disorders are very common among women of reproductive age and should be evaluated and managed accordingly. Polycystic ovary syndrome is present in 5% to 8% of adult women and undiagnosed in many women (149). Because androgen disorders are associated with significant cardiovascular disease, the condition should be diagnosed promptly and treated. This condition becomes of more immediate concern in older women of reproductive age. Management of bleeding disorders associated with androgen excess consists of an appropriate diagnostic evaluation followed by the use of oral contraceptives (in the absence of significant contraindications or the desire for conception) or the use or insulin-sensitizing agents, coupled with dietary and exercise modification (150).

Anatomic Causes  Anatomic causes of abnormal bleeding occur more frequently in women of reproductive age than in women in other age groups. Uterine leiomyomas and endometrial polyps are common conditions that most often are asymptomatic; however, they remain important causes of abnormal bleeding (151). Uterine leiomyomas occur in as many as one half of all women older than age 35 years and are the most common tumors of the genital tract (151,152). One study of a randomly selected population estimated a cumulative prevalence of greater than 80% in black women and nearly 70% in white women (153). Leiomyomas are estimated to be clinically significant in at least 25% of women of reproductive age in the United States. They are more common in African-American women than white women and have been associated with obesity (154,155). Abnormal bleeding is the most common symptom for women with leiomyomas. Although the number of uterine leiomyomas and their size do not appear to influence the occurrence of abnormal bleeding, submucosal myomas are the most likely to cause bleeding.

The mechanism of abnormal bleeding related to leiomyomas is not well established. Several theories have been postulated, including dysregulation of a number of growth factors that regulate angiogenesis in a uterus in which leiomyomas are present. Growth factors that are currently being investigated for their role in the process of abnormal bleeding associated with leiomyomas include basic fibroblast growth factor, vascular endothelial growth factor, heparin-binding epidermal growth factor, platelet-derived growth factor, transforming growth factor-β, parathyroid hormone-related protein, and prolactin (156). Endometrial polyps are a cause of intermenstrual bleeding, irregular bleeding, and menorrhagia, although as with leiomyomas, most endometrial polyps are asymptomatic. Endometrial polyps can cause menorrhagia and metrorrhagia, and they may be associated with dysmenorrhea. The incidence of endometrial polyps increases with age throughout the reproductive years (151). The diagnosis is based on either visualization with hysteroscopy or sonohysterography or the microscopic assessment of tissue obtained by a biopsy done in the office or a curettage specimen. One study using sonohysterography found polyps in 33% of symptomatic premenopausal women older than the age of 29 years who were experiencing abnormal bleeding versus 10% in asymptomatic women (157). In this study, polyps also were associated with leiomyomas, both intracavitary and intramural, which were present in 13% and 58%, respectively, of symptomatic women with bleeding. Endometrial polyps can regress spontaneously. In one study in which asymptomatic women underwent repeat sonohysterography after 2.5 years, four of seven polyps resolved; these polyps tended to be smaller than those that did not resolve (158). The larger polyps were more likely to result in abnormal bleeding. Whereas polyps may...
resolve spontaneously over time, a clinically important question is whether they are likely to undergo malignant transformation. Because even asymptomatic polyps usually are removed at the time of identification, this question is difficult to answer. A review of the pathology of resected polyps suggests that the chance of malignancy is less than 5% and likely approximates 0.5% (151). In one large series, it was rare to find atypia or carcinoma in an endometrial polyp from a premenopausal woman (159).

Abnormal bleeding, either intermenstrual or postcoital, can be caused by cervical lesions. Bleeding can also result from endocervical polyps and infectious cervical lesions, such as condylomata, herpes simplex virus ulcerations, chlamydial cervicitis, or cervicitis caused by other organisms. Other benign cervical lesions, such as wide eversion of endocervical columnar epithelium or nabothian cysts, may be detected on examination but rarely cause bleeding.

**Coagulopathies and Other Hematologic Causes**  The presence of excessively heavy menses should prompt an evaluation of hematologic status. A complete blood count will be helpful in detecting anemia, significant problems such as leukemia, or disorders associated with thrombocytopenia. Abnormal liver function, which can be seen with alcoholism or other chronic liver diseases, results in inadequate production of clotting factors and can lead to excessive menstrual bleeding. Coagulation abnormalities such as von Willebrand’s disease, occurring in up to 1% of the population, can have a variable clinical picture and may escape diagnosis until the reproductive years (76,160,161). Administration of oral contraceptives, which increase the level of factor VIII, can be helpful, and newer therapies, including desmopressin acetate, may be necessary, particularly before surgical procedures are performed.

**Infectious Causes**  Women with cervicitis, particularly chlamydial cervicitis, can experience irregular bleeding and postcoital spotting (see Chapter 16). Therefore, cervical testing for C. trachomatis should be considered, especially for adolescents, women in their 20s, and women who are not in a monogamous relationship. Endometritis can cause excessive menstrual flow. Thus, a woman who seeks treatment for menorrhagia and increased menstrual pain and has a history of light-to-moderate previous menstrual flow may have an upper genital tract infection or PID (endometritis, salpingitis, oophoritis). Occasionally, chronic endometritis will be diagnosed when an endometrial biopsy is obtained for evaluation of abnormal bleeding in a patient without specific risk factors for PID.

**Neoplasia**  Abnormal bleeding is the most frequent symptom of women with invasive cervical cancer. An obvious cervical lesion should be evaluated by biopsy, because the results of cervical cytology testing may be falsely negative with invasive lesions as a result of tumor necrosis. Unopposed estrogen has been associated with a variety of abnormalities of the endometrium, from cystic hyperplasia to adenomatous hyperplasia, hyperplasia with cytologic atypia, and invasive carcinoma. Although vaginal neoplasia is uncommon, the vagina should be evaluated carefully when abnormal bleeding is present. Attention should be directed to all surfaces of the vagina, including anterior and posterior areas that may be obscured by the vaginal speculum on examination.

**Diagnosis**  For all women, the evaluation of excessive and abnormal menses includes a thorough medical and gynecologic history, the exclusion of pregnancy, the consideration of possible malignancy, and a careful gynecologic examination. For women of normal weight between the ages of approximately 20 and 35 years who do not have clear risk factors for STDs, who have no signs of androgen excess, who are not using exogenous hormones, and who have no other findings on examination, management may be based on a clinical diagnosis. Additional laboratory or imaging studies may be indicated if the diagnosis is not apparent on the basis of examination and history.
Laboratory Studies  In any patients with excessive bleeding, an objective measurement of hematologic status should be performed with a complete blood count to detect anemia or thrombocytopenia. A pregnancy test should be performed to rule out pregnancy-related problems. In addition, because of the possibility of a primary coagulation problem, screening coagulation studies such as a prothrombin time and partial thromboplastin time should be considered; an assessment of platelet function may be appropriate as a screening test for von Willebrand’s disease (85).

Imaging Studies  Women with abnormal bleeding who have a history consistent with chronic anovulation, who are obese, or who are older than 35 to 40 years of age require further evaluation. A pelvic ultrasonographic examination may be helpful in delineating anatomic abnormalities if the examination results are suboptimal or if an ovarian mass is suspected. A pelvic ultrasonographic examination is the best technique for evaluating the uterine contour, endometrial thickness, and ovarian structure (162). The use of a vaginal probe transducer allows assessment of endometrial and ovarian disorders, particularly in women who are obese. Because of variation in endometrial thickness with the menstrual cycle, measurements of endometrial stripe thickness are significantly less useful in premenopausal than postmenopausal women (163). Sonohysterography is especially helpful in visualizing intrauterine problems such as polyps or submucous leiomyoma (164). Although these sonographic techniques are helpful in visualizing intrauterine pathology, histologic evaluation is required to rule out malignancy (164). Other techniques, such as CT scanning and MRI, are not as helpful in the initial evaluation of causes of abnormal bleeding and should be reserved for specific indications, such as exploring the possibility of other intraabdominal disorders or adenopathy.

Endometrial Sampling  Endometrial sampling should be performed to evaluate abnormal bleeding in women who are at risk for endometrial polyps, hyperplasia, or carcinoma. Such sampling is mandatory in the evaluation of anovulatory bleeding in women older than 35 to 40 years of age, in younger women who are obese, and in those with a history of prolonged anovulation (165). The technique of D & C, which in the past was used extensively for the evaluation of abnormal bleeding, has been replaced largely by endometrial biopsy in the office. The classic study in which a D & C was performed before hysterectomy with the conclusion that less than one half of the endometrium was sampled in more than one half of the patients has led to questioning the use of D & C for endometrial diagnosis (166,167). Hysteroscopy, either diagnostic or operative, with endometrial sampling, can be performed either in the office or operating room (168).

A number of devices are designed for endometrial sampling (Fig. 14.17), including an inexpensive disposable flexible plastic sheath with an internal plunger that allows tissue aspiration, disposable plastic cannulae of varying diameters that attach to a manually locking syringe that allows the establishment of a vacuum, and cannulae (both rigid metal and plastic) with tissue traps that attach to an electric vacuum pump. Several studies comparing the adequacy of sampling using these devices with D & C have shown a comparable ability to detect abnormalities. It should be noted that these devices are designed to obtain a tissue sample rather than a cytologic washing.

Management  Attention should be directed to establishing a cause of abnormal bleeding. In most cases, medical therapy is effective in managing abnormal bleeding and should be attempted before surgical management. When medical therapy fails in women with anovulatory uterine bleeding who no longer desire future childbearing, endometrial ablation is an efficient and cost-effective alternative to hysterectomy, although this therapy may not be definitive (169). In women with leiomyomas, hysterectomy provides a definitive cure (170). A variety of surgical alternatives to hysterectomy are available to women with symptomatic uterine leiomyomas (171,172).
Nonsurgical Management  Most bleeding problems, including anovulatory bleeding, can be managed nonsurgically (173). Treatment with NSAIDs, such as ibuprofen and mefenamic acid, has been shown to decrease menstrual flow by 30% to 50% (174). Antifibrinolytics such as *tranexamic acid* have been shown to be effective in reducing menstrual blood loss, although this indication is not approved by the U.S. Food and Drug Administration (175–177). *Levonorgestrel*-containing intrauterine devices also have been shown to reduce menstrual blood loss significantly and to result in improvements in health-related quality of life that may be comparable to hysterectomy (178,179).

Hormonal management of abnormal bleeding frequently can control excessive or irregular bleeding. The treatment of choice for anovulatory bleeding is medical therapy with oral contraceptives (132). Oral contraceptives have long been used clinically to decrease menstrual flow (88,180,181). Although this effect was first demonstrated with oral contraceptive formulations that contained higher doses of both estrogens and progestins than the agents used today, low-dose combined oral contraceptives have been shown to have a similar effect (182). Low-dose oral contraceptives may be used during the perimenopausal years in healthy nonsmoking women who have no major cardiovascular risk factors. The benefits of menstrual regulation in such women often override the potential risks. The medical treatment of acute abnormal bleeding in reproductive-age women is the same as that described for adolescents.

For patients in whom estrogen use is contraindicated, progestins, both oral and parenteral, can be used to control excessive bleeding. Cyclic oral *medroxyprogesterone acetate*, administered from days 5 to 26 of the cycle, reduces menstrual flow, although it is less effective than the progestin-containing intrauterine device (179). The benefits of progestins to the patient with oligomenorrhea and anovulation include a regular flow and the prevention of long intervals of amenorrhea, which may end in unpredictable, profuse bleeding. This therapy reduces the risk of hyperplasia resulting from persistent, unopposed estrogen stimulation of the endometrium. Depot formulations of *medroxyprogesterone acetate* also have been used to establish amenorrhea in women at risk of excessive bleeding. Oral, parenteral, or intrauterine delivery of progestins may be used in selected women with atypical endometrial hyperplasia who wish to maintain their fertility (183). Continued monitoring every 3 months is indicated; although the long-term prognosis is uncertain, recurrences are frequent (183). *Danazol* is effective in decreasing bleeding and inducing amenorrhea; it currently is rarely used for ongoing management of abnormal bleeding because of its androgenic side effects, including weight gain, hirsutism, alopecia, and
irreversible voice changes. Gonadotropin-releasing hormone analogues have also been used for short-term treatment of abnormal bleeding but are not effective for acute therapy given their initial effect as a GnRH agonist (177).

The levonorgestrel-containing IUS has been shown to decrease menstrual blood loss by 80% to 90% (184). Because of its 5-year duration of efficacy, it has been suggested as a cost-effective alternative to hysterectomy for excessive bleeding (185).

Surgical Therapy The surgical management of abnormal bleeding should be reserved for situations in which medical therapy has been unsuccessful or is contraindicated. Although sometimes appropriate as a diagnostic technique, D & C is questionable as a therapeutic modality. One study reported a measured reduction in menstrual blood loss for the first menstrual period only (186). Other studies have suggested a longer-lasting benefit (187).

The surgical options range from a variety of techniques for endometrial ablation or resection (see Chapter 21) to hysterectomy (see Chapter 22) to a variety of conservative surgical techniques for management of uterine leiomyoma, including hysteroscopy with resection of submucous leiomyomas, laparoscopic techniques of myomectomy, uterine artery embolization, and magnetic resonance-guided focused ultrasonography ablation. The choice of procedure depends on the cause of the bleeding, the patient’s preferences, the physician’s experience and skills, the availability of newer technologies, and a careful assessment of risks versus benefits based on the patient’s medical condition, concomitant gynecologic symptoms or conditions, and desires for future fertility. The assessment of the relative advantages, risks, benefits, complications, and indications of these procedures is a subject of ongoing clinical research (188,189). The proposed advantages of techniques other than hysterectomy include a shorter recovery time and less early morbidity. However, symptoms can recur or persist; repeat procedures or subsequent hysterectomy may be required if conservative options are chosen. Quality-of-life outcomes should be assessed, and current studies do not indicate there is a definitive management advantage to any particular technique (190–192). Much has been written about the psychologic sequelae of hysterectomy, and some of the aforementioned surgical techniques have been developed in an effort to provide less drastic management options. Most well-controlled recent studies have suggested that, in the absence of preexisting psychopathology, indicated but elective surgical procedures for hysterectomy have few, if any, significant psychologic sequelae (including depression) (193) (see Chapter 12).

Pelvic Masses Conditions diagnosed as a pelvic mass in women of reproductive age are presented in Table 14.7.

Differential Diagnosis It is difficult to determine the frequency of diagnoses of pelvic mass in women of reproductive age, because many pelvic masses are not ultimately treated with surgery. Nonovarian or nongynecologic conditions may be confused with an ovarian or uterine mass (Table 14.8). The frequency of masses found at laparotomy has been studied, although the percentages are affected by varying indications for surgery, indications for referral, type of practice (gynecologic oncology versus general gynecology), and patient populations (a higher percentage of African-Americans with uterine leiomyomas, for example). Benign masses, such as functional ovarian cysts or asymptomatic uterine leiomyoma, often do not require surgery.

Age is an important determinant of the likelihood of malignancy. In one study of women who underwent laparotomy for pelvic mass, malignancy was seen in only 10% of those younger than 30 years of age, and most of these tumors had low malignant potential.
SECTION IV  General Gynecology

Table 14.7  Conditions Diagnosed as a Pelvic Mass in Women of Reproductive Age

- Full urinary bladder
- Urachal cyst
- Sharply anteflexed or retroflexed uterus
- Pregnancy (with or without concomitant leiomyomas)
  - Intrauterine
  - Tubal
  - Abdominal
- Ovarian or adnexal masses
  - Functional cysts
  - Inflammatory masses
  - Tubo-ovarian complex
  - Diverticular abscess
  - Appendiceal abscess
  - Matted bowel and omentum
  - Peritoneal cyst
  - Stool in sigmoid
  - Neoplastic tumors
    - Benign
    - Malignant
- Paraovarian or paratubal cysts
  - Intraligamentous myomas
  - Less common conditions that must be excluded:
    - Pelvic kidney
    - Carcinoma of the colon, rectum, appendix
    - Carcinoma of the fallopian tube
    - Retroperitoneal tumors (anterior sacral meningocele)
    - Uterine sarcoma or other malignant tumors

Table 14.8  Ultrasonographic Characteristics of Adnexal Masses That May Be Useful in Predicting Malignancy

- Unilocular cyst vs. multilocular vs. solid components
- Regular contour vs. irregular border
- Smooth walls vs. nodular vs. irregular
- Presence or absence of ascites
- Unilateral vs. bilateral
- Wall thickness
- Internal echogenicity
- Presence of other intra-abdominal pathology (liver, etc.)
- Vascular characteristics and color flow Doppler pattern
The most common tumors found during laparotomy for pelvic mass are mature cystic teratomas or dermoids (seen in one third of women younger than 30 years of age) and endometriomas (approximately one fourth of women 31 to 49 years of age) (194).

**Uterine Masses**

Uterine leiomyomas, most of which are asymptomatic, are by far the most common benign uterine tumors (195). Other benign uterine growths, such as uterine vascular tumors, are rare. Uterine leiomyomas may be diagnosed on physical examination or with pelvic imaging. They may be subserosal, intramucosal, or submucosal in location within the uterus or located in the cervix, in the broad ligament, or on a pedicle (Fig. 14.18). They are estimated to be present in a high percentage of all women of reproductive age and may be discovered incidentally during routine annual examination. Asymptomatic fibroids may be present in 40% to 50% of women older than 35 years of age (155). Using ultrasonography screening, other authors have estimated a cumulative incidence by age 50 of greater than 80% in African-American women and nearly 70% in white women (153). Leiomyomas may occur singly but often are multiple. They may cause a range of symptoms, from abnormal bleeding to pelvic pressure; however, fewer than one half of uterine leiomyomas are estimated to produce symptoms (196).

The cause of uterine leiomyomas is unknown. Several studies have suggested that each leiomyoma arises from a single neoplastic cell within the smooth muscle of the myometrium (197). There appears to be an increased familial incidence, and they may be more common in women who are obese (155). Hormonal responsiveness and binding has been demonstrated in vitro. Fibroids have the potential to enlarge during pregnancy as well as to regress after menopause.

![Figure 14.18](entered_image) Uterine leiomyomas in various anatomic locations. (From Hacker NF, Moore JG. *Essentials of obstetrics and gynecology.* 3rd ed. Philadelphia, PA: WB Saunders, 1998:413, with permission.)
Grossly, fibroids are discrete nodular tumors that vary in size and number (Fig. 14.18). They may be microscopic or huge (a uterine weight of 74 lb has been reported). They may cause symmetric uterine enlargement or they may distort the uterine contour significantly. The consistency of an individual leiomyoma varies from hard and stony (as with a calcified leiomyoma) to soft (as with cystic degeneration), although the usual consistency is described as firm or rubbery. Although they do not have a true capsule, the margins of the tumor are blunt, non-infiltrating, and pushing, and are usually separated from the myometrium by a pseudocapsule of connective tissue, which allows easy enucleation at the time of surgery. There is usually one major blood vessel supplying each tumor. The cut surface is characteristically whorled.

Degenerative changes are reported in approximately two thirds of all surgical specimens (198). Leiomyomas with an increased number of mitotic figures may occur in various forms: in women who are pregnant or taking progesterone agents, with necrosis, and as a smooth muscle tumor of uncertain malignant potential (defined as having 5 to 9 mitoses per 10 high-power fields [hpf] that do not demonstrate nuclear atypia or giant cells, or with a lower mitotic count [2–4 mitoses/10 hpf] that does demonstrate atypical nuclear features or giant cells). Studies suggest that “malignant degeneration” of a preexisting leiomyoma is extremely uncommon (199).

Leiomyosarcoma is a rare malignant neoplasm composed of cells that have smooth muscle differentiation (see Chapter 33); cytogenetic studies suggest that they arise de novo via distinct pathogenetic pathways (200). The typical patient with leiomyosarcoma is in her mid-50s and seeks treatment for abnormal bleeding. In most cases, diagnoses are determined (postoperatively) after microscopic examination of a uterus removed because of suspected leiomyomas. Sarcomas that have a malignant behavior have 10 mitoses/hpf or greater.

Uterine leiomyomas are frequently diagnosed on the basis of clinical findings of an enlarged, irregular uterus on pelvic examination. They are also frequently noted on ultrasonography obtained for a variety of indications and may be an incidental finding. However, any pelvic tumor potentially can be confused with an enlarged uterus.

The most common initial symptom associated with fibroids, and the one that most frequently leads to surgical intervention, is menorrhagia. Chronic pelvic pain may also be present. Pain may be characterized as dysmenorrhea, dyspareunia, or pelvic pressure (see Chapter 15). Acute pain may result from torsion of a pedunculated leiomyoma or infarction and degeneration. The following urinary symptoms may be present:

1. Frequency may result from extrinsic pressure on the bladder.
2. Partial ureteral obstruction may be caused by pressure from large tumors at the pelvic brim. Reports suggest some degree of ureteral obstruction in 30% to 70% of tumors above the pelvic brim. Ureteral compression is three to four times more common on the right, because the left ureter is protected by the sigmoid colon.
3. Rarely, complete urethral obstruction results from elevation of the base of the bladder by the cervical or lower uterine leiomyoma with impingement on the region of the internal sphincter.

Leiomyomas are an infrequent primary cause of infertility and have been reported as a sole cause in only a small percentage of infertile patients (201,202). Pregnancy loss or complications such as preterm labor, intrauterine growth restriction, and malpresentation can occur in women with leiomyomas, although most patients have uncomplicated pregnancies and deliveries (201). One study calculated a 10% rate of pregnancy complications in women with fibroids (203). Although growth of leiomyomas may occur with pregnancy, no demonstrable change in size (based on serial ultrasonographic examination)
has been noted in 70% to 80% of patients (204,205). The risk of pregnancy complications is influenced by both myoma location and size (206).

The following symptoms may infrequently be associated with leiomyomas:

1. Rectosigmoid compression, with constipation or intestinal obstruction
2. Prolapse of a pedunculated submucous tumor through the cervix, with associated symptoms of severe cramping and subsequent ulceration and infection (uterine inversion also can occur)
3. Venous stasis of the lower extremities and possible thrombophlebitis secondary to pelvic compression
4. Polycythemia
5. Ascites

Ovarian Masses

During the reproductive years, the most common ovarian masses are benign. Ovarian masses can be functional or neoplastic, and neoplastic tumors can be benign or malignant. Functional ovarian masses include follicular and corpus luteal cysts. About two thirds of ovarian tumors are encountered during the reproductive years. Most ovarian tumors (80% to 85%) are benign, and two thirds of these occur in women between 20 and 44 years of age. The chance that a primary ovarian tumor is malignant in a patient younger than 45 years of age is less than 1 in 15. Most tumors produce few or only mild, nonspecific symptoms. The most common symptoms include abdominal distension, abdominal pain or discomfort, lower abdominal pressure sensation, and urinary or gastrointestinal symptoms. If the tumor is hormonally active, symptoms of hormonal imbalance, such as vaginal bleeding related to estrogen production, may be present. Acute pain may occur with adnexal torsion, cyst rupture, or bleeding into a cyst. Pelvic findings in patients with benign and malignant tumors may differ. Masses that are unilateral, cystic, mobile, and smooth are most likely to be benign, whereas those that are bilateral, solid, fixed, irregular, and associated with ascites, cul-de-sac nodules, and a rapid rate of growth are more likely to be malignant.

In assessing ovarian masses, the distribution of primary ovarian neoplasms by decade of life can be helpful (207). Ovarian masses in women of reproductive age are most likely to be benign, but the possibility of malignancy must be considered (208) (Fig. 14.19).

Nonneoplastic Ovarian Masses Functional ovarian cysts include follicular cysts, corpus luteum cysts, and theca lutein cysts. All are benign and usually do not cause symptoms or require surgical management. Cigarette smoking has been associated with an increased risk of functional cysts (209). Oral contraceptive use has been associated with a decreased risk (210). The annual rate of hospitalization for functional ovarian cysts has been estimated to be as high as 500 per 100,000 woman-years in the United States, although little is known about the epidemiology of the condition (211). The most common functional cyst is the follicular cyst, which is rarely larger than 8 cm. A cystic follicle can be defined as a follicular cyst when its diameter is greater than 3 cm. These cysts are usually found incidental to pelvic examination, although they may rupture, causing pain and peritoneal signs. They usually resolve in 4 to 8 weeks with expectant management (212).

Corpus luteum cysts are less common than follicular cysts. Corpus luteum cysts may rupture, leading to a hemoperitoneum and requiring surgical management. Patients taking anticoagulant therapy are at particular risk for rupture. Rupture of these cysts occurs more often on the right side and may occur during intercourse. Most ruptures occur on cycle
days 20 to 26 (213). Unruptured corpus luteum cysts can cause pain, presumably because of bleeding into the enclosed ovarian cyst cavity. They can produce symptoms that can be difficult to discern from adnexal torsion.

Theca lutein cysts are the least common of functional ovarian cysts. They are usually bilateral and occur with pregnancy, including molar pregnancies. They may be associated with multiple gestations, molar pregnancies, choriocarcinoma, diabetes, Rh sensitization, clomiphene citrate use, human menopausal gonadotropin–human chorionic gonadotropin ovulation induction, and the use of GnRH analogs. Theca lutein cysts may be quite large (up to 30 cm), are multicystic, and regress spontaneously (214,215).

Combination monophasic oral contraceptive therapy has been reported to markedly reduce the risk of functional ovarian cysts (216). It appears that, in comparison with previously available higher-dose pills, the effect of cyst suppression with current low-dose oral contraceptives is attenuated (217,218). Most studies have suggested that the use of
triphasic oral contraceptives is not associated with an appreciable increased risk of functional ovarian cysts (219).

**Other Benign Masses** Women with endometriosis may develop ovarian endometriomas ("chocolate" cysts), which can enlarge to 6 to 8 cm in size. A mass that does not resolve with observation may be an endometrioma (see Chapter 29).

Although enlarged, polycystic ovaries were originally considered the *sine qua non* of PCOS. They probably represent a final common phenotype of a wide variety of causes and are not always present with other features of the syndrome. The prevalence of PCOS among the general population depends on the diagnostic criteria used. In one study, 257 volunteers were examined with ultrasonography; 22% were found to have polycystic ovaries (220). The finding of bilateral generously sized ovaries on examination or polycystic ovaries on ultrasonographic examination should prompt evaluation for the full-blown syndrome, which includes hyperandrogenism and chronic anovulation as well as polycystic ovaries (150,221). Therapy for PCOS is medical and generally not surgical.

**Neoplastic Masses** More than 80% of benign cystic teratomas (dermoid cysts) occur during the reproductive years, although dermoid cysts have a wider age distribution than other ovarian germ cell tumors (Fig. 14.20) (222). Histologically, benign cystic teratomas have an admixture of elements. In one study of ovarian masses that were surgically excised, dermoid cysts represented 62% of all ovarian neoplasms in women younger than 40 years of age (207). Malignant transformation occurs in less than 2% of dermoid cysts in women of all ages; most cases occur in women older than 40 years of age. The risk of torsion with dermoid cysts is approximately 15%, and it occurs more frequently than with ovarian tumors in general, perhaps because of the high-fat content of most dermoid cysts, allowing them to float within the abdominal and pelvic cavity. As a result of this fat content, on pelvic examination a dermoid cyst frequently is described as anterior in location. They are bilateral in approximately 10% of cases, although many have advanced the argument against bivalving a normal-appearing contralateral ovary because of the risk of adhesions, which may result in infertility. **An ovarian cystectomy is almost always possible, even if it appears that only a small amount of ovarian tissue remains.** Preserving a small amount of ovarian cortex in a young patient with a benign lesion is

![Figure 14.20](image-url)
preferable to the loss of the entire ovary (223). Laparoscopic cystectomy often is possible, and intraoperative spill of tumor contents is rarely a cause of complications (224,225).

The risk of epithelial tumors increases with age. Although serous cystadenomas are often considered the more common benign neoplasm, in one study, benign cystic teratomas represented 66% of benign tumors in women younger than 50 years of age; serous tumors accounted for only 20% (207). **Serous tumors are generally benign; 5% to 10% have borderline malignant potential, and 20% to 25% are malignant.** Serous cystadenomas are often multilocular, sometimes with papillary components. The surface epithelial cells secrete serous fluid, resulting in a watery cyst content. Psammoma bodies, which are areas of fine calcific granulation, may be scattered within the tumor and are visible on radiograph. A frozen section is necessary to distinguish between benign, borderline, and malignant serous tumors because this distinction cannot be made on gross examination alone. Mucinous ovarian tumors may grow to large dimensions. Benign mucinous tumors typically have a lobulated, smooth surface, are multilocular, and may be bilateral in up to 10% of cases. Mucoid material is present within the cystic loculations (Fig. 14.21). **Five to ten percent of mucinous ovarian tumors are malignant.** They may be difficult to distinguish histologically from metastatic gastrointestinal malignancies. Other benign ovarian tumors include fibromas (a focus of stromal cells), Brenner tumors (which appear grossly similar to fibromas and which are frequently found incidentally), and mixed forms of tumors, such as the cystadenofibroma (Fig. 14.22).

**Other Adnexal Masses**

Masses that include the fallopian tube are related primarily to inflammatory causes in the reproductive age group. A tubo-ovarian abscess can be present in association with PID (see Chapter 16). In addition, a complex inflammatory mass consisting of bowel, tube, and ovary may be present without a large abscess cavity. Ectopic pregnancies can occur in the reproductive age group and must be excluded when a patient presents with pain, a positive pregnancy test, and an adnexal mass (see Chapter 18). Paraovarian cysts may be noted either on examination or on imaging studies. In many instances, a normal ipsilateral ovary can be visualized using ultrasonography. The frequency of malignancy in paraovarian tumors is quite low and may be more common in paraovarian masses larger than 5 cm (225,226).
Diagnosis

A complete pelvic examination, including rectovaginal examination and Pap test, should be performed. *Estimations of the size of a mass should be presented in centimeters* rather than in comparison to common objects or fruit (e.g., orange, grapefruit, tennis ball, golf ball). After pregnancy has been excluded, one simple office technique that can help determine whether a mass is uterine or adnexal includes sounding and measuring the depth of the uterine cavity. Diagnosis of uterine leiomyomas usually is based on the characteristic finding of an irregularly enlarged uterus. The size and location of the usually multiple leiomyomas can be confirmed and documented with pelvic ultrasonography (Fig. 14.23). If the examination is adequate to confirm uterine leiomyoma and symptoms are absent, ultrasonography is not always necessary unless an ovarian mass cannot be excluded.
Other Studies  Endometrial sampling with an endometrial biopsy or D & C is mandatory when both pelvic mass and abnormal bleeding are present. An endometrial lesion—carcinoma or hyperplasia—may coexist with a benign mass such as a leiomyoma. In a woman with leiomyomas, abnormal bleeding cannot be assumed to be caused solely by the fibroids. Clinicians differ in recommendations about the need for endometrial biopsy when the diagnosis is leiomyomas with regular menses.

If urinary symptoms are prominent, studies of the urinary tract may be necessary, including cystometric measurements if incontinence or pressure are present. Cystoscopy may sometimes be necessary or appropriate to rule out intrinsic bladder lesions.

Laboratory Studies  Laboratory studies that are indicated for women of reproductive age with a pelvic mass include pregnancy test, cervical cytology, complete blood count, erythrocyte sedimentation rate, and testing of stool for occult blood. The value of tumor markers, such as CA125 in a premenopausal woman with a pelvic mass, has been widely debated. A number of benign conditions, including uterine leiomyomas, PID, pregnancy, and endometriosis can cause elevated CA125 levels; thus, measurement of CA125 levels is not useful in most circumstances because it may lead to unnecessary surgical intervention.

Imaging Studies  Other studies may be necessary or appropriate. The most commonly indicated study is pelvic ultrasonography, which will help document the origin of the mass to determine whether it is uterine, adnexal, bowel, or gastrointestinal. The ultrasonographic examination also provides information about the size of the mass and its consistency—unilocular cyst, mixed echogenicity (Fig. 14.24), multiloculated cyst, solid mass (Fig. 14.25)—which can help determine management.

The value of transvaginal and transabdominal ultrasonography in the diagnosis of pelvic masses has been compared. Transvaginal ultrasonography has the advantage of providing additional information about the internal architecture or anatomy of the mass. Heterogeneous pelvic masses, described as tub-oovarian abscesses on transabdominal

![Figure 14.24 Transvaginal ultrasonogram of a unilocular ovarian cyst. This is characteristic of a benign process or corpus luteum cyst.](image-url)
ultrasonography, can with transvaginal ultrasonography be differentiated as pyosalpinx, hydrosalpinx, tubo-ovarian complex, and tubo-ovarian abscess (101) (Fig. 14.26).

The diagnostic accuracy of transvaginal ultrasonography in diagnosing endometrioma can be quite high (Fig. 14.27). Endometriomas can have a variety of ultrasonographic appearances, from purely cystic, to varying degrees of complexity with septation or debris, to a solid appearance. A variety of scoring systems have been developed with the
intent of predicting benign versus malignant adnexal masses; the ultrasonographic characteristics used in many types of scoring systems are listed in Table 14.8 (227–229). Risk of malignancy indices have been developed that use ultrasound characteristics in conjunction with menopausal status and CA125 values in an attempt to predict the risk of malignancy in ovarian masses (230–232). Although an analysis of such features may be helpful, histologic confirmation of surgically removed persistent masses remains the standard of care (233).

Computed tomography seldom is indicated as a primary diagnostic procedure, although it may be helpful in planning treatment when a malignancy is strongly suspected or when a nongynecologic disorder may be present. Abdominal flat-plate radiography is not a primary diagnostic procedure, although if used for other indications, it may reveal calcifications that can assist in the discovery or diagnosis of a mass. Pelvic calcifications (teeth) consistent with a benign cystic teratoma (Fig. 14.28), a calcified uterine fibroid, or scattered calcifications consistent with psammoma bodies of a papillary serous cystadenoma can be seen with abdominal radiography.

Ultrasoundography, CT imaging, or an intravenous pyelography may be appropriate to demonstrate ureteral deviation, compression, or dilation in the presence of moderately large and laterally located fibroids or other pelvic mass. Such findings rarely provide an indication for surgical intervention for otherwise asymptomatic leiomyomas.

**Hysteroscopy provides direct evidence of intrauterine pathology or submucous leiomyomas that distort the uterine cavity** (see Chapter 21). Hysterosalpingography will demonstrate indirectly the contour of the endometrial cavity and any distortion or obstruction of the uterotubal junction secondary to leiomyomas, an extrinsic mass, or peritubal adhesions. The techniques combining hysterosalpingography, in which fluid is instilled into the uterine cavity, with transvaginal ultrasonography have been helpful in the diagnosis of intrauterine pathology. Hysterosalpingography or sonohysterography may be indicated in women with infertility and uterine leiomyoma (195).

Magnetic resonance imaging may be most useful in the diagnosis of uterine anomalies, although its value rarely justifies the increased cost of the procedure over ultrasonography for the diagnosis of other pelvic masses (234–236).
Management

The management of a pelvic mass is based on an accurate diagnosis. An explanation of this diagnosis should be conveyed to the patient, along with a discussion of the likely course of the disease (e.g., growth of uterine leiomyomas, regression of fibroids at menopause, regression of a follicular cyst, the uncertain malignant potential of an ovarian mass). All options for management should be presented and discussed, although it is appropriate for the physician to state a recommended approach with an explanation of the reasons for the recommendation. Management should be based on the primary symptoms and may include observation with close follow-up, temporizing surgical therapies, medical management, or definitive surgical procedures.

Leiomyomas

The management of uterine leiomyomas is dependent on the patient’s age and proximity to anticipated menopause, symptoms, patient preference, and the experience and skills of the clinician. Variability in reporting data regarding severity of symptoms, uterine anatomy, and response to therapy make it difficult to compare different types of therapies, which include observation, medical, surgical, and radiologic-based techniques difficult (151,237).

Nonsurgical Management

Judicious patient observation and follow-up are indicated primarily for uterine leiomyomas; intervention is reserved for specific indications and symptoms (171). Periodic examinations are indicated to ensure that the tumors are not growing rapidly. Uterine size should be recorded on the patient’s chart, and the location of palpable and ultrasonographically localized leiomyomas should be described and diagramed.

The use of GnRH agonists results in a 40% to 60% decrease in uterine volume and can be of value in some clinical situations. Treatment results in hypoestrogenism, which has been associated with reversible bone loss and symptoms such as hot flashes. Thus, treatment has been limited to short-term use, although low-dose hormonal therapy may be effective in

Figure 14.28 Benign cystic teratoma (dermoid cyst) of the ovary with teeth seen on abdominal radiograph.
minimizing the hypoestrogenic effects. Regrowth of leiomyomas is experienced within a few months after stopping therapy in about one half of women treated. Some indications for the use of GnRH agonists in women with leiomyomas are as follows:

1. Preservation of fertility in women with large leiomyomas before attempting conception or preoperative treatment before myomectomy
2. Treatment of anemia to allow recovery of normal hemoglobin levels before surgical management, minimizing the need for transfusion or allowing autologous blood donation
3. Treatment of women approaching menopause in an effort to avoid surgery
4. Preoperative treatment of large leiomyomas to make vaginal hysterectomy, hysteroscopic resection or ablation, or laparoscopic destruction more feasible
5. Treatment of women with medical contraindications to surgery
6. Treatment of women with personal or medical indications for delaying surgery

Therapies combining GnRH agonists with estrogen add-back therapy (estrogen–progestin, progestin alone, and recently tibolone) have shown promise in reducing side effects of agonist therapy alone, although this therapy is a costly alternative (238,239). Tibolone, a synthetic steroid with estrogenic, progestational, and androgenic activity, has been widely used outside the United States for treatment of menopausal symptoms; its use with GnRH agonists as add-back therapy holds promise for longer-term therapy of leiomyoma (240). Selective estrogen or progesterone receptor modulators, GnRH antagonists, antiprogestins such as mifepristone, and other nonhormonal medications hold promise for future therapy and are under investigation (241–243). As the role of growth factors in leiomyoma-associated bleeding is better elucidated, treatment targeted at the growth factor or its receptor may prove useful. In addition, as the molecular biology and genetics of leiomyoma are better understood, newer nonsurgical therapies may be developed.

Surgical Therapy Determining potential indications for surgical treatment requires careful judgment and assessment of the degree of associated symptoms. Asymptomatic leiomyomas do not usually require surgery. Potential indications for surgery include the following:

1. Abnormal uterine bleeding with resultant anemia, unresponsive to hormonal or other conservative management
2. Chronic pain with severe dysmenorrhea, dyspareunia, or lower abdominal pressure or pain
3. Acute pain, as in torsion of a pedunculated leiomyoma or prolapsing submucosal fibroid
4. Urinary symptoms or signs such as hydronephrosis after complete evaluation
5. Infertility with leiomyomas as the only abnormal finding
6. Recurrent pregnancy loss with distortion of the endometrial cavity
7. Markedly enlarged uterine size with compression symptoms or discomfort

Rapid enlargement of the uterus during the premenopausal years or any increase in uterine size in a postmenopausal woman have been suggested as indications for surgery because
of the inability to exclude uterine sarcoma. Although the absolute risk of uterine sarcomas developing in a fibroid uterus has been reported to be less than 2 to 3 per 1,000, one study found sarcomas to be no more common in women with rapid uterine growth than those without such growth (244). However, rapid enlargement has not been well defined, and serial measurements may be hampered by variations in the interpretation of size by the examiner or series of examiners. A high level of suspicion of pelvic malignancy has been listed as among the indications for surgery, as has growth of leiomyoma after menopause (195).

Hysterectomy has long been viewed as the definitive management of symptomatic uterine leiomyomas (see Chapter 22). Myomectomy is an alternative to hysterectomy for patients who desire childbearing, who are young, or who prefer that the uterus be retained. Recent studies suggest that the morbidity of abdominal myomectomy and hysterectomy are similar, although previous reports had suggested higher risks for myomectomy, including the risks of hemorrhage and transfusion requirements (245,246). Blood loss and risk of transfusion are greater for women with larger uteri (247). Laparoscopic myomectomy minimizes the size of the abdominal incision, although several small incisions are required. The biggest concerns with laparoscopic myomectomy include the removal of large myomas through small incisions and the repair of the uterus (171). Instruments that efficiently morcellate the myomas have been developed, although skilled surgical techniques are required. There is controversy as to whether laparoscopic suturing provides strength and healing equivalent to that achieved with laparotomy. Risks include the need to convert to a laparotomy and the risk of uterine rupture with subsequent pregnancy (171). Vaginal myomectomy is indicated in the case of a prolapsed pedunculated submucous fibroid. Hysteroscopic resection of small submucous leiomyomas is a technique that may offer benefits for a selected group of patients (see Chapter 21). The risk of recurrence for leiomyomas has been reported to be as high as 50% after myomectomy, with up to one third requiring repeat surgery (196,248). Endometrial ablation can decrease bleeding for women with primary intramural fibroids and can be performed using a variety of techniques, including laser ablation, thermal ablation, resection, or chemical destruction (171).

The preoperative use of GnRH agonists for both hysterectomy and myomectomy results in a decrease in uterine size. The expense, side effects, and time required to achieve a significant decrease in size are limitations to their use. The use of GnRH agonists may make surgical plans less distinct and thus myomectomy technically more difficult.

Nonextirpative approaches to the management of leiomyomas include myolysis, MRI-directed focused ultrasonography, and uterine artery embolization, although long-term safety and efficacy of these methods have not yet been demonstrated. Myolysis or ablation can be performed with the use of lasers, radiofrequency, needle electrodes, cryoprobes, focused ultrasonography directed by MRI, ultrasonography, or laparoscopy (249).

Uterine artery embolization has been reported to provide short-term relief of bulk-related and bleeding symptoms of leiomyoma, although serious consequences, including infection, massive bleeding, and necrosis requiring emergency surgery have been reported (172,250). Pain is frequently a consequence, and patients should be well informed about possible complications (251). The procedure has been characterized as investigational (171).

Ovarian Masses

The now-routine application of ultrasound technology to gynecologic examinations has led to the more frequent detection of ovarian cysts. Ultrasonography is a relatively easy diagnostic study to perform, but this ease has led to the labeling of physiologic ovarian...
morphology, cystic follicles, as pathologic and the subsequent referral of patients for therapies, including surgery, without indications. Treatment of ovarian masses that are suspected to be functional tumors is expectant. A number of randomized prospective studies have shown no acceleration of the resolution of functional ovarian cysts (which were associated with the use of clomiphene citrate or human menopausal gonadotropins) with oral contraceptives compared with observation alone (212,252,253). However, oral contraceptives are effective in reducing the risk of subsequent ovarian cysts and may be appropriate for women who desire both contraception and their noncontraceptive benefits.

Symptomatic cysts should be evaluated promptly, although mildly symptomatic masses suspected to be functional should be managed with analgesics rather than surgery to avoid the development of adhesions that may impair subsequent fertility. Surgical intervention is warranted in the presence of severe pain or the suspicion of malignancy or torsion. On ultrasonography, large cysts and those that have multiloculations, septa, papillae, and increased blood flow should be suspected of neoplasia. If a malignant mass is suspected at any age, exploratory laparotomy should be performed promptly.

Ovarian or adnexal torsion is suspected on the basis of peritoneal signs and the acuity of onset. Doppler flow studies suggesting abnormal flow are highly predictive of torsion (254). The absence of internal ovarian flow is not specific to torsion and may be seen with cystic lesions, although in these situations peripheral flow usually can be visualized (255). Visualization of a twisted vascular pedicle has also been shown to be highly predictive (256). Normal flow does not exclude torsion, and in one study 60% of surgically confirmed cases of torsion had normal Doppler flow (257).

The management of suspected ovarian torsion, which can occur at any age from prepubertal to postmenopausal, is surgical. When torsion is confirmed by laparoscopy, untwisting of the mass and ovarian preservation rather than extirpation are generally indicated (258,259) This management is particularly important in prepubertal and young women (260). The value of oophoropexy in preventing recurrent torsion is not well established.

Ultrasonographic or CT-directed aspiration procedures of ovarian masses should not be used in women in whom there is a suspicion of malignancy. In the past, laparoscopic surgery for ovarian masses has been reserved for diagnostic or therapeutic purposes in patients at very low risk for malignancy. Although it is feasible to perform laparoscopic surgical staging and treatment of ovarian low-malignant-potential tumors and early-stage ovarian cancer safely, the role of laparoscopy versus laparotomy in a woman with ovarian cancer has been debated (261). Concerns related to laparoscopy in managing gynecologic malignancy include the accuracy of intraoperative diagnosis, inadequate resection, significance of tumor spillage, inaccurate or delayed surgical staging, delay in therapy, and the possibility of port-site metastasis. In laparoscopic oophorectomy for presumed benign disease, there is a possibility of a missed diagnosis of malignancy, which would necessitate reexamination, even with frozen section. Whether laparoscopic management results in long-term compromise of outcome is unclear; thus, the laparoscopic management of complex masses that may be malignant remains controversial (262–264).

The management of presumed benign ovarian masses with operative laparoscopy is now common (Fig. 14.29), although complication rates are higher with complicated operative laparoscopy procedures such as those required for extensive endometriosis (265,266). The choice of surgical approach (laparotomy or laparoscopy) should be based on the surgical indications, the patient’s condition, the surgeon’s expertise and training, informed patient preference, and the most recent data supporting the chosen approach. The clear advantage of this technique is the shorter hospital stay, shorter recovery time, and lessened postoperative pain (265). Surgical complications include bowel
injury, ureteral or other urinary tract injury, cannula site vessel injury, or incisional hernia (267). In one series the overall complication rate was 13.3% (267). Randomized clinical trials evaluating laparoscopy versus laparotomy in the treatment of ovarian masses have been performed and typically demonstrate a shorter hospitalization time with less postoperative pain and a shorter recovery period (224,268,269).

The role of laparoscopy has been even more controversial in the removal of dermoid cysts than with other benign masses. Concern focuses on prevention of spill of the cyst contents. Randomized clinical trials have been reported with variable findings regarding spill: some studies suggest that cyst contents are more likely to spill with laparoscopy, whereas others do not find a difference or note no increase in morbidity when spillage occurred (270–272). Culdotomy and the use of an endoscopic specimen bag have been associated with lower rates of tumor spillage (272,273).

**Vulvar Conditions**

In postmenarchal individuals, vulvar symptoms are most often related to a primary vaginitis and a secondary vulvitis. The mere presence of vaginal discharge can lead to vulvar irritative symptoms, or candidal vulvitis may be present (Fig. 14.30). The causes of vaginitis and cervicitis are covered in Chapter 16. Adult women describe vulvar symptoms using a variety of terms (itching, pain, discharge, discomfort, burning, external dysuria, soreness, pain with intercourse or sexual activity). **Burning with urination from noninfectious causes may be difficult to distinguish from a urinary tract infection, although some women can distinguish pain when the urine hits the vulvar area (an external dysuria) from burning pain (often suprapubic in location) during urination.** Itching is a very common vulvar symptom. A variety of vulvar conditions and lesions can present with pruritus. As in adolescents, vulvovaginal symptoms may be caused by STDs, nonsexually transmitted vaginitis, or UTI. The distinction between symptoms related to a UTI and those of vaginitis is difficult, and consideration should be given to testing for both *C. trachomatis* and obtaining a urine culture, particularly in young reproductive-age women (125).
A number of skin conditions that occur on other areas of the body may occur on the vulvar area. Table 14.9 contains a list of these conditions classified by either infectious or noninfectious causes. Whereas the diagnosis of some of these conditions is apparent from inspection alone (e.g., a skin tag) (Fig. 14.31), any lesions that appear atypical or in which the diagnosis is not clear should be analyzed by biopsy, as the risks of malignant lesions increases with age.

Pigmented vulvar lesions include benign nevi (Fig. 14.32), lentigines, melanosis, seborrheic keratosis, condyloma, and some vulvar intraepithelial neoplasias (VIN), especially multifocal VIN 3. **Suspicious pigmented vulvar lesions in particular should warrant biopsy to rule out VIN or malignant melanoma** (274). Approximately 10% of white women have a pigmented vulvar lesion; some of these lesions may be malignant (see Chapter 36) or have the potential for progression (VIN) (see Chapter 17). There has been an increase in rates of VIN in women younger than age 50, along with increasing rates of vulvar squamous cell carcinoma in situ, possibly related to increasing rates of human papillomavirus infection. Heightened awareness among clinicians may play a role in the increasing frequency of diagnosis; suspicious lesions warrant vulvar biopsy.

The behavior of some nevocellular lesions (representing about 2% of nevi) is not well established but has been linked to melanoma (275). Multiple hyperpigmented lesions of typical lentigo simplex and melanosis are common, and any areas with irregular borders should be evaluated by biopsy.

### Vulvar Biopsy

A vulvar biopsy is essential in distinguishing benign from premalignant or malignant vulvar lesions, especially because many types of lesions may have a somewhat similar appearance. Vulvar biopsies should be performed liberally in women of reproductive age to ensure that these lesions are diagnosed and treated appropriately. A prospective study of vulvar lesions evaluated by biopsy in a gynecologic clinic found lesions occurring in the

![Figure 14.31](image-url) **Figure 14.31** Large benign skin tag from left labium majus.
SECTION IV General Gynecology

following order of frequency: epidermal inclusion cyst, lentigo, Bartholin duct obstruction, carcinoma in situ, melanocytic nevi, acrochordon, mucous cyst, hemangiomas, postinflammatory hyperpigmentation, seborrheic keratoses, varicosities, hidradenomas, verruca, basal cell carcinoma, and unusual tumors such as neurofibromas, ectopic tissue, syringomas, and abscesses (276). Clearly, the frequency with which a lesion would be reported after a tissue biopsy is related to the frequency with which all lesions of a given pathology are evaluated in this manner. Thus, this listing probably underrepresents such common lesions as condylomata (see Fig. 14.16).

Biopsy is easily performed in the office using a local anesthetic. Typically, 1% lidocaine is infiltrated beneath the lesion using a small (25- to 27-gauge) needle. Disposable punch biopsy instruments come in a variety of sizes from 2 to 6 mm in diameter. They have the advantage of being sharp and thus facilitate obtaining a good specimen. Sterilizable instruments also are also available and may be a more ecologically sound choice if they can be maintained and sharpened periodically. These skin biopsy instruments, along with fine forceps, scissors, and a scalpel, should be available in all outpatient gynecologic settings. For smaller biopsies, it is usually not necessary to place a suture. Topical silver nitrate can be used for hemostasis. Multiple tissue samples may be appropriate to obtain representative areas of a lesion if the lesion has a variable appearance or is multifocal. Although the vulvar biopsy procedure involves minimal discomfort, the biopsy sites will be painful for several days after the procedure. The prescription of a topical anesthetic such as 2% lidocaine jelly, to be applied periodically and before urinating, is appreciated by patients who require this procedure. Infection of the site can occur, and patients should be cautioned to report excessive erythema or purulent drainage.

Other Vulvar Conditions Classification and description of intraepithelial lesions of the vulva are presented in Chapter 17.

Pseudofolliculitis This is similar to what has been described as pseudofolliculitis barbæ (razor bumps), may occur in women who follow the increasingly popular practice of

Figure 14.32 Pigmented vulvar lesion.
shaving pubic hair (276). **Pseudofolliculitis** consists of an inflammatory reaction surrounding an ingrown hair and occurs most commonly among individuals with curly hair, particularly African Americans.

**Fox-Fordyce Disease**  This condition is characterized by a chronic, pruritic eruption of small papules or cysts formed by keratin-plugged apocrine glands. It is commonly present over the lower abdomen, mons pubis, labia majora, and inner portions of the thighs. **Hidradenitis suppurativa** is a chronic condition involving the apocrine glands with the formation of multiple deep nodules, scars, pits, and sinuses that occur in the axilla, vulva, and perineum. Hyperpigmentation and secondary infection are often seen. Hidradenitis suppurativa can be extremely painful and debilitating. It is often treated with antibiotics (with coverage of both aerobic and anaerobic bacteria). Estrogens or antian- drogen therapy has been attempted; surgical therapy with wide local excision may be necessary. Therapy with isotretinoin and steroids has been reported to be successful (277,278).

**Acanthosis nigricans**  This disease involves widespread velvety pigmentation in skin folds, particularly the axillae, neck, thighs, submammary area, and vulva and surrounding skin (Fig. 14.33). It is of particular interest to gynecologists because of its association with hyperandrogenism and PCOS; as such, it is associated with obesity, chronic anovulation, acne, glucose intolerance, and cardiovascular disease (150,279). Several drugs, including metformin, octreotide, retinoids, and topical cholecalciferol (vitamin D3) analogs, are also beneficial in treating acanthosis nigricans (280).

**Extramammary Paget’s Disease**  This is an intraepithelial neoplasia containing vacuolated Paget’s cells (see Chapter 17). Clinically, it may have an appearance varying from moist, oozing ulcerations to an eczematoid lesion with scaling and crusting, to a grayish lesion (39). A biopsy to confirm the diagnosis is mandatory.
**Vulvar Intraepithelial Neoplasia**  VIN is associated with human papillomavirus infection and is increasing in frequency, particularly among young women (see Chapter 17) (281). Diagnosis requires biopsy of any suspicious vulvar lesions, particularly those that are pigmented or discolored. The increasing frequency of this entity dictates a careful vulvar inspection during annual gynecologic examinations.

**Vulvar Tumors, Cysts, and Masses**

*Condylomata acuminata*  These are very common vulvar lesions and are usually easily recognized and treated with topical therapies such as *trichloracetic* and *bichloracetic acid*. Other sexually transmitted organisms, such as the virus responsible for molluscum contagiosum and the lesions of syphilis and condylomata lata, may occasionally be mistaken for vulvar condylomata acuminata caused by human papillomavirus (see Chapter 16). A summary of benign vulvar tumors is listed in Table 14.10. There is argument regarding whether sebaceous cysts exist on the vulva or whether these lesions are histopathologically epidermal or epidermal inclusion cysts (282). So-called sebaceous cysts are clinically indistinguishable from epidermal inclusion cysts that may result from the burial of fragments of skin after the trauma of childbirth or episiotomy, or that arise from occluded pilosebaceous ducts. These cysts are seldom symptomatic, although if infection develops, incision and drainage may be required.

It has been argued that the commonly cited concept of milk lines extending into the vulva and accounting for lesions of mammarylike anogenital glands (e.g., fibroadenoma, lactating glands) is not supported by observations in human embryos; such studies show that primordia of the mammary glands do not extend beyond the axillary–pectoral area (283). Eccrine or apocrine glands have been suggested as the probable source of these unusual lesions.

</table>
Bartholin Duct Cysts  These are common vulvar lesions. They result from occlusion of the duct with accumulation of mucus and are frequently asymptomatic. Infection of the gland may result in the accumulation of purulent material, with the formation of a rapidly enlarging, painful, inflammatory mass (a Bartholin abscess). An inflatable bulb-tipped catheter has been described by Word and is quite easy to use (284). The small catheter is inserted through a small stab wound into the abscess after infiltration of the skin with local anesthesia; the balloon of the catheter is inflated with 2 to 3 mL of saline and the catheter remains in place for 4 to 6 weeks, allowing epithelialization of a tract and the creation of a permanent gland opening.

Skene’s Duct Cysts  These are cystic dilations of the Skene glands, typically located adjacent to the urethral meatus within the vulvar vestibule. Although most are small and often asymptomatic, they may enlarge and cause urinary obstruction, requiring excision.

Painful Intercourse  Painful intercourse (dyspareunia) may be caused by many different vulvovaginal conditions, including common vaginal infections and vaginisms (see Chapters 11 and 15). A careful sexual history is essential, as is a careful examination of the vulvar area and vagina. Vulvodynia is the term used to describe unexplained vulvar pain, sexual dysfunction, and the resultant psychological disability (285). The term vulvar vestibulitis has been used to describe a situation in which there is pain during intercourse, primarily during entry (286–288). The condition is characterized by tender areas surrounding the vulvar vestibule and hymenal ring (see Chapter 15). A number of recent studies have failed to demonstrate a consistent relationship with any genital infectious organism, including C. trachomatis, gonorrhea, Trichomonas, mycoplasma, Ureaplasma, Gardnerella, candida, or human papillomavirus (289–291). Although the symptoms of dyspareunia with insertion can be disabling, no curative therapies have been found. Both medical and behavioral therapies are of some benefit, and although some authors encourage surgery, this treatment is controversial (292,293). The visible lesion of vestibular papillomatosis may be a nonspecific response to discharge or inflammation.

Vulvar Ulcers  A number of STDs can cause vulvar ulcers, including herpes simplex virus, syphilis, lymphogranuloma venereum, and granuloma inguinale (see Chapter 16). Crohn’s disease can include vulvar involvement with abscesses, fistulae, sinus tracts, fenestrations, and other scarring. Although medical treatment with systemic steroids and other systemic agents is the mainstay of therapy, surgical therapy of both intestinal and vulvar disease may be required.

Behçet’s Disease  This condition is characterized by genital and oral ulcerations with ocular inflammation (294). The cause and the most effective therapy are not well established (295).

Lichen Planus  This condition causes oral and genital ulcerations. Typically, there is desquamative vaginitis with erosion of the vestibule. Treatment is based on the use of both topical and systemic steroids. Plasma cell mucositis appears as erosions in the vulvar area, particularly the vestibule. Biopsy is essential in establishing the diagnosis.

Vaginal Conditions  Vaginal discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis to cervical carcinoma may cause vaginal discharge. Infectious vaginal conditions are addressed more completely in Chapter 16. Vaginal lesions may occasionally be palpable to a woman. More commonly, vaginal lesions are discovered on examination by a clinician. They may contribute to symptoms (such as bleeding or discharge), or they may be entirely asymptomatic.
Vaginitis, cervicitis, and vaginal or cervical lesions (including malignancies) can be causes of vaginal discharge. Other noninfectious causes of discharge are as follows:

1. Retained foreign body—tampon, pessary
2. Ulcerations—tampon-induced, lichen planus, herpes simplex infection
3. Malignancy—cervical, vaginal

Some vaginal lesions are asymptomatic and are noted incidentally on examination. Fibroepithelial polyps consist of polypoid folds of connective tissue, capillaries, and stroma covered by vaginal epithelium. Although they can be excised easily in the office, their vascularity can be troublesome, and excision is not necessary unless the diagnosis is in question. Cysts of embryonic origin can arise from mesonephric, paramesonephric, and urogenital sinus epithelium. Gartner’s duct cysts are of mesonephric origin and are usually present on the lateral vaginal wall. They rarely cause symptoms and, therefore, do not require treatment. Other embryonic cysts can arise anterior to the vagina and beneath the bladder. Cysts that arise from the urogenital sinus epithelium are located in the area of the vulvar vestibule. Vaginal adenosis, the presence of epithelial-lined glands within the vagina, has been associated with in utero exposure to diethylstilbestrol. No therapy is necessary, other than close observation and periodic palpation to detect nodules that may need to be evaluated by biopsy to rule out vaginal clear cell adenocarcinoma (see Chapter 34).

Women will sometimes describe a bulging lesion of the vagina and vulvar area, variably associated with symptoms of pressure or discomfort. The most common cause of such a lesion is one of the disorders of vaginal support: cystocele, rectocele, or urethrocele. Management of these conditions is discussed in Chapter 24. Other genital lesions, such as urethral diverticula or occasionally embryonic cysts, may cause similar symptoms.

Postmenopausal Age Group

Abnormal Bleeding

Differential Diagnosis

The causes of postmenopausal bleeding and the percentage of patients who seek treatment for different conditions are presented in Table 14.11.

Benign Disorders

Women who are taking hormone therapy during menopause may be using a variety of hormonal regimens that can result in bleeding (see Chapter 32). Because unopposed estrogen therapy can result in endometrial hyperplasia, various regimens of progestins are typically added to the estrogen regimen; they may be given in a continuous or periodic fashion (296). It has been suggested that endometrial sampling is indicated for any unexpected bleeding that occurs with hormonal therapy. A significant change in withdrawal bleeding or breakthrough bleeding (e.g., absence of withdrawal bleeding for several months followed by resumption of bleeding or a marked increase in the amount of bleeding) should prompt endometrial sampling.

Patient compliance has been a significant issue with hormone therapy. Missed doses of medication and failure to take the medication in the prescribed fashion can lead to irregular bleeding or spotting that is benign in origin but that can result in patient dissatisfaction (297).

The problems that women most often report with hormone therapy include vaginal bleeding and weight gain. The use of a continuous low-dose combined regimen has the advantage that for many women, bleeding will ultimately cease after several months, during which irregular and unpredictable bleeding may occur (298). Some women are unable to tolerate these initial months of irregular bleeding. The risk of endometrial hyperplasia or neoplasia with this regimen appears to be low.

Other benign causes of bleeding include atrophic vaginitis as well as endometrial and cervical polyps, which may become apparent as postcoital bleeding or spotting. Women who experience bleeding after menopause may attempt to minimize the extent of the problem; they may describe only “spotting” or “pink or brownish discharge.” However, any indication of bleeding or spotting should be evaluated. In the absence of hormone therapy, any bleeding after menopause (classically defined as absence of menses for 1 year) should prompt evaluation with endometrial sampling. At least one fourth of postmenopausal women with bleeding have a neoplastic lesion. Endometrial polyps and other abnormalities can be seen in women who are taking tamoxifen. These polyps are more likely to involve cystic dilation of glands, stromal condensation around the glands, and squamous metaplasia of the overlying epithelium (299). These polyps can be benign, although they must be distinguished from endometrial malignancies, which may also occur with this medication. The incidence of endometrial polyps not associated with tamoxifen increases with age during the reproductive years; it is not clear, however, whether the incidence subsequently peaks or decreases during the postmenopausal years (151). Endometrial polyps are more likely to be malignant in postmenopausal women, and hypertension has been associated with an increased risk of malignancy (159).

Neoplasia

Endometrial, cervical, and ovarian malignancies must be ruled out in the presence of postmenopausal bleeding. A Pap test is essential when postmenopausal bleeding is noted, although the Pap test is an insensitive diagnostic test for detecting endometrial cancer. The Pap test results are negative in some cases of invasive cervical carcinoma because of tumor necrosis.

Cervical malignancy is diagnosed by cervical biopsy of grossly visible lesions and colposcopically directed biopsy for women with abnormal Pap test results (see Chapter 17). Functional ovarian tumors may produce estrogen and lead to endometrial hyperplasia or carcinoma, which may cause bleeding.

Diagnosis

Pelvic examination to detect local lesions and a Pap test to assess cytology are essential first steps in finding the cause of postmenopausal bleeding. Pelvic ultrasonographic examination
and, in particular, vaginal ultrasonography or sonohysterography can suggest the cause of bleeding (300,301). Endometrial sampling, through office biopsy, hysteroscopy, or D & C, is usually considered essential. Initial biopsy done in the office is more cost-effective than D & C, surgery, or observation alone (302). The cost-effectiveness of other screening strategies, including transvaginal ultrasonography or sonohysterography, has not been well studied. It has been suggested that an endometrial thickness of less than 6-10 mm measured by transvaginal ultrasonography is unlikely to indicate endometrial cancer. A meta-analysis of studies comparing endometrial pathology with ultrasonography findings suggested that an endometrial thickness of less than 6 mm essentially excludes malignancy (303).

**Management**

**Benign Disorders**  The management of bleeding caused by atrophic vaginitis includes topical or systemic use of estrogens after other causes of abnormal bleeding have been excluded. Cervical polyps can easily be removed in the office.

**Endometrial Hyperplasia**  The terminology used to describe endometrial hyperplasia is confusing, and the clinician must consult with the pathologist to ensure an understanding of the diagnosis. The following lesions are considered to be benign: anovulatory, proliferative, cystic glandular hyperplasia, simple cystic hyperplasia, simple hyperplasia, and adenomatous hyperplasia without atypia. These terms reflect and describe an exaggerated proliferative response of the endometrium. In most cases, benign endometrial hyperplasia is resolved with D & C or progestin therapy. Repeat surveillance with endometrial biopsy may be warranted.

The presence of atypia with abnormal proliferation, including features of back-to-back crowding of the glands with epithelial activity demonstrated by papillary projections into the glands, is associated with an increased risk of progression to endometrial carcinoma. These architectural abnormalities may be associated with individual cellular atypia (enlarged, irregular nuclei, chromatin clumping, and prominent nucleoli). The presence of mitotic activity also can be variable.

The management of endometrial hyperplasia is based on an understanding of the natural history of the lesion involved. In one study, only 2% of 122 patients with hyperplasia without cytologic atypia progressed to carcinoma, whereas 23% of those with atypical hyperplasia subsequently developed carcinoma (304). Architectural complexity and crowding appears to place patients at greater risk for progression than does the presence of cytologic atypia alone. Atypical endometrial hyperplasia is considered part of a continuum with endometrial cancer, and there is a concern that the diagnosis remains uncertain as long as the uterus is in situ (183). Hysterectomy is recommended for treatment of atypical endometrial hyperplasia in postmenopausal women.

Data suggest that most women with endometrial hyperplasia without atypia will respond to progestin therapy and are not at increased risk of developing cancer (305). Patients who do not respond are at a significantly increased risk of progressing to invasive cancer and should be advised to have a hysterectomy. Patients who are less likely to respond can be identified on the basis of cytologic atypia. Progestin therapy may be used in women with atypical endometrial hyperplasia who are poor operative candidates, and these women should initially have an endometrial biopsy every 3 months to check for recurrence (183). A suggested scheme of management is outlined in Figure 14.34. This treatment is discussed in more detail in Chapter 33.
Perform D&C to rule out endometrial carcinoma in symptomatic patients

Desire to retain uterus

Provera 10–20 mg/day for 11 to 14 days per month

Repeat endometrial biopsy in 3 to 6 months

Persistent atypical hyperplasia

Trial of high dose progestins (e.g., Provera 40–100 mg/day for 3 months)

Persistent atypical hyperplasia

Hysterectomy

No desire to retain uterus

Hysterectomy

Normal or atrophic endometrium

• Continue Provera 5 mg/day 10 days/month for 12 months
• Consider annual endometrial biopsy
• Ovulation induction if childbearing desired

Figure 14.34 Management of endometrial hyperplasia. (From Berek JS, Hacker NF. Practical gynecologic oncology. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:422, with permission.)
Pelvic Mass

Differential Diagnosis

**Ovarian Masses**  During the postmenopausal years, the ovaries become smaller (219):

1. **Before menopause,** the dimensions are approximately $3.5 \times 2 \times 1.5$ cm.

2. **In early menopause,** the ovaries are approximately $2 \times 1.5 \times 0.5$ cm.

3. **In late menopause,** they are even smaller: $1.5 \times 0.75 \times 0.5$ cm.

The postmenopausal palpable ovary (PMPO) syndrome is based on the concept that any ovary that is palpable on examination beyond menopause is abnormal and deserves evaluation (306); however, this finding has not been shown to be a reliable predictor of malignancy (see Chapter 35). Clearly, body habitus makes a difference in the ease of examination, but a postmenopausal ovary that, on palpation, is comparable in size to a premenopausal ovary is abnormally large. Ovarian cancer is predominantly a disease of postmenopausal women; the incidence increases with age, and the average patient age is about 56 to 60 years (see Chapter 35).

With increased use of pelvic ultrasonographic evaluation, a new problem has arisen in postmenopausal women: the discovery of a small ovarian cyst. This is particularly troublesome in a woman who is entirely asymptomatic and whose ultrasonographic examination was performed for indications unrelated to pelvic pathology. It has been suggested that **when the cyst is asymptomatic, small (less than 5 cm in diameter), unilocular, and thin walled, with a normal CA125 level, the risk of malignancy is extremely low and these masses can be followed conservatively, without surgery** (307,308). Surgery may be indicated in some women with a strong family history of ovarian, breast, endometrial, or colon cancer, or a mass that appears to be enlarging (see Chapter 35). The addition of color flow Doppler examination and other ultrasonographic characteristics may be helpful in distinguishing benign from malignant masses (309,310) (Table 14.8).

**Uterine and Other Masses**  In women who have been receiving regular gynecologic care, the discovery of a new pelvic mass after menopause is worrisome because the likelihood of malignant neoplasm is high if it is an ovarian tumor. Many postmenopausal women have not had regular gynecologic care, however, so the discovery of a mass may reflect the persistence of uterine leiomyoma that had not previously been discovered. Some women may not remember having been told they had a pelvic mass. Thus, a review of medical records may be helpful in determining the preexistence of a benign pelvic mass. Uterine leiomyomas are hormonally responsive and typically decrease in size or resolve after menopause. An increased risk of leiomyomas has been demonstrated with the menopausal use of hormone therapy, and leiomyomas may be less likely to decrease in size or even to increase in size with hormone therapy (151). Other benign masses can occur in this age group, including paraovarian cysts and unusual tumors, such as benign retroperitoneal cysts of müllerian type (311). The risk of leiomyosarcomas increases with age, and benign leiomyoma may coexist with leiomyosarcomas.

**Diagnosis**  A personal and family medical history is helpful in detecting individuals at increased risk for the development of ovarian cancer. Several hereditary family cancer syndromes involve ovarian neoplasms (see Chapter 35). However, **patients with hereditary forms of epithelial ovarian cancer account for only a small percentage of all cases; 90% to 95% of cases of ovarian cancer are sporadic and without identifiable heritable risk.**
In postmenopausal women with a pelvic mass, a CA125 measurement may be helpful in predicting a higher likelihood of a malignancy, which may guide decisions regarding management, consultation, or referral (312). Currently, a high index of suspicion by both women and their clinicians represents the best way to detect early ovarian cancer. Persistent symptoms such as an increase in abdominal size, bloating, fatigue, abdominal pain, indigestion, inability to eat normally, urinary frequency, pelvic pain, constipation, back pain, new onset of urinary incontinence, or unexplained weight loss require evaluation and consideration of the possibility of ovarian cancer. A physical examination, transvaginal ultrasonography, and CA125 measurement are appropriate. A normal CA125 level does not rule out ovarian cancer; up to 50% of early-stage ovarian malignancies and 20% to 25% of advanced cancers have normal values of CA125 (312).

Management

The use of improved imaging techniques may allow the nonoperative management of ovarian masses that are probably benign (Table 14.8). A suspicious or persistent complex mass requires surgical evaluation. A physician trained to appropriately stage and debulk ovarian cancer, such as a gynecologic oncologist, should perform the surgery in a hospital with the necessary support and consultative services to optimize the patient’s outcome (312). When a malignant ovarian mass is discovered and the appropriate operation cannot be performed by the generalist obstetrician–gynecologist, a gynecologic oncologist should be consulted. Comprehensive surgical staging facilitates appropriate therapy and optimizes prognosis.

Vulvar Conditions

Anatomic changes that occur in postmenopausal women include atrophy of the labia majora and increasing prominence of the labia minora. The epithelium of the hymen and vestibule become thin; there is a shift in vaginal cellular maturation in response to estrogen deprivation, with resultant thinning. Although these changes lead to minimal symptoms in most women, external dysuria, pruritus, tenderness, dyspareunia, and bleeding can result from fissuring and excoriations. Because of the risk of VIN and malignancy, suspicious lesions require vulvar biopsy.

Vulvar Dystrophies

Several vulvar conditions occur most commonly in postmenopausal women. Symptoms are primarily itching and vulvar soreness, in addition to dyspareunia.

In the past, numerous terms have been used to describe disorders of vulvar epithelial growth that produce a number of nonspecific gross changes. These terms have included leukoplakia, lichen sclerosus et atrophicus, atrophic and hyperplastic vulvitis, and kraurosis vulvae. The malignant potential of the vulvar dystrophies is less than 5%; at particular risk is the patient with cellular atypia on initial biopsy. The International Society for the Study of Vulvar Diseases (ISSVD) has recommended a classification of vulvar dystrophies (see Chapter 17).

Squamous Hyperplasia

Squamous hyperplasia is seen most often in postmenopausal women but may occur during the reproductive years. Pruritus is the most common symptom. The lesion appears thickened and hyperkeratotic, and there may be excoriation. Squamous hyperplasia tends to be discrete but may be symmetric and multiple. Biopsy is necessary to confirm the diagnosis and to evaluate the presence of atypia and exclude malignancy. The relationship of nonneoplastic epithelial disorders of the vulva to malignancy is controversial.
In managing vulvar symptoms, aggravating factors such as vaginal discharge and environmental factors should be evaluated and managed with local comfort measures and hygiene. Corticosteroid lotions, ointments, and creams are the mainstay of treatment for squamous cell hyperplasia. Medium-potency fluorinated steroids are usually effective in alleviated pruritus; this therapy can be switched to a lower potency hydrocortisone to avoid steroid-induced atrophy that can be associated with prolonged use of fluorinated steroids.

**Lichen Sclerosus**

Lichen sclerosus is the most common white lesion of the vulva. Lichen sclerosus can occur at any age, although it is most common among postmenopausal women and prepubertal girls. The symptoms are pruritus, dyspareunia, and burning. Lichen sclerosus characteristically is associated with decreased subcutaneous fat to the extent that the vulva is atrophic with small or absent labia minora, obliteration of the anatomic landmarks, thin labia majora, and sometimes phimosis of the prepuce. The surface is pale with a shiny, crinkled pattern, often with fissures and excoriation. The lesion tends to be symmetric and often extends to the perineal and perianal areas. The diagnosis is confirmed by biopsy. Invasive cancer has been associated with lichen sclerosus.

Treatment is with an ultrapotent topical steroid such as 0.05% clobetasol. Approximately 80% of patients respond satisfactorily (313). Maintenance therapy is important and may include the use of a lower potency steroid or the use of a topical emollient (314).

**Urethral Lesions**

The urethra and vagina have a common embryonic origin and are steroid-dependent tissues. Urethral caruncles and prolapse of the urethral mucosa are examples of vulvar lesions that may be seen in other age groups, but that occur more commonly among older women. Both conditions can be treated with topical or systemic estrogen preparations. Various vulvar skin lesions, including seborrheic keratoses and cherry hemangiomas (senile hemangiomas), occur more commonly on aging skin.

**Vaginal Conditions**

Up to 40% of postmenopausal women have symptoms of atrophic vaginitis. Symptoms include an external dysuria, pruritus, tenderness, dyspareunia, and bleeding from fissuring or ulcerations. In addition to the clinical findings of a shiny, flat, thin-appearing vaginal mucosa without rugae, microscopic examination of vaginal secretions reveals an increased number of white blood cells. Treatment with local or systemic estrogens effectively manages the symptoms and restores normal pH levels with ongoing therapy. Systemic absorption does occur with topical estrogen therapy, and rates of absorption differ depending on the degree of atrophy. Topical emollients may be helpful if estrogens are not desired or are contraindicated.

Pelvic Pain and Dysmenorrhea

Andrea J. Rapkin
Candace N. Howe

- Acute pelvic pain is rapid in onset, often associated with unstable vital signs and obvious abnormalities on physical examination and laboratory assessment. Improper diagnosis can result in significant morbidity and even mortality.

- Timely and thorough assessment, guided by organ system (reproductive, gastrointestinal, urinary) and type of pathologic category (infection, obstruction, torsion, rupture, neoplasm, pregnancy related) will ensure effective diagnosis and management.

- Chronic pelvic pain is debilitating and can affect all aspects of physical and psychosocial functioning. The complex pathophysiology and symptom presentation is characterized by neurological, psychological, and behavioral alterations. Because of the shared innervation and functional interconnections between the pelvic viscera, somatic structures, and the central nervous system, more than one system is generally involved.

- A caring, supportive, and well-informed multidisciplinary approach is crucial for appropriate diagnosis and successful treatment of chronic pelvic pain.

- A thorough history and physical examination are extremely important to successful management of both chronic and acute pain, although the specific foci of each differ, as do the ancillary laboratory and diagnostic procedures performed to diagnose acute, life-threatening processes as opposed to chronic pain conditions.

Pelvic pain is the most challenging symptom confronting the practitioner. The problems of acute, cyclic, and chronic pelvic pain encompass a large proportion of gynecologic symptoms. The etiology of gynecologic sources of pelvic pain are diverse and can be further complicated by the similar, and sometimes concurrent, symptoms of gastrointestinal, urological, musculoskeletal, and psychological origins.
Definitions

Acute pain is intense and characterized by sudden onset, sharp rise, and short course. Cyclic pain refers to pain that occurs with a definite association to the menstrual cycle. Dysmenorrhea, or painful menstruation, is the most common cyclic pain phenomenon and is classified as primary or secondary on the basis of associated anatomic pathology (1). Chronic pelvic pain has been defined as pain of greater than 6 months in duration, localized to the anatomic pelvis, and severe enough to cause functional disability or necessitating medical care (2,3). Whereas acute pain is often associated with profound autonomic reflex responses, such as nausea, emesis, diaphoresis, and apprehension, obvious autonomic reflex responses are not present in chronic pelvic pain. In addition, acute pelvic pain often is associated with signs of inflammation or infection, such as fever and leukocytosis, which are absent in chronic pain states. The pathophysiology of acute pelvic pain involves mediators of inflammation present in high concentration as a result of infection, ischemia, or chemical irritation (4–6). By contrast, the etiology of chronic pelvic pain often is obscure. Additionally, chronic pain is characterized by physiologic, affective, and behavioral responses that are quite different from those associated with acute pain (7,8). Acute pain, if inadequately treated and repetitive, can set up an environment of chronic neurogenic inflammation, which results in hyperalgesia and allodynia via neuroplastic changes and ultimately contributes to chronic pelvic pain (6,9–11).

Acute Pain

The differential diagnosis of acute pelvic pain is outlined in Table 15.1. Assessing the character of the pain is helpful in creating a differential diagnosis. Rapid onset of pain is most consistent with perforation of a hollow viscus or ischemia. Colic or severe cramping pain is commonly associated with muscular contraction or obstruction of a hollow viscus, such as intestine or uterus, whereas pain perceived over the entire abdomen suggests a generalized reaction to an irritating fluid within the peritoneal cavity such as blood, purulent fluid, or contents of an ovarian cyst.

The viscera are relatively insensitive to pain. The first perception of visceral pain is a vague, deep, poorly localizable sensation associated with autonomic reflex responses; however, once the pain becomes localized, the pain is called referred pain. Referred pain is well localized and superficial. It is appreciated within the nerve distribution or dermatome of the spinal cord segment innervating the involved viscus. The location of the referred pain provides insight into the location of the primary disease process. The innervation of the pelvic organs is outlined in Table 15.2 (12).

Evaluation

In the evaluation of acute pelvic pain, early diagnosis is critical because significant delay increases morbidity and mortality. Central to correct diagnosis is an accurate history (Fig. 15.1). The date and character of the last and previous menstrual periods and the presence of abnormal bleeding or discharge should be ascertained. The menstrual, sexual, and contraceptive history and any history of sexually transmitted conditions and previous gynecologic disorders are important. Pain history should be obtained (2,4,13,14), including how and when the pain started, the presence of gastrointestinal symptoms (eg, anorexia, nausea, vomiting, constipation, obstruction, flatus pattern), urinary symptoms (eg, urgency, frequency, hematuria, or dysuria), and signs of infection (eg, fever, chills). The patient should be questioned about her medical history and any previous surgery.

Abnormal Pregnancy

An ectopic pregnancy is defined as implantation of the fetus in a site other than the uterine cavity (15–20). The diagnosis and treatment of ectopic pregnancy is discussed in Chapter 18 (21–27).

Symptoms

Implantation of the fetus in the fallopian tube produces pain only with acute dilation of the tube. If tubal rupture occurs, localized abdominal pain tends to be temporarily relieved and is replaced by generalized pelvic and abdominal pain as the hemoperitoneum develops. A period of amenorrhea followed by bleeding and pain compose the classic triad of symptoms. A mass in the cul-de-sac may produce an urge to defecate. Referred pain to the right shoulder often develops if the intraabdominal blood collection transverses the right colic gutter and irritates the diaphragm (C-3 to C-5 innervation).

Signs

Abdominal examination is usually notable for tenderness and guarding in one or both lower quadrants. With the development of hemoperitoneum, generalized abdominal distention and rebound tenderness are prominent, and bowel sounds are often decreased. Pelvic examination generally reveals mild tenderness on motion of the cervix. Adnexal tenderness is usually more pronounced on the side of the ectopic pregnancy.

Leaking or Ruptured Ovarian Cyst

Functional cysts (e.g., follicle, corpus luteum) are the most common ovarian cysts and rupture more readily than do benign or malignant neoplasms. The pain associated with rupture of the ovarian follicle at the time of ovulation is called mittelschmerz. The
A small amount of blood leaking into the peritoneal cavity and high concentration of follicular fluid prostaglandins could cause this midcycle pelvic pain. However, the pain is mild or moderate and self-limited, and with an intact coagulation system, hemoperitoneum is unlikely. A hemorrhagic corpus luteum cyst can develop in the luteal phase of the menstrual cycle. Rupture of this cyst can produce either a small amount of intraperitoneal bleeding or frank hemorrhage resulting in significant blood loss and hemoperitoneum. Nonmalignant neoplasms, most commonly cystic teratomas (dermoid cysts) or cystadenomas, as well as inflammatory ovarian masses, such as endometriomas, can also leak or rupture. A history of a dermoid cyst or endometrioma that has not yet undergone surgical extirpation is not uncommon.

**Symptoms**

An ovarian cyst that is not undergoing torsion, rapidly expanding, infected, or leaking does not cause acute pain. **A corpus luteum cyst is the most common cyst to rupture and...**
SECTION IV   General Gynecology

lead to hemoperitoneum. Symptoms of a ruptured corpus luteum cyst are similar to those of a ruptured ectopic pregnancy. The onset of pain is usually sudden and is associated with increasing generalized abdominal pain and occasionally dizziness or syncope if a hemoperitoneum develops. A ruptured endometrioma or benign cystic teratoma (dermoid cyst) produces similar symptoms; however, dizziness and signs of hypovolemia are not present because blood loss is minimal.

Signs
Hypovolemia is present only when there is a hemoperitoneum. The most important sign is the presence of significant abdominal tenderness, often associated with rebound tenderness because of peritoneal irritation. The abdomen can be moderately distended with decreased bowel sounds. On pelvic examination, a mass is often palpable if the cyst is leaking and not completely ruptured. Fever and leukocytosis are rare. The hematocrit is decreased only if active bleeding is present.

Diagnosis
The diagnosis of a ruptured cyst is confirmed by pregnancy test, complete blood count, and ultrasound or culdocentesis. If orthostasis is not present and the peripheral hematocrit levels are relatively normal, a hematocrit of 16% or less of the fluid obtained from the cul-de-sac is usually consistent with leakage of a small amount of blood into the peritoneal fluid and not a hemoperitoneum.

Management
Orthostasis, anemia, or hematocrit of the culdocentesis fluid of greater than 16% suggests hemoperitoneum and usually requires surgical treatment by laparoscopy or laparotomy. Culdocentesis is very helpful in determining the cause of peritonitis: fresh blood suggests a corpus luteum; chocolate “old” blood, an endometrioma; oily sebaceous fluid, a benign teratoma; purulent fluid, pelvic inflammatory disease (PID) or tubo-ovarian abscess. Patients who are not orthostatic or anemic and who have a small amount of blood in the cul-de-sac fluid (culdocentesis fluid hematocrit less than 16%) can often be observed in the hospital, without surgical intervention, or even discharged home from the emergency room after observation.

Torsion of Adnexa

Torsion (twisting) of the vascular pedicle of an ovary, fallopian tube, paratubal cyst, or rarely just a fallopian tube results in ischemia and rapid onset of acute pelvic pain. A benign cystic teratoma is the most common neoplasm to undergo torsion. Because of adhesions, ovarian carcinoma and inflammatory masses rarely are affected by torsion (28). It is also unusual for a normal tube and ovary to torque, although a polycystic ovary can undergo torsion.

Symptoms
The pain of torsion can be severe and constant or, if the torsion is partial and intermittently untwists, intermittent. The onset of the torsion and the symptoms of abdominal pain frequently coincide with lifting, exercise, or intercourse. Autonomic reflex responses are usually present (e.g., nausea, emesis, apprehension).

Signs
On examination, the abdomen is very tender, and localized rebound tenderness can be noted in the lower quadrants. The most important sign is the presence of a large pelvic mass on physical examination. Mild temperature elevation and leukocytosis may accompany the
infarction. The diagnosis must be suspected in any woman with acute pain and unilateral adnexal mass.

**Diagnosis**

The process of torsion occludes the lymphatic and venous drainage of the involved adnexa; therefore, the mass rapidly increases in size and can be palpated on examination or visualized by ultrasound. Ultrasound confirms the presence of a mass.

**Management**

Adnexal torsion must be treated surgically. If the tissue has not infarcted, the adnexa may be untwisted and a cystectomy performed if appropriate. If necrosis has occurred, an oophorectomy was indicated previously. Now, even with a necrotic-appearing ovary, there is evidence that sparing the adnexa can preserve the ovarian hormonal and reproductive function (28, 29). Treatment may be accomplished by laparoscopy or laparotomy, depending on the size of the mass.

**Acute Salpingo-oophoritis**

The management of acute salpingo-oophoritis and PID are discussed in Chapter 16 (30–35).

**Symptoms**

Gonococcal PID is manifested by the acute onset of pelvic pain that increases with movement, fever, purulent vaginal discharge, and sometimes nausea and vomiting. The pain is often associated with a menstrual period, a time when pathogens have ready access to the upper genital tract. Chlamydial salpingo-oophoritis is associated with more insidious symptoms, which can be confused with the symptoms of irritable bowel syndrome.

**Signs**

Direct and rebound abdominal tenderness with palpation are usually notable on examination. **The most important signs of acute salpingo-oophoritis are cervical motion tenderness and bilateral adnexal tenderness.** Evaluation of the pelvis may be difficult because of acute pain, but lack of a discrete mass or masses differentiates acute salpingo-oophoritis from tubo-ovarian abscess or torsion. Often present is leukocytosis, or at least an elevated erythrocyte sedimentation rate (ESR), a nonspecific, although more sensitive, sign of inflammation.

**Diagnosis**

Other origins of pelvic pain such as appendicitis can be mistaken for PID. Laparoscopy can be used to diagnose salpingitis and rule out other causes of pelvic pain; however, it cannot be used for the diagnosis of endometritis, which is usually based on clinical findings.

**Tubo-ovarian Abscess**

Tubo-ovarian abscesses, a sequela of acute salpingitis, are usually bilateral, but unilateral abscess formation can occur. The symptoms and signs are similar to those of acute salpingitis, although pain and fever have often been present for longer than 1 week before presentation to the emergency room. A ruptured tubo-ovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

**Signs**

Tubo-ovarian abscesses can be palpated on bimanual examination as very firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or “point” in the pelvic cul-de-sac.
Diagnosis

The clinical diagnosis of tubo-ovarian abscess can be substantiated by ultrasonography. The differential diagnosis of a unilateral mass includes not only tubo-ovarian abscess but also adnexal torsion, endometrioma, leaking ovarian cyst, and periappendiceal or diverticular abscess. If physical and ultrasound examination results are not definitive, laparoscopy or laparotomy must be performed.

Management

A ruptured tubo-ovarian abscess rapidly leads to diffuse peritonitis evidenced by tachycardia and rebound tenderness in all four quadrants of the abdomen. If the abscess is progressive, hypotension and oliguria ensue, making exploratory laparotomy with resection of infected tissue mandatory (35–37) (see Chapter 16).

Uterine Leiomyomas

Leiomyomas are uterine smooth muscle tumors (see Chapter 14). Discomfort may be present when myomas are intramural, fundal, or encroaching on adjacent bladder, rectum, or supporting ligaments of the uterus. Acute pelvic pain attributable to uterine leiomyomas is rare, however (38). The pain is usually reported as dyspareunia, dysmenorrhea, or noncyclic pelvic pain. However, a recent study showed that fibroids are more likely to cause dyspareunia and noncyclic pelvic pain than dysmenorrhea. The same study did not find an association between worsening pain with increased fibroid volume or number.

Acute pelvic pain can develop if the myoma undergoes degeneration or torsion. Degeneration of myomas occur secondary to loss of blood supply, usually attributable to rapid growth associated with pregnancy. In a nonpregnant woman, degenerating uterine leiomyoma often is misdiagnosed, frequently being confused with subacute salpingo-oophoritis. A pedunculated subserosal leiomyoma can undergo torsion ischemic necrosis; when this situation occurs, it is associated with pain similar to that of adnexal torsion. When a submucous leiomyoma becomes pedunculated, the uterus contracts forcefully as if to expel a foreign body, and the resulting pain is similar to that of labor. The cramping pain is usually associated with hemorrhage.

Signs

Abdominal examination reveals an irregular solid mass or masses arising from the uterus. If degeneration occurs, the inflammation can cause abdominal tenderness in response to palpation and mild localized rebound tenderness. Elevation of temperature and leukocytosis also can occur.

Diagnosis and Management

Ultrasound is useful in distinguishing adnexal from uterine etiology of an eccentric mass. However, if fever is present, it is important to rule out tubo-ovarian abscess. Degeneration of a leiomyoma is treated with observation and pain medication. A pedunculated, torqued, subserosal leiomyoma can easily be excised laparoscopically; however, surgery is not mandatory. A submucous leiomyoma with pain and hemorrhage should be excised transcervically, with hysteroscopic guidance if needed.

Endometriosis

Women with endometriosis often experience dysmenorrhea, dyspareunia, and dyschezia. These women often have a history of luteal phase bleeding or infertility. Acute pain attributable to endometriosis is usually premenstrual and menstrual; however, if nonmenstrual acute generalized pain occurs, a ruptured endometrioma (chocolate endometriotic cyst within the ovary) should be considered.
The management of endometriosis is discussed in Chapter 29.

**Diagnosis**

The abdomen is often tender in the lower quadrants. Significant distention or rebound tenderness is usually not present. Pelvic examination often reveals a fixed, retroverted uterus with tender nodules in the uterosacral region or thickening of the cul-de-sac. An adnexal mass, if present, usually is fixed to the broad ligament and cul-de-sac. In a patient who has an established diagnosis of endometriosis or who has recently been treated surgically for the disease, a trial of ovarian hormonal suppression (pseudomenopause) can be used to treat the condition and to confirm the correlation between the current pain and the underlying diagnosis of endometriosis.

**Gastrointestinal Tract**

**Appendicitis**

The most common intestinal source of acute pelvic pain in women is appendicitis. Lifetime incidence in the United States is 7%, and it is the most common cause of emergent abdominal surgery (39). The symptoms and signs of appendicitis can be similar to those of PID. The first symptom of appendicitis is typically diffuse abdominal pain, especially periumbilical pain, followed by anorexia, nausea, and vomiting. Within a matter of hours, the pain generally shifts to the right lower quadrant. Fever, chills, emesis, and obstipation may ensue. However, this classic symptom pattern is often absent. Atypical abdominal pain can occur when the appendix is retrocecal or entirely within the true pelvis (which occurs in 15% of the population) (39). In this setting, tenesmus and diffuse suprapubic pain may occur. The patient with appendicitis is more likely to have pronounced and persistent gastrointestinal symptoms than the patient with salpingo-oophoritis.

**Signs**

Local tenderness is usually elicited on palpation of the right lower quadrant (McBurney point). The appearance of severe generalized muscle guarding, abdominal rigidity, rebound tenderness, right-sided mass, tenderness on rectal examination, positive psoas sign (pain with forced hip flexion or passive extension of hip), and obturator signs (pain with passive internal rotation of flexed thigh) indicates appendicitis. A low-grade fever is generally present, but the temperature may be normal. High temperatures are typically seen with appendiceal perforation. The pelvic examination usually does not disclose cervical motion or bilateral adnexal tenderness, but right-sided unilateral adnexal tenderness can be present.

**Diagnosis**

Many patients with acute appendicitis have normal total leukocyte counts; however, a left shift is usually revealed in the evaluation. Findings of ultrasound examination of the pelvic organs generally are normal, whereas the appendix may appear abnormal on ultrasound or computed tomography (CT). Gastrografin barium enema, or CT with contrast with normal filling of the appendix rules out appendicitis. Diagnostic laparoscopy can be useful to rule out other sources of pelvic pathology, but it is occasionally difficult to visualize the appendix sufficiently to rule out early appendiceal inflammation.

**Management**

Initial management is intravenous administration of fluids, strict restriction of any oral intake, and preoperative antibiotics followed by laparoscopy or laparotomy. Laparotomy has a false-positive rate of 20%, making it an acceptable approach, and is preferable.
to continued observation with the risk of eventual rupture and peritonitis. Not only is a ruptured appendix life threatening, but it also may have profound sequelae for the fertility of a woman of reproductive age.

**Acute Diverticulitis**

Acute diverticulitis is a condition in which there is inflammation of a diverticulum or outpouching of the wall of the colon, usually involving the sigmoid colon. Diverticulitis typically affects postmenopausal women but can occur in women in their 30s and 40s.

**Symptoms**

The severe, left lower quadrant pain of diverticulitis can occur following a long history of symptoms of irritable bowel (bloating, constipation, and diarrhea), although diverticulosis usually is asymptomatic. Diverticulitis is less likely to lead to perforation and peritonitis than is appendicitis. Fever, chills, and constipation typically are present, but anorexia and vomiting are uncommon.

**Signs**

Abdominal examination reveals distention with left lower quadrant tenderness on direct palpation and localized rebound tenderness. Abdominal and pelvic examination may reveal a poorly mobile, doughy inflammatory mass in the left lower quadrant. Bowel sounds are hypoactive, whereas they are absent with peritonitis. Leukocytosis frequently is observed.

**Diagnosis and Management**

Computed axial tomography is a useful adjunct to history and physical examination. It will reveal a swollen, edematous bowel and can rule out an abscess. A barium enema is contraindicated. Diverticulitis is initially managed medically with intravenous administration of fluids, strict restriction of oral intake, and broad-spectrum intravenous antibiotics. A diverticular abscess, obstruction, fistula, or free perforation requires surgical intervention.

**Intestinal Obstruction**

The most common causes of intestinal obstruction in women are postsurgical adhesions, hernia formation, inflammatory bowel disease, and carcinoma of the bowel or ovary.

**Symptoms**

Intestinal obstruction is heralded by the onset of colicky abdominal pain followed by abdominal distention, vomiting, constipation, and obstipation. Higher and more acute obstruction results in early vomiting, whereas colonic obstruction presents with a greater degree of abdominal distention and obstipation. Vomiting first consists of gastric contents, followed by bile, then material with feculent odor, depending on the level of obstruction.

**Signs**

Marked abdominal distention is present with abdominal obstruction. At the onset of mechanical obstruction, bowel sounds are high pitched and maximal during an episode of colicky pain. As the obstruction progresses, bowel sounds decrease and, when absent, suggest ischemic bowel. Elevated white blood cell (WBC) count and fever often are present in the late stages.
CHAPTER 15 Pelvic Pain and Dysmenorrhea

Diagnosis and Management

An upright abdominal x-ray series shows a characteristic gas pattern, distended loops of bowel, and air fluid levels; and it helps to determine whether obstruction is partial or complete (no colonic gas seen). Complete obstruction requires surgical management, whereas partial obstruction often can be managed with intravenous fluids and nasogastric suction. The cause of the obstruction should be determined and treated if possible.

Urinary Tract

Ureteral colic that is due to ureteral lithiasis is caused by a sudden increase in intraluminal pressure and associated inflammation. Urinary tract infections producing acute pain include cystitis and pyelonephritis. The most common microbes causing urinary tract infections are *E. coli* followed by *Proteus, Klebsiella*, and *Pseudomonas*.

Symptoms and Signs

The pain of lithiasis is typically severe and crampy; it can radiate from the costovertebral angle to the groin. Hematuria is often present. Cystitis is associated with dull suprapubic pain, urinary frequency, urgency, dysuria, and occasionally hematuria. Because urethritis can occur secondary to chlamydia or gonorrhea and has similar symptoms, these infections must be ruled out if appropriate. Pyelonephritis is associated with flank and costovertebral angle pain, although lateralizing lower abdominal pain occasionally is present. There is pain with firm pressure over the costovertebral angle in the case of lithiasis or pyelonephritis. Peritoneal signs are absent. Suprapubic tenderness may accompany cystitis.

Diagnosis

Diagnosis of stone is afforded by urinalysis revealing red blood cells and outlining the stone using ultrasound or CT urography or intravenous pyelography (uric acid stones may not detected by CT). The diagnosis of urinary tract infection is based on urinalysis revealing bacteria and leukocytes (>10 WBCs/high-power field) and subsequently confirmed by culture.

Management

Expectant medical treatment consists of intravenous administration of fluids or oral hydration and pain control. Surgical management, such as lithotripsy or open surgery, also is an option for renal lithiasis. Nonpregnant women (and pregnant women who are afebrile with a normal WBC count) with pyelonephritis and all women with cystitis can be treated on an outpatient basis. Nonpregnant women can be treated with a 14-day course of a *fluoroquinolone* or *trimethoprim/sulfamethoxazole* (some recommend one intravenous dose of a third-generation cephalosporin before discharging patients with oral antibiotics) (see Chapter 16) (40–43). It is important to follow up urine culture sensitivities and treat accordingly. If there is no improvement or if any immunocompromising conditions are present such as HIV, intravenous drug use/abuse, diabetes, pregnancy, or chronic steroid use, the patient should be hospitalized and given intravenous antibiotics.

Tuberculosis should be excluded as a cause of pyelonephritis if the characteristic hematuria with sterile pyuria is present and the patient’s condition does not improve with antibiotics.

Diagnostic Tools for the Evaluation of Acute Pelvic Pain

All women of reproductive age with acute pelvic pain should have a complete blood count with differential, ESR, urinalysis, and a sensitive qualitative urine or serum pregnancy test. The sedimentation rate is nonspecific but often is the only abnormal
laboratory finding in women with subacute PID. Other studies that may be helpful include pelvic ultrasound, culdocentesis with hematocrit if bloody fluid is obtained, and Gram stain with culture if the fluid is purulent. The presence of a mass in the cul-de-sac precludes culdocentesis. Pelvic ultrasound is useful to rule out ectopic gestation or to assess the adnexae if the results of the examination are confusing or difficult to interpret because of obesity or guarding. Abdominal x-ray series or upper or lower Gastrografin studies are helpful to rule out gastrointestinal pathology when gastrointestinal symptoms predominate. Computed tomography scan is useful for evaluation of retroperitoneal masses or abscesses related to the gastrointestinal tract.

Diagnostic laparoscopy is reserved for establishing the diagnosis in patients who have acute abdomen of uncertain cause, for elucidating the nature of an ambiguous adnexal mass, or for delineating whether a pregnancy is intrauterine or extrauterine (if ultrasound results are negative or equivocal). If there is clinical evidence of salpingo-oophoritis, diagnostic laparoscopy can be used to confirm the diagnosis. Visualization is hampered if diagnostic laparoscopy is performed for a large pelvic mass (>12 cm) and is relatively contraindicated in patients with peritonitis, severe ileus, or bowel obstruction. In these settings, laparotomy is preferable.

Cyclic Pain: Primary and Secondary Dysmenorrhea

Dysmenorrhea is a common gynecologic disorder affecting as many as 50% of menstruating women (11). Primary dysmenorrhea refers to menstrual pain without pelvic pathology, whereas secondary dysmenorrhea is defined as painful menses associated with underlying pathology. Primary dysmenorrhea usually appears within 1 to 2 years of menarche, when ovulatory cycles are established. The disorder affects younger women but may persist into the 40s. Secondary dysmenorrhea usually develops years after menarche and can occur with anovulatory cycles. The differential diagnosis of secondary dysmenorrhea is outlined in Table 15.3 (2).

Primary Dysmenorrhea

The cause of primary dysmenorrhea is increased endometrial prostaglandin production (44–48). These compounds are found in higher concentrations in secretory endometrium than in proliferative endometrium. The decline of progesterone levels in the late luteal phase triggers lytic enzymatic action, resulting in a release of phospholipids with the generation of arachidonic acid and activation of the cyclooxygenase (COX) pathway. The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid are depicted in Fig. 15.1 (46). Increased synthesis of prostanoids in women with primary dysmenorrhea results in higher uterine tone with high-amplitude contractions causing dysmenorrhea (47–49). It is theorized that women suffering from dysmenorrhea have upregulated COX enzyme activity and prostanoid synthase activity. This has lead to the use of nonsteroidal anti-inflammatory drugs (NSAIDs), which act as COX enzyme inhibitors, for therapy (48). In the past it was shown that vasopressin concentrations are also higher in women with dysmenorrhea (49). However, a more current study did not show vasopressin elevations and purported that treatment with a vasopressin antagonist, atosiban, had no effect on dysmenorrhea (50).

Symptoms

The pain of primary dysmenorrhea usually begins a few hours before or just after the onset of a menstrual period and may last 48 to 72 hours. The pain is similar to labor, with suprapubic cramping, and may be accompanied by lumbosacral backache,

pain radiating down the anterior thigh, nausea, vomiting, diarrhea, and rarely syncopal episodes. The pain of dysmenorrhea is colicky in nature and, unlike abdominal pain that is due to chemical or infectious peritonitis, is relieved by abdominal massage, counter-pressure, or movement of the body.

**Signs**

On examination, the vital signs are normal. The suprapubic region may be tender to palpation. Bowel sounds are normal, and there is no upper abdominal tenderness and no abdominal rebound tenderness. **Bimanual examination at the time of the dysmenorrheic episode often reveals uterine tenderness; however, severe pain does not occur with movement of the cervix or palpation of the adnexal structures.** The pelvic organs are normal in primary dysmenorrhea.

**Diagnosis**

To diagnose primary dysmenorrhea, it is necessary to rule out underlying pelvic pathology and confirm the cyclic nature of the pain. The differential diagnosis of secondary dysmenorrhea includes primary dysmenorrhea and noncyclic pelvic pain. Whereas the diagnosis of primary dysmenorrhea is based on history and presence of a normal pelvic examination,
the diagnosis of secondary dysmenorrhea may require review of a pain diary and an ultrasound examination or laparoscopy or hysteroscopy or both. During the pelvic examination, the size, shape, and mobility of the uterus; the size and tenderness of adnexal structures; and the nodularity or fibrosis of uterosacral ligaments or rectovaginal septum should be assessed. Cervical studies for gonorrhea and chlamydia and, if relevant, a complete blood count with an ESR, are helpful to rule out subacute salpingo-oophoritis. If no abnormalities are found, a tentative diagnosis of primary dysmenorrhea can be established.

**Treatment**

Prostaglandin synthase inhibitors, or NSAIDs, are effective for the treatment of primary dysmenorrhea (51). The inhibitors should be taken before or at the onset of pain and then continuously every 6 to 8 hours to prevent reformation of prostaglandin by-products. The medication should be taken for the first few days of menstrual flow. A 4- to 6-month course of therapy is warranted to determine whether the patient will respond to treatment. Changes in dosages and types of inhibitors should be attempted if initial treatment is not successful. The medication may be contraindicated in patients with gastrointestinal ulcers or bronchospastic hypersensitivity to aspirin. Side effects are usually mild and include nausea, dyspepsia, diarrhea, and occasionally fatigue.

Leukotrienes have been found to mediate inflammation within the uterus and, in addition to prostaglandins, contribute to dysmenorrhea. For patients who fail to respond to NSAIDs, leukotriene receptor antagonists, commonly used to treat asthma, are potential therapeutic agents (52).

For patients with primary dysmenorrhea who have no contraindications to hormonal contraceptive agents (such as oral combined or progesterone only, either cyclic or continuous, transdermal, vaginal ring, injectable preparations, or intrauterine devices) and who desires contraception, oral contraceptives are more effective than placebo alone and resulted in less absence from work or school in one review (53). Hormonal contraceptives inhibit ovulation, decrease endometrial proliferation, and create an endocrine milieu similar to the early proliferative phase of the menstrual cycle, when prostaglandin levels are lowest. Decreased prostaglandin levels result in less uterine cramping. If the patient does not respond to this regimen, hydrocodone or codeine may be added for 2 to 3 days per month; however, before addition of the narcotic medication, psychological factors should be evaluated, and other organic pathology should be ruled out with diagnostic laparoscopy.

Nonpharmacologic pain management, in particular acupuncture or transcutaneous electrical nerve stimulation (TENS), may also be useful (54,55). Acupuncture is thought to excite receptors or nerve fibers, blocking pain impulses through interactions with mediators like serotonin and endorphins (55). It has been found to be effective for treating dysmenorrhea in a few small studies (54,55). The body’s perception of pain signals is altered with TENS. It does not directly affect uterine contractions (55). In one study of women with primary dysmenorrhea undergoing TENS, 30% reported marked pain relief, 60% moderate pain relief, and 10% no relief (56). It appears that TENS is more effective for pain relief at high frequency than at low frequency (55).

Another alternative method of treatment is spinal manipulation. In clinical trials, however, it has not been found to be effective (57,58). Methods used only rarely to treat primary dysmenorrhea include surgical laparoscopic uterine nerve ablation and presacral neurectomy.

**Secondary Dysmenorrhea**

Secondary dysmenorrhea is cyclic menstrual pain that occurs in association with underlying pelvic pathology. It usually occurs years after the onset of menarche, but the definition does not reflect age of onset. The pain of secondary dysmenorrhea often begins...

1 to 2 weeks before menstrual flow and persists until a few days after the cessation of bleeding. The mechanisms underlying secondary dysmenorrhea are diverse and not fully elucidated, although most involve either excess prostaglandin production or hypertonic uterine contractions secondary to cervical obstruction, intrauterine mass, or the presence of a foreign body. However, NSAIDs and hormonal contraceptives are less likely to provide pain relief in women with secondary dysmenorrhea than in those with primary dysmenorrhea. The most common cause of secondary dysmenorrhea is endometriosis, followed by adenomyosis and intrauterine device (for a discussion of endometriosis, see diagnosis of acute and chronic pain, this chapter and Chapter 29). The differential diagnosis of secondary dysmenorrhea is outlined in Table 15.3. The management of secondary dysmenorrhea is treatment of the underlying disorder (Fig. 15.2).

Adenomyosis

Adenomyosis is defined as presence of endometrial tissue within the myometrium, at least 1 high-power field from the basis of the endometrium, whereas endometriosis is characterized by ectopic endometrium appearing within the peritoneal cavity. Adenomyosis, endometriosis, and uterine leiomyomas frequently coexist. Although occasionally noted in women in their younger reproductive years, the average age of symptomatic women is usually older than 40 years. Increasing parity may be a risk factor according to one study (59,60).

Symptoms

Adenomyosis often is asymptomatic. Symptoms typically associated with adenomyosis include excessively heavy or prolonged menstrual bleeding, dyspareunia, dyschezia, and dysmenorrhea. Symptoms often begin up to a week before the onset of a menstrual flow and may not resolve until after the cessation of menses.

Signs

The uterus is diffusely enlarged, although usually less than 14 cm in size, and is often soft and tender, particularly at the time of menses. Mobility of the uterus is not restricted, and there is no associated adnexal pathology.

Diagnosis

Adenomyosis is a clinical diagnosis and can be confirmed only by pathology review. Imaging studies, although helpful, are not definitive. Because of their cost and negligible improvement in diagnostic accuracy, these studies are not recommended routinely. In women with diffuse uterine enlargement and a negative pregnancy test results, secondary dysmenorrhea may be attributed to adenomyosis; however, the pathologic confirmation of suspected adenomyosis can be made only at the time of hysterectomy. In one study to confirm preoperative diagnosis of adenomyosis before hysterectomy, the clinical diagnosis of adenomyosis was confirmed in only 48% of the cases (26).
CHAPTER 15 Pelvic Pain and Dysmenorrhea

Management

The management of adenomyosis depends on the patient’s age and desire for future fertility. Relief of secondary dysmenorrhea caused by adenomyosis can be ensured after hysterectomy, but less invasive approaches can be tried initially. Nonsteroidal anti-inflammatory agents, oral contraceptives, and menstrual suppression using progestins have all been found to be useful. Treatment follows the same protocol as treatment for endometriosis.

Chronic Pelvic Pain

Chronic pelvic pain remains an inclusive, general diagnosis that encompasses many more specific causes, from endometriosis to nerve entrapment syndrome. Various forms of chronic pelvic pain affect 12% to 20% of women in the United States (61,62). The differential diagnosis of chronic pelvic pain is outlined in Table 15.3.

Patients with chronic pelvic pain are frequently anxious and depressed. Their marital, social, and occupational lives have usually been disrupted. These patients have often had poor treatment outcomes after traditionally effective gynecologic and medical therapy and may have undergone multiple unsuccessful surgical procedures for pain. About 12% to 19% of hysterectomies are performed for pelvic pain, and 30% of patients who present to pain clinics have already had a hysterectomy (63,64). Approximately 60% to 80% of patients undergoing laparoscopy for chronic pelvic pain have no intraperitoneal pathology, nor do they have tissue distortion that correlates with the pain (2). Additionally, the relationship between the pain response and certain types of prevalent intraperitoneal pathology, such as endometriosis, adhesions, or venous congestion, can be inconsistent. Nongynecologic causes of pain, such as irritable bowel syndrome, interstitial cystitis, abdominal wall or pelvic floor myofascial syndrome, or neuropathy, are frequently overlooked but common causes of chronic pelvic pain.

Recent investigations have suggested that “plasticity” of the nervous system or alterations in signal processing may be involved in the maintenance of painful states (2,5,10). Various neurohumoral modulators, such as prostaglandins, vasoactive intestinal peptide, substance P, and endorphins, can modulate peripheral neurotransmission and also affect neurotransmission at the level of the spinal cord (6,65). Chronic exposure to these neuroinflammatory factors can cause adaptive changes within the peripheral and central nervous system that predispose to allodynia and hyperalgesia (6,9–11). The spinal cord is not a simple conduit between the periphery and the brain. It is an important site of “gating” mechanisms, such as excitation, inhibition, convergence, and summation of neural stimuli (66). The pain sensation is also modified by neurotransmitters within the brain, such as norepinephrine, serotonin, and γ-aminobutyric acid (GABA), as well as by endogenous endorphin and nonendorphin algesic systems. Different regions of the brain are also important in altering the sensory and affective components of the pain response. Evidence from animal studies indicates that supraspinal factors can interact at the level of the dorsal horn to modulate the sensory perception of pain from the pelvic viscera (9,67). Overlapping afferent input from nearby viscera can cause a perception of referred pain, making the diagnosis of origin difficult (9). The sensory and affective component of pain is affected by early experience, conditioning, fear, arousal, depression, and anxiety (68).

Evaluation of Chronic Pelvic Pain

On the first visit, a thorough pain history should be performed, taking into consideration the nature of each pain symptom: location, radiation, severity, aggravating and alleviating factors; effect of menstrual cycle, stress, work, exercise, intercourse, and
orgasm; the context in which pain arose; and the social and occupational toll of the pain (Table 15.5). A visual analog pain scale listing numbers 0 through 10 and stating “no pain” and “worst possible pain” is helpful in assessing the severity of pain and comparing the changes in severity over subsequent visits (69). The use of a questionnaire is helpful and can help better record and define the patient’s symptoms. An outline of a woman’s body can be used to help the patient define the location and characteristics of pain experienced (2).

The patient should be questioned about symptoms specific to the types of pathology (see Table 15.3):

1. **Genital** (abnormal vaginal bleeding, discharge, dysmenorrhea, dyspareunia, infertility)

2. **Enterocoeic** (constipation, diarrhea, flatulence, hematochezia, and relationship of pain and pain relief to bowel movements)

3. **Musculoskeletal/neuropathic** (trauma, exacerbation with exercise, or postural changes)

4. **Urologic** (urgency, frequency, nocturia, dysuria, incontinence, hematuria)

The history should include gynecologic, medical, and surgical factors; medication intake; prior evaluations for pain; and operative and pathology reports (2).

Symptoms of an acute process (fever, anorexia, nausea, emesis, significant diarrhea, hematochezia, obstipation, abdominal distention, undiagnosed uterine bleeding, pregnancy, or recent abortion) should alert the physician to the possibility of an acute condition requiring immediate medical or surgical intervention. This occurrence is especially important if symptoms are accompanied by elevated temperature, orthostasis, peritoneal signs, pelvic or abdominal mass, abnormal complete blood count, positive genital or urinary tract cultures, or a positive pregnancy test result.

A complete physical examination should be performed, with particular attention directed to the abdominal and lumbosacral areas, external genitalia, and internal organs via vaginal,
The examination should include the Carnett test, which is an evaluation of the abdomen with muscles tensed (head raised off the table or with straight leg raising) to differentiate abdominal wall and visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with these maneuvers (70,71). While standing, the patient should be examined for hernias, both abdominal (inguinal and femoral) and pelvic (cystocele and enterocele). An attempt should be made to locate by palpation the tissues that reproduce the patient’s pain. If abdominal wall sources of pain are noted, it is useful to block these areas with local anesthetics and then perform the pelvic examination (70,71).

The Psychological Component

A pain history includes the current and past psychological history and focuses on psychosocial factors; history of past (or current) physical, sexual, or emotional abuse; history of psychiatric hospitalization; suicide attempts; and chemical dependency (2,72). Many studies have shown that childhood abuse in general and childhood sexual abuse in particular are risk factors for chronic pelvic pain (72). The attitude of the patient and her family toward the pain, resultant behavior of the patient and her family, and current upheavals in the patient’s life should be discussed. The part of the history relating to sensitive issues may have to be revisited after establishing rapport with the patient.

It is vital to appreciate the various influences that can distort pain perception and expression. A distinction can be drawn between factors leading to a painful condition and those now maintaining it. Whatever the original cause of the pain, when pain has persisted for any length of time, it is likely that other factors are now maintaining or at least contributing to it. The full physical evaluation, outlined previously, should be accompanied by a review of psychosocial factors. Pain is commonly accompanied by anxiety and depression, and these conditions need to be carefully assessed and treated (2). In a typical gynecologic setting, referral to a psychologist for parallel evaluation can evoke resistance. The inference is drawn that the referring physician is ascribing the pain to psychological causes. The patient needs to understand the reason for this referral and to be reassured that it is a routine and necessary part of the evaluation.

Gynecologic Causes

The most common gynecologic disorders noted at the time of laparoscopy performed to assess chronic pelvic pain are endometriosis and adhesions. Patients with obvious gynecologic pathology, such as benign or malignant ovarian cysts, uterine leiomyomas of size sufficient to encroach on supporting ligaments or other somatic structures, or significant pelvic relaxation should be evaluated and treated in a manner that is appropriate for the underlying condition (see Chapters 14 and 24). Pain associated with these conditions is generally not severe, and appropriate surgical management is therapeutic.

Endometriosis

A thorough discussion of the management of endometriosis is presented in Chapter 29 (73–101).

Endometriosis can be demonstrated in 15% to 40% of patients undergoing laparoscopy for chronic pelvic pain (73). Endometriosis produces a low-grade inflammatory reaction; over time this results in adhesions between confluent pelvic organs (74,75). However, the cause of the pain is not well established. There is no correlation between the location of disease and pain symptoms (76,77). There also appears to be no relationship between the incidence or severity of pain and the stage of the endometriotic lesions, and as many as 30% to 50% of patients have no pain regardless of stage. Similarly, 40% to 60% of patients have no tenderness on examination regardless of stage (77). However, other studies have shown that deeply infiltrating endometriosis lesions that involve the
rectovaginal septum and the bowel, ureters, and bladder are strongly associated with pain (75,78,79). Vaginal and uterosacral endometrioses are associated with deep dyspareunia (80). Dyspareunia may be caused by pressure on inflamed tissues and neural invasion, in addition to stretching and tearing during intercourse of pelvic structures bound by adhesions.

Prostaglandin E and F$_{2\alpha}$ production from explants of petechial lesions present in mild, low-stage disease was found to be significantly greater than from the explants of powder-burn or black lesions, which are more common in patients with higher-stage endometriosis (81). Therefore, prostaglandin production may account for severe pain in some patients with mild disease.

Endometriosis is a surgical diagnosis based on identification of characteristic lesions.

**Adhesions**

Adhesions noted at the time of laparoscopy are often in the same general region of the abdomen as the source of the pelvic pain (102); however, neither the specific location (i.e., adnexa structures, parietal, visceral peritoneum, or bowel) nor density of the adhesions correlates consistently with the presence of pain symptoms (103). Various studies of adhesiolysis have not consistently demonstrated a significant long-term reduction in pain scores, whereas others show an improvement but one no greater than in the placebo group (laparoscopy without adhesiolysis) (104–107). In one study of lysis of adhesions, a subgroup of women with anxiety, depression, multiple somatic symptoms, and social and occupational disruption responded poorly to adhesiolysis. The group without these characteristics had significant improvement in pain (104,105). A prospective study, however, noted a significant improvement in pain with two of three methods of assessment only if the adhesions were dense and involved the bowel (108).

**Symptoms**

Noncyclic abdominal pain, sometimes increased with intercourse or activity, is a common source of pain in women with adhesions, but there is no symptom pattern specific for adhesions. Chronic pelvic pain developing from adhesions is thought to result from restriction of bowel mobility and distention (109). Furthermore, dense adhesions involving bowel can cause partial or complete bowel obstruction.

**Signs**

The abdominal wall must be carefully evaluated for myofascial or neurological sources of pain. Most women with adhesions have had a prior surgical procedure with possible injury to abdominal wall structures that may be the cause of pain. Decreased mobility of pelvic organs or adnexal enlargement can often be detected in patients with adhesions.

**Diagnosis**

Diagnostic laparoscopy is recommended if somatic causes are ruled out and the results of the psychological evaluation are negative. Recent advances in microlaparoscopy have enabled the development of a new technique known as “conscious pain mapping,” whereby physicians may better locate the specific adhesions associated with pelvic pain using local anesthesia and conscious sedation (110,111). In an observational study of 50 women using local anesthesia, manipulation of appendiceal and pelvic adhesions contributed to pelvic pain (112). Further studies are needed to correlate the lysis of such painful adhesions with pain relief. Thus far, laparoscopic pain mapping has not been shown to improve outcome over traditional laparoscopic therapy (2,14).
Management

Currently, the causal role of adhesions in the genesis of pelvic pain is uncertain, and lysis is recommended only after thorough multidisciplinary evaluation and in the context of an integrated treatment approach that addresses stress, mood, and associated behavioral responses. Repeated surgical procedures for lysis are not recommended.

Pelvic Congestion

In 1954, Taylor suggested that emotional stress could lead to autonomic nervous system dysfunction manifested as smooth muscle spasm and congestion of the veins draining the ovaries and uterus (113). Transuterine venography in women with chronic pelvic pain often reveals delayed disappearance of contrast medium from the uterine and ovarian veins (114). Considering that pregnant and postpartum women have asymptomatic pelvic congestion, the role of congested veins in the causation of pelvic pain is uncertain. The specific neurotransmitters involved in mediating sympathetic efferent–maintained pain syndrome are unknown.

Signs and Symptoms

Pelvic congestion most commonly affects women of reproductive age. Typical symptoms include bilateral lower abdominal and back pain, secondary dysmenorrhea, dyspareunia, abnormal uterine bleeding, chronic fatigue, and irritable bowel symptoms. Pain usually begins with ovulation and lasts until the end of menses. The uterus is often bulky, and the ovaries are enlarged with multiple functional cysts. The uterus, parametria, and uterosacral ligaments are tender.

Diagnosis

Transuterine venography has been the primary method for diagnosis, although other modalities, such as pelvic ultrasound, magnetic resonance imaging, and laparoscopy, may disclose varicosities (115). Because of the cost and possible side effects of treatment, further management should be based on related symptoms and not simply on the presence of varicosities.

Management

Treatment of suspected pelvic congestion ranges from the less invasive hormonal suppression and cognitive behavioral pain management to the more invasive ovarian vein embolization or hysterectomy and salingo-ovariectomy. Low-estrogen, progestin-dominant continuous oral contraceptives, high-dose progestins, and gonadotropin-releasing hormone (GnRH) analogues often provide pain relief (116,117). Hormonal suppression should be the initial mode of treatment for women with suspected pelvic congestion. Medroxyprogesterone acetate, 30 mg daily, has been found to be useful (118). Percutaneous transcatheter embolization can be used in women who do not respond to medical or hormonal therapy (119). Concurrently, a multidisciplinary approach incorporating psychotherapy, behavioral pain management, or both is important. A positive interaction between medroxyprogesterone acetate and pain management has been noted (118). Technically more invasive, transcatheter embolotherapy selectively catheters the ovarian and internal iliac veins, followed by contrast venography and embolization (120). Several small, uncontrolled studies with limited follow-up have reported pain reduction with transcatheter embolization of pelvic veins (121–123). For women who have completed their childbearing, hysterectomy with possible oophorectomy is a reasonable option.

Subacute Salpingo-oophoritis

Patients with salpingo-oophoritis usually present with symptoms and signs of acute infection. Atypical or partially treated infection may not be associated with fever or peritoneal signs. Subacute or atypical salpingo-oophoritis is often a sequela of chlamydia or mycoplasma
infection. Abdominal tenderness, cervical motion, and bilateral adnexal tenderness are typical of pelvic infection (see Chapter 16).

Ovarian Remnant Syndrome

In a reproductive-aged patient who has had a bilateral salpingo-oophorectomy, with or without a hysterectomy, for severe endometriosis or PID, chronic pelvic pain may be caused by ovarian remnant syndrome. This syndrome results from residual ovarian cortical tissue that is left in situ after a difficult dissection in an attempt to perform an oophorectomy. This tissue can become encased in adhesions and result in painful cysts. Often, the patient has had multiple pelvic operations with the uterus and adnexa removed sequentially. Laparoscopic oophorectomy, combined with a difficult dissection, is a strong risk factor.

It is important not to confuse ovarian remnant syndrome with residual ovary syndrome, which results after a hysterectomy in which one or both ovaries are left intact. If adhesions develop and encase the ovaries, cyclical expansion of the ovaries can result in pain and, in some cases, a tender mass.

Symptoms

The patient usually reports lateralizing pelvic pain, often cycling with ovulation or the luteal phase, described as sharp and stabbing or as constant, dull, and nonradiating, possibly with associated genitourinary or gastrointestinal symptoms. Symptoms tend to arise 2 to 5 years after initial oophorectomy. A tender mass in the lateral region of the pelvis is pathognomonic. The patient may also report deep dyspareunia, constipation, or flank pain.

Diagnosis

Ultrasonography usually confirms a mass with the characteristics of ovarian tissue. The accuracy of ultrasound can be improved by treating the patient with a 5- to 10-day course of clomiphene citrate (Clomid), 100 mg daily, to stimulate follicular development. In a patient who has had bilateral salpingo-oophorectomy and is not taking hormone therapy, estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture (FSH <40 mIU/mL and estradiol >30 pg/mL), although on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels. The patient may have a persistent estrogenized state based on the vulvar and vaginal examination and lack postmenopausal symptoms such as hot flashes, night sweats, and mood changes.

Management

Initial medical treatment with danazol, high-dose progestins, or oral contraceptives usually provides mixed results. Patients usually experience relief of pain with a GnRH agonist, although these medications are impractical for long-term therapy. Those who achieve relief with GnRH agonists also experience relief with subsequent surgery. Laparoscopic examination is usually not productive because the ovarian mass may be missed or adhesions may prevent accurate diagnosis. Laparotomy is necessary for treatment, and the corrective surgery tends to be arduous, often involving inadvertent cystotomy, enterotomy, postoperative small bowel obstructions, and hematoma formation. Surgical pathology usually reveals the presence of ovarian tissue, sometimes with endometriosis, corpus lutea or follicle cysts, and fibrous adhesions. Clomiphene citrate can be used 7 to 10 days before surgery to induce folliculogenesis, allowing ovarian tissue to be found more easily.
The uterus, cervix, and adnexa share with the lower ileum, sigmoid colon, and rectum the same visceral innervation, with pain signals traveling through sympathetic nerves to spinal cord segments T10 to L1 (129). It is often difficult, therefore, to determine whether lower abdominal pain is of gynecologic or enterocolic origin. Skillful medical history and examination are necessary to distinguish gynecologic from gastrointestinal causes of pain. In addition, inflammatory bowel disease, such as Crohn’s disease or ulcerative colitis, infectious enterocolitis, intestinal neoplasms, appendicitis, and hernia must be ruled out with appropriate history and physical examination, complete blood count, and stool cultures as well as visualization of colonic mucosa when appropriate.

Irritable bowel syndrome (IBS) is one of the more common causes of lower abdominal pain and may account for up to 60% of referrals to the gynecologist for chronic pelvic pain (129). An estimated 35% of patients with chronic pelvic pain have a concurrent diagnosis of IBS (130). Women who have had a hysterectomy for chronic pelvic pain are twice as likely to have IBS (131). The exact causes of IBS are unknown; however, patients with IBS have pain with smaller volume of distention of the bowel than those without IBS (132). These patients also have an abnormal pain referral pattern with colonic distention. Visceral hypersensitivity or hyperalgesia has been postulated as the cause of pain, although the cause of this hyperalgesia is not known (133).

Symptoms
The predominant symptom of IBS is abdominal pain (134). Other symptoms include abdominal distention, excessive flatulence, alternating diarrhea and constipation, increased pain before a bowel movement, decreased pain after a bowel movement, and pain exacerbated by events that increase gastrointestinal motility, such as high-fat diet, stress, anxiety, depression, and menses. The pain is usually intermittent, occasionally constant, cramplike, and more likely to occur in the left lower quadrant. The patient with IBS can be placed into one of three categories: constipation-predominant, diarrhea-predominant, and pain-predominant (alternating bowel habits) depending on their main symptoms (135). The Rome II criteria for diagnosis (Table 14.4) include at least 12 weeks (not necessarily consecutive) in the preceding 12 months of abdominal discomfort or pain that has at least two of the following features: relief with defecation, onset associated with change in stool frequency, or onset associated with change in form (appearance) of stool (136,137).

Signs
On physical examination, the findings of a palpable tender sigmoid colon or discomfort during insertion of the finger into the rectum and hard feces in the rectum are suggestive of IBS (129).

Diagnosis
The diagnosis of IBS is usually based on history and physical examination, and although suggestive, especially in young women, the findings are not specific. In one study, 91% of patients with IBS had two or more IBS symptoms (abdominal distention, relief of pain with bowel movement, more frequent bowel movements with the onset of pain, looser bowel movements with the onset of pain), whereas 30% of patients with organic disease had two or more of these symptoms (138). Therefore, a complete blood count, stool sample to test for white cells and occult blood, and sigmoidoscopy or colonoscopy or barium enema are usually required, particularly in older individuals and in young individuals who have not responded to initial treatment (139). The results of these studies are all normal in patients with IBS.
Management

Current medical therapy for IBS is generally unsatisfactory, and placebo response rates are high (140). Treatment consists of reassurance, education, stress reduction, bulk-forming agents and other symptomatic treatments, and low-dose tricyclic antidepressants (139,141). These patients should eliminate triggers in their diet, such as food containing lactose, sorbitol, alcohol, fat, and fructose. Products that contain caffeine can also cause abdominal bloating, cramping, and more frequent bowel movements. After the patient has tried these lifestyle changes, if she remains symptomatic, a short-term trial of antispasmodics such as dicyclomine or hycoscyamine can be given (139,141). Finally, Tegaserod, which is a 5-HT4 agonist, approved by the U.S. Food and Drug Administration for treatment of IBS, can be used on a short-term trial basis (141).

A multidisciplinary management approach consisting of medical and psychological approaches is recommended. It addresses the cognitive, affective, and behavioral components of the pain. Therapy may decrease the intensity of nociceptor stimulation as well as change the interpretation of the meaning of pain.

Urologic Causes

Chronic pelvic pain of urologic origin may be related to recurrent cystourethritis, urethral syndrome, sensory urgency of uncertain cause, as well as interstitial cystitis. With an appropriate diagnostic workup, infiltrating bladder tumors, ureteral obstruction, renal lithiasis, and endometriosis can easily be ruled out as possible causes.

Urethral Syndrome

Urethral syndrome is defined as a symptom complex including dysuria, frequency and urgency of urination, suprapubic discomfort, and often dyspareunia in the absence of any abnormality of the urethra or bladder. The cause of urethral syndrome is uncertain and has been attributed to a subclinical infection, urethral obstruction, and psychogenic and allergic factors (142). The symptoms of urethral syndrome may actually evolve into the initial stages of interstitial cystitis.

Symptoms

Urinary urgency, frequency, suprapubic pressure, and other less frequent symptoms such as bladder or vaginal pain, urinary incontinence, postvoid fullness, dyspareunia, and suprapubic pain are commonly observed.

Signs

Physical and neurologic examinations should be performed. The anal reflex should document that S2 to S4 spinal segments have not been interrupted (142). Anatomic abnormalities, including pelvic relaxation, urethral caruncle, and hypoestrogenism, should be evaluated. The patient should also be evaluated for vaginitis. The urethra should be carefully palpated to detect purulent discharge.

Diagnosis

A clean catch or catheterized urine specimen for routine urinalysis and culture should be obtained to rule out urinary tract infection. As indicated, urethral and cervical cultures for chlamydia should be obtained, and a wet prep for vaginitis should be performed. Urethral syndrome should be considered if the results of urine and urethral cultures are negative, the evaluation does not disclose vulvovaginitis, and no allergic phenomenon causing contact dermatitis of the urethra can be detected. The possibility of ureaplasma, chlamydia, candida, trichomonas, gonorrhea, and herpes should be eliminated. Cystoscopic evaluation should be performed to rule out urethral diverticulum, interstitial cystitis, and cancer.
Management

Various forms of therapy have been suggested for urethral syndrome. Those patients in whom no infectious agent is present but who have sterile pyuria respond to a 2- to 3-week course of doxycycline or erythromycin (142). Long-term, low-dose antimicrobial prophylaxis is often used in women with urgency and frequency symptoms who have had a history of recurrent urinary tract infections. Some of these women may continue to have symptoms when their urine is not infected, and then bacterial infection redevelops over time (142). It is recommended that all postmenopausal women be given a trial of local estrogen therapy for about 2 months. If there is no improvement after antibiotic or estrogen therapy, urethral dilation can be considered. Positive results also have been noted with biofeedback techniques (142).

Interstitial Cystitis

Interstitial cystitis occurs more often in women than men. Most patients are between 40 and 60 years of age. The cause of interstitial cystitis is unknown, although an autoimmune etiology is generally accepted (142).

Symptoms

Symptoms include severe and disabling urinary frequency and urgency, nocturia, dysuria, and occasional hematuria. Suprapubic, pelvic, urethral, vaginal, or perineal pain is common and can be relieved to some extent by emptying of the bladder.

Signs

Pelvic examination usually reveals anterior vaginal wall and suprapubic tenderness. Urinalysis may reveal microhematuria without pyuria, although results may be normal.

Diagnosis

The diagnosis is based on symptoms and characteristic cystoscopic findings (142,143). The use of a pelvic pain and urgency/frequency symptom scale and a bladder potassium intravesical test can promote early diagnosis (144); however, it is still a point of debate as to whether a positive potassium test is definitive for interstitial cystitis or if it just shows bladder hyperalgesia. Cystoscopy performed in a conscious patient may reveal only bladder hypersensitivity; with anesthesia, however, and sufficient distention of the bladder, submucosal hemorrhages and cracking of the mucosa may be noted along with characteristic glomerulations, Hunner’s ulcers or patches, and fibrosis (129,145,146). Although the histologic features of the biopsy specimen are nonspecific, there is usually submucosal edema, vasodilation, and infiltration by macrophages, plasma cells, and eosinophils.

Management

Because the etiology is uncertain, management has been empirical. Diet changes, stress reduction, and behavioral changes can be initiated, such as recording a voiding diary and training the pelvic floor muscle (146). Various pharmaceutical approaches, including anticholinergic, antispasmodic, and anti-inflammatory agents, have been used. Response to treatment also has been noted with the use of tricyclic antidepressants or pentosan polysulfate sodium, which is approved for therapy (145). Hydrostatic bladder distention may produce temporary relief by creating detrusor ischemia and decreased innervation of the bladder wall, and repeated bladder instillations of heparin with lidocaine are useful. Biofeedback, TENS, and behavioral therapy have also been used with some success (142).
Nerve Entrapment

Abdominal cutaneous nerve injury or entrapment may occur spontaneously or within weeks to years after transverse suprapubic skin or laparoscopy incisions (70,147). The ilioinguinal (T12 and L1) or iliohypogastric (T12 and L1) nerves may become trapped between the transverse and internal oblique muscles, especially when the muscles contract. Alternatively, the nerve may be ligated or traumatized during the surgery. Femoral nerve injury, one of the most commonly injured nerves in gynecologic laparotomies, usually results when deep lateral retractor blades compress the nerve between the blade and the lateral pelvic side wall (148,149). Symptoms of nerve entrapment include sharp, burning, aching pain and paresthesias in the dermatomal distribution of the involved nerve (4,150,151). Femoral nerve damage results in inability to flex at the hip joint or to extend at the knee (148,149). In general with nerve entrapment, hip flexion and exercise or activity exacerbates pain and rest or infiltration with a local anesthetic relieves pain (152). The pain is usually judged as coming from the abdomen, not the skin.

Signs

On examination, the pain usually can be localized with the fingertip. The maximal point of tenderness in an iliohypogastric or ilioinguinal injury is usually at the rectus margin, medial and inferior to the anterior iliac spine. A tentative diagnosis can be confirmed by diagnostic nerve block with 3 to 5 mL of 0.25% bupivacaine. Patients usually report immediate relief of symptoms after injection, and at least 50% experience relief lasting longer than a few hours over a week or two (70).

Management

Many patients may require no further intervention after nerve block, although some patients require up to five biweekly injections. If injection is successful in producing only limited pain relief and there are no contributory visceral or psychological factors, cryoneuropathy or surgical removal of the involved nerve is recommended. Medication for neuropathic pain such as anticonvulsants or antidepressants may be useful.

Myofascial Pain

Myofascial syndrome has been documented in about 15% of patients with chronic pelvic pain (152). These patients are noted to have trigger points, which are hyperirritable areas within a tight band of skeletal muscle or within its fascia (153,154). Trigger points are initiated by pathogenic autonomic reflex of visceral or muscular origin (154–156). They are painful on compression. The referred pain of the trigger point occurs in a dermatomal distribution, and it is thought to be caused by nerves from the muscle or deeper structures sharing a common second-order neuron in the spinal cord. The patient can experience weakness and restriction in range of motion of the affected muscle. Painful trigger points characteristically can be abolished with the injection of local anesthetic into the painful area (153). Trigger points are often present in women with chronic pelvic pain irrespective of presence or type of underlying pathology. In one study, 89% of women with chronic pelvic pain had abdominal, vaginal, or lumbosacral trigger points (153). In the absence of the initial or ongoing organic pathology, various factors are theorized to predispose to the chronicity of the myofascial syndrome, including psychological, hormonal, and biomechanical factors (154).

Fibromyalgia, a myofascial pain syndrome, is made up of the triad of diffuse pain, fatigue, and nonrestorative sleep (156). Women are more commonly affected than
men. To diagnose the syndrome, the patient must have tender points in all four quadrants. It is thought to be caused by a central nervous system sensitization that results in abnormal perception of chronic pain. Fibromyalgia is closely associated with chronic fatigue syndrome, a combination of regional myofascial problems including infections and autoimmune disorders or dysautonomias. The management includes education, environmental changes (well-balanced diet, adequate time for sleep, and an environment conducive to restful sleep), exercise and stretching, and counseling including techniques for relaxation and maximizing coping mechanisms (156). Medications used include NSAIDs, low-dose tricyclic antidepressants, selective serotonin reuptake inhibitors, and benzodiazepines to improve sleep (156).

**Symptoms**

Abdominal wall pain is often exacerbated during the premenstrual period or by stimuli to the dermatome of trigger points (e.g., full bladder, bowel, or any stimulation to organs that share the dermatome of the involved nerve) (4,150,151,155).

**Signs**

On examination, fingertip pressure on the trigger points evokes local and referred pain. Tensing of the rectus muscles by either straight leg lifting or raising the head off the table increases the pain. A specific jump sign can be elicited by palpation with fingertip or a cotton swab. An electric (tingling) sensation confirms correct needle placement (153).

**Management**

Massage therapy can help relieve the pain in some cases. “Myofascial release” is a special vigorous message that can be effective (154,156). Alternatively, sustained pressure to a trigger point with adequate force for a specified period can inactive the irritable nerve (150,156). Injection of the trigger point with 3 mL of 0.25% bupivacaine provides relief that usually outlasts the duration of the anesthetic action. After four to five biweekly injections, the procedure should be abandoned if long-lasting relief is not obtained. Acupuncture can also be helpful (156). Concomitant with injection of trigger points, multidisciplinary pain management should be undertaken, especially if anxiety, depression, history of physical or sexual abuse, sexual dysfunction, or social or occupational disruption are present.

**Low Back Pain Syndrome**

In women who experience lower-back pain without pelvic pain, gynecologic pathology rarely is the cause of their pain. However, low-back pain may accompany gynecologic pathology. Back pain may be caused by gynecologic, vascular, neurologic, psychogenic, or spondylogenic (related to the axial skeleton and its structure) pathology.

**Symptoms**

Women with low-back pain syndrome often have pain occurring after trauma or physical exertion, in the morning on arising, or with fatigue. Nongynecologic low-back pain can intensify with the menstrual cycle.

**Signs**

Examination consists of inspection, evaluation with movement, and palpation. Various anatomic structures in the spine should be considered as sources of pain. Muscles, vertebral joints, and disks (including lumbosacral junction, paravertebral sacrospinal muscles, and sacroiliac joints) are common sources of spondylogenic pain that must be examined carefully (2,157).
**Diagnosis**

Diagnostic imaging studies performed while the patient is standing, lying, and sitting with maximal flexion can be helpful. An elevated ESR suggests pain of inflammatory or neoplastic origin.

**Management**

Orthopedic or rheumatologic consultation should be sought before initiating management for back pain unless the source could be referred gynecologic pain.

**Psychological Factors**

From a psychological perspective, various factors may promote the chronicity of pain, including the meaning attached to the pain, anxiety, the ability to redirect attention, personality, mood state, past experience, and reinforcement contingencies that may amplify or attenuate pain (158). The Minnesota Multiphasic Personality Inventory (MMPI) studies of women with chronic pelvic pain reveal a high prevalence of a convergence “V” profile (elevated scores on the hypochondriasis, hysteria, and depression scales). Treatment of a known pathology or presumed cause without obvious physical findings that results in subjective improvement in pain severity and increased activity level produces a significant improvement in personality profile (159). There is also a close relationship between depression and pain (160). Both give rise to similar behavior, such as behavioral and social withdrawal and decreased activity, and may be mediated by the same neurotransmitters, including norepinephrine, serotonin, and endorphins. Antidepressants appear to relieve both depression and pain. Childhood physical and sexual abuse has also been noted to be more prevalent in women with chronic pelvic pain than in those with other types of pain (52% versus 12%) (161,162). In a comparison of women with chronic pelvic pain, women with nonpelvic chronic pain (headache), and pain-free women, a higher lifetime prevalence of major sexual abuse (56%) and physical abuse (50%) was found in the chronic pelvic pain group (163). However, another study of chronic pain syndromes and their relation to childhood abuse found that severe childhood sexual abuse did not seem to directly affect chronic pain, whereas childhood physical abuse did influence it (164). Childhood sexual abuse had a greater impact on depression, but childhood physical violence did not (164). Individual differences in personality and habitual coping strategies may also influence response to pain and pain recurrence. Childhood abuse possibly leads to an increased vulnerability to psychosocial stress and impaired coping strategies (164).

If patients are taught self-efficacy and adaptive pain coping skills through psychological treatment interventions, pain can be reduced and functioning improved. Dramatizing the pain is a coping mechanism that is used by pain sufferers to generate support from others around them (165). This practice, combined with pain-related anxiety and fear, propagates pain (159).

**Management of Chronic Pelvic Pain**

**Multidisciplinary Approach**

In patients with no obvious pathology and in those with pathology that has an equivocal role in pain production, multidisciplinary therapy is usually preferable. This approach incorporates the skills of the gynecologist, psychologist, and physical therapist.

The approach to women with chronic pain must be therapeutic, optimistic, supportive, and sympathetic. Offering regular follow-up appointments is preferable to asking the
patient to return only if pain persists because the latter reinforces pain behavior. Specific pain management skills should be taught using cognitive/behavioral approaches. Women are offered ways to enhance opportunities for control of pain. Psychotherapy is indicated for women who have pronounced depression, sexual difficulties, or indications of past trauma. Various strategies, including relaxation techniques, stress management, sexual and marital counseling, hypnosis, and other psychotherapeutic approaches, have been found to be crucial. Psychological group treatment has also been shown to be a very cost-effective approach for helping patients to learn stress reduction techniques and develop coping behavioral mechanisms (166). Acupuncture may also be helpful (167). Uterosacral, inferior and superior hypogastric, iliohypogastric, pudendal, or epidural nerve blocks should be used where appropriate (13,14,168).

Various studies of multidisciplinary pain management have been performed. Retrospective, uncontrolled studies revealed relief of pain in 85% of the subjects (167,169). One prospective randomized study revealed a similar response rate, which was significantly better than that of traditional therapy for pain and associated symptom reduction, improvement of daily functioning, and quality of life (170).

**Medical Therapy**

A low dose of a tricyclic antidepressant, anticonvulsant, or selective serotonin/norepinephrine reuptake inhibitor is combined with cognitive behavioral therapy directed toward reducing reliance on pain medication, increasing activity, and relieving the impact the pain has on the women's overall lifestyle (13,14). Women with depression should be treated with an appropriate therapeutic dose of antidepressant medication. Antidepressants such as tricyclic antidepressants in low doses or serotonin/norepinephrine reuptake inhibitors (SNRIs) that elevate central norepinephrine concentrations are useful for pain modulation and pain reduction. Only one small, randomized, controlled trial has looked at the effect of selective serotonin reuptake inhibitors on pelvic pain. It failed to show a significant difference in pain or functional ability in a short follow-up period (171).

**Surgical Therapy**

**Laparoscopy**

Women with disabling cyclic pain that does not respond to nonsteroidal anti-inflammatory medication or oral contraceptives should undergo laparoscopic evaluation. Diagnostic laparoscopy has become a standard procedure in the evaluation of patients with chronic noncyclic pelvic pain; however, laparoscopy should be withheld until other nongynecologic somatic or visceral causes of pain have been excluded. During diagnostic laparoscopy, endometriotic lesions should be excised for biopsy, and if infection is suspected, cultures should be performed. All visible endometriosis should be surgically excised or electrocoagulated. Patients with dysmenorrhea may benefit from transection of the uterosacral ligaments. The uterosacral ligaments carry the principal afferent nerve supply from the uterus to the hypogastric nerve. The original procedure was performed by colpotomy and had a success rate of 70% (172). Laparoscopic nerve ablation was found to relieve dysmenorrhea in 85% of patients (173). Nonrandomized retrospective and prospective studies have suggested that diagnostic laparoscopy provides a positive psychological effect on the treatment of chronic pelvic pain; however, this should not be the main goal of laparoscopy (174).

**Lysis of Adhesions**

The role of pelvic adhesions in pain is unclear, and the efficacy of lysis of adhesions is even more in doubt. Adhesiolyis, even via laparoscopy, is frequently complicated by adhesion reformation and has not been shown to be effective for relief of pain in
controlled trials (107,175,176). Other causes must be treated first, and psychological consultation and management should precede or accompany the lysis of adhesions.

Presacral Neurectomy and Uterine Nerve Ablation

Presacral neurectomy or sympathectomy was first described for dysmenorrhea (177). **Laparoscopic uterine nerve ablation (LUNA)** was developed to offer a more technically straightforward, permanent surgical procedure for chronic pelvic pain (178). The discovery of highly successful medical therapies has largely supplanted presacral neurectomy and LUNA; however, presacral neurectomy and LUNA may be indicated for primary or secondary dysmenorrhea unrelieved by traditional therapy and unresponsive to multidisciplinary pain management. The response rate to presacral neurectomy for secondary dysmenorrhea varies between 50% and 75% (176). LUNA and presacral neurectomy for primary dysmenorrhea have not been found to provide statistically significant differences in short-term pain relief, but it appears that presacral neurectomy may be more effective than LUNA in the long term (176). The neurectomy only relieves pain deriving from the cervix, uterus, and proximal fallopian tubes (T11 to L2). The nerve supply to the adnexal structures (T9 to T10) bypasses the hypogastric nerve. Therefore, lateralizing visceral pain is unlikely to be relieved by presacral neurectomy. Intraoperative complications, such as hemorrhage or ureteral injury, can occur in a small percentage of cases. The sacral nerve supply is unaffected by division of the presacral nerve; thus, normal micturition, defecation, and parturition are preserved. A local anesthetic hypogastric block performed under fluoroscopic guidance can help to predict the response to this operation.

Hysterectomy

Although 19% of hysterectomies are performed to cure pelvic pain, 30% of patients presenting to pain clinics have already undergone hysterectomy without experiencing pain relief (63,64). A multidisciplinary approach including a gynecologist, physical therapist, and a psychologist was shown to decrease the frequency of hysterectomies in one study from 16.3% of patients with chronic pelvic pain to 5.8% (179).

Hysterectomy is particularly useful for women who have completed childbearing and have secondary dysmenorrhea or chronic pain related to endometriosis, to uterine pathology, such as adenomyosis, or to pelvic congestion. Before recommending hysterectomy for pain or unilateral adnexectomy for unilateral pain, it is useful to apply the **PREPARE** pneumatic in discussions with the patient (180): the Procedure that is being done, Reason or indication, Expectation or desired outcome of the procedure, Probability that the outcome will be achieved, Alternatives and nonsurgical options, and Risks as well as Expense (see Chapter 3). Hysterectomy for central pelvic pain in women with dysmenorrhea, dyspareunia, and uterine tenderness provided relief of pain in 77% of women in one retrospective study (181) and in 74% of women in one prospective cohort study (182). Nevertheless, 25% of women in the retrospective study noted that pain persisted or worsened at 1-year follow-up (181). Persistent pain in the prospective study was associated with multiparity, prior history of PID, absence of pathology, and Medicaid payer status (182).

The American College of Obstetricians and Gynecologists has outlined criteria that should be met before performing a hysterectomy for pelvic pain (183). They require at least 6 months of pelvic pain without any otherwise correctable pathology. When deciding on the surgical approach, consideration should be given to a vaginal or laparoscopic hysterectomy over an abdominal approach if there are no extensive adhesions expected or large uterine/fibroid size does not preclude it. There have been many studies that confirm less morbidity and shorter hospital stays with vaginal compared with abdominal hysterectomies (184,185). A prospective study of abdominal versus vaginal versus...
laparoscopically assisted surgery did not find any statistical difference or worsening of outcomes of urinary or sexual function between the different approaches at 6 months (85).

SECTION IV General Gynecology

Vaginitis is diagnosed by office-based testing.

More prolonged antifungal therapy is indicated for women with complicated vulvovaginal candidiasis (VVC) than for those with uncomplicated disease.

Women with normal physical examination findings and no evidence of fungal infection disclosed by microscopy are unlikely to have VVC and should not be treated empirically unless results of a vaginal yeast culture are positive.

Cervicitis is commonly associated with bacterial vaginosis (BV), which, if not treated concurrently, leads to significant persistence of the symptoms and signs of cervicitis.

Metronidazole should be included in the antimicrobial regimen used to treat patients with pelvic inflammatory disease (PID) if concurrent bacterial vaginosis is present.

Trocar drainage, with or without placement of a drain, is successful in as many as 90% of patients with PID complicated by tubo-ovarian abscess that fails to respond to antimicrobial therapy within 72 hours.

Because false-negative results are common with herpes simplex virus (HSV) cultures, especially in patients with recurrent infections, type-specific glycoprotein G-based antibody assay tests are useful in confirming a clinical diagnosis of genital herpes.

Suppressive treatment partially decreases symptomatic and asymptomatic viral shedding and the potential for transmission.

Genitourinary tract infections are among the most frequent disorders for which patients seek care from gynecologists. By understanding the pathophysiology of these diseases and having an effective approach to their diagnosis, physicians can institute appropriate antimicrobial therapy to treat these conditions and reduce long-term sequelae.
The Normal Vagina

Normal vaginal secretions are composed of vulvar secretions from sebaceous, sweat, Bartholin, and Skene glands; transudate from the vaginal wall; exfoliated vaginal and cervical cells; cervical mucus; endometrial and oviductal fluids; and micro-organisms and their metabolic products. The type and amount of exfoliated cells, cervical mucus, and upper genital tract fluids are determined by biochemical processes that are influenced by hormone levels (1). Vaginal secretions may increase in the middle of the menstrual cycle because of an increase in the amount of cervical mucus. These cyclic variations do not occur when oral contraceptives are used and ovulation does not occur.

The vaginal desquamative tissue is made up of vaginal epithelial cells that are responsive to varying amounts of estrogen and progesterone. Superficial cells, the main cell type in women of reproductive age, predominate when estrogen stimulation is present. Intermediate cells predominate during the luteal phase because of stimulation by progestogen. Parabasal cells predominate in the absence of either hormone, a condition that may be found in postmenopausal women who are not receiving hormonal therapy.

The normal vaginal flora is mostly aerobic, with an average of six different species of bacteria, the most common of which is hydrogen peroxide–producing lactobacilli. The microbiology of the vagina is determined by factors that affect the ability of bacteria to survive (2). These factors include vaginal pH and the availability of glucose for bacterial metabolism. The pH level of the normal vagina is lower than 4.5, which is maintained by the production of lactic acid. Estrogen-stimulated vaginal epithelial cells are rich in glycogen. Vaginal epithelial cells break down glycogen to monosaccharides, which can then be converted by the cells themselves, and lactobacilli to lactic acid.

Normal vaginal secretions are floccular in consistency, white in color, and usually located in the dependent portion of the vagina (posterior fornix). Vaginal secretions can be analyzed by a wet-mount preparation. A sample of vaginal secretions is suspended in 0.5 mL of normal saline in a glass tube, transferred to a slide, covered with a slip, and assessed by microscopy. Some clinicians prefer to prepare slides by suspending secretions in saline placed directly on the slide. Secretions should not be placed on the slide without saline because this method causes drying of the vaginal secretions and does not result in a well-suspended preparation. Microscopy of normal vaginal secretions reveals many superficial epithelial cells, few white blood cells (less than 1 per epithelial cell), and few, if any, clue cells. Clue cells are superficial vaginal epithelial cells with adherent bacteria, usually Gardnerella vaginalis, which obliterates the crisp cell border when visualized microscopically. Potassium hydroxide 10% (KOH) may be added to the slide, or a separate preparation can be made, to examine the secretions for evidence of fungal elements. The results are negative in women with normal vaginal microbiology. Gram stain reveals normal superficial epithelial cells and a predominance of gram-positive rods (lactobacilli).

Vaginal Infections

Bacterial Vaginosis

Bacterial vaginosis (BV) has previously been referred to as nonspecific vaginitis or Gardnerella vaginitis. It is an alteration of normal vaginal bacterial flora that results in the loss of hydrogen peroxide–producing lactobacilli and an overgrowth of predominantly anaerobic bacteria (3,4). The most common form of vaginitis in the United States is BV (5). Anaerobic bacteria can be found in less than 1% of the flora of normal women. In women with BV, however, the concentration of anaerobes, as well as G. vaginalis and Mycoplasma hominis, is 100 to 1,000 times higher than in normal women. Lactobacilli are usually absent.
It is not known what triggers the disturbance of normal vaginal flora. It has been postulated that repeated alkalinization of the vagina, which occurs with frequent sexual intercourse or use of douches, plays a role. After normal hydrogen peroxide–producing lactobacilli disappear, it is difficult to reestablish normal vaginal flora, and recurrence of BV is common.

Numerous studies have shown an association of BV with significant adverse sequelae. Women with BV are at increased risk for pelvic inflammatory disease (PID) (6), postabortal PID (7), postoperative cuff infections after hysterectomy (8), and abnormal cervical cytology (9). Pregnant women with BV are at risk for premature rupture of the membranes (10), preterm labor and delivery (10), chorioamnionitis, and postcesarean endometritis (11). In women with BV who are undergoing surgical abortion or hysterectomy, perioperative treatment with metronidazole eliminates this increased risk (12,13).

**Diagnosis**

Office-based testing is required to diagnose BV. It is diagnosed on the basis of the following findings (14):

1. A fishy vaginal odor, which is particularly noticeable following coitus, and vaginal discharge are present.
2. Vaginal secretions are gray and thinly coat the vaginal walls.
3. The pH of these secretions is higher than 4.5 (usually 4.7 to 5.7).
4. Microscopy of the vaginal secretions reveals an increased number of clue cells, and leukocytes are conspicuously absent. In advanced cases of BV, more than 20% of the epithelial cells are clue cells.
5. The addition of KOH to the vaginal secretions (the “whiff” test) releases a fishy, aminelike odor.

Clinicians unable to perform microscopy should use alternative diagnostic tests such as a pH and amines test card, detection of G. vaginalis ribosomal RNA, or Gram stain (15). Culture of G. vaginalis is not recommended as a diagnostic tool because of its lack of specificity.

**Treatment**

Ideally, treatment of BV should inhibit anaerobes but not vaginal lactobacilli. The following treatments are effective (16):

1. **Metronidazole**, an antibiotic with excellent activity against anaerobes but poor activity against lactobacilli, is the drug of choice for the treatment of BV. A dose of 500 mg administered orally twice a day for 7 days should be used. Patients should be advised to avoid using alcohol during treatment with oral metronidazole and for 24 hours thereafter.

2. **Metronidazole** gel, 0.75%, one applicator (5 g) intravaginally once or twice daily for 5 days, may also be prescribed.

The overall cure rates range from 75% to 84% with the aforementioned regimens (16). **Clindamycin in the following regimens also is effective in treating BV:**

1. **Clindamycin** cream, 2%, one applicator full (5 g) intravaginally at bedtime for 7 days
2. **Clindamycin**, 300 mg, orally twice daily for 7 days
SECTION IV  General Gynecology

3. **Clindamycin** ovules, 100 mg, intravaginally once at bedtime for 3 days

4. **Clindamycin** bioadhesive cream, 2%, 100 mg intravaginally in a single dose

Many clinicians prefer intravaginal treatment to avoid systemic side effects such as mild to moderate gastrointestinal upset and unpleasant taste. Treatment of the male sexual partner has not been shown to improve therapeutic response and therefore is not recommended.

**Trichomonas Vaginitis**

Trichomonas vaginitis is caused by the sexually transmitted, flagellated parasite, *Trichomonas vaginalis*. The transmission rate is high; 70% of men contract the disease after a single exposure to an infected woman, which suggests that the rate of male-to-female transmission is even higher. The parasite, which exists only in trophozoite form, is an anaerobe that has the ability to generate hydrogen to combine with oxygen to create an anaerobic environment. It often accompanies BV, which can be diagnosed in as many as 60% of patients with trichomonas vaginitis.

**Diagnosis**

Local immune factors and inoculum size influence the appearance of symptoms. Symptoms and signs may be much milder in patients with a small inocula of trichomonads, and trichomonas vaginitis often is asymptomatic (17,18).

1. Trichomonas vaginitis is associated with a profuse, purulent, malodorous vaginal discharge that may be accompanied by vulvar pruritus.

2. Vaginal secretions may exude from the vagina.

3. In patients with high concentrations of organisms, a patchy vaginal erythema and colpitis macularis (“strawberry” cervix) may be observed.

4. The pH of the vaginal secretions is usually higher than 5.0.

5. Microscopy of the secretions reveals motile trichomonads and increased numbers of leukocytes.

6. Clue cells may be present because of the common association with BV.

7. The whiff test may be positive.

Morbidity associated with trichomonal vaginitis may be related to BV. Patients with trichomonas vaginitis are at increased risk for postoperative cuff cellulitis following hysterectomy (8). **Pregnant women with trichomonas vaginitis are at increased risk for premature rupture of the membranes and preterm delivery.** Because of the sexually transmitted nature of trichomonas vaginitis, women with this infection should be tested for other sexually transmitted diseases (STDs), particularly *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Serologic testing for syphilis and human immunodeficiency virus (HIV) infection should also be considered.

**Treatment**

The treatment of trichomonal vaginitis can be summarized as follows:

1. **Metronidazole** is the drug of choice for treatment of vaginal trichomoniasis. Both a single-dose (2 g orally) and a multidose (500 mg twice daily for 7 days) regimen are highly effective and have cure rates of about 95%.
2. The sexual partner should also be treated.

3. *Metronidazole* gel, although highly effective for the treatment of BV, should not be used for the treatment of vaginal trichomoniasis.

4. Women who do not respond to initial therapy should be treated again with *metronidazole*, 500 mg, twice daily for 7 days. If repeated treatment is not effective, the patient should be treated with a single 2-g dose of *metronidazole* once daily for 5 days or *tinidazole*, 2 g, in a single dose for 5 days.

5. Patients who do not respond to repeated treatment with *metronidazole* or *tinidazole* and for whom the possibility of reinfection has been excluded should be referred for expert consultation. In these uncommon refractory cases, an important part of management is to obtain cultures of the parasite to determine its susceptibility to *metronidazole* and *tinidazole*.

### Vulvovaginal Candidiasis

An estimated 75% of women experience at least one episode of vulvovaginal candidiasis (VVC) during their lifetimes (19). Nearly 45% of women will experience two or more episodes (20). Fortunately, few are plagued with a chronic, recurrent infection. *Candida albicans* is responsible for 85% to 90% of vaginal yeast infections. Other species of *Candida*, such as *C. glabrata* and *C. tropicalis*, can cause vulvovaginal symptoms and tend to be resistant to therapy. Candida are dimorphic fungi existing as blastospores, which are responsible for transmission and asymptomatic colonization, and as mycelia, which result from blastospore germination and enhance colonization and facilitate tissue invasion. The extensive areas of pruritus and inflammation often associated with minimal invasion of the lower genital tract epithelial cells suggest that an extracellular toxin or enzyme may play a role in the pathogenesis of this disease. A hypersensitivity phenomenon also may be responsible for the irritative symptoms associated with VVC, especially for patients with chronic, recurrent disease. Patients with symptomatic disease usually have an increased concentration of these micro-organisms (>10^9/mL) compared with asymptomatic patients (<10^9/mL) (21).

Factors that predispose women to the development of symptomatic VVC include antibiotic use (22,23), pregnancy (24), and diabetes (25). Pregnancy and diabetes are both associated with a qualitative decrease in cell-mediated immunity, leading to a higher incidence of candidiasis.

It is helpful to categorize women with VVC as having either uncomplicated or complicated disease (Table 16.1).

</tbody>
</table>

**Diagnosis**

The symptoms of VVC consist of vulvar pruritus associated with a vaginal discharge that typically resembles cottage cheese.

1. **The discharge can vary from watery to homogeneously thick.** Vaginal soreness, dyspareunia, vulvar burning, and irritation may be present. External dysuria (“splash” dysuria) may occur when micturition leads to exposure of the inflamed vulvar and vestibular epithelium to urine. Examination reveals erythema and edema of the labia and vulvar skin. Discrete pustulopapular peripheral lesions may be present. The vagina may be erythematous with an adherent, whitish discharge. The cervix appears normal.

2. **The pH of the vagina in patients with VVC is usually normal (<4.5).**

3. **Fungal elements, either budding yeast forms or mycelia, appear in as many as 80% of cases.** The results of saline preparation of the vaginal secretions usually are normal, although there may be a slight increase in the number of inflammatory cells in severe cases.

4. **The whiff test is negative.**

5. **A presumptive diagnosis can be made in the absence of fungal elements confirmed by microscopy if the pH and the results of the saline preparation evaluations are normal and the patient has increased erythema based on examination of the vagina or vulva. A fungal culture is recommended to confirm the diagnosis.** Conversely, women with a normal physical examination findings and no evidence of fungal elements disclosed by microscopy are unlikely to have VVC and should not be empirically treated unless a vaginal yeast culture is positive.

**Treatment**

1. **Topically applied azole drugs are the most commonly available treatment for VVC and are more effective than nystatin (16) (Table 16.2).** Treatment with azoles results in relief of symptoms and negative cultures in 80% to 90% of patients who have completed therapy. Symptoms usually resolve in 2 to 3 days. There is a trend to shorten the duration of therapy to 1 to 3 days. Although the shorter period of therapy implies a shortened duration of treatment, the short-course formulations have higher concentrations of the antifungal agent, causing an inhibitory concentration in the vagina that persists for several days.

2. **An oral antifungal agent, fluconazole, used in a single 150-mg dose, has been approved for the treatment of VVC.** It appears to have equal efficacy when compared with topical azoles in the treatment of mild to moderate VVC (26). Patients should be advised that their symptoms will persist for 2 to 3 days so they will not expect additional treatment.

3. **Women with complicated VVC benefit from an additional 150-mg dose of fluconazole given 72 hours after the first dose.** Patients with complications also can be treated with a more prolonged topical regimen lasting 10 to 14 days. Adjunctive treatment with a weak topical steroid, such as 1% hydrocortisone cream, may be helpful in relieving some of the external irritative symptoms.
Recurrent Vulvovaginal Candidiasis

A small number of women develop recurrent VVC (RVVC), defined as four or more episodes in a year. These women experience persistent irritative symptoms of the vestibule and vulva. Burning replaces itching as the prominent symptom in patients with RVVC. The diagnosis should be confirmed by direct microscopy of the vaginal secretions and by fungal culture.

Many women with RVVC presume incorrectly they have a chronic yeast infection. Many of these patients have chronic atopic dermatitis or atrophic vulvovaginitis.

The treatment of patients with RVVC consists of inducing a remission of chronic symptoms with fluconazole (150 mg every 3 days for 3 doses). Patients should then be maintained on a suppressive dose of this agent (fluconazole, 150 mg weekly) for 6 months. On this regimen, 90% of women with RVVC will remain in remission. After suppressive therapy, approximately one half will remain asymptomatic. Recurrence will occur in the other half and should prompt reinstitution of suppressive therapy (27).

Inflammatory Vaginitis

Desquamative inflammatory vaginitis is a clinical syndrome characterized by diffuse exudative vaginitis, epithelial cell exfoliation, and a profuse purulent vaginal discharge (28). The cause of inflammatory vaginitis is unknown, but Gram stain findings reveal a relative absence of normal long gram-positive bacilli (lactobacilli) and...
their replacement with gram-positive cocci, usually streptococci. Women with this disorder have a purulent vaginal discharge, vulvovaginal burning or irritation, and dyspareunia. A less frequent symptom is vulvar pruritus. Vaginal erythema is present, and there may be an associated vulvar erythema, vulvovaginal ecchymotic spots, and colpitis macularis. The pH of the vaginal secretions is uniformly higher than 4.5 in these patients.

Initial therapy is the use of 2% clindamycin cream, one applicator full (5 g) intravaginally once daily for 7 days. Relapse occurs in about 30% of patients, who should be retreated with intravaginal 2% clindamycin cream for 2 weeks. When relapse occurs in postmenopausal patients, supplementary hormonal therapy should be considered.

Atrophic Vaginitis

Estrogen plays an important role in the maintenance of normal vaginal ecology. Women undergoing menopause, either naturally or secondary to surgical removal of the ovaries, may develop inflammatory vaginitis, which may be accompanied by an increased, purulent vaginal discharge. In addition, they may have dyspareunia and postcoital bleeding resulting from atrophy of the vaginal and vulvar epithelium. Examination reveals atrophy of the external genitalia, along with a loss of the vaginal rugae. The vaginal mucosa may be somewhat friable in areas. Microscopy of the vaginal secretions shows a predominance of parabasal epithelial cells and an increased number of leukocytes.

Atrophic vaginitis is treated with topical estrogen vaginal cream. Use of 1 g of conjugated estrogen cream intravaginally each day for 1 to 2 weeks generally provides relief. Systemic estrogen therapy should be considered to prevent recurrence of this disorder.

Cervicitis

The cervix is made up of two different types of epithelial cells: squamous epithelium and glandular epithelium. The cause of cervical inflammation depends on the epithelium affected. The ectocervical epithelium can become inflamed by the same micro-organisms that are responsible for vaginitis. In fact, the ectocervical squamous epithelium is an extension of and is continuous with the vaginal epithelium. Trichomonas, candida, and HSV can cause inflammation of the ectocervix. Conversely, N. gonorrhoeae and C. trachomatis infect only the glandular epithelium (29).

Diagnosis

The diagnosis of cervicitis is based on the finding of a purulent endocervical discharge, generally yellow or green in color and referred to as “mucopus” (30).

1. After removal of ectocervical secretions with a large swab, a small cotton swab is placed into the endocervical canal and the cervical mucus is extracted. The cotton swab is inspected against a white or black background to detect the green or yellow color of the mucopus. In addition, the zone of ectopy (glandular epithelium) is friable or easily induced to bleed. This characteristic can be assessed by touching the ectropion with a cotton swab or spatula.

2. Placement of the mucopus on a slide that can be Gram stained will reveal the presence of an increased number of neutrophils (>30 per high-power field). The presence of intracellular gram-negative diplococci, leading to the presumptive diagnosis of gonococcal endocervicitis, also may be detected. If the Gram stain results are negative for gonococci, the presumptive diagnosis is chlamydial cervicitis.
3. Tests for both gonorrhea and chlamydia, preferably using nuclei acid amplification tests, should be performed. The microbial etiology of endocervicitis is unknown in about 50% of cases in which neither gonococci nor chlamydia is detected.

Treatment of cervicitis consists of an antibiotic regimen recommended for the treatment of uncomplicated lower genital tract infection with both chlamydia and gonorrhea (16) (Table 16.3). It is imperative that all sexual partners be treated with a similar antibiotic regimen. Cervicitis is commonly associated with BV, which, if not treated concurrently, leads to significant persistence of the symptoms and signs of cervicitis.

Pelvic Inflammatory Disease

PID is caused by micro-organisms colonizing the endocervix ascending to the endometrium and fallopian tubes. It is a clinical diagnosis implying that the patient has upper genital tract infection and inflammation. The inflammation may be present at any point along a continuum that includes endometritis, salpingitis, and peritonitis (Fig. 16.1).

Pelvic inflammatory disease commonly is caused by the sexually transmitted microorganisms *N. gonorrhoeae* and *C. trachomatis* (31–33). Endogenous micro-organisms found in the vagina, particularly the BV micro-organisms, also often are isolated from the upper genital tract of women with PID. The BV micro-organisms include anaerobic bacteria such as *Prevotella* and peptostreptococci as well as *G. vaginalis*. BV often occurs in women with PID, and the resultant complex alteration of vaginal flora may facilitate the ascending spread of pathogenic bacteria by enzymatically altering the cervical mucus barrier (34). Less frequently, respiratory pathogens such as *Haemophilus influenzae*, group A streptococci, and pneumococci can colonize the lower genital tract and cause PID.

### Diagnosis

Traditionally, the diagnosis of PID has been based on a triad of symptoms and signs, including pelvic pain, cervical motion and adnexal tenderness, and the presence of fever. It is now recognized that there is wide variation in many symptoms and signs among women with this condition, which makes the diagnosis of acute PID difficult. Many women with PID exhibit subtle or mild symptoms that are not readily recognized as PID. Consequently, delay in diagnosis and therapy probably contributes to the inflammatory sequelae in the upper reproductive tract (35).
In the diagnosis of PID, the goal is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but sufficiently specific to avoid giving antibiotic therapy to women who are not infected. Genitourinary tract symptoms may indicate PID; therefore, the diagnosis of PID should be considered in women with any genitourinary symptoms, including, but not limited to, lower abdominal pain, excessive vaginal discharge, menorrhagia, metrorrhagia, fever, chills, and urinary symptoms (36). Some women may develop PID without having any symptoms.

Pelvic organ tenderness, either uterine tenderness alone or uterine tenderness with adnexal tenderness, is present in patients with PID. Cervical motion tenderness suggests the presence of peritoneal inflammation, which causes pain when the peritoneum is stretched by moving the cervix and causing traction of the adnexa on the pelvic peritoneum. Direct or rebound abdominal tenderness may be present.

Evaluation of both vaginal and endocervical secretions is a crucial part of the workup of a patient with PID (37). In women with PID, an increased number of polymorphonuclear leukocytes may be detected in a wet mount of the vaginal secretions or in the mucopurulent discharge.

More elaborate tests may be used in women with severe symptoms because an incorrect diagnosis may cause unnecessary morbidity (38) (Table 16.4). These tests include endometrial biopsy to confirm the presence of endometritis, ultrasound or radiologic tests to characterize a tubo-ovarian abscess, and laparoscopy to confirm salpingitis visually.
CHAPTER 16  Genitourinary Infections and Sexually Transmitted Diseases

Treatment

Therapy regimens for PID must provide empirical, broad-spectrum coverage of likely pathogens (16,39), including *N. gonorrhoeae, C. trachomatis*, gram-negative facultative bacteria, *anaerobes*, and streptococci. Recommended regimens for the treatment of PID are listed in Table 16.5. An outpatient regimen of cefoxitin and doxycycline is as effective as an inpatient parenteral regimen of the same antimicrobials (40). Therefore, hospitalization is recommended only when the diagnosis is uncertain, pelvic abscess is suspected, clinical disease is severe, or compliance with an outpatient regimen is in question.

Hospitalized patients can be considered for discharge when their fever has lysed (>99.5°F for more than 24 hours), the white blood cell count has become normal, rebound tenderness is absent, and repeat examination shows marked amelioration of pelvic organ tenderness (41).

Sexual partners of women with PID should be evaluated and treated for urethral infection with chlamydia or gonorrhea (Table 16.3). One of these STDs usually is found in the male sexual partners of women with PID not associated with chlamydia or gonorrhea (42,43).

**Tubo-ovarian Abscess**

An end-stage process of acute PID, tubo-ovarian abscess is diagnosed when a patient with PID has a pelvic mass that is palpable during bimanual examination. The condition usually reflects an agglutination of pelvic organs (tube, ovary, bowel) forming a palpable complex. Occasionally, an ovarian abscess can result from the entrance of micro-organisms through an ovulatory site. Tubo-ovarian abscess is treated with an antibiotic regimen administered in a hospital (Table 16.5). About 75% of women with tubo-ovarian abscess respond to antimicrobial therapy alone. Failure of medical therapy suggests the need for drainage of the abscess (44). Although drainage may require surgical exploration, percutaneous drainage guided by imaging studies (ultrasound or computed tomography) should be used as an initial option if possible. Trocar drainage, with or without placement of a drain, is successful in up to 90% of cases in which the patient failed to respond to antimicrobial therapy after 72 hours (45).
SECTION IV  General Gynecology

Other Major Infections

Genital Ulcer Disease

In the United States, most patients with genital ulcers have genital HSV or syphilis (46–49). Chancroid is the next most common cause of sexually transmitted genital ulcers, followed by the rare occurrence of lymphogranuloma venereum (LGV) and granuloma inguinale (donovanosis). These diseases are associated with an increased risk for HIV infection. Other infrequent and noninfectious causes of genital ulcers include abrasions, fixed drug eruptions, carcinoma, and Behçet’s disease.

Diagnosis

A diagnosis based on history and physical examination alone often is inaccurate. Therefore, all women with genital ulcers should undergo a serologic test for syphilis (49).
CHAPTER 16  Genitourinary Infections and Sexually Transmitted Diseases

Because of the consequences of inappropriate therapy, such as tertiary disease and congenital syphilis in pregnant women, diagnostic efforts are directed at excluding syphilis. Optimally, the evaluation of a patient with a genital ulcer should include dark-field examination or direct immunofluorescence testing for *Treponema pallidum*, culture or antigen testing for HSV, and culture for *Haemophilus ducreyi*. Dark-field or fluorescent microscopes and selective media to culture for *H. ducreyi* often are not available in most offices and clinics. Even after complete testing, the diagnosis remains unconfirmed in one fourth of patients with genital ulcers. For this reason, most clinicians base their initial diagnosis and treatment recommendations on their clinical impression of the appearance of the genital ulcer (Fig. 16.2) and knowledge of the most likely cause in their patient population (47).

Several clinical presentations are highly suggestive of specific diagnoses:

1. A painless and minimally tender ulcer, not accompanied by inguinal lymphadenopathy, is likely to be syphilis, especially if the ulcer is indurated.

A nontreponemal rapid plasma reagin (RPR) test, or venereal disease research laboratory (VDRL) test, and a confirmatory treponemal test—fluorescent treponemal antibody absorption (FTA ABS) or microhemagglutinin—*T. pallidum*
Grouped vesicles mixed with small ulcers, particularly with a history of such lesions, are almost always pathognomonic of genital herpes. Nevertheless, laboratory confirmation of the findings is recommended because the diagnosis of genital herpes is traumatic for many women, alters their self-image, and affects their perceived ability to enter new sexual relationships and bear children. Culture is the most sensitive and specific test; sensitivity approaches 100% in the vesicle stage and 89% in the pustular stage and drops to as low as 33% in patients with ulcers. Nonculture tests are about 80% as sensitive as culture tests. Because false-negative results are common with HSV cultures, especially in patients with recurrent infections, type-specific glycoprotein G-based antibody assays are useful in confirming a clinical diagnosis of genital herpes.

One to three extremely painful ulcers, accompanied by tender inguinal lymphadenopathy, are unlikely to be anything except chancroid. This is especially true if the adenopathy is fluctuant.

An inguinal bubo accompanied by one or several ulcers is most likely chancroid. If no ulcer is present, the most likely diagnosis is LGV.

**Treatment**

**Chancroid**  Recommended regimens for the treatment of chancroid include azithromycin, 1 g orally in a single dose; ceftriaxone, 250 mg intramuscularly in a single dose; ciprofloxacin, 500 mg orally twice a day for 3 days; or erythromycin base, 500 mg orally 4 times daily for 7 days. Patients should be reexamined 3 to 7 days after initiation of therapy to ensure the gradual resolution of the genital ulcer, which can be expected to heal within 2 weeks unless it is unusually large.

**Herpes**  A first episode of genital herpes should be treated with acyclovir, 400 mg orally three times a day; or famciclovir, 250 mg orally three times a day; or valacyclovir, 1.0 orally twice a day for 7 to 10 days or until clinical resolution is attained. Although these agents provide partial control of the symptoms and signs of clinical herpes, it neither eradicates latent virus nor affects subsequent risk, frequency, or severity of recurrences after the drug is discontinued. Daily suppressive therapy (acyclovir, 400 mg orally twice daily; or famciclovir, 250 mg twice daily; or valacyclovir, 1.0 g orally once a day) reduces the frequency of HSV recurrences by at least 75% among patients with six or more recurrences of HSV per year. Suppressive treatment partially, but not totally, decreases symptomatic and asymptomatic viral shedding and the potential for transmission (48).

**Syphilis**  Parenteral administration of penicillin G is the preferred treatment of all stages of syphilis. Benzathine penicillin G, 2.4 million units intramuscularly in a single dose, is the recommended treatment for adults with primary, secondary, or early latent syphilis. The Jarisch-Herxheimer reaction—an acute febrile response accompanied by headache, myalgia, and other symptoms—may occur within the first 24 hours after any therapy for syphilis; patients should be advised of this possible adverse reaction.

Latent syphilis is defined as those periods after infection with *T. pallidum* when patients are seroreactive but show no other evidence of disease. Patients with latent syphilis of longer than 1 year’s duration or of unknown duration should be treated with benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units...
intragamally each, at 1-week intervals. All patients with latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis, neurosyphilis, gumma, and iritis). Quantitative nontreponemal serologic tests should be repeated at 6 months and again at 12 months. An initially high titer (1:32) should decline at least fourfold (two dilutions) within 12 to 24 months.

**Genital Warts**

External genital warts are a manifestation of human papillomavirus (HPV) infection (50). The nononcogenic HPV types 6 and 11 are usually responsible for external genital warts. The warts tend to occur in areas most directly affected by coitus, namely the posterior fourchette and lateral areas on the vulva. Less frequently, warts can be found throughout the vulva, in the vagina, and on the cervix. Minor trauma associated with coitus can cause breaks in the vulvar skin, allowing direct contact between the viral particles from an infected man and the basal layer of the epidermis of his susceptible sexual partner. Infection may be latent or may cause viral particles to replicate and produce a wart. External genital warts are highly contagious; more than 75% of sexual partners develop this manifestation of HPV infection when exposed.

The goal of treatment is removal of the warts; it is not possible to eradicate the viral infection. Treatment is most successful in patients with small warts that have been present for less than 1 year. It has not been determined whether treatment of genital warts reduces transmission of HPV. Selection of a specific treatment regimen depends on the anatomic site, size, and number of warts, as well as expense, efficacy, convenience, and potential adverse effects (Table 16.6). Recurrences more often result from reactivation of subclinical infection than reinfection by a sex partner; therefore, examination of sex partners is not absolutely necessary. However, many of these sex partners may have external genital warts and may benefit from therapy and counseling concerning transmission of warts.

**Human Immunodeficiency Virus**

It is estimated that almost 40% to 50% of individuals with HIV are women. Intravenous drug use and heterosexual transmission are responsible for most of the cases of acquired immunodeficiency syndrome (AIDS) in women in the United States (51). Infection with HIV produces a spectrum of disease that progresses from an asymptomatic state to full-blown AIDS. The pace of disease progression in untreated adults is variable. The median time between infection with HIV and the development of AIDS is 10 years, with a range from a few months to more than 12 years. In a study of adults infected with HIV, symptoms developed in 70% to 85% of infected adults, and AIDS

| Table 16.6 Treatment Options for External Genital and Perianal Warts |
|---------------------------------|-----------------|-----------------|
| **Modality**                    | **Efficacy (%)**| **Recurrence Risk** |
| Cryotherapy                     | 63–88           | 21–39           |
| Imiquimod 5% cream**            | 33–72           | 13–19           |
| Podophyllin 10%–25%             | 32–79           | 27–65           |
| Podofilox 0.5%**                | 45–88           | 33–60           |
| Trichloroacetic acid 80%–90%    | 81              | 36              |
| Electrodesiccation or cautery   | 94              | 22              |
| Laser**                         | 43–93           | 29–95           |
| Interferon                      | 44–61           | 0–67            |

*May be self-applied by patients at home.

*Expensive; reserve for patients who have not responded to other regimens.
developed in 55% to 60% within 12 years after infection. The natural history of the disease can be significantly altered by antiretroviral therapy. Women with HIV-induced altered immune function are at increased risk for infections such as tuberculosis (TB), bacterial pneumonia, and *Pneumocystis carinii* pneumonia (PCP). Because of its impact on the immune system, HIV affects the diagnosis, evaluation, treatment, and follow-up of many other diseases and may decrease the efficacy of antimicrobial therapy for some STDs.

**Diagnosis**

Infection is most often diagnosed by HIV type 1 antibody tests. Antibody testing begins with a sensitive screening test such as ELISA or a rapid assay. If confirmed by Western blot or other supplemental testing, a positive antibody test result confirms that a person is infected with HIV and is capable of transmitting the virus to others. HIV antibody is detectable in more than 95% of patients within 6 months of infection. Women diagnosed with any STD, particularly genital ulcer disease, should be offered HIV testing (47). Women at risk for STD, such as those with multiple sexual partners or whose partners have multiple sexual partners, should be offered HIV testing.

The initial evaluation of an HIV-positive woman includes screening for diseases associated with HIV such as TB and STDs, administration of recommended vaccinations (hepatitis B, pneumococcal, and influenza), and behavioral and psychosocial counseling. Intraepithelial neoplasia is strongly associated with HPV infection and has been found to occur in high frequency in women with both HPV and HIV.

**Treatment**

Decisions regarding the initiation of antiretroviral therapy should be guided by monitoring the laboratory parameters of HIV RNA (viral load) and CD4+ T-cell count, as well as the clinical condition of the patient. The primary goals of antiretroviral therapy are maximal and durable suppression of viral load, restoration or preservation of immunologic function, improvement of quality of life, and reduction of HIV-related morbidity and mortality. In general, women with acute retroviral syndrome, those within 6 months of HIV seroconversion, and patients who have symptoms should be offered treatment (52). In addition, treatment should be offered to those women with fewer than 350 CD4+ T cells or plasma HIV RNA levels exceeding 100,000 copies/mL (bDNA assay). Patients must be willing to accept therapy to avoid the emergence of resistance caused by poor compliance. It has been shown that dual nucleoside regimens used in addition to a protease inhibitor or nonnucleoside reverse transcriptase inhibitor provide a better durable clinical benefit than monotherapy.

In addition, patients with less than 200 CD4+ T cells/μL should receive prophylaxis against opportunistic infections, such as trimethoprim-sulfamethoxazole or aerosol pentamidine for the prevention of PCP pneumonia (52).

**Urinary Tract Infection**

**Acute Cystitis**

Women with acute cystitis generally have an abrupt onset of multiple, severe urinary tract symptoms including dysuria, frequency, and urgency associated with suprapubic or low-back pain. Suprapubic tenderness may be noted on physical examination. Urinalysis reveals pyuria and sometimes hematuria. Several factors increase the risk for cystitis, including sexual intercourse, the use of a diaphragm and a spermicide, delayed postcoital micturition, and a history of a recent urinary tract infection (53–55).
Diagnosis

*Esherichia coli* is the most common pathogen isolated from the urine of young women with acute cystitis, and it is present in 80% of cases (56). *Staphylococcus saprophyticus* is present in an additional 5% to 15% of patients with cystitis. The pathophysiology of cystitis in women involves the colonization of the vagina and urethra with coliform bacteria from the rectum. For this reason, the effects of an antimicrobial agent on the vaginal flora play a role in the eradication of bacteriuria.

Treatment

High concentrations of *trimethoprim* and *fluoroquinolone* in vaginal secretions can eradicate *E. coli* while minimally altering normal anaerobic and microaerophilic vaginal flora. An increasing linear trend in the prevalence of resistance of *E. coli* (9%–18%) to *trimethoprim* and *trimethoprim-sulfamethoxazole* has been noted. In contrast, no such increase in resistance was noted with nitrofurantoin and ciprofloxacin. Nitrofurantoin (macrocysts, 100 mg orally twice daily for 7 days) or a *fluoroquinolone* (ciprofloxacin, 250 mg orally twice daily for 3 days) are the optimal choices for empirical 3-day therapy for uncomplicated cystitis (57).

In patients with typical symptoms, an abbreviated laboratory workup followed by empirical therapy is suggested. The diagnosis can be presumed if pyuria is detected by microscopy or leukocyte esterase testing. Urine culture is not necessary, and a short course of antimicrobial therapy should be given. No follow-up visit or culture is necessary unless symptoms persist or recur.

Recurrent Cystitis

About 20% of premenopausal women with an initial episode of cystitis have recurrent infections. More than 90% of these recurrences are caused by exogenous reinfection. Recurrent cystitis should be documented by culture to rule out resistant micro-organisms. Patients may be treated by one of three strategies: (i) continuous prophylaxis, (ii) postcoital prophylaxis, or (iii) therapy initiated by the patient when symptoms are first noted.

Postmenopausal women may also have frequent reinfections. Hormonal therapy or topically applied estrogen cream, along with antimicrobial prophylaxis, is helpful in treating these patients.

Urethritis

Women with dysuria caused by urethritis have a more gradual onset of mild symptoms, which may be associated with abnormal vaginal discharge or bleeding related to concurrent cervicitis. Patients may also have a new sex partner or experience lower abdominal pain. Physical examination may reveal the presence of mucopurulent cervicitis or vulvovaginal herpetic lesions. *C. trachomatis*, *N. gonorrhoeae*, or genital herpes may cause acute urethritis. Pyuria is present on urinalysis, but hematuria is rarely seen. Treatment regimens for chlamydia and gonococcal infections are presented in Table 16.3.

Occasionally, vaginitis caused by *C. albicans* or trichomonas is associated with dysuria. On careful questioning, patients generally describe external dysuria, sometimes associated with vaginal discharge, and pruritus and dyspareunia. They usually do not experience urgency or frequency. Pyuria and hematuria are absent.

Acute Pyelonephritis

The clinical spectrum of acute, uncomplicated pyelonephritis in young women ranges from gram-negative septicemia to a cystitislike illness with mild flank pain. *E. coli* accounts for more than 80% of these cases (58). Microscopy of unspun urine reveals...
pyuria and gram-negative bacteria. A urine culture should be obtained in all women with suspected pyelonephritis; blood cultures should be performed in those who are hospitalized because results are positive in 15% to 20% of cases. In the absence of nausea and vomiting and severe illness, outpatient oral therapy can be given safely. Patients who have nausea and vomiting, are moderately to severely ill, and are pregnant should be hospitalized. Outpatient treatment regimens include trimethoprim-sulfamethoxazole (160–800 mg every 12 hours) or a quinolone (eg, ofloxacin, 200–300 mg every 12 hours) for 10 to 14 days. Inpatient treatment regimens include the use of parenteral ceftriaxone (1–2 g daily), ampicillin (1 g every 6 hours), and gentamicin (especially if Enterococcus species are suspected) or aztreonam (1 g every 8–12 hours). Symptoms should resolve after 72 hours. If fever and flank pain persist after 72 hours of therapy, ultrasound or computed tomography should be considered to rule out a perinephric or intrarenal abscess or ureteral obstruction. A follow-up culture should be obtained 2 weeks after the completion of therapy (58).

References

Cervical intraepithelial neoplasia (CIN) arises in an area of metaplasia in the transformation zone at the advancing squamocolumnar junction (SCJ) in most cases. Metaplasia advances from the original SCJ inward, toward the external os and over the columnar villi, which establishes an area called the transformation zone. CIN is most likely to begin either during menarche or after pregnancy, when metaplasia is most active; after menopause, metaplasia is less active and a woman has a lower risk of developing CIN.

Most CIN 1 (and some CIN 2) lesions regress spontaneously if untreated; nevertheless, CIN refers to a lesion that may progress to invasive carcinoma. This term is equivalent to the term dysplasia, which means abnormal maturation; consequently, proliferating metaplasia without mitotic activity should not be called dysplasia. Squamous metaplasia should not be diagnosed as dysplasia (or CIN) because it does not progress to invasive cancer.

Approximately 90% of intraepithelial neoplasia is attributed to human papillomavirus (HPV) infection. Only certain types of HPV cause high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, and -58). Type 16 is the most common form of HPV found in invasive cancer and in CIN 2 and CIN 3; it is found in 47% of women with cancer in these stages.

Potentially premalignant squamous lesions fall into three categories: (i) atypical squamous cells (ASC), (ii) low-grade squamous intraepithelial lesions (LSIL), and (iii) high-grade squamous intraepithelial lesions (HSIL). The ASC category is subdivided into two categories: those of unknown significance (ASC-US) and those in which high-grade lesions must be excluded (ASC-H).
• The LSIL category includes CIN 1 (mild dysplasia) and the changes of HPV, termed koilocytic atypia. The HSIL category includes CIN 2 and CIN 3 (moderate dysplasia, severe dysplasia, and carcinoma in situ).

• The spontaneous regression rate of biopsy-proven CIN 1 is 60% to 85% in prospective studies. The regressions typically occur within a 2-year follow-up with cytology and colposcopy. For LSIL that persists for longer than 2 years, the choice of treatment is optional. Expectant management is still appropriate in some patients, and ablative therapies, including cryotherapy and laser ablation, are acceptable treatment modalities.

• When a cytologic specimen suggests the presence of HSIL, colposcopy and directed biopsy should be performed. Although high-grade CIN can be treated with a variety of techniques, the preferred treatment for CIN 2 and 3 is loop electrosurgical excision procedure (LEEP).

• Atypical endocervical cells pose a risk for adenocarcinoma in situ (AIS), which must be considered a serious cancer precursor of adenocarcinoma.

• After sampling to rule out invasive disease, VAIN 3 lesions can be treated with laser therapy. Patients with vaginal intraepithelial neoplasia (VAIN) 1 (and possibly VAIN 2) and HPV infection do not require treatment. These lesions often regress, are multifocal, and recur quickly when treated with ablative therapy.

• Vulvar intraepithelial neoplasia, grade 3 (VIN 3), is treated by simple excision, laser ablation, or superficial (partial) vulvectomy, with or without split-thickness skin grafting. Excision of small foci of disease produces excellent results, and although multifocal or extensive lesions may be difficult to treat by this approach, it offers the most cosmetic result. VIN 1-2 is also generally associated with dystrophic changes or HPV and can be managed expectantly.

Intraepithelial disease frequently occurs in the cervix, vagina, and vulva, and it may coexist in these areas. The cause and epidemiologic basis are common to all three locations, and treatment typically is ablative and conservative. Early diagnosis and management are essential to prevent disease from progressing to invasive cancer.

Cervical Intraepithelial Neoplasia

The concept of preinvasive disease of the cervix was introduced in 1947, when it was recognized that epithelial changes could be identified that had the appearance of invasive cancer but were confined to the epithelium (1). Subsequent studies showed that if these lesions are not treated, they can progress to cervical cancer (2). Improvements in cytologic assessment led to the identification of early precursor lesions called dysplasia, which signaled possible development of future cancer. For a number of years, carcinoma in situ (CIS) was treated very aggressively (most often with hysterectomy), whereas dysplasias were believed to be less significant and were not treated or were treated by colposcopic biopsy and cryosurgery. The concept of cervical intraepithelial neoplasia (CIN) was introduced in 1968, when Richart indicated that all dysplasias have the potential for progression (3). It is now recognized that most CIN 1 (and some CIN 2) lesions regress spontaneously if untreated (4); nevertheless, CIN refers to a lesion that may progress to invasive carcinoma. This term is equivalent to the term dysplasia, which means abnormal maturation; consequently, proliferating metaplasia without mitotic activity should not be called dysplasia. Squamous metaplasia should not be diagnosed as dysplasia (or CIN) because it does not progress to invasive cancer.

The criteria for the diagnosis of intraepithelial neoplasia may vary according to the pathologist, but the significant features are cellular immaturity, cellular disorganization, nuclear
abnormalities, and increased mitotic activity. The extent of the mitotic activity, immature cellular proliferation, and nuclear atypicality identify the degree of neoplasia. If the mitoses and immature cells are present only in the lower one third of the epithelium, the lesion usually is designated as CIN 1. Involvement of the middle and upper thirds is diagnosed as CIN 2 and CIN 3, respectively (Fig. 17.1).

Cervical Anatomy

The cervix is composed of *columnar epithelium*, which lines the endocervical canal, and *squamous epithelium*, which covers the exocervix (5). The point at which they meet is called the *squamocolumnar junction* (SCJ) (Figs. 17.2 and 17.3).

---

**Figure 17.1** Diagram of cervical intraepithelial neoplasia compared with normal epithelium.

**Figure 17.2** The cervix and the transformation zone.
**The Squamocolumnar Junction**

The SCJ rarely remains restricted to the external os. Instead, it is a dynamic point that changes in response to puberty, pregnancy, menopause, and hormonal stimulation (Fig. 17.4). In neonates, the SCJ is located on the exocervix. At menarche, the production of estrogen causes the vaginal epithelium to fill with glycogen. Lactobacilli act on the glycogen to lower the pH, stimulating the subcolumnar reserve cells to undergo metaplasia (5).

Metaplasia advances from the original SCJ inward, toward the external os and over the columnar villi. This process establishes an area called the *transformation zone*. The transformation zone extends from the original SCJ to the physiologically active SCJ. As the metaplastic epithelium in the transformation zone matures, it begins to produce glycogen and eventually resembles the original squamous epithelium, colposcopically and histologically (Figs. 17.5a and b).

In most cases, CIN is believed to originate as a single focus in the transformation zone at the advancing SCJ. The anterior lip of the cervix is twice as likely to develop CIN as the posterior lip, and CIN rarely originates in the lateral angles. Once CIN occurs, it can progress horizontally to involve the entire transformation zone, but it usually does not replace the original squamous epithelium. This progression usually results in CIN with a sharp external border. Proximally, CIN involves the cervical clefts, and this area tends to have the most severe CIN lesions. The extent of involvement of these cervical glands has significant therapeutic implications because the entire gland must be destroyed to ensure elimination of the CIN (5). The only way to determine where the original SCJ was located is to look for nabothian cysts or cervical cleft openings, which indicate the presence of columnar epithelium. Once the metaplastic epithelium matures and forms glycogen, it is called the *healed* transformation zone and is relatively resistant to oncogenic stimuli. However, the entire SCJ with early metaplastic cells is susceptible to oncogenic factors, which may cause these cells to transform into CIN. Therefore, **CIN is most likely to begin either during menarche or after pregnancy, when metaplasia is most active.** Conversely, after menopause a woman undergoes little metaplasia and is at a lower risk of developing CIN. Oncogenic
factors are introduced through sexual intercourse. Although several agents, including sperm, seminal fluid histones, trichomonas, chlamydia, and herpes simplex virus have been studied, it is now known that HPV plays an important role in the development of CIN.

Normal Transformation Zone

The original squamous epithelium of the vagina and exocervix has four layers (5):

1. The **basal layer** is a single row of immature cells with large nuclei and a small amount of cytoplasm.

2. The **parabasal layer** includes two to four rows of immature cells that have normal mitotic figures and provide the replacement cells for the overlying epithelium.
3. The intermediate layer includes four to six rows of cells with larger amounts of cytoplasm in a polyhedral shape separated by an intercellular space. Intercellular bridges, where differentiation of glycogen production occurs, can be identified with light microscopy.

4. The superficial layer includes five to eight rows of flattened cells with small uniform nuclei and a cytoplasm filled with glycogen. The nucleus becomes pyknotic, and the cells detach from the surface (exfoliation). These cells form the basis for Papanicolaou (Pap) testing.
Columnar Epithelium  Columnar epithelium has a single layer of columnar cells with mucus at the top and a round nucleus at the base. The glandular epithelium is composed of numerous ridges, clefts, and infoldings and, when covered by squamous metaplasia, leads to the appearance of gland openings. Technically, the endocervix is not a gland, but the term gland openings often is used.

Metaplastic Epithelium  Metaplastic epithelium, found at the SCJ, begins in the subcolumnar reserve cell (Fig. 17.4). Under stimulation of lower vaginal acidity, the reserve cells proliferate, lifting the columnar epithelium. The immature metaplastic cells have large nuclei and a small amount of cytoplasm without glycogen. As the cells mature normally, they produce glycogen, eventually forming the four layers of epithelium. The metaplastic process begins at the tips of the columnar villi, which are exposed first to the acid vaginal environment. As the metaplasia replaces the columnar epithelium, the central capillary of the villus regresses, and the epithelium flattens out, leaving the epithelium with its typical vascular network. As metaplasia proceeds into the cervical clefts, it replaces columnar epithelium and similarly flattens the epithelium. The deeper clefts, however, may not be completely replaced by the metaplastic epithelium, leaving mucus-secreting columnar epithelium trapped under the squamous epithelium. Some of these glands open onto the surface; others are completely encased, with mucus collecting in nabothian cysts. Gland openings and nabothian cysts mark the original SCJ and the outer edge of the original transformation zone (5) (Figs 17.5a and b).

Human Papillomavirus  The cytologic changes of HPV were first recognized by Koss and Durfee (6) in 1956 and given the term koilocytosis. Their significance was not recognized until 20 years later, when Meisels and colleagues (7) reported these changes in mild dysplasia (Fig. 17.6). Molecular biologic studies have shown high levels of HPV DNA and capsid antigen, indicating
productive viral infection in these koilocytic cells (8). The HPV genome has been found in all grades of cervical neoplasia (9). Infection with HPV is the primary cause of cervical cancer (10). As the CIN lesions become more severe (Fig. 17.7), the koilocytes disappear, the HPV copy numbers decrease, and the capsid antigen disappears, indicating that the virus is not capable of reproducing in less differentiated cells (11). Instead, portions of the HPV DNA become integrated into the host cell. Integration of the transcriptionally active DNA into the host cell appears to be essential to malignant growth (12). Malignant transformation requires the expression of E6 and E7 oncoproteins produced by HPV (13).

Because HPV will not grow in cell culture, there is no direct evidence of the carcinogenesis of HPV. However, a cell culture system for growing keratinocytes has been described that allows for stratification and differentiation of specific keratinase types (14). When normal cells are transfected with the plasmid-containing HPV-16, the transfected cells produced cystologic abnormalities identical to those seen in intraepithelial neoplasia. The E6 and E7 oncoproteins are identifiable in the transfected cell lines, providing strong laboratory evidence of a cause-and-effect relationship (15). Cervical cancer cell lines that contain active copies of HPV-16 or -18 (SiHa, HeLa, C 4-11, Ca Ski) show the presence of HPV-16 E6 and E7 oncoproteins (16).

HPV DNA can be detected in most women with cervical neoplasia (17,18). There have been more than 120 types of HPV identified, with 30 of these HPV types primarily infecting the squamous epithelium of the lower anogenital tract of men and women (19,20). Detection of HPV is associated with a 250-fold increase risk of high-grade CIN (21). The percentage of intraepithelial neoplasia attributed to HPV infection approaches 90% (18).

Only certain types of HPV count for about 90% of high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, and -58) (18). Type 16 is the most common HPV found in invasive cancer and in CIN 2 and CIN 3, and it is found in 47% of women with cancer in these stages (22). It is also the most common HPV type found in women with normal cytology.

Unfortunately, HPV-16 is not very specific; it can be found in 16% of women with low-grade lesions and in up to 14% of women with normal cytology. Human papillomavirus type-18
is found in 23% of women with invasive cancers, 5% of women with CIN 2 and CIN 3, 5% of women with HPV and CIN 1, and fewer than 2% of patients with negative findings (18). Therefore, HPV-18 is more specific than HPV-16 for invasive tumors.

Usually, HPV infections do not persist. Those that do persist can remain latent for many years. Most women have no clinical evidence of disease, and the infection is eventually suppressed or eliminated (17). Other women exhibit low-grade cervical lesions that may regress spontaneously. In most women, the infection will clear in 9 to 15 months (23). A minority of women exposed to HPV develop persistent infection that may progress to CIN (17,24). Persistent high-risk HPV infection increases the risk of high-grade disease 300-fold and is required for the development and maintenance of CIN 3 (25,26). Factors that may have a role in this progression include smoking, contraceptive use, infection with other sexually transmitted diseases, or nutrition (17,22). Any factor that influences the integration of HPV DNA into the human genome may cause progression to invasive disease (27).

**Human Papillomavirus Vaccine Development**

Historically, vaccines have represented a cost-effective method for preventing disease induced by microbial agents and other pathogens. The development of a vaccine for HPV could lead to a potential reduction in the incidence of cervical cancer and its precursor lesions, other associated cancers (anal, penile, vaginal, vulvar), and genital warts (28). Recently three separate trials have been performed to test the efficacy of various HPV vaccines. Each trial was able to show that the vaccine they were using was efficacious in preventing persistent HPV infection. In a randomized trial of an experimental HPV-16 VLP vaccine 1,533 women were randomized to either the vaccine or placebo. Each subject had no history of abnormal Pap test results and no more than five male sexual partners. The vaccine was given at day 0, month 2, and month 6, and the median follow-up period was 17.4 months. The primary endpoint to this trial was persistent HPV-16 infection, and the secondary endpoint was the tolerability of the vaccine. This trial found that there was a decrease in persistent and transient HPV-16 infection as well as in cases of CIN in vaccinated versus placebo subjects (29).

Another trial of a bivalent L1 VLP vaccine for the prevention of HPV-16 and -18 used a similar protocol. Women were enrolled if they had a history of no more than six sexual partners and no history of abnormal Pap test results. They also had to test negative cytologically for the high-risk HPV types. The primary objective was to assess the effectiveness of the vaccine in the prevention of infection with HPV-16 and -18, and the secondary objective was to assess its efficacy in prevention of cytologic and histologic abnormalities and cancer. The 1,113 participants were followed for 27 years. The results of this trial found that the efficacy of the vaccine was more than 85% for persistent infection and 93% for cytologic abnormalities (30).

In a phase 2 trial of a quadrivalent HPV vaccine, the primary endpoints were persistent HPV infection, any type of intraepithelial neoplasia, genital tract cancer, and external genital lesions. In an intention-to-treat analysis, the overall efficacy of the vaccine was 89%. The conclusions of this phase 2 trial were that the vaccine was highly effective in reducing the incidence of persistent HPV infection. The study did not, however, have enough power to assess vaccine efficacy for the disease endpoints or for each HPV type separately. This study also found that the vaccine was highly immunogenic and induced high antibody titers to each HPV type (31).

**Papanicolaou Test Classification**

In 1988, the first National Cancer Institute (NCI) workshop held in Bethesda, Maryland, resulted in the development of the Bethesda System for cytologic reporting (32). A standardized method of reporting cytology findings was needed to facilitate peer review and quality assurance. The terminology was refined in the Bethesda III System (2001). According to this system, potentially premalignant squamous lesions fall into three...
categories: (i) atypical squamous cells (ASC), (ii) low-grade squamous intraepithelial lesions (LSIL), and (iii) high-grade squamous intraepithelial lesions (HSIL) (33). The ASC category is subdivided into two categories: those of unknown significance (ASC-US), and those in which high-grade lesions must be excluded (ASC-H). Low-grade squamous intraepithelial lesions include CIN 1 (mild dysplasia) and the changes of HPV, termed koilocytotic atypia. The HSIL category includes CIN 2 and CIN 3 (moderate dysplasia, severe dysplasia, and carcinoma in situ). A comparison of the various terms as they relate is shown in Table 17.1.

Cellular changes associated with HPV (ie, koilocytosis and CIN 1) are incorporated within the category of LSIL because the natural history, distribution of various HPV types, and cyologic features of both of these lesions are the same (27). Long-term follow-up studies have shown that lesions properly classified as koilocytosis progress to high-grade intraepithelial neoplasia in 14% of cases (33) and that lesions classified as mild dysplasia progress to severe dysplasia or CIS in 16% of cases (4). It was initially thought that lesions classified as koilocytosis would contain only low-risk HPV types, such as HPV-6 and -11, whereas high-risk HPV types, such as HPV-16 and -18, would be limited to true neoplasms, including CIN 1, thus justifying the distinction. Histopathologic and molecular virologic correlation, however, has shown a similar heterogeneous distribution of low- and high-risk HPV types in both koilocytosis and CIN 1 (34). Studies evaluating the dysplasia, CIS, and CIN terminology have had a lack of interobserver and intraobserver reproducibility (35). The greatest lack of reproducibility is between koilocytosis and CIN 1 (36). Thus, on the basis of clinical behavior, molecular biologic findings, and morphologic features, HPV changes and CIN 1 appear to be the same disease. The rationale for combining CIN 2 and CIN 3 into the category of HSIL is similar. The biologic studies reveal the similar mix of high-risk HPV types in the two lesions, and the separation of the lesions has been shown to be irreproducible (35,36). In addition, the management of CIN 2 and CIN 3 is similar.

Diagnosis

The Papanicolaou Test

The Pap test has been successful in reducing the incidence of cervical cancer by 79% and the mortality by 70% since 1950 (37). Unfortunately, 20% of women in the
United States do not undergo regular screening and have not had a Pap test in the previous 3 years. Recently the annual incidence rate has dropped from 8 to 5 cases per 100,000 women. This means that approximately 8,200 women per year are acquiring cervical cancer (37–39). Cases of cervical cancer continue to occur in patients who have had regular Pap tests. The Agency for Health Care and Policy Research, now renamed the Agency for Healthcare Research and Quality (AHRQ), undertook a literature review of conventional cervical cytology testing techniques and compared them with newer technologies designed to reduce the false-negative rate (40). For this project, five reports were analyzed, and the conclusion was that the sensitivity of conventional cytologic testing in detecting cervical cancer precursor lesions was 51%. This is a false-negative rate of 49%.

In three recent reviews of the accuracy of cervical cytology assessment, the sensitivity of the Pap test in detecting CIN 2–3 ranged from 47% to 62% and the specificity ranged from 60% to 95% (41–43). Approximately 30% of new cancer cases each year result from women who have undergone Pap testing, but errors of sampling, fixation, or interpretation occur (44). Previously, it had been widely believed that sensitivity of the Pap test was in the 80% range (45). Recommendations for Pap test screening were based on this perceived 80% sensitivity. The recommendation that three annual Pap tests be performed is predicated on a false-negative rate that would reduce the risk for missed lesions to less than 1% after the first three tests. If the test sensitivity were 80%, then the sensitivity of three negative tests would be 99.2%, which achieves the screening goal. However, the 51% test sensitivity would have a sensitivity of only 86.8% after three tests.

It is obvious that improvement in the conventional Pap test technique is necessary. False-negative errors occur in sampling, preparation, and interpretation. Sampling errors occur because a lesion is too small to exfoliate cells or the device used did not pick up the cells and transfer them to the glass slide. Preparation errors may occur because of poor fixation on the glass slide, leading to air-drying and an inability to interpret the results. The slide may also be too thick and obscured by vaginal discharge, blood, or mucus. The thick slide also leads to poor fixation because the fixative does not penetrate the cell sample. Interpretive errors occur when the slide contains diagnostic cells that the screening technician did not identify.

Using a liquid-based medium to collect the cytologic sample and preserve the collected cervical cells can alleviate sampling and preparation errors. The sample is then processed to provide a uniform, thin layer of cervical cells without debris on a glass slide. The AHRQ reported that liquid-based cytology assessment improved the sensitivity of the Pap test to the stated goal of 80%. The cell sample is collected with an endocervical brush used in combination with a plastic spatula or with a plastic broom. The sample is then rinsed in a vial containing liquid preservative. With this technique, 80% to 90% of the cells are transferred to the liquid media, as compared with the only 10% to 20% transferred to the glass slide with conventional cytologic testing. In addition, using liquid-based media eliminates air-drying. The cells are retrieved from the vial by passing the liquid through a filter, which traps the larger epithelial cells, separating them from the small blood and inflammatory cells. This process leads to a thin layer of diagnostic cells properly preserved and more easily interpreted by the cytologist. This technique reduces by 70% to 90% the rate of unsatisfactory samples encountered with conventional cytologic testing (46). Liquid-based cytology is now commonly performed by most of the laboratories in the United States.

A second new technology for assessment of cervical cytology is the AutoPap Screening System, which has been approved by the U.S. Food and Drug Administration for primary screening and rescreening of samples initially interpreted as normal. This technique uses an automated microscope coupled to a special digital camera. The system scans the slide and uses computer imaging techniques to analyze each field of view on the slide. Computer algorithms are then used to rank each slide on the basis of the probability that the sample may contain an abnormality. The selected slides are then reviewed by a cyto technologist or a cytopathologist. This technique has reduced the false-negative rate by 32% (47). The AutoPap Screening System currently is not in widespread use.
The Bethesda System for reporting the results of cervical cytology was developed as a uniform system of cytology that would provide clear guidance for clinical management (32). It creates a standardized framework for laboratory reports that include a descriptive diagnosis and an evaluation of specimen adequacy. The Bethesda System has been modified to reflect the development of new technologies and research findings.

In the 2001 Bethesda System, specimen adequacy is categorized as satisfactory or unsatisfactory for evaluation. If a specimen is found to be unsatisfactory, cervical cytology is repeated in 2 to 4 months. The category satisfactory but limited by has been eliminated from the new system; however, if sampling of the transformation zone is inadequate or obscuring factors are present, cervical cytology can be repeated in 6 to 12 months. The general categorizations are (i) negative for intraepithelial lesion or malignancy, (ii) epithelial cell abnormality, and (iii) other. In the category of negative for intraepithelial lesions or malignancy are included organisms such as trichomonas vaginalis, candida, bacterial vaginosis, as well as actinomyces and herpes simplex virus. Also included in this category are reactive cellular changes, glandular cells status after hysterectomy, and atrophy. The category epithelial cell abnormality includes squamous cell and glandular cell abnormalities. The atypical squamous cell group differs from the 1992 guidelines in that ASCUS has been modified and that the term atypical squamous cells favor reactive has been eliminated. Atypical squamous cells are divided into undetermined significance (ASC-US) and cannot exclude high-grade squamous intraepithelial lesion (ASC-H). Low-grade squamous intraepithelial lesion (LSIL) encompasses HPV and CIN 1. High-grade squamous intraepithelial lesion (HSIL) includes CIN 2 and 3 and CIS.

The glandular cell group has changed from the 1992 guidelines in that the designation of atypical glandular cells of undetermined significance (AGUS) has been eliminated in favor of more descriptive groupings of atypical glandular cells. The group of glandular cell abnormalities includes atypical glandular cells (AGC) endocervical, endometrial, or glandular cells not otherwise specified; and atypical glandular cells (endocervical or glandular) favor neoplasia (Table 17.2).

**Screening Guidelines**

Recommendations for cervical cancer screening are slightly conflicting. The American Cancer Society (ACS) updated recommendations of 2002 states that screening with conventional Pap testing should occur every year. If liquid-based cytology is being used, screening can be extended to every 2 years. Screening should begin at the age of 21 or within 3 years of the onset of sexual activity, and screening can stop at age 70 if there has been no abnormal Pap test result in the past 10 years. The ACS also states that screening after hysterectomy for benign disease is not necessary (48).

The American College of Obstetricians and Gynecologists (ACOG) differs from the ACS recommendations by stating that women younger than the age of 30 should undergo cervical cytology screening yearly, and those older than the age of 30 without any other risk factors (history of CIN 2 or 3, immunocompromised, diethylstilbestrol exposure in utero) can extend their screening interval to 2 to 3 years using either liquid-based or conventional Pap testing. Furthermore, ACOG states that using combination cervical cytology and HPV DNA screening is appropriate for women age 30 and older. If results are negative using this combination, a woman can be retested at only 3-year intervals (49) (Table 17.3).

In 2003, the U.S. Food and Drug Administration approved HPV DNA testing combined with cervical cytology as a screening technique for women older than age 30. When the results of both tests are negative, the woman does not have to be retested for 3 years. The negative predictive value of a double negative test exceeds 99% (19). Because most HPV infections are transient, clear spontaneously, and do not lead to real cancer precursors, especially in young women where the prevalence is higher, it should not be used for screening in young women than 30 (50). Women who have negative test
Table 17.2 Bethesda System 2001

**Specimen Type:** Indicate conventional smear (Pap smear) vs. liquid based vs. other

**Specimen Adequacy**
- Satisfactory for evaluation (describe presence or absence of endocervical/transformation zone component and any other quality indicators, eg, partially obscuring blood, inflammation, etc.)
- Unsatisfactory for evaluation . . . (specify reason)
- Specimen rejected/not processed (specify reason)
- Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)

**General Categorization** (optional)
- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality: See Interpretation/Result (specify “squamous” or “glandular” as appropriate)
- Other: See Interpretation/Result (eg, endometrial cells in a woman 40 years of age)

**Automated Review**
If case examined by automated device, specify device and result.

**Ancillary Testing**
Provide a brief description of the test methods and report the result so that it is easily understood by the clinician.

**Interpretation/Result**

**Negative for Intraepithelial Lesion or Malignancy** (when there is no cellular evidence of neoplasia, state this in the General Categorization above and/or in the Interpretation/Result section of the report, whether or not there are organisms or other nonneoplastic findings)

**Organisms**
- *Trichomonas vaginalis*
- Fungal organisms morphologically consistent with *Candida* spp.
- Shift in flora suggestive of bacterial vaginosis
- Bacteria morphologically consistent with *Actinomyces* spp.
- Cellular changes consistent with herpes simplex virus

**Other Nonneoplastic Findings** (optional to report; list not inclusive):
- Reactive cellular changes associated with:
  - inflammation (includes typical repair)
  - radiation
  - intrauterine contraceptive device (IUD)
  - Glandular cells status posthysterectomy
  - Atrophy

**Other**
- Endometrial cells (in a woman 40 years of age)
  (specify if “negative for squamous intraepithelial lesion”)

**Epithelial Cell Abnormalities**

**Squamous Cell**
- Atypical squamous cells
- Of undetermined significance (ASC-US)
- Cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL) encompassing: HPV/mild dysplasia/CIN 1
- High-grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIS/CIN 2 and CIN 3
  - with features suspicious for invasion (if invasion is suspected)
- Squamous cell carcinoma

Educational Notes and Suggestions (optional)

Suggestons should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included).

results for both cytology and HPV have a 1 in 1,000 chance of having CIN 2 or worse detected in the following 6 months (51). Prospective studies report less than 2 per 1,000 women will develop CIN 2 or greater in the following 3 years (51–53). This high negative predictive value allows for the screening interval to be extended to 3 years, which is supported by both ACOG and the American Cancer Society (ACS).

Atypical Squamous Cells

The ASC category is restricted to those test results disclosing abnormal cells that are truly of unknown significance. The ASC category does not include benign, reactive, and reparative changes that should be classified as normal in the Bethesda system. Because of the lack of diagnostic criteria and the fear of medical–legal action, the diagnosis has become quite common, ranging from 3% to 25% in some centers (54). When standardized diagnostic criteria are used, the rate of ASC results should be 3% to 5% (55). The older term, ASCUS (Bethesda II classification) is now subdivided into ASC-US and ASC-H (Bethesda III classification).

</table>
The cytologic diagnosis of ASC-US is associated with a 10% to 20% incidence of CIN 1 and a 3% to 5% risk for CIN 2 or 3 (56–59). It has become apparent that CIN 1 is most often a benign HPV infection and will regress spontaneously in more than 60% of cases (60); therefore, the goal of triage of an AS-CUS Pap test result is to identify more advanced CIN 2 and 3 lesions.

Triage options include the following: (i) Repeat Pap test every 4 to 6 months with referral for colposcopy if any subsequent abnormality is detected, (ii) immediate colposcopy, and (iii) HPV testing.

The option of repeat Pap testing is weakened by the 20% to 50% false-negative rate in identifying CIN lesions as well as the noncompliance of the patient. About 50% of patients will still undergo colposcopy because of subsequent abnormal Pap test results, making this option nearly as costly as immediate colposcopy (56). Immediate colposcopy is assumed to be the most sensitive method of detecting CIN 2 or 3 (56,59). Because 80% of patients will not have significant lesions, it is important to avoid overinterpretation of the colposcopic findings and to be conservative in performing biopsies. There is also the risk that pathologists will overinterpret the biopsy results and the patient will be diagnosed with CIN when metaplasia is the only finding.

Several studies have documented the usefulness of HPV testing in the assessment of ASC-US Pap test results (61–63). These studies have shown that HPV testing can identify 90% of the patients with CIN 2 or 3 lesions. To compare the aforementioned triage method in a prospective, randomized fashion, the NCI funded an ASC-US/LSIL Triage Study (ALTS) (64). Patients with ASC-US or LSIL were randomized to three triage arms: (i) immediate colposcopy, (ii) HPV test, and (iii) conservative management by repeat Pap test. There were 1,163 women in the immediate colposcopy group, and 14 refused the examination. The results of colposcopy are assumed to reflect the prevalent disease rates, which were as follows: CIN 1, 14.3%; CIN 2, 16.1%; and CIN 3, 5%. Thus, 75% of the women with ASC-US had negative colposcopy results and either did not have a biopsy (25%) or had a biopsy with negative results. The HPV test results were positive in 56.1% of the patients, and 6.1% of the patients did not return for colposcopy. Of the 494 who underwent colposcopy, the results were as follows: CIN 1, 22.5%; CIN 2, 11.9%; and CIN 3, 15.6%. The sensitivity of HPV test was 95.9% for the detection of CIN 2 and 96.3% for the detection of CIN 3.

In the conservatively managed group, only one follow-up Pap test was reported. To be effective, it is recognized that Pap testing must be done every 6 months. Despite this, the results of the single follow-up Pap test were included. Using a cutoff that includes any positive finding of ASC-US or greater, the sensitivity is 85% for CIN 2 and 85.3% for CIN 3, with 58.6% of patients being referred for colposcopy. If LSIL is used as a cutoff, 26.2% of the patients are referred, with sensitivity of 64.0% for both CIN 2 and 3. Using HSIL as the cutoff, 6.9% are referred, and the sensitivity falls to 44%.

The conclusion of the ALTS trial is that HPV triage is highly sensitive in identifying CIN 2 and 3 lesions and that it cuts the rate of referral for colposcopy by approximately one half. Although the final cost-utility analysis of ALTS data is not complete, HPV testing seems to be an appropriate strategy for the initial management of ASC-US (65). When mathematical models are used to simulate the natural history of HPV and cervical cancer in a cohort of U.S. women, a 2- to 3-year screening strategy that uses cytologic assessment in combination with either HPV DNA testing or reflex HPV testing should be more effective in reducing the rate of cancer and be less costly than annual conventional cytology (66).

In 2001, the American Society for Colposcopy and Cervical Pathology (ASCCP) sponsored an NCI Consensus Conference to provide guidelines for the management of abnormal cervical cytology. Researchers used information from the ALTS Trial and Bethesda III terminology. They recommended that women with ASC-US should be
SECTION IV  General Gynecology

managed with (i) a program of two repeat Pap tests with referral of any abnormality to colposcopy, (ii) immediate colposcopy, and (iii) testing for high-risk type HPV. Testing for HPV DNA is the preferred method when liquid-based cytology is used. Women who have positive test results should be referred for colposcopy, and those who are negative should receive yearly cytology assessment (62).

**Low-grade Squamous Intraepithelial Lesions**

The cytologic diagnosis of LSIL is reproducible and accounts for 1.6% of cytologic diagnoses (55). About 75% of the patients have CIN, with 20% being CIN 2 or 3 (56–58). These patients require additional evaluation. The ALTS trial closed the HPV test arm early because the HPV positivity rate was 82% and, therefore, was not a valid discriminator in determining the presence of disease. The ALTS trial found that a cytology interpretation of LSIL is associated with a 25% risk of histologic CIN grade 2 or 3 within 2 years. However, no effective triage strategy was identified to spare many women from colposcopic referral without increasing their risk of CIN 3 and invasive carcinoma (67). The ALTS trial confirmed the validity of the current practice of performing colposcopy to evaluate a single LSIL result.

**High-grade Squamous Intraepithelial Lesions**

Any woman with a cytologic specimen suggesting the presence of HSIL should undergo colposcopy and directed biopsy. After colposcopically directed biopsy and determination of the distribution of the lesion, ablative therapy and destruction of the entire transformation zone should be performed.

**Colposcopy Findings**

**Acetowhite Epithelium**

Epithelium that turns white after application of acetic acid (3%–5%) is called acetowhite epithelium (40). The application of acetic acid coagulates the proteins of the nucleus and cytoplasm and makes the proteins opaque and white (5).

The acetic acid does not affect mature, glycogen-producing epithelium because the acid does not penetrate below the outer one third of the epithelium. The cells in this region have very small nuclei and a large amount of glycogen (not protein). These areas appear pink during colposcopy. Dysplastic cells are those most affected. They contain large nuclei with abnormally large amounts of chromatin (protein). The columnar villi become “plumper” after acetic acid is applied; these cells are then easier to see. They appear slightly white, particularly in the presence of the beginning signs of metaplasia. The immature metaplastic cells have larger nuclei and also show some effects of the acetic acid. Because the metaplastic epithelium is very thin, it is not as white or opaque as CIN but instead appears gray and filmy (5).

**Leukoplakia**

Translated literally, leukoplakia is white plaque (5). In colposcopic terminology, this plaque is white epithelium visible before application of acetic acid. Leukoplakia is caused by a layer of keratin on the surface of the epithelium. Immature squamous epithelial cells have the potential to develop into keratin-producing cells or glycogen-producing cells. In the vagina and on the cervix, the normal differentiation is toward glycogen. Keratin production is abnormal in the cervicovaginal mucosa. Leukoplakia can be caused by HPV; keratinizing CIN; keratinizing carcinoma; chronic trauma from diaphragm, pessary, or tampon use; and radiotherapy.

Leukoplakia should not be confused with the white plaque of a monilial infection, which can be completely wiped off with a cotton-tipped applicator. Currently, the most common reason for leukoplakia is HPV infection (Fig. 17.8). Because it is not possible to see through the thick keratin layer to the underlying vasculature during colposcopy, such areas should undergo biopsy to rule out keratinizing carcinoma.
Figure 17.8  Colposcopy of cervical intraepithelial neoplasia 2 associated with human papillomavirus infection of the cervix.

**Punctuation**  Dilated capillaries terminating on the surface appear from the ends as a collection of dots and thus are referred to as punctation (Fig. 17.9). When these vessels occur in a well-demarcated area of acetowhite epithelium, they indicate an abnormal epithelium—most often CIN (5) (Fig. 17.10). The punctate vessels are formed as the metaplastic epithelium migrates over the columnar villi. Normally, the capillary regresses; however, when CIN occurs, the capillary persists and appears more prominent.
**Mosaic**  Terminal capillaries surrounding roughly circular or polygonal-shaped blocks of acetowhite epithelium crowded together are called mosaic because their appearance is similar to mosaic tile (Fig. 17.11). These vessels form a “basket” around the blocks of abnormal epithelium. They may arise from a coalescence of many terminal punctate vessels or from the vessels that surround the cervical gland openings (5). Mosaicism tends to be associated with higher-grade lesions and CIN 2 (Fig 17.12) and CIN 3 (Fig. 17.13).

**Atypical Vascular Pattern**  Atypical vascular patterns are characteristic of invasive cervical cancer and include looped vessels, branching vessels, and reticular vessels. These patterns are discussed in Chapter 34.

**Endocervical Curettage**  ASCCP guidelines do not require endocervical curettage. In cases when an endocervical sample is needed, a cytobrush is sufficient for sampling the endocervical canal.

**Cervical Biopsy**  The cervical biopsy is performed at the area most likely to have dysplasia. If the lesion is large or multifocal, multiple biopsies may be necessary to be assured of a complete sample of the affected tissue.

**Correlation of Findings**  Ideally, both the pathologist and colposcopist should review the colposcopic findings and the results of cytologic assessment, cervical biopsy, and endocervical sample before deciding therapy. This is particularly true when operators are first learning the technique of colposcopy. The cytology results should not be sent to one laboratory and the histology results to another. The colposcopist should not treat the report but rather treat the disease. When the cytology and biopsy results correlate, the colposcopist can be reasonably certain that the worst lesion has been identified. If the cytology indicates a more significant lesion than the histology, the patient should undergo further evaluation, and additional biopsies as necessary. An algorithm for the evaluation, treatment, and follow-up of abnormal Pap test results is presented in Fig. 17.14.

---

CHAPTER 17 Intraepithelial Disease of the Cervix, Vagina, and Vulva

A Figure 17.11 (A) Mosaic pattern and punctation. This pattern develops as islands of dysplastic epithelium proliferate and push the ends of the superficial blood vessels away, creating a pattern that looks like mosaic tiles. (B) Diagram of mosaic pattern.

Histologic Terminology

CIN 1

The spontaneous regression rate of biopsy-proven CIN 1 is 60% to 85% in prospective studies. The regressions typically occur within a 2-year follow-up with cytology and colposcopy (4,68–71). This information has led to the recommendation that patients who have biopsy diagnoses of CIN 1 with satisfactory colposcopy and who agree to
SECTION IV General Gynecology

Figure 17.12 Human papillomavirus/cervical intraepithelial neoplasia 3. Cribriform pattern of HPV at periphery with mosaicism and punctation near the squamocolumnar junction.

The evaluation every 6 months may be treated by observation with Pap testing performed at 6 and 12 months or HPV DNA testing at 12 months. After two negative test results or a single negative HPV DNA test, annual screening may be resumed. Colposcopy and repeat cytology at 12 months is another acceptable alternative (68). If the lesions progress during follow-up or persist at 2 years, ablative treatment should be performed. Regression of CIN 1 decreases after 24 months, with the regression rate becoming the same as for CIN 2 by 5 years (72).

Figure 17.13 Cervical intraepithelial neoplasia grade 3.
For patients with persistent CIN 1 after 24 months, the choice of treatment is optional. Expectant management is still acceptable, as long as the patient is cooperative with follow up. Patients with chronic systemic disease associated with immunosuppression, such as those requiring steroids or antirejection drugs, may have chronically persistent low-grade abnormalities. Ablative therapies, including cryotherapy or laser ablation, seem preferable to excisional procedures including loop electrosurgical excision procedure (LEEP) (62). A randomized prospective trial comparing cryosurgery with laser and LEEP showed no difference in persistent disease rate (4%) or recurrent disease rate (17%). Cryosurgery has the advantage of low cost and ease of use. The disadvantages are lack of tissue specimen, inability to adapt to lesion size, and posttreatment vaginal discharge. If colposcopy findings are unsatisfactory, an endocervical biopsy is imperative.
to exclude an occult high-grade lesion, which could be present in up to 10% of cases when the squamocolumnar lesion is not visualized.

**CIN 2 and 3**

All CIN 2 and 3 lesions require treatment. This recommendation is based on a meta-analysis showing that CIN 2 progresses to CIS in 20% of cases and to invasion in 5%. Progression of CIS to invasion is 5% (73).

Although CIN can be treated with a variety of techniques, the preferred treatment for CIN 2 and 3 has become LEEP. These techniques allow a specimen to be sent for evaluation and enable the pathologist to identify occult microinvasive cancer or adenomatous lesions to ensure these lesions have been treated adequately. The persistent and recurrent disease rates are 4% to 10% (74,75).

**Treatment of CIN**

Most of the ablative techniques used to treat CIN can be performed in an outpatient setting, which is one of the main objectives in the management of this disease. Because all therapeutic modalities carry an inherent recurrence rate of up to 10%, cytologic follow-up at about 3-month intervals for 1 year is necessary. Ablative therapy is appropriate when the following conditions exist:

1. There is no evidence of microinvasive or invasive cancer on cytology, colposcopy, endocervical curettage, or biopsy.
2. The lesion is located on the ectocervix and can be seen entirely.
3. There is no involvement of the endocervix with high-grade dysplasia as determined by colposcopy and endocervical curettage.

**Cryotherapy**

Cryotherapy destroys the surface epithelium of the cervix by crystallizing the intracellular water, resulting in the eventual destruction of the cell. The temperature needed for effective destruction must be in the range of (–20° to –30°C). Nitrous oxide (–89°C) and carbon dioxide (–65°C) produce temperatures below this range and, therefore, are the most commonly used gases for this procedure.

The technique believed to be most effective is a freeze-thaw-freeze method in which an ice ball is achieved 5 mm beyond the edge of the probe. The time required for this process is related to the pressure of the gas; the higher the pressure, the faster the ice ball is achieved. Cryotherapy has been shown to be an effective method of treatment for CIN with very acceptable failure rates under certain conditions (76–79). It is a relatively safe procedure with few complications. Cervical stenosis is rare but can occur. Posttreatment bleeding is uncommon and is usually related to infection.

Cure rates are related to the grade of the lesion; CIN 3 has a greater chance of treatment failure (Table 17.4). Townsend has shown that cures are also related to the size of the lesion; those covering most of the ectocervix have failure rates as high as 42%, compared with a 7% failure rate for lesions less than 1 cm in diameter (80). Positive findings on endocervical curettage also can reduce the cure rate significantly. Endocervical gland involvement is important because the failure rate in women with gland involvement was 27%, compared with 9% in those who did not have such involvement (81).

Cryotherapy should be considered acceptable therapy when the following criteria are met:

1. Cervical intraepithelial neoplasia, grade 1 to 2
2. Small lesion
CHAPTER 17 Intraepithelial Disease of the Cervix, Vagina, and Vulva

3. Ectocervical location only

4. Negative endocervical sample

5. No endocervical gland involvement on biopsy

Laser Ablation

Laser ablation has been used effectively for the treatment of CIN (Table 17.5). However, because of the expense of the equipment as well as necessity for special training, laser ablation has fallen out of favor. Additionally, because much early CIN is being managed conservatively, the need for any kind of ablation is decreasing.

Loop Electrosurgical Excision

Laser electrosurgical excision is a valuable tool for the diagnosis and treatment of CIN (82–92). It offers the advantage of performing a operation that is simultaneously diagnostic and therapeutic during one outpatient visit (93–104).

The tissue effect of electricity depends on the concentration of electrons (size of the wire), the power (watts), and the water content of the tissue. If low power or a large-diameter wire is used, the effect will be electrocautery, and the thermal damage to tissue will be extensive. If the power is high (35–55 watts) and the wire loop is small (0.5 mm), the effect will be electrosurgical, and the tissue will have little thermal damage. The actual cutting is a result of a steam envelope developing at the interface between the wire loop and the water-laden tissue. This envelope is then pushed through the tissue, and the combination of electron flow and acoustical events separates the tissue. After the excision, a 5-mm diameter ball electrode is used, and the power is set at 50 watts. The ball is placed near the surface so that a spark occurs between the ball and the tissue. This process is called electrofulguration, and it results in some thermal damage that

NED = No evidence of disease.
leads to hemostasis. If too much fulguration occurs, the patient will develop an eschar with more discharge, and the risk for infection and late bleeding will be higher.

Recent research has shown that LEEP is associated with an increased risk of overall preterm delivery, preterm delivery after premature rupture of membranes, and low-birth-weight infants in subsequent pregnancies at greater than 20 weeks gestation (105). Loop excision should not be used before an intraepithelial lesion that requires treatment has been identified. The risk of the “see and treat” philosophy is that in women with only metaplasia, the entire transformation zone will be removed along with varying amounts of the cervical canal, thus potentially compromising fertility (90,92). This is particularly true of young women, who may have large, immature transformation zones with extensive acetowhite areas. Complications following loop electrosurgical excision are fairly minimal and compare favorably with those following laser ablation and conization. Intraoperative hemorrhage, postoperative hemorrhage, and cervical stenosis can occur but at acceptably low rates, as noted in Table 17.6. The SCJ is visible in more than 90% of patients after this procedure. Effectiveness of LEEP and comparison of LEEP to other excision procedures are shown in Tables 17.7 through 17.9.

Conization

Conization of the cervix plays an important role in the management of CIN. Before the availability of colposcopy, conization was the standard method of evaluating an abnormal Pap test result. Conization is both a diagnostic and therapeutic procedure and has the advantage over ablative therapies of providing tissue for further evaluation to rule out invasive cancer (97,99,102,104,106).

Conization is indicated for diagnosis in women with HSIL based on a Pap test under the following conditions:

1. Limits of the lesion cannot be visualized with colposcopy.
2. The SCJ is not seen at colposcopy.

3. Endocervical curettage (ECC) histologic findings are positive for CIN 2 or CIN 3.

4. There is a substantial lack of correlation between cytology, biopsy, and colposcopy results.

5. Microinvasion is suspected based on biopsy, colposcopy, or cytology results.

6. The colposcopist is unable to rule out invasive cancer.

Lesions with positive margins are more likely to recur after conization (97,99,102) (Table 17.10). Endocervical gland involvement also is predictive of recurrence (23.6% with gland involvement compared with 11.3% without gland involvement) (107). When compared with conization, LEEP is the simpler technique, and short-term results are similar to those obtained with conization or laser excision (74,108). In a prospective study examining the long-term effects of LEEP, conization, and laser excision, no difference in recurrence of dysplasia or in pregnancy outcomes was found (109) (Table 17.11, 17.12).

Hysterectomy

Hysterectomy is currently considered too radical for treatment of CIN. In a study of 38 cases of invasive cancer occurring after hysterectomy among 8,998 women (0.4%), the

incidence of significant bleeding, infection, and other complications, including death, is higher with hysterectomy than with other means of treating CIN (110). There are some situations in which hysterectomy remains a valid and appropriate (although mandatory) method of treatment for CIN:

1. Microinvasion
2. CIN 3 at limits of conization specimen in selected patients
3. Poor compliance with follow-up
4. Other gynecologic problems requiring hysterectomy, such as fibroids, prolapse, endometriosis, and pelvic inflammatory disease

Glandular Cell Abnormalities

Atypical Glandular Cells

The Bethesda System update in 2001 eliminates the category atypical glandular cells of undetermined significance (AGUS). The term should now be atypical glandular cells (AGC). This classification is divided into favor neoplasia and not otherwise specified (NOS). The NOS group is further divided into endocervical or endometrial origin. Also included in the glandular cell category is endocervical carcinoma in situ and adenocarcinoma. Atypical endocervical cells are important because of their risk for significant disease. In a series of 63 patients from whom subsequent cervical biopsy or hysterectomy specimens were evaluated, 17 women had CIN 2 or CIN 3, 5 women had adenocarcinoma.

in situ, and two women had invasive adenocarcinoma (107). An additional eight patients had CIN 1, and 2 women had endometrial hyperplasia. Overall, 32 patients (50.8%) had significant cervical lesions. This is a much higher positive rate than that for ASC-US Pap test results.

Adenocarcinoma

In adenocarcinoma in situ (AIS), the endocervical glandular cells are replaced by tall columnar cells with nuclear stratification, hyperchromasia, irregularity, and increased mitotic activity (112). Cellular proliferation results in crowded, cribriform glands. However, the normal branching pattern of the endocervical glands is maintained. Most neoplastic cells resemble those of the endocervical mucinous epithelium. Endometrioid and intestinal cell types occur less often. About 50% of women with cervical AIS also have squamous CIN. Thus, some of the AIS lesions represent incidental findings in specimens removed for treatment of squamous neoplasia. Because AIS is located near or above the transformation zone, conventional cervical specimens may not be effective for detecting AIS. Obtaining specimens by cytobrush may improve detection of AIS. If the focus of AIS is small, cervical biopsy and endocervical curettage may have negative findings. In such cases, a more comprehensive survey of the cervix by conization is necessary. This type of specimen also allows exclusion of coexisting invasive adenocarcinoma. The term microinvasion should not be used to describe adenocarcinomas. Once the gland has been invaded, there is no definable technique for identifying the true “depth of invasion” because the invasion may have originated from the mucosal surface or the periphery of the underlying glands. The “breakthrough” of the basement membrane cannot truly be described; therefore, the tumor is either AIS or invasive adenocarcinoma.

With the recent apparent increase in invasive adenocarcinoma of the endocervix, more attention has been directed toward AIS. There is evidence that AIS may progress to invasive cancer (84). In a series of 52 cases of adenocarcinoma of the uterine cervix, the results of 18 endocervical biopsies were interpreted as negative 3 to 7 years before the presentation with cancer (112). In five of these cases, AIS was found.

In a study of the anatomic distribution of AIS in 23 women (113), all patients had AIS involving both the surface and the glandular endocervical epithelium, often with the deepest glandular cleft also involved. The entire endocervical canal was at risk; nearly one half of the patients had lesions 1.5 to 3 cm from the external os. Overall, 15 patients had unifocal disease, 3 had multifocal disease, and 5 had AIS of undermined type; 11 of the 23 patients had squamous intraepithelial lesions as well as AIS. In a study of 40 patients with AIS who had cervical conization (110), 23 of 40 patients (58%) had coexisting squamous intraepithelial lesions, and 2 had invasive squamous cell carcinoma. Of the 22 patients who underwent hysterectomy, the margins on the cone specimen were positive in 10 patients, and 70% had residual AIS, including 2 patients with foci of invasive adenocarcinoma. One of the 12 patients with negative margins had focal residual adenocarcinoma in the hysterectomy specimen, and 18 women had conization only with negative margins and no

</table>
relapse of disease after a medium interval of 3 years. Thus, positive margins on the conization specimen are significant findings in these patients.

In a more alarming study of 28 patients with AIS (115), of the 8 patients with positive margins who underwent repeat conization or hysterectomy, 3 had residual AIS, and 1 patient had invasive adenocarcinoma. Of 10 patients with negative margins who underwent hysterectomy or repeat conization, 4 had residual AIS. One patient in whom the cone margin could not be evaluated was found to have invasive adenocarcinoma. Of the 15 patients treated conservatively with repeat conization of the cervix and close follow-up, 7 (47%) had a recurrent glandular lesion detected after the conization, including invasive adenocarcinoma in 2 women. More disturbing is the finding that a glandular lesion was not suspected in 48% of the patients, based on Pap test and endocervical curettage results obtained before conization of the cervix.

**AIS must be considered a serious cancer precursor of adenocarcinoma.** The entire endocervical canal is at risk, and detection of the lesion with cytologic assessment or endocervical curettage may not be reliable. Any patient with a positive cone margin should undergo repeat conization. If fertility is not desired, a hysterectomy should be performed because of the risk of recurrence, even in the presence of negative margins.

### Vaginal Intraepithelial Neoplasia

**Vaginal intraepithelial neoplasia (VAIN)** often accompanies CIN and is believed to have a similar cause (116). Such lesions may be extensions onto the vagina from the CIN, or they may be satellite lesions occurring mainly in the upper vagina. **Because the vagina does not have a transformation zone with immature epithelial cells to be infected by HPV, the mechanism of entry of HPV is by way of skin abrasions from coitus or tampon use.** As these abrasions heal with metaplastic squamous cells, the HPV may begin its growth in a manner similar to that in the cervical transformation zone.

**Signs**

VAIN lesions are asymptomatic. Because they often accompany active HPV infection, the patient may report vulvar warts or an odoriferous vaginal discharge from vaginal warts.

**Screening**

Women with an intact cervix should undergo routine cytologic screening. **Because VAIN is nearly always accompanied by CIN, the Pap test result is likely to be positive when VAIN is present. The vagina should be carefully inspected by colposcopic examination at the time of colposcopy for any CIN lesion.** Particular attention should be paid to the upper vagina. **Women who have persistent positive Pap test results after treatment of CIN should be examined carefully for VAIN.** For women in whom the cervix has been removed for cervical neoplasia, Pap testing should be performed at regular intervals initially, depending on the diagnosis and severity of lesion, and yearly thereafter.

**Diagnosis**

Colposcopic examination and directed biopsy are the mainstays of diagnosis of VAIN. Typically, the lesions are located along the vaginal ridges, are ovoid in shape and slightly raised, and often have surface spicules. VAIN 1 lesions usually are accompanied by a significant amount of koilocytosis, indicating their HPV origin (Fig. 17.15). As the lesions progress to VAIN 2, they exhibit a thicker acetowhite epithelium, a more raised external border, and less iodine uptake (Fig. 17.16A). When VAIN 3 occurs, the surface may
become papillary, and the vascular patterns of punctuation and mosaic may occur (Fig. 17.16B). Early invasion is typified by vascular patterns similar to those of the cervix.

Treatment

Patients with VAIN 1 and HPV infection do not require treatment. These lesions often regress, are multifocal, and recur quickly when treated with ablative therapy. VAIN 2 lesions can be managed expectantly or treated by laser ablation. VAIN 3 lesions are more likely to harbor an early invasive lesion. In a study of 32 patients who underwent upper vaginectomy for VAIN 3 (117), occult invasive carcinoma was found in 9 patients (28%). It is recommended in older patients that VAIN 3 lesions located in the dimples of the vaginal cuff be excised to rule out occult invasive cancer. VAIN 3 lesions that are adequately sampled to rule out invasive disease can be treated with laser therapy. The major advantage of laser vaporization therapy is the ability to control exactly the depth and width of destruction by direct vision through the colposcope. The other major advantage of laser therapy is the rapid posttreatment healing phase. This process takes about 3 to 4 weeks, after which time a new epithelium has formed completely and, in most cases, has a mature glycogen-containing epithelium.

Tissue Interaction

When the laser beam contacts tissue, its energy is absorbed by the water in the cells, causing it to boil instantly. The cells explode into a puff of vapor (thus the term laser vaporization). The protein and mineral content is incinerated by the heat and leaves a charred appearance at the base of the exposed area. The depth of laser destruction is a function of the power of the beam (in watts), the area of the beam (in millimeters squared), and the length of time the laser remains in the tissue. The beam must be moved uniformly across the tissue surface to prevent deep destruction. The laser beam vaporizes a central area and leaves a narrow zone of heat necrosis surrounding the laser crater. The goal of laser vaporization is to minimize this area of tissue necrosis. This goal is accomplished by using high wattage (20 watts) with medium beam size (1.5 mm) and moving the beam uniformly but quickly over the surface. The zone of thermal necrosis will be 0.1 mm when the laser is used in this manner. Some lasers have a function
SECTION IV General Gynecology

Called *super pulse*, in which the laser beam is electronically switched off and on thousands of times per second, thereby allowing the tissue to cool between pulses to create less thermal necrosis.

Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under colposcopic control to observe the depth of destruction by wiping away the epithelial tissue as it is ablated. Excision is an excellent method for treatment of upper vaginal lesions in a small area. Occasionally, total vaginectomy will be required for a VAIN 3 lesion occupying the entire

Figure 17.16 (A) Vaginal intraepithelial neoplasia grade 2. (B) Vaginal intraepithelial neoplasia grade 3.
vagina. It should be accompanied by a split-thickness skin graft. This aggressive treatment for widespread vaginal lesions should not be used for VAIN 2.

The malignant potential of VAIN appears to be less than that of CIN. In a review of 136 cases of CIS of the vagina over a 30-year period (116), 4 cases (3%) progressed to invasive vaginal cancer despite the use of various treatment methods.

### Vulvar Intraepithelial Disease

#### Vulvar Dystrophies

In the past, terms such as leukoplakia, lichen sclerosis et atrophicus, primary atrophy, sclerotic dermatosis, atrophic and hyperplastic vulvitis, and kraurosis vulvae have been used to denote disorders of epithelial growth and differentiation (118). In 1966, Jeffcoate (119) suggested that these terms did not refer to separate disease entities because their macroscopic and microscopic appearances were variable and interchangeable. He assigned the generic term chronic vulvar dystrophy to the entire group of lesions.

The International Society for the Study of Vulvar Disease (ISSVD) recommended that the old dystrophy terminology be replaced by a new classification under the pathologic heading nonneoplastic epithelial disorders of skin and mucosa. This classification is shown in Table 17.13. In all cases, diagnosis requires biopsy of suspicious-looking lesions, which are best detected by careful inspection of the vulva in a bright light aided, if necessary, by a magnifying glass (120).

The malignant potential of these nonneoplastic epithelial disorders is low, particularly now that the lesions with atypia are classified as vulvar intraepithelial neoplasia (VIN). However, patients with lichen sclerosis and concomitant hyperplasia may be at particular risk (121).

#### Vulvar Intraepithelial Neoplasia

As with the vulvar dystrophies, there has been confusion regarding the nomenclature for VIN. Four major terms have been used: erythroplasia of Queyrat, Bowen’s disease, carcinoma in situ simplex, and Paget’s disease. In 1976, the ISSVD decreed that the first three

VIN, vulvar intraepithelial neoplasia.

lesions were merely gross variants of the same disease process and that all of these entities should be included under the umbrella term *squamous cell carcinoma in situ* (stage 0) (90). In 1986, the ISSVD recommended the term *vulvar intraepithelial neoplasia* (Table 17.13).

VIN is graded as 1 (mild dysplasia), 2 (moderate dysplasia), or 3 (severe dysplasia or CIS) on the basis of cellular immaturity, nuclear abnormalities, maturation disturbance, and mitotic activity. In VIN 1, immature cells, cellular disorganization, and mitotic activity occur predominantly in the lower one third of the epithelium, whereas in VIN 3, immature cells with scanty cytoplasm and severe chromatinic alterations occupy most of the epithelium (Fig. 17.17). Dyskeratotic cells and mitotic figures occur in the superficial layer. The appearance of VIN 2 is intermediate between VIN 1 and VIN 3. Additional cytopathic changes of HPV infection, such as perinuclear halos with displacement of the nuclei by the intracytoplasmic viral protein, thickened cell borders, binucleation, and multinucleation, are common in the superficial layers of VIN, especially in VIN 1 and VIN 2. These viral changes are not definitive evidence of neoplasia but are indicative of viral exposure (122). Most vulvar condylomas are associated with HPV-6 and -11, whereas HPV-16 is detected in more than 80% of VIN cases by molecular techniques.

VIN 3 can be unifocal or multifocal. Typically, multifocal VIN 3 presents with small hyperpigmented lesions on the labia majora (Fig. 17.18). Some cases of VIN 3 are more confluent, extending to the posterior fourchette and involving the perineal tissues. The term *bowenoid papulosis* (*bowenoid dysplasia*) has been used to describe multifocal VIN lesions ranging from grade 1 to 3. Clinically, patients with Bowenoid papulosis present with multiple small pigmented papules (40% of cases) that are usually less than 5 mm in diameter. Most women with these lesions are in their 20s, and some are pregnant. After childbirth, the lesions may regress spontaneously. However, the term *bowenoid papulosis* is no longer recommended by the ISSVD.

**Paget’s Disease of the Vulva**

Extramammary Paget’s disease of the vulva (AIS) was described 27 years after the description by Sir James Paget of the mammary lesion that now bears his name (123).
CHAPTER 17  Intraepithelial Disease of the Cervix, Vagina, and Vulva

Figure 17.18 Vulvar carcinoma in situ: carcinoma in situ extending into the hair follicle.

Some patients with vulvar Paget’s disease have an underlying adenocarcinoma, although the precise frequency is difficult to ascertain.

**Histology**

*Most cases of vulvar Paget’s disease are intraepithelial.* Because these lesions demonstrate apocrine differentiation, the malignant cells are believed to arise from undifferentiated basal cells, which convert into an appendage type of cell during carcinogenesis (Fig. 17.19). The “transformed cells” spread intraepithelially throughout the squamous epithelium and may extend into the appendages. In most patients with an underlying invasive carcinoma of the apocrine sweat gland, Bartholin gland, or anorectum, the malignant cells are believed to migrate through the dermal ductal structures and reach the epidermis. In such cases, metastasis to the regional lymph nodes and other sites can occur.

Paget’s disease must be distinguished from superficial spreading melanoma. All sections should be studied thoroughly using differential staining, particularly periodic acid–Schiff (PAS) and mucicarmine stains. Mucicarmine has routinely positive results in the cells of Paget’s disease and negative results in melanotic lesion.

**Clinical Features**

Paget’s disease of the vulva predominantly affects postmenopausal white women, and the presenting symptoms are usually pruritus and vulvar soreness. The lesion has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva (Fig. 17.20). It may extend to involve the mons pubis, thighs, and buttocks. Extension to the mucosa of the rectum, vagina, or urinary tract also has been described (124). The more extensive lesions are usually raised and velvety in appearance.

A second synchronous or metachronous primary neoplasm is associated with extramammary Paget’s disease in about 4% of patients, much less common than believed.
in the past (125). Associated carcinomas have been reported in the cervix, colon, bladder, gallbladder, and breast. When the anal mucosa is involved, there usually is an underlying rectal adenocarcinoma (121).

**Treatment**

**VIN** The treatment of VIN 3 has varied from wide excision to the performance of a superficial or “skinning” vulvectomy (126–129). Although the treatment originally recommended for CIS of the vulva was wide excision, fears that the disease frequently was preinvasive led to the widespread use of superficial vulvectomy (128). Because progression is relatively uncommon, typically occurring in 5% to 10% of cases (126), extensive surgery is not warranted. This is particularly true because many VIN 3 lesions are found in premenopausal women.
The therapeutic alternatives for VIN 3 are simple excision, laser ablation, and superficial vulvectomy with or without split-thickness skin grafting. Excision of small foci of disease produces excellent results and has the advantage of providing a histopathologic specimen. Although multifocal or extensive lesions may be difficult to treat by this approach, it offers the potential for the most cosmetic result. Repeat excision is often necessary but can usually be accomplished without vulvectomy (127,129).

The carbon dioxide laser can be used for multifocal lesions but is unnecessary for unifocal disease. The disadvantages are that it can be painful and costly and does not provide a histopathologic specimen (130).

Superficial vulvectomy is appropriate to treat extensive and recurrent VIN 3 (129). The goal of the surgery is to extirpate all of the disease while preserving as much of the normal vulvar anatomy as possible. The anterior vulva and the clitoris should be preserved if possible. In some patients, the disease extends up the anus, which also must be resected. An effort should be made to close the vulvar defect primarily, reserving the use of skin grafts for instances in which the vulvar defect cannot be closed because the resection is so extensive. Split-thickness skin grafts can be harvested from the thighs or buttocks, but the latter is more easily concealed (131).
**SECTION IV  General Gynecology**

**Paget’s Disease**  Unlike squamous cell CIS, in which the histologic extent of disease usually correlates closely with the macroscopic lesion, Paget’s disease usually extends well beyond the gross lesion (132). This extension results in positive surgical margins and frequent local recurrence unless a wide local excision is performed (133). Underlying adenocarcinomas are usually apparent clinically, but this finding does not occur invariably; therefore, the underlying dermis should be removed for adequate histologic evaluation. For this reason, laser therapy is unsatisfactory in treating primary Paget’s disease. If underlying invasive carcinoma is present, it should be treated in the same manner as a squamous vulvar cancer. This treatment usually requires radical vulvectomy and at least an ipsilateral inguinal-femoral lymphadenectomy.

Recurrent lesions are almost always in situ, although there has been at least one report of an underlying adenocarcinoma in recurrent Paget’s disease (125). In general, it is reasonable to treat recurrent lesions with surgical excision.

Early Pregnancy Loss and Ectopic Pregnancy

Thomas G. Stovall

- As many as 30% of pregnancies may be spontaneously lost.
- Following an ectopic pregnancy, there is a 10-fold increase in the risk of a subsequent ectopic pregnancy.
- Single-dose methotrexate appears to be the treatment of choice if medical therapy is indicated and selected.
- Unless the patient has documented cardiac activity in the ectopic, medical therapy should be instituted unless all the treatment criteria are met and the patient has had at least two hCG levels and a transvaginal ultrasound.
- Surgical management and medical therapy appear to be equivalent in a randomized comparison.

An abnormal gestation can be either intrauterine or extrauterine. Extrauterine or ectopic pregnancy occurs when the fertilized ovum becomes implanted in tissue other than the endometrium. Although most ectopic gestations are located in the ampullary segment of the fallopian tube, such pregnancies may also occur in other sites (Table 18.1). Abnormal intrauterine pregnancy often results in pregnancy loss early in gestation. Such losses can be related to a number of factors. With both abnormal intrauterine and extrauterine gestation, early recognition is key to diagnosis and management.

Abnormal Intrauterine Pregnancy

Spontaneous Abortion

Anembryonic gestation, inevitable abortion, incomplete abortion, and completed abortion are types of first-trimester abortions. About 15% to 20% of known pregnancies terminate in spontaneous abortion. With the use of serial human chorionic gonadotropin (hCG) measurements to detect early subclinical pregnancy losses, the percentage
In a study of 347 patients with a first-trimester pregnancy documented by ultrasonography, the overall rate of pregnancy loss was 6.1% to 4.2% in patients without bleeding and 12.4% in patients with bleeding (1). In women who have had one prior spontaneous abortion, the rate of spontaneous abortion in a subsequent pregnancy is about 20%; in women who have had three consecutive losses, the rate is 50%. The causes of this condition are varied and most often unknown (Table 18.2). Patients should be reassured that, in most cases, spontaneous abortion does not recur.

### Threatened Abortion

Threatened abortion is defined as vaginal bleeding before 20 weeks of gestation. It occurs in about 30% to 40% of all pregnancies. The bleeding is usually light and may be associated with mild lower abdominal or cramping pain. It is often not possible to differentiate clinically between threatened abortion, completed abortion, and ectopic pregnancy in an unruptured tube. The differential diagnosis in these patients includes consideration of possible cervical polyps, vaginitis, cervical carcinoma, gestational trophoblastic disease, ectopic pregnancy, trauma, and foreign body. On physical examination, the abdomen usually is not tender, and the cervix is closed. Bleeding can be seen coming from the os, and usually there is no cervical motion or adnexal tenderness. Although most patients experience bleeding at 8 to 10 weeks of gestation, the actual loss usually occurs
CHAPTER 18 Early Pregnancy Loss and Ectopic Pregnancy

Early Pregnancy Loss

before 8 weeks of gestation. Only 3.2% of patients experience a pregnancy loss after 8 weeks of gestation (2).

Unless the patient has an intrauterine pregnancy documented by ultrasonography, eliminating the possibility of an ectopic pregnancy, evaluation of a threatened abortion should include serial measurements of hCG. Endovaginal ultrasonography can detect a gestational sac at an hCG level of 1,000 to 2,000 mIU/mL. By 7 weeks of gestation, a fetal pole with fetal cardiac activity can be seen. When a gestational sac is visualized, subsequent loss of the pregnancy occurs in 11.5% of patients. If a yolk sac is present, the loss rate is 8.5%; with an embryo of 5 mm, the loss rate is 7.2%; with an embryo of 6 to 10 mm, the loss rate is 3.2%; and when the embryo is 10 mm, the loss rate is only 0.5%. The fetal loss rate after 14 weeks of gestation is about 2% (3). Transvaginal measurement of gestational sac size is useful in differentiating viable from nonviable intrauterine pregnancies. A mean sac diameter greater than 13 mm without a visible yolk sac or a mean sac diameter greater than 17 mm lacking an embryo predicts nonviability in all cases (4).

There is no effective therapy for a threatened intrauterine pregnancy. Bed rest, although advocated, is not effective. Progesterone or sedatives should not be used. All patients should be counseled and reassured so that they understand the situation. Vaginal infection, if present, should be treated.

Inevitable Abortion

With an inevitable abortion, the volume of bleeding is often greater than with other types of abortion, and the cervical os is open and effaced, but no tissue has been passed. Most patients have crampy lower abdominal pain, and some have cervical motion or adnexal tenderness. When it is certain that the pregnancy is not viable because the cervical os is dilated or excessive bleeding is present, suction curettage should be performed. Blood type and Rh determination and a complete blood count should be obtained if there is any concern about the amount of bleeding. Rh(D) immune globulin (RhoGAM) should be given either before or after the uterus is evacuated if the patient’s blood is Rh negative.

Incomplete Abortion

An incomplete abortion is a partial expulsion of the pregnancy tissue. Before 6 weeks of gestation, the placenta and fetus are generally passed together, but after this time, they

often are passed separately. Although most patients have vaginal bleeding, only some have passed tissue. Lower abdominal cramping is invariably present, and the pain may be described as resembling labor. On physical examination, the cervix is dilated and effaced, and bleeding is present. Often, clots are admixed with products of conception. If the bleeding is profuse, the patient should be examined promptly for tissue protruding from the cervical os; removal of this tissue with a ring forceps reduces the bleeding. A vasovagal bradycardia may occur and responds to removal of the tissue. All patients with an incomplete abortion should undergo suction curettage as quickly as possible. A complete blood count, maternal blood type, and Rh determination should be obtained; Rh-negative patients should receive Rh\(_{0}\) (D) immune globulin.

If the patient is febrile, broad-spectrum antibiotic therapy should be administered before suction curettage is performed to reduce the incidence of postabortal endometritis and pelvic inflammatory disease, thereby reducing potential deleterious effects on fertility. The antibiotic regimen chosen should be similar to the regimens used for treatment of pelvic inflammatory disease (PID). In patients who do not have clinical signs of infection, prophylactic antibiotic therapy should be instituted. Suggested regimens include doxycycline (100 mg orally twice daily), tetracycline (250 mg orally four times daily for 5–7 days) or another antibiotic of similar spectrum.

### Ectopic Gestation

#### Incidence

The most comprehensive data available on ectopic pregnancy rates have been collected by the Centers for Disease Control and Prevention (5). These data show a significant increase in the number of ectopic pregnancies in the United States during the past 20 years (Fig. 18.1). In 1989, the latest year for which statistics were published, an estimated 88,400 ectopic pregnancies occurred, at a rate of 16 ectopic pregnancies per 1,000 reported pregnancies. These numbers represent a fivefold increase compared with the 1970 rates. The highest rates occurred in women aged 35 to 44 years (27.2 per 1,000 reported pregnancies). When the data are analyzed by race, the risk for ectopic pregnancy among African Americans and other minorities (20.8 per 1,000) is 1.6 times greater than the risk among whites (13.4 per 1,000). In 1988, 44 deaths were attributed to complications of ectopic pregnancy, which represents 15% of all maternal deaths. The risk for death is higher for African Americans and other minorities than for whites (6). For both races, teenagers have the highest mortality rates, but the rate for African American and other minority teenagers is almost five times that of white teenagers. **After an ectopic pregnancy, there is a 7- to 13-fold increase in the risk of a subsequent ectopic pregnancy. The chance that a subsequent pregnancy will be intrauterine is 50% to 80%, and the chance that the pregnancy will be tubal is 10% to 25%; the remaining patients will be infertile** (7–9). Many variables make accurate assessment of risk difficult (e.g., size and location of the ectopic pregnancy, status of the contralateral adnexa, treatment method, and history of infertility).

#### Etiology and Risk Factors

Tubal damage results from inflammation, infection, and surgery. Inflammation and infection may cause damage without complete tubal obstruction. Complete blockage may result from salpingitis, incomplete tubal ligation, tubal fertility surgery, partial salpingectomy, or congenital midsegment tubal atresia (10–14). Damage to the mucosal portion of the tube or fimbria accounts for about one half of all tubal pregnancies (15). Tubal diverticula may result in abnormalities that entrap the blastocyst or impede transport (16,17). Tubal pregnancy may occur in a blocked tube with contralateral tubal patency, with the sperm migrating across the abdomen to fertilize an egg released from the blocked side.
Myoelectrical activity is responsible for propulsive activity in the fallopian tube (16). This activity facilitates movement of the sperm and ova toward each other and propels the zygote toward the uterine cavity. Estrogen increases smooth muscle activity, and progesterone decreases muscle tone. Aging results in progressive loss of myoelectrical activity along the fallopian tube, which may explain the increased incidence of tubal pregnancy in perimenopausal women (16). Hormonal control of the muscular activity in the fallopian tube may explain the increased incidence of tubal pregnancy associated with failures of the morning-after pill, minipill, progesterone-containing intrauterine devices (IUDs), and ovulation induction. Blighted ova occur more commonly in tubal conceptions than in intrauterine conceptions, although there is no increase in the incidence of chromosomal abnormalities in ectopic pregnancies (18).

Independent factors consistently shown to increase the risk for tubal pregnancy include the following:

1. Previous laparoscopically proven PID
2. Previous tubal pregnancy
3. Current IUD use
4. Previous tubal surgery for infertility

Figure 18.1 Estimation of the number of ectopic pregnancies (United States, 1970–1989). Dashed lines represent the upper and lower limits of 95% confidence intervals.
Many other risk factors, including contraceptive choice, prior surgery, previous pregnancies, and fertility status, also have been identified.

**Pelvic Infection**

The relationship of PID, tubal obstruction, and ectopic pregnancy is well documented (13,19). In a study of 415 women with laparoscopically proven PID, the incidence of tubal obstruction increased with successive episodes of PID: 13% after one episode, 35% after two, and 75% after three (19). Furthermore, after one episode of PID, the ratio of ectopic pregnancy to intrauterine pregnancy was 1 in 24, a sixfold increase over the incidence for women with laparoscopically negative results (1 in 147). In a prospective study of 1,204 patients followed until first pregnancy after infection, 47 of 746 (6%) women with laparoscopically documented PID had a tubal gestation, which is significantly higher than the 0.9% incidence that occurred in the control group (20).

Chlamydia is an important pathogen causing tubal damage and subsequent tubal pregnancy. Because many cases of chlamydia salpingitis are indolent, cases may not be recognized or, if recognized, may be treated on an outpatient basis. Chlamydia has been cultured from 7% to 30% of patients with tubal pregnancy (7,21). A strong association between chlamydia infection and tubal pregnancy has been shown with serologic tests for chlamydia (22–25). Conception is three times as likely to be tubal in women with anti-Chlamydia trachomatis titers higher than 1:64 than in those women whose titers were negative (7,26).

**Contraceptive Use**

Inert and copper-containing IUDs prevent both intrauterine and extrauterine pregnancies (27,28). Women who conceive with an IUD in place, however, are 0.4 to 0.8 times more likely to have a tubal pregnancy than those not using contraceptives. Because IUDs prevent implantation more effectively in the uterus than in the tube, a woman conceiving with an IUD is 6 to 10 times more likely to have a tubal pregnancy than if she conceives without using contraception (27,28).

With copper IUDs, 4% of contraceptive failures are tubal pregnancies. Progesterone IUDs are less effective than copper IUDs in preventing tubal pregnancy; 17% of failures result in tubal pregnancy. Furthermore, the rate of ectopic pregnancy in women using progesterone IUDs is higher than in women not using contraceptives: 1.9 per 100 woman-years (versus 0.5 for copper IUDs) (29). This finding suggests that failures occur for different reasons. Although all IUDs prevent intrauterine implantation, copper IUDs prevent fertilization by cytotoxic and phagocytic effects on the sperm and oocytes. Progesterone-containing IUDs are probably less effective in preventing conception.

Duration of IUD use does not increase the absolute risk for tubal pregnancy (1.2 per 1,000 years of exposure), but with increasing use, there is an increase in the percentage of pregnancies that are tubal (30). With the exception of the Dalkon shield, for which past use of an IUD is associated with a twofold increased risk (31), the link between past use of IUDs and the risk of tubal pregnancy is unclear. One study showed that previous use of an IUD for longer than 2 years was associated with a fourfold risk, but this risk was present for only the first year after discontinuation of IUD use (27). However, subsequent studies have found no increased risk for tubal pregnancy following IUD use (30,32).

The risk of the pregnancy being ectopic with combination oral contraceptive use has been calculated to be 0.5 to 4% (27,28,33). **Past use of oral contraceptives does not increase the subsequent risk for ectopic pregnancy** (8). Progesterone-only contraceptives, including oral contraceptives (minipill) and subdermal implants (Norplant), protect against both intrauterine and ectopic pregnancy when compared with no contraceptive use. If a pregnancy does occur, however, the chance of the pregnancy being ectopic is 4% to 10% for the minipill (34,35) and up to 30% if pregnancy occurs while implants are in place (36,37).
Condom and diaphragm use protects against both intrauterine and ectopic pregnancy, and there is no increased incidence of ectopic pregnancy (30,33,38).

### Sterilization

The greatest risk of pregnancy, including ectopic pregnancy, occurs in the first 2 years after sterilization (39). Despite a greater proportion of poststerilization failures resulting in ectopic pregnancy, the absolute rate of ectopic pregnancy is decreased after sterilization. Calculating cumulative lifetime risk for ectopic pregnancy according to method of contraception, sterilized women have a lower cumulative risk for ectopic pregnancy than IUD users or nonusers of contraception, and women using barrier methods or oral contraceptives have the lowest risk (40).

The risk of tubal pregnancy after any sterilization procedure is 5% to 16% (10,39,40). The risk depends on the sterilization technique: about one half of postelectrocautery failures are ectopic, compared with 12% after nonlaparoscopic, nonelectrocautery procedures (41). Laparoscopic coagulation has a reduced risk of pregnancy compared with mechanical devices, but the risk of ectopic pregnancy is increased ninefold when a failure does occur (10,42,43).

Tubal repair or reconstruction may be performed to correct an obstruction, lyse adhesions, or evacuate an unruptured ectopic pregnancy. Although it is clear that tubal surgery is associated with an increased risk for ectopic pregnancy, it is unclear whether the increased risk results from the surgical procedure or from the underlying problem. A four- to fivefold increased risk is associated with salpingostomy, neosalpingostomy, fimbrioplasty, anastomosis, and lysis of complex peritubal and periovarian adhesions (7,11,43). After tubal surgery, the overall rate of ectopic pregnancy is 2% to 7%, and the viable intrauterine pregnancy rate is 50%.

There has been a concern that conservation of the tube at the time of removal of an ectopic pregnancy would increase the risk for recurrent ectopic pregnancy. However, after either tubal removal or conservation, the rates for intrauterine pregnancy (40%) and ectopic pregnancy (12%) have been found to be identical (44). In another study, the incidence of ectopic pregnancy could be predicted by the status of the contralateral tube: normal (7%), abnormal (18%), or absent (25%) (42). In a study of pregnancy outcomes of 1,152 patients treated for ectopic pregnancy, preservation of the tube did not increase the incidence of repeat ectopic pregnancy, but it did improve overall fertility rates (45).

Sterilization reversal also increases risk for ectopic pregnancy. The exact risk depends on the method of sterilization, site of tubal occlusion, residual tube length, coexisting disease, and surgical technique. In general, the risk for reanastomosis of a cauterized tube is about 15%, and it is less than 3% for reversal of Pomeroy or Falope ring procedures (46,47).

### Prior Abdominal Surgery

Many patients with ectopic pregnancies have a history of previous abdominal surgery (7,8,48). The role of abdominal surgery in ectopic pregnancy is unclear. In one study, there appeared to be no increased risk for cesarean delivery, ovarian surgery, or removal of an unruptured appendix (49). Other studies have shown that ovarian cystectomy or wedge resection increases the risk for ectopic pregnancy, presumably because of peritubal scarring (50,51). Although there is general agreement that an increased risk for ectopic pregnancy is associated with a ruptured appendix (7,43), one study did not confirm this finding (49).

### Other Causes

**Abortion** There is no established association between ectopic pregnancy and spontaneous abortion (7,9,52). With recurrent abortion (fewer than two consecutive abortions), the risk is increased 2 to 4 times. This may reflect a shared risk factor, such as with luteal...
phase defect. Uncomplicated elective abortion, regardless of the number of procedures or gestational age at which they were performed, is not associated with increased risk (7,8,53,54). In areas with a high incidence of illegal abortion, the risk is increased 10-fold. Presumably, this increased incidence is secondary to postoperative infection and improperly performed procedures (54).

**Infertility** Although the incidence of ectopic pregnancy increases with age and parity, there also is a significant increase in nulliparous women undergoing infertility treatment (7,8,44). For nulliparous women, conceptions after at least 1 year of unprotected intercourse are 2.6 times more likely to be tubal (55). Additional risks for infertile women are associated with specific treatments, including reversal of sterilization, tuboplasty, ovulation induction, and *in vitro* fertilization (IVF).

Hormonal alterations characteristic of clomiphene citrate and gonadotropin ovulation-induction cycles may predispose tubal implantation. About 1.1% to 4.6% of conceptions associated with ovulation induction are ectopic pregnancies (8,55). In many of these patients, the results of hysterosalpingography are normal, and there is no evidence of intraoperative tubal pathology. Hyperstimulation, with high estrogen levels, may play a role in tubal pregnancy (56,57); however, not all studies have shown this relationship (58).

The first pregnancy obtained with IVF was a tubal pregnancy (59). About 2% to 8% of IVF conceptions are tubal. Tubal factor infertility is associated with a further increased risk of 17% (60–62). Predisposing factors are unclear but may include placement of the embryo high in the uterine cavity, fluid reflux into the tube, and a predisposing tubal factor that prevents the refluxed embryo from returning to the uterine cavity.

**Salpingitis Isthmica Nodosa** Salpingitis isthmica nodosa (SIN) is a noninflammatory pathologic condition of the tube in which tubal epithelium extends into the myosalpinx and forms a true diverticulum. The reported prevalence ranges from 1 in 146 to 11 in 100. This condition is found more often in the tubes of women with an ectopic pregnancy than in nonpregnant women (17,63,64). Myometrial electrical activity over the diverticula has been found to be abnormal (16). Whether tubal pregnancy is caused by SIN or whether the association is coincidental is unknown.

**Endometriosis or Leiomyomas** Endometriosis or leiomyomas can cause tubal obstruction. However, neither is commonly associated with ectopic pregnancy.

**Diethylstilbestrol** Women exposed to diethylstilbestrol (DES) *in utero* who subsequently conceive are at increased risk for ectopic pregnancy. In several case-control studies, these women were more than twice as likely to have a tubal pregnancy (65,66). The Collaborative Diethylstilbestrol-Adenosis Project, which monitored 327 DES-exposed women, found that about 50% had uterine cavity abnormalities (65). In DES-exposed women, the risk for ectopic pregnancy was 13% in those who had uterine abnormalities compared with 4% in those who had a normal uterus. No specific type of defect was related to the risk for ectopic pregnancy.

**Smoking** Current cigarette smoking is associated with a more than twofold increased risk for tubal pregnancy (28,51,67–69). A case-control study showed a dose relationship: current smokers of more than 20 cigarettes a day had a relative risk of 2.5 compared with nonsmokers, whereas smokers of 1 to 10 cigarettes had a risk of 1.3 (68). Alterations of tubal motility, ciliary activity, and blastocyst implantation are associated with nicotine intake.

**Histologic Characteristics** Chorionic villi, usually found in the lumen, are pathognomonic findings of tubal pregnancy. Gross or microscopic evidence of an embryo is seen in two thirds of cases...
(70). An unruptured tubal pregnancy is characterized by irregular dilation of the tube, with a blue discoloration caused by hematosalpinx. The ectopic pregnancy may not be readily apparent. Bleeding associated with tubal pregnancies is mainly extraluminal but may be luminal (hematosalpinx) and may extrude from the fimbriated end. A hematoma is frequently seen surrounding the distal segment of the tube. Patients who have tubal pregnancies that spontaneously resolved and those treated with methotrexate frequently have an enlargement of the ectopic mass associated with blood clots and extrusion of tissue from the fimbriated end. Hemoperitoneum is nearly always present but is confined to the cul-de-sac unless tubal rupture has occurred. The natural progression of tubal pregnancy is either expulsion from the fimbriated end (tubal abortion), involution of the conceptus, or rupture, usually around the eighth gestational week. Some tubal pregnancies form a chronic inflammatory mass that is associated with involution and reestablishment of menses and thus is difficult to diagnose. Extensive histologic sampling may be required to disclose a few ghost villi.

Histologic findings associated with tubal gestation include evidence of chronic salpingitis and SIN. Inflammation associated with salpingitis causes adhesions as a result of fibrin deposition. Healing and cellular organization lead to permanent scarring between folds of tissue. This scarring may allow transport of sperm but not the passage of the larger blastocyst. About 45% of patients with tubal pregnancies have pathologic evidence of prior salpingitis (71).

The cause of SIN is unknown but is speculated to be an adenomyosis-like process or, less likely, inflammation (72,73). This condition is rare before puberty, indicating a noncongenital origin. Tubal diverticula are identified in about one half of patients who have ectopic pregnancies, as opposed to 5% of women who do not have ectopic pregnancies (17).

Histologic findings include the Arias-Sella reaction, which is characterized by localized hyperplasia of endometrial glands that are hypersecretory (74). The cells have enlarged nuclei that are hyperchromatic and irregular. The Arias-Sella reaction is a nonspecific finding that can be seen in patients with intrauterine pregnancies (Fig. 18.2).

### Diagnosis

The diagnosis of ectopic pregnancy is complicated by the wide spectrum of clinical presentations, from asymptomatic cases to acute abdomen and hemodynamic shock. The diagnosis and management of a ruptured ectopic pregnancy is straightforward; the primary goal is achieving hemostasis. **If an ectopic pregnancy can be identified before rupture or irreparable tubal damage occurs, consideration may be given to optimizing future fertility.** With patients presenting earlier in the disease process, the number of those without symptoms or with minimal symptoms has increased. Therefore, there must be a high degree of suspicion of ectopic pregnancy, especially in areas of high prevalence. History and physical examination identify patients at risk, improving the probability of detection of ectopic pregnancy before rupture occurs.

### History

Patients who have an ectopic pregnancy generally have an abnormal menstrual pattern or the perception of a spontaneous pregnancy loss. Pertinent points in the history include the menstrual history, previous pregnancy, history of infertility, current contraceptive status, risk factor assessment, and current symptoms.

The classic symptom triad of ectopic pregnancy is pain, amenorrhea, and vaginal bleeding. This symptom group is present in only about 50% of patients, however, and is most typical in patients in whom an ectopic pregnancy has ruptured. Abdominal
pain is the most common presenting symptom, but the severity and nature of the pain vary widely. There is no pathognomonic pain that is diagnostic of ectopic pregnancy. Pain may be unilateral or bilateral and may occur in the upper or lower abdomen. The pain may be dull, sharp, or crampy and either continuous or intermittent. With rupture, the patient may experience transient relief of the pain, as stretching of the tubal serosa ceases. Shoulder and back pain, thought to result from hemoperitoneal irritation of the diaphragm, may indicate intraabdominal hemorrhage.

Physical Examination

The physical examination should include measurements of vital signs and examination of the abdomen and pelvis. Frequently, the findings before rupture and hemorrhage are nonspecific, and vital signs are normal. The abdomen may be nontender or mildly tender, with or without rebound. The uterus may be slightly enlarged, with findings similar to a normal pregnancy (75). Cervical motion tenderness may or may not be present. An adnexal mass may be palpable in up to 50% of cases, but the mass varies markedly in size, consistency, and tenderness. A palpable mass may be the corpus luteum and not the ectopic pregnancy. With rupture and intraabdominal hemorrhage, the patient develops tachycardia followed by hypotension. Bowel sounds are decreased or absent. The abdomen is distended, with marked tenderness and rebound tenderness. Cervical motion tenderness is present. Frequently, the findings of the pelvic examination are inadequate because of pain and guarding.

History and physical examination may or may not provide useful diagnostic information. The accuracy of the initial clinical evaluation is less than 50% (76). Additional tests are frequently required to differentiate early viable intrauterine pregnancy or suspected ectopic or abnormal intrauterine pregnancy.
Laboratory Assessment

Quantitative β-hCG measurements are the diagnostic cornerstone for ectopic pregnancy. The hCG enzyme immunoassay, with a sensitivity of 25 mIU/mL, is an accurate screening test for detection of ectopic pregnancy. The assay is positive in virtually all documented ectopic pregnancies.

Reference Standards

There are three reference standards for β-hCG measurement. The World Health Organization introduced the First International Standard (1st IS) in the 1930s. Testing for hCG and its subunits have improved over the years. The Second International Standard (2nd IS), introduced in 1964, has varying amounts of β-hCG and β subunits. A purified preparation of β-hCG is now available. Originally referred to as the First International Reference Preparation (1st IRP), the test standard is now referred to as the Third International Standard (3rd IS). Although each standard has its own scale, as a general rule, the 2nd IS is about one half of the 3rd IS. For example, if a level is reported as 500 mIU/mL (2nd IS), it is equivalent to a level of 1,000 mIU/mL (3rd IS). The assay standard used must be known to interpret hCG results correctly (77). In several recent articles, attention has been drawn to a problem known as phantom hCG, in which the presence of heterophile antibodies or proteolytic enzymes causes a false-positive hCG result. Because the antibodies are large glycoproteins, significant quantities of the antibody are not excreted in the urine. Thus, in the patient with hCG levels less than 1,000 mIU/mL, a urine pregnancy test should be performed and confirmatory positive results obtained before instituting treatment (78,79).

Doubling Time

The hCG level correlates somewhat with the gestational age (80). During the first 6 weeks of amenorrhea, serum hCG levels increase exponentially. Thus, during this period, the doubling time of hCG is relatively constant, regardless of the initial level. After the sixth week of gestation, when hCG levels are higher than 6,000 to 10,000 mIU/mL, the hCG rise is slower and not constant (81).

The hCG doubling time can help to differentiate an ectopic pregnancy from an intrauterine pregnancy—a 66% rise in the hCG level over 48 hours (85% confidence level) represents the lower limit of normal values for viable intrauterine pregnancies (82). About 15% of patients with viable intrauterine pregnancies have less than a 66% rise in hCG level over 48 hours, and a similar percentage with an ectopic pregnancy have more than a 66% rise. If the sampling interval is reduced to 24 hours, the overlap between normal and abnormal pregnancies is even greater. Patients with normal intrauterine pregnancies usually have more than a 50% rise in their hCG levels over 48 hours when the starting level is less than 2,000 mIU/mL. The hCG pattern that is most predictive of an ectopic pregnancy is one that has reached a plateau (a doubling time of more than 7 days). For falling levels, a half-life of less than 1.4 days is rarely associated with an ectopic pregnancy, whereas a half-life of more than 7 days is most predictive of ectopic pregnancy.

Serial hCG levels are usually required when the results of the initial ultrasonography examination are indeterminate (i.e., when there is no evidence of an intrauterine gestation or extrauterine cardiac activity consistent with an ectopic pregnancy). When the hCG level is less than 2,000, doubling time helps to predict viable intrauterine gestation (normal rise) versus nonviability (subnormal rise). With normally rising levels, a second ultrasonography examination is performed when the level is expected (by extrapolation) to reach 2,000 mIU/mL. Abnormally rising levels (less than 2,000 mIU/mL and less than 50% rise over 48 hours) indicate a nonviable pregnancy. The location (i.e., intrauterine versus extrauterine) must be determined surgically, either by laparoscopy or dilation and curettage. Indeterminate ultrasonography results, and an hCG
SECTION IV General Gynecology

level of less than 2,000 mIU/mL is diagnostic of nonviable gestation, either ectopic pregnancy or a complete abortion. In general, rapidly falling hCG levels (50% over 48 hours) occur with a completed abortion, whereas with an ectopic pregnancy levels rise or plateau.

Single hCG Level

A single hCG measurement has limited usefulness because there is considerable overlap of values between normal and abnormal pregnancies at a given gestational age. The ectopic pregnancy site and hCG level do not correlate (83). Also, many patients in whom the diagnosis of ectopic pregnancy is being considered are uncertain about their menstrual dates. A single hCG level may be useful when measured by sensitive enzyme immunoassays that, if negative, exclude a diagnosis of ectopic pregnancy. Measurement of a single level may also be helpful in predicting pregnancy outcome after timed conceptions using advanced reproductive technology. If the hCG level is more than 300 mIU/mL on day 16 to 18 after artificial insemination, there is an 88% chance of a live birth (84). If the hCG level is less than 300 mIU/mL, the chance of a live birth is only 22%. Also, a single hCG level may facilitate the interpretation of ultrasonography when an intrauterine gestation is not visualized. An hCG level greater than the ultrasound discriminatory zone indicates a possible extrauterine pregnancy. However, determination of serial hCG levels may be needed to differentiate an ectopic pregnancy from a completed abortion. Further tests are required for patients in whom ultrasonography examination results are inconclusive and hCG levels are below the discriminatory zone.

Serum Progesterone

In general, the mean serum progesterone level in patients with ectopic pregnancies is lower than that in patients with normal intrauterine pregnancies (85,86). However, in studies of more than 5,000 patients with first-trimester pregnancies, a spectrum of progesterone levels has been found in patients with both normal and abnormal pregnancies (87–89). About 70% of patients with a viable intrauterine pregnancy have serum progesterone levels higher than 25 ng/mL, whereas only 1.5% of patients with ectopic pregnancies have serum progesterone levels higher than 25 ng/mL, and most of these pregnancies exhibit cardiac activity (87–89).

A serum progesterone level can be used as an ectopic pregnancy screening test for both normal and abnormal pregnancy, particularly in settings in which hCG levels and ultrasonography are not readily available. A serum progesterone level of less than 5 ng/mL is highly suggestive of an abnormal pregnancy, but it is not 100% predictive. The risk of a normal pregnancy with a serum progesterone level of less than 5 ng/mL is about 1 in 1,500 (90). Thus, serum progesterone measurements alone cannot be used to predict pregnancy nonviability.

Other Endocrinologic Markers

In an effort to improve early detection of ectopic pregnancy, various endocrinologic and protein markers have been studied. Estradiol levels increase slowly from conception until 6 weeks of gestation and then rise rapidly as placental production of estradiol increases (91). Estradiol levels are significantly lower in ectopic pregnancies when compared with viable pregnancies. However, there is considerable overlap between normal and abnormal pregnancies as well as between intrauterine and extrauterine pregnancies (92,93).

Maternal serum creatine kinase has been studied as a marker for ectopic pregnancy diagnosis (94). Maternal serum creatine kinase levels were significantly higher in all patients with tubal pregnancy when compared with those in patients who had missed abortions or normal intrauterine pregnancies. No correlation was found between the creatine kinase level and the clinical presentation of the patient, however, and there was no correlation with the hCG levels. Schwangerschafts protein 1 (SP1), also known as pregnancy-associated plasma protein C (PAPP-C) or pregnancy-specific β glycoprotein (PSBS), is produced by the syncytiotrophoblast (92). The main advantage of SP1 level assessment may be in the diagnosis of conception after recent hCG administration. A level of 2 ng/L might be used
CHAPTER 18 Early Pregnancy Loss and Ectopic Pregnancy

for the diagnosis of pregnancy; however, it is doubtful that a diagnosis can be established
before delay of menses. Although the level of SP1 increases late in all patients with a
nonviable pregnancy, a single SP1 level assessment does not have prognostic value (95).

Relaxin is a protein hormone produced solely by the corpus luteum of pregnancy. It appears
in the maternal serum at 4 to 5 weeks of gestation, peaks at about 10 weeks of gestation,
and decreases until term (96). Relaxin levels are significantly lower in ectopic pregnancies
and spontaneous abortions than in normal intrauterine pregnancies. Prorenin and active
renin levels are significantly higher in viable intrauterine pregnancies than in either ectopic
pregnancies or spontaneous abortions, with a single level of more than 33 pg/mL excluding
the diagnosis of ectopic pregnancy (97). However, the clinical utility of relaxin, prorenin,
and renin levels in diagnosing ectopic pregnancy has not yet been determined.

CA125 is a glycoprotein, the origin of which is uncertain during pregnancy. Levels of
CA125 rise during the first trimester and return to a nonpregnancy range during the second
and third trimesters. After delivery, maternal serum concentrations increase (98,99). Levels
of CA125 have been studied in an effort to predict spontaneous abortion. Although a posi-
tive correlation has been found between elevated CA125 levels 18 to 22 days after concep-
tion and spontaneous abortion, repeat measurements at 6 weeks of gestation did not
correlate with outcome (100). Conflicting results have been reported—one study showed
a higher serum CA125 level in normal than in ectopic pregnancies 2 to 4 weeks after a
missed menses, whereas another study found higher CA125 levels for ectopic pregnancies
compared with normal pregnancies (101,102).

Maternal serum a-fetoprotein (AFP) levels are elevated in ectopic pregnancies (103,104);
however, the use of AFP measurements as a screening technique for ectopic pregnancy has not
been studied. A combination of AFP with three other markers—β-hCG, progesterone, and
estradiol—has 98.5% specificity and 94.5% accuracy for the prediction of ectopic pregnancy.

C-reactive protein is an acute-phase reactant that increases with trauma or infection.
Levels of this protein are lower in patients with ectopic pregnancy than in patients with an
acute infectious process. Thus, when an infectious process is part of the differential diag-
nosis, measurement of C-reactive protein may be beneficial (105).

Ultrasonography

Improvements in ultrasonography have resulted in the earlier diagnosis of intrauterine and
ectopic gestations (106). However, the sensitivity of the β-hCG assay usually allows the
diagnosis of pregnancy before direct visualization by ultrasonography.

The complete examination should include both transvaginal and transabdominal ultrasonog-
raphy. Transvaginal ultrasonography is superior to transabdominal ultrasonography in
evaluating intrapelvic structures. The closeness of the vaginal probe to the pelvic organs
allows use of higher frequencies (5–7 mHz), which improves resolution. Intrauterine preg-
nancy can be diagnosed 1 week earlier with transvaginal than with transabdominal
ultrasoundonography. Evidence of an empty uterus, detection of adnexal masses and free peri-
toneal fluid, and direct signs of ectopic pregnancy are more reliably established with a trans-
vaginal procedure (107–111). Transabdominal ultrasonography permits visualization of both
the pelvis and abdominal cavity and should be included as part of the complete ectopic preg-
nancy evaluation to detect adnexal masses and hemoperitoneum.

The earliest ultrasonographic finding of an intrauterine pregnancy is a small fluid
space and the gestational sac, surrounded by a thick echogenic ring, located eccen-
trically within the endometrial cavity. The earliest normal gestational sac is seen at 5
weeks of gestation with transabdominal ultrasonography and at 4 weeks of gestation
with transvaginal ultrasonography (112). As the gestational sac grows, a yolk sac is
seen within it, followed by an embryo with cardiac activity.
The appearance of a normal gestational sac may be simulated by intrauterine fluid collection, the pseudogestational sac, which occurs in 8% to 29% of patients with ectopic pregnancy (113–115). This ultrasonographic lucency, centrally located, probably represents bleeding into the endometrial cavity by the decidual cast. Clots within this lucency may mimic a fetal pole.

Morphologically, identification of the double decidual sac sign (DDSS) is the best method of ultrasonographically differentiating true sacs from pseudosacs (116). The double sac, believed to be the decidua capsularis and parietalis, is seen as two concentric echogenic rings separated by a hypoechoogenic space. Although useful, this approach has some limitations in sensitivity and specificity—the DDSS sensitivity ranges from 64% to 95% (115). Pseudosacs may occasionally appear as the DDSS; intrauterine sacs of failed pregnancies may appear as pseudosacs.

The appearance of a yolk sac within the gestational sac is superior to the DDSS in confirming intrauterine pregnancy (117). The yolk sac is consistently visible on transabdominal ultrasonography with a gestational sac size of 2 cm and on transvaginal ultrasonography with a gestational sac size of 0.6 to 0.8 cm (118,119). Intrauterine sacs smaller than 1 cm on transabdominal ultrasonography and smaller than 0.6 cm on transvaginal ultrasonography are considered indeterminate. Larger sacs without DDSS or yolk sac represent either a failed intrauterine or ectopic pregnancy.

The presence of cardiac activity within the uterine cavity is definitive evidence of an intrauterine pregnancy. This finding essentially eliminates the diagnosis of ectopic pregnancy because the incidence of combined intrauterine and extrauterine pregnancy is 1 in 30,000.

The presence of an adnexal gestational sac with a fetal pole and cardiac activity is the most specific but least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases (105,120,121). The recognition of other characteristics of ectopic pregnancy has improved ultrasonographic sensitivity. Adnexal rings (fluid sacs with thick echogenic rings) that have a yolk sac or nonliving embryo are accepted as specific ultrasonographic signs of ectopic pregnancy (122). Adnexal rings are visualized in 22% of ectopic pregnancies using transabdominal ultrasonography and in 38% using transvaginal ultrasonography (107). Other studies have identified adnexal rings in 33% to 50% of ectopic pregnancies (105,121). The adnexal ring may not always be apparent because bleeding around the sac results in the appearance of a nonspecific adnexal mass.

Complex or solid adnexal masses are frequently associated with ectopic pregnancy (1,3,19); however, the mass may represent a corpus luteum, endometrioma, hydrosalpinx, ovarian neoplasm (e.g., dermoid cyst), or pedunculated fibroid. The presence of free cul-de-sac fluid is frequently associated with ectopic pregnancy and is no longer considered evidence of rupture. The presence of intraabdominal free fluid should raise concern about tubal rupture (123).

Accurate interpretation of ultrasonography findings requires correlation with the hCG level (discriminatory zone) (114,119,122,124). All viable intrauterine pregnancies can be visualized by transabdominal ultrasonography for serum hCG levels higher than 6,500 mIU/mL; none can be seen at 6,000 mIU/mL. The inability to detect an intrauterine gestation with serum hCG levels higher than 6,500 mIU/mL indicates the presence of an abnormal (failed intrauterine or ectopic) pregnancy. Intrauterine sacs seen at hCG levels below the discriminatory zone are abnormal and represent either failed intrauterine pregnancies or the pseudogestational sacs of ectopic pregnancy. If there is no definite sign of an intrauterine gestation (the empty uterus sign) and the hCG level is below the discriminatory zone, the differential diagnosis includes the following considerations:
CHAPTER 18  Early Pregnancy Loss and Ectopic Pregnancy

1. Normal intrauterine pregnancy too early for visualization
2. Abnormal intrauterine gestation
3. Recent abortion
4. Ectopic pregnancy
5. Nonpregnant patient

The discriminatory zone has been lowered progressively with improvements in ultrasound resolution. Discriminatory zones for transvaginal ultrasonography have been reported at levels from 1,000 to 2,000 mIU/mL (114,119,122,124). Discriminatory zones vary according to the expertise of the examiner and capability of the equipment. Although the discriminatory zone for intrauterine pregnancy is well established, there is no such zone for ectopic pregnancy. Levels of hCG have not been shown to correlate with the size of ectopic pregnancy. Regardless of how high the hCG level may be, nonvisualization does not exclude ectopic pregnancy. An ectopic pregnancy may be present anywhere in the abdominal cavity, making ultrasonographic visualization difficult.

Doppler Ultrasonography

A Doppler shift occurs whenever the source of an ultrasound beam is moving. The usual sources of Doppler-shifted frequencies are red blood cells. The presence of intravascular blood flow, flow direction, and flow velocity can be determined (125). Pulsed Doppler provides ultrasonicographic control over which vessels are sampled. The vascular information is provided both by the shape of the time-velocity waveform (high- or low-resistance flow) and by its systolic, diastolic, and mean velocities (or Doppler frequency shifts) (126). Color-flow Doppler ultrasonography analyzes very-low-amplitude signals from an entire ultrasound tomogram; the Doppler shift is then modulated into color. This information is used to gauge generalized tissue vascularity and to guide pulsed Doppler vascular sampling of specific vessels.

The waveform in the uterine arteries in the nongravid state and in the first trimester of pregnancy shows a high-resistance (little or no diastolic flow), low-velocity pattern. Conversely, a high-velocity, low-resistance signal is localized to the area of developing placentaion (127–129). This pattern, seen near the endometrium, is associated with normal and abnormal intrauterine pregnancies and is termed peritrophoblastic flow. Whereas transvaginal ultrasonography requires a well-developed double decidual sac (or possibly cardiac activity) to localize an intrauterine gestation, the use of Doppler techniques allows detection of an intrauterine pregnancy at an earlier date. The combined use of Doppler and two-dimensional imaging allows the differentiation of pseudogestational sacs and true intrauterine gestational sacs (130) and the differentiation of the empty uterus sign as either the presence of an intrauterine pregnancy (normal and abnormal) or absence of an intrauterine pregnancy (with an increased risk for ectopic pregnancy) (123).

A similar high-velocity, low-impedence flow characterizes ectopic pregnancies. The addition of Doppler to the ultrasonographic evaluation of suspected ectopic pregnancy improves diagnostic sensitivity for individual diagnoses: from 71% to 87% for ectopic pregnancy, from 24% to 59% for failed intrauterine pregnancy, and from 90% to 99% for normal intrauterine pregnancy (122,123,130).

Dilation and Curettage

Uterine curettage is performed when the pregnancy has been confirmed to be nonviable and the location of the pregnancy cannot be determined by ultrasonography. The decision to evacuate the uterus in the presence of a positive pregnancy test must be made with caution to avoid the unintentional disruption of a viable intrauterine pregnancy.
Although suction curettage traditionally has been performed in the operating room, it can now be accomplished under local anesthesia on an outpatient basis. Endometrial sampling methods (e.g., a Novak curettage or Pipelle endometrial sampling device) are accurate in diagnosing abnormal uterine bleeding, but their reliability for intrauterine pregnancy evacuation has not been studied. These devices might miss intrauterine villi and falsely suggest the diagnosis of ectopic pregnancy.

It is essential to confirm the presence of trophoblastic tissue as rapidly as possible so that therapy may be instituted. Once tissue is obtained by curettage, it can be added to saline, in which it will float (Fig. 18.3). Decidual tissue does not float. Chorionic villi are usually identified by their characteristic lacy frond appearance. The sensitivity and specificity of this technique are 95% when the tissue is examined with the aid of a dissecting microscope. Because flotation of curettage sample tissue is not 100% accurate in differentiating an intrauterine from extraterine gestation, histologic confirmation or serial β-hCG level measurement is required. The presence of chorionic villi may be assessed rapidly with frozen section analysis, which avoids the waiting period of at least 48 hours for permanent histologic evaluation. Immunocytochemical staining techniques have been used to identify intermediate trophoblasts that are not normally identified by light microscopy (74).

When frozen section analysis is not available, serial assessment of hCG levels permits rapid diagnosis. After evacuation of an abnormal intrauterine pregnancy, the hCG level decreases by greater than 15% within 12 to 24 hours. A borderline fall may represent

![Figure 18.3](image_url)

**Figure 18.3**  When floated in saline, chorionic villi are often readily distinguishable as lacy fronds of tissue. (From Stovall TG, Ling FW. Extrauterine pregnancy: clinical diagnosis and management. New York, NY: McGraw-Hill, 1993:186, with permission.)
interassay variability. A repeat level should be obtained in 24 to 48 hours to confirm the decline. If the uterus is evacuated and the pregnancy is extrauterine, the hCG level plateaus or continues to increase, indicating the presence of extrauterine trophoblastic tissue.

**Culdocentesis**

Culdocentesis has been used widely as a diagnostic technique for ectopic pregnancy. With the use of hCG testing and transvaginal ultrasonography, however, culdocentesis is rarely indicated. The purpose of the procedure is to determine the presence of nonclotting blood, which increases the likelihood of ruptured ectopic pregnancy. After exposing the posterior vaginal fornix with a bivalve vaginal speculum, the posterior lip of the cervix is grasped with a tenaculum. The cul-de-sac is then entered through the posterior vaginal wall with an 18- to 20-gauge spinal needle with a syringe attached. As the cul-de-sac is entered, suction is applied, and the intraperitoneal contents are aspirated. If nonclotting blood is obtained, the results are positive. If serous fluid is present, results are negative. A lack of fluid return or clotted blood is nondiagnostic.

Historically, if the culdocentesis results were positive, laparotomy was performed for a presumed diagnosis of ruptured tubal pregnancy. However, the results of culdocentesis do not always correlate with the status of the pregnancy. Although about 70% to 90% of patients with ectopic pregnancy have a hemoperitoneum demonstrated by culdocentesis, only 50% of patients have a ruptured tube (131). Furthermore, about 6% of women with positive culdocentesis results do not have an ectopic gestation at the time of laparotomy. Nondiagnostic taps occur in 10% to 20% of patients with ectopic pregnancy and, therefore, are not definitive of the diagnosis.

**Laparoscopy**

Laparoscopy is the gold standard for the diagnosis of ectopic pregnancy. Generally, the fallopian tubes are easily visualized and evaluated, although the diagnosis of ectopic pregnancy is missed in 3% to 4% of patients who have very small ectopic gestations. The ectopic gestation usually is seen distorting the normal tubal architecture. With earlier diagnosis, the possibility that a small ectopic pregnancy may not be visualized increases. Pelvic adhesions or previous tubal damage may compromise assessment of the tube. False-positive results occur when tubal dilation or discoloration is misinterpreted as an ectopic pregnancy, in which case the tube can be incised unnecessarily and damaged.

**Diagnostic Algorithm**

The presenting symptoms and physical findings of patients with unruptured ectopic pregnancies are similar to those of patients with normal intrauterine pregnancies (89). History, risk-factor assessment, and physical examination are the initial steps in the management of suspected ectopic pregnancy. Patients in a hemodynamically unstable condition should undergo immediate surgical intervention. Patients with a stable, relatively asymptomatic condition may be assessed as outpatients.

If the diagnosis of ectopic pregnancy can be confirmed without laparoscopy, several potential benefits result. First, both the anesthetic and surgical risks of laparoscopy are avoided; second, medical therapy becomes a treatment option. Because many ectopic pregnancies occur in histologically normal tubes, resolution without surgery may spare the tube from additional trauma and improve subsequent fertility. An algorithm for the diagnosis of ectopic pregnancy without laparoscopy proved to be 100% accurate in a randomized clinical trial (132,133) (Fig. 18.4). This screening algorithm shows the combined use of history and physical examination, serial hCG levels, serum progesterone levels, vaginal ultrasonography, and dilation and curettage. When hCG levels and transvaginal ultrasonography are available in a timely fashion, serum progesterone screening is not required. Serial hCG levels are used to assess pregnancy viability, correlated with transvaginal ultrasonography findings, and measured serially after a suction curettage. For patients in a stable condition, a treatment decision is never based on a single hCG level. After the initial evaluation, the patient
Figure 18.4 Nonlaparoscopic algorithm for diagnosis of ectopic pregnancy.
is seen again at 24 to 48 hours for a repeat hCG level. At this time, transvaginal ultrasonography often is repeated so the findings can be correlated with the two hCG levels.

In this algorithm, **transvaginal ultrasonography** is used as follows:

1. **The identification of an intrauterine gestational sac or pregnancy effectively excludes the presence of an extrauterine pregnancy. If the patient has a rising hCG level of more than 2,000 mIU/mL, and no intrauterine gestational sac is identified, the patient is considered to have an extrauterine pregnancy and can be treated without further testing.**

2. **Adnexal cardiac activity, when seen, definitively confirms the diagnosis of ectopic pregnancy.**
SECTION IV  General Gynecology

3. A tubal mass as small as 1 cm can be identified and characterized. Masses greater than 3.5 cm with cardiac activity or larger than 4 cm without cardiac activity should not be treated with medical therapy.

Suction curettage is used to differentiate nonviable intrauterine pregnancies from ectopic gestations (less than 50% rise in hCG level over 48 hours, an hCG level of less than 2,000 mIU/mL, and indeterminate ultrasonography findings). Performance of this procedure avoids unnecessary use of methotrexate in patients with abnormal intrauterine pregnancy that can be diagnosed only by evacuating the uterus. An unlikely potential problem with suction curettage is missing either an early nonviable intrauterine pregnancy or combined intrauterine and extrauterine pregnancies.

Treatment
Ectopic pregnancy can be treated either medically or surgically. Both methods are effective, and the choice depends on the clinical circumstances, the site of the ectopic pregnancy, and the available resources.

Surgical Treatment
Operative management is the most widely used treatment for ectopic pregnancy. There has been debate about which surgical procedure is best. Salpingo-oophorectomy was once considered appropriate because it was theorized that this technique would eliminate transperitoneal migration of the ovum or zygote, which was thought to predispose to recurrent ectopic pregnancy (134). Ovarian removal results in all ovulations occurring on the side with the remaining normal fallopian tube. Subsequent studies have not confirmed that ipsilateral oophorectomy increases the likelihood of conceiving an intrauterine pregnancy; therefore, this practice is not recommended (135).

Salpingectomy Versus Salpingostomy
Linear salpingostomy is currently the procedure of choice when the patient has an unruptured ectopic pregnancy and wishes to retain her potential for future fertility. The products of conception are removed through an incision made into the tube on its antimesenteric border. The procedure can be accomplished with a needle-tip cautery, laser, scalpel, or scissors. It can be done with operative laparoscopic techniques or laparotomy. In a study in which patients treated with either salpingectomy or salpingostomy were followed for a period of 3 years to about 12.5 years, there was no difference in pregnancy rates (136). A history of infertility is the most significant determinant of future fertility, and such patients probably are served better by salpingectomy to decrease their subsequent chance of a recurrent ectopic pregnancy. Linear salpingostomy is as effective as segmental resection with primary reanastomosis, even for ectopic pregnancies occurring in the isthmic tubal segment, and it is technically less difficult and has a shorter operative time (137).

Milking the tube to effect a tubal abortion has been advocated; if the pregnancy is fimbrial, this technique may be effective. However, when milking was compared with linear salpingostomy for ampullary ectopic pregnancies, milking was associated with a twofold increase in the recurrent ectopic pregnancy rate (138).

Laparotomy Versus Laparoscopy
Salpingostomy, salpingectomy, or segmental resection can be accomplished by laparoscopy or laparotomy. The approach used depends on the hemodynamic stability of the patient, the size and location of the ectopic mass, and the surgeon’s expertise. Laparotomy is indicated when the patient becomes hemodynamically unstable, whereas laparoscopy is reserved for patients who are hemodynamically stable.
ruptured ectopic pregnancy does not necessarily require laparotomy. However, if large blood clots are present or the intraabdominal blood cannot be evacuated in a timely manner, laparotomy should be considered. Cornual or interstitial pregnancies often require laparotomy, although laparoscopic management has been described (139). Laparotomy is chosen for the management of most ovarian and abdominal pregnancies. In some cases, the patient may have extensive abdominal or pelvic adhesive disease, making laparoscopy difficult and laparotomy more feasible.

Laparoscopy has advantages over laparotomy for management of ectopic pregnancy. In a case-control study of 50 patients comparing the use of laparoscopy and laparotomy for ectopic pregnancy management, hospital stay was significantly shorter (1.3 ± 0.8 versus 3.0 ± 1.1 days), operative time was shorter (78 ± 26 versus 104 ± 27 minutes), and convalescence was shorter (9 ± 8 versus 26 ± 16 days) in the laparoscopy group (140). In a randomized study in which 30 patients in each group were compared, patients undergoing laparoscopic management had less estimated blood loss, shorter hospital stay, equivalent tubal pregnancy rates, and similar pregnancy and persistent trophoblast rates (141). In another study, patients were assigned during alternate months to undergo laparoscopic management (N = 26) or laparotomy (N = 37) (142). There were no differences in operative time, although patients undergoing laparoscopy had a significant decrease in blood loss, postoperative hospital stay, narcotic requirement, and time to return to normal activity. Laparoscopic management was associated with significant cost savings when compared with laparotomy (more than $5,528 ± $1,586 versus more than $6,793 ± $155). Using a prospective analysis, 105 patients with tubal pregnancy were stratified with regard to age and risk factors and then randomized to undergo either laparoscopic management or laparotomy (143). Subsequently, 73 patients underwent second-look laparoscopy to assess the degree of adhesion formation. Patients treated by laparotomy had significantly more adhesions at the surgical site than those treated by laparoscopy, but tubal patency rates were similar. Pregnancy rates were not analyzed.

Reproductive Outcome

Reproductive outcome after ectopic pregnancy usually is evaluated by determining tubal patency by hysterosalpingography, the subsequent intrauterine pregnancy rate, and the recurrent ectopic pregnancy rate. Pregnancy rates are similar in patients treated by either laparoscopy or laparotomy. Tubal patency on the ipsilateral side after conservative laparoscopic management is about 84%.

In a study of 143 patients followed after undergoing laparoscopic procedures for ectopic pregnancy, the overall intrauterine pregnancy rates for laparoscopic salpingostomy (60%) and laparoscopic salpingectomy (54%) were not significantly different (144). If the patient had evidence of tubal damage, pregnancy rates (42%) were significantly lower than in those women who did not have tubal damage (79%). In another study, the reproductive outcome of 188 patients followed for a mean of 7.2 years (range 3–15 years) was reported after conservation by laparotomy for ectopic pregnancy (145). An intrauterine pregnancy occurred in 83 (70%) patients, with a recurrent ectopic pregnancy rate of 13%, suggesting that reproductive outcome after an ectopic pregnancy treated by laparotomy is similar to that of patients undergoing laparoscopic or medical management. Thus, when compared with medical therapy, surgical management appears to have equal reproductive outcome, although a prospective randomized trial has not been reported.

Medical Treatment

The drug most frequently used for medical management of ectopic pregnancy is methotrexate, although other agents have been studied, including potassium chloride (KCl), hyperosmolar glucose, prostaglandins, and RU-486. These agents may be given systemically (intravenously, intramuscularly, or orally) or locally (laparoscopic direct injection, transvaginal ultrasonographically directed injection, or retrograde salpingography).
**Methotrexate**

*Methotrexate* is a folic acid analogue that inhibits dehydrofolate reductase and thereby prevents synthesis of DNA. It has been used extensively in the treatment of gestational trophoblastic disease (see Chapter 37). **Commonly reported side effects include leukopenia, thrombocytopenia, bone marrow aplasia, ulcerative stomatitis, diarrhea, and hemorrhagic enteritis.** Other reported side effects include alopecia, dermatitis, elevated liver enzyme levels, and pneumonitis (146). However, **no significant side effects have been reported at the low doses used for ectopic pregnancy treatment.** Minor side effects have been reported with multiple doses; *citrovorum factor* reduces the incidence of these side effects and is generally used when prolonged treatment is required. Importantly, long-term follow-up of women treated with *methotrexate* for gestational trophoblastic disease shows no increase in congenital malformations, spontaneous abortions, or tumors recurring after chemotherapy (147). Treatment of ectopic pregnancy differs from that of gestational trophoblastic disease in that a smaller total dose of *methotrexate* is required and shorter treatment duration is used.

Initially, *methotrexate* was used for the treatment of trophoblastic tissue left in situ after exploration for an abdominal pregnancy (148). In 1982, Tanaka and colleagues treated an unruptured interstitial gestation with a 15-day course of intramuscular *methotrexate* (149). The use of *methotrexate* for primary treatment of ectopic pregnancy has been reported in more than 300 patients (150–159).

A trial of **intramuscular methotrexate** (1 mg/kg/day) followed by *citrovorum factor* (0.1 mg/kg/day) on alternate days was given to 100 patients with a success rate of 96% (153,155). This outpatient treatment protocol used *methotrexate* plus *citrovorum factor* given only until the hCG level began to decline. Treatment was given until there was at least a 15% decline between two consecutive daily hCG levels. *Citrovorum factor* is given on the day after the *methotrexate* is administered, even if no further *methotrexate* is indicated. Once *methotrexate* is discontinued, hCG levels are measured weekly until the results are negative. A second course of *methotrexate* plus *citrovorum factor* is given only if there is a plateau or rise in the hCG level. Of the 96 patients successfully treated, 17 required only one *methotrexate* and *citrovorum factor* dose, and 19 required four doses. Four patients treated with *methotrexate* failed therapy and required surgical treatment for tubal rupture, and each of these cases differed with respect to ectopic pregnancy size, hCG level, and time of rupture. Of five ectopic pregnancies with cardiac activity, four were successfully treated. No conclusions can be drawn regarding risk factors or predictors of ectopic pregnancy rupture.

*Methotrexate* was administered to 31 patients for treatment of ectopic pregnancy in a single-dose intramuscular injection of 50 mg/m² without *citrovorum factor*. Of 30 evaluable patients, 29 (96.7%) were successfully treated, and no patients experienced *methotrexate*-related side effects. Some 500 patients have now been treated using the single-dose protocol outlined in Table 18.3 (160). ** Compared with the multidose protocol, single-dose methotrexate is less expensive, patient acceptance is greater because less monitoring is required during treatment, the incidence of side effects is decreased, and the treatment results and prospects for future fertility are comparable.**

**Initiating Methotrexate** Outlined in Table 18.4 is a checklist that should be followed by the physician before initiating *methotrexate*. It also includes instructions that are helpful to the patient.

**Patient Follow-Up** After intramuscular administration of *methotrexate*, patients are monitored on an outpatient basis. Patients who report severe pain or pain that is prolonged are evaluated by measuring hematocrit levels and performing transvaginal ultrasonography. The ultrasonography findings during follow-up, although usually

D & C, dilation and curettage; hCG, human chorionic gonadotropin; CBC, complete blood count; SGOT, serum glutamic-oxaloacetic transaminase; BUN, blood urea nitrogen; IM, intramuscularly. If less than a 15% decline in hCG level between days 4 and 7, give second dose of methotrexate, 50 mg/m², on day 7. If more than a 15% decline in hCG level between days 4 and 7, follow weekly until hCG is below 10 mIU/mL. In patients not requiring D & C, hCG >2,000 mIU/mL and no gestational sac on transvaginal ultrasonography, days 0 and 1 are combined.

Patients are asked not to become pregnant for at least 2 months after treatment. Hysterosalpingography can be performed, although the procedure is not mandatory.

Table 18.4 Initiation of Methotrexate: Physician Checklist and Patient Instructions

**Physician Checklist**

- Obtain hCG level.
- Perform transvaginal ultrasound within 48 hours.
- Perform endometrial curettage if hCG level is less than 2,000 mIU/mL.
- Obtain normal liver function (SGOT), normal renal function (BUN, creatinine), and a normal CBC (WBC <2,000/mL and platelet count >100,000).
- Administer RhoGAM if patient is Rh-negative.
- Obtain informed consent.
- Prescribe FeSO₄ 325 mg PO bid if hematocrit is less than 30%.
- Schedule follow-up appointment on days 4, 6, and 7.

**Patient Instructions**

- Refrain from alcohol use, multivitamins containing folic acid, and sexual intercourse until hCG level is negative.
- Call your physician if:
  - You experience prolonged or heavy vaginal bleeding.
  - The pain is prolonged or severe (lower abdomen and pelvic pain is normal during the first 10–14 days of treatment).
- You use oral contraception or barrier contraceptive methods.

About 4%–5% of women experience unsuccessful methotrexate treatment and require surgery. hCG, human chorionic gonadotropin; SGOT, serum glutamic-oxaloacetic transaminase; BUN, blood urea nitrogen; CBC, complete blood count; WBC, white blood cell; PO, by mouth; bid, twice daily.
Candidates for Methotrexate  To maximize the safety of treatment and to eliminate the possibility of treating in the presence of a nonviable or early viable intrauterine pregnancy, patients considered candidates for methotrexate treatment should include those to whom the following factors apply:

1. An hCG level is present after salpingostomy or salpingotomy.

2. The hCG level is rising or reached a plateau at least 12 to 24 hours after suction curettage.

3. No intrauterine gestational sac or fluid collection is detected by transvaginal ultrasonography, the hCG level is greater than 2,000 mIU/mL, the hCG level is rising, and an ectopic pregnancy mass of 4.0 cm or less without cardiac activity or 3.5 cm or less with cardiac activity is visualized.

Ultrasonography findings should be interpreted with caution because most unruptured ectopic pregnancies will be accompanied by fluid in the cul-de-sac.

Side Effects  Opponents of methotrexate therapy cite potential side effects as the reason not to use it. Most reported side effects have occurred in patients treated with intravenous methotrexate with higher doses and for more prolonged treatment courses than are now required. When using the single-dose intramuscular regimen, the incidence of side effects is less than 1%, and the failure rate is comparable to that of conservative laparoscopic surgery. One problem that remains puzzling is the inability to predict treatment failures with the use of methotrexate. However, the same is true with conservative surgical procedures; thus, the need to monitor hCG levels after salpingostomy or methotrexate remains. In a review of more than 350 women treated with intramuscular methotrexate, a high hCG concentration was found to be the most important factor associated with failure of treatment with a single-dose methotrexate protocol (162). In patients with an hCG level of less than 10,000 mIU/mL, the overall success rate was 93.4%, as compared with 60.7% when the hCG level was greater than 10,000 mIU/mL. Although surgical management of ectopic pregnancy remains the mainstay of treatment worldwide, methotrexate treatment is appropriate in select patient populations.

Reproductive Function  Although there are few data, reproductive function after methotrexate treatment can be assessed on the basis of tubal patency and pregnancy outcome. Tubal patency is reported to be 50% to 100%, with a mean of 71%, after systemic methotrexate treatment. In two separate reports of 23 and 62 patients, the tubal patency rates on the ipsilateral side were 81.4% and 82.3%, respectively (156,163). Pregnancy outcome after methotrexate administration was reported in a group of 14 patients who attempted pregnancy after receiving multiple intramuscular doses. Of these 14 women, 11 (78.6%) became pregnant; 10 of 11 (90.9%) were intrauterine pregnancies, and one (9%) was an extrauterine pregnancy (156). The mean time from first attempting to achieving pregnancy was 2.3 months (range, 1 to 4 months). In another study of 49 patients who were attempting pregnancy after completion of single-dose intramuscular methotrexate administration, 39 (80%) became pregnant; 34 (87%) were intrauterine pregnancies, and 5 (13%) were ectopic pregnancies (164). The mean time from attempting to achieving pregnancy was 3.2 ± 1.1 months. In 87 pregnancies after methotrexate therapy, the combined intrauterine pregnancy rate was 86%, and the ectopic pregnancy rate was 14%.

In a combined series of 527 patients treated by laparoscopic linear salpingostomy or salpingotomy, the intrauterine pregnancy rate was 54%, and the recurrent ectopic pregnancy rate was 13% (165). Comparison of laparoscopically treated patients with methotrexate-treated patients suggests that the two methods have similar reproductive outcomes.
CHAPTER 18 Early Pregnancy Loss and Ectopic Pregnancy

Other Drugs and Techniques

Salpingocentesis is a technique in which agents such as KCl, methotrexate, prostaglandins, and hyperosmolar glucose are injected into the ectopic pregnancy transvaginally using ultrasonographic guidance, transcervical tubal cannulization, or laparoscopy. Agents injected under ultrasonographic guidance have included methotrexate (166–170), KCl (171), combined methotrexate and KCl (172), and prostaglandin E₂ (173). The potential advantages of salpingocentesis include a one-time injection with the potential avoidance of systemic side effects. Reproductive function after this form of treatment has not been reported. Because of the limited experience, this treatment cannot be recommended until there is further study.

Agents injected into the amniotic sac at laparoscopy have included prostaglandin F₂a (174), hyperosmolar glucose (175), and methotrexate (176). This method has the obvious disadvantage of requiring laparoscopy, but it can be used if laparoscopy has been performed. Other agents reported for the treatment of ectopic pregnancy include RU-486 (177) and anti-hCG antibody (178).

Types of Ectopic Pregnancy

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Spontaneous Resolution</td>
<td>Some ectopic pregnancies resolve by resorption or by tubal abortion, obviating the need for medical or surgical therapy (179–183). The proportion of ectopic pregnancies that resolve spontaneously and the reason they do so while others do not are unknown. There are no specific criteria for patient selection that predict successful outcome after spontaneous resolution. A falling hCG level is the most common indicator used, but tubal rupture can occur even with falling hCG levels.</td>
</tr>
<tr>
<td>Persistent Trophoblastic Tissue</td>
<td>Persistent ectopic pregnancy occurs when a patient has undergone conservative surgery (e.g., salpingostomy, fimbrial expression) and viable trophoblastic tissue remains. Histologically, there is no identifiable embryo, the implantation usually is medial to the previous tubal incision, and residual chorionic villi usually are confined to the tubal muscularis. Peritoneal trophoblastic tissue implants may also be responsible for persistence (184–189). The incidence of persistent ectopic pregnancy has increased with the increased use of surgery that conserves the tubes. Persistence is diagnosed when the hCG levels plateau after conservative surgery. Persistent ectopic gestation is best diagnosed by an initial measurement of serum hCG or progesterone levels 6 days postoperatively and at 3-day intervals thereafter (187). Risk factors for persistent ectopic pregnancy are based on the type of surgical procedure, the initial hCG level, the duration of amenorrhea, and the size of the ectopic pregnancy. A slower decline of serum hCG levels has been seen in patients treated by salpingostomy compared with patients treated by salpingectomy. The incidence of persistence after laparoscopic linear salpingostomy ranges from 3% to 20% (190,191). It is uncertain whether the incidence of persistent ectopic pregnancy is the same or greater when the procedure is performed by laparoscopy versus laparotomy. In a review of medical records from 157 patients who underwent salpingostomy for intact ampullary ectopic pregnancy, 16 of 103 patients (16%) undergoing laparoscopic salpingostomy were treated for persistent ectopic pregnancy, whereas 1 of 54 women (2%) who had salpingostomy by laparotomy was treated for persistent ectopic pregnancy (185). In one study, 23% of women with a preoperative hCG level of less than 3,000 mIU/mL developed persistent ectopic pregnancy, whereas persistent ectopic pregnancy occurred in only 1 of 67 women with a level of more than 3,000 mIU/mL (188). It also was noted that 36% of women with an hCG level of more than 1,000 mIU/mL on the second postoperative day and 64% of...</td>
</tr>
</tbody>
</table>
patients with an hCG level of more than 1,000 mIU/mL on the seventh postoperative day developed persistence. Amenorrhea of less than 7 weeks’ duration and ectopic mass smaller than 2 cm have also been reported to increase the risk of persistent ectopic pregnancy (186,188).

Persistent ectopic pregnancy can be treated surgically or medically; surgical therapy consists of either repeat salpingostomy or, more commonly, salpingectomy. Methotrexate offers an alternative to patients who are hemodynamically stable at the time of diagnosis. Methotrexate may be the treatment of choice because the persistent trophoblastic tissue may not be confined to the tube and, therefore, not readily identifiable during repeat surgical exploration (191–193).

**Chronic Ectopic Pregnancy**

Chronic ectopic pregnancy is a condition in which the pregnancy does not completely resorb during expectant management. The condition arises when there is persistence of the chorionic villi with bleeding into the tubal wall, which is distended slowly and does not rupture. It may also arise from chronic bleeding from the fimbriated end of the fallopian tube with subsequent tamponade. In a series of 50 patients with a chronic ectopic pregnancy, pain was present in 86%, vaginal bleeding was present in 68%, and both symptoms were present in 58% (194). Ninety percent of the patients had amenorrhea ranging from 5 to 16 weeks (mean, 9.6 weeks). Most patients develop a pelvic mass that usually is symptomatic. The hCG level usually is low but may be absent; ultrasonography may be helpful in the diagnosis; rarely, bowel involvement or ureteral compression or obstruction exists (194,195).

This condition is treated surgically with removal of the affected tube. Often, the ovary must be removed because there is inflammation with subsequent adhesion development. A hematoma may be present secondary to chronic bleeding.

**Nontubal Ectopic Pregnancy**

**Cervical Pregnancy** The incidence of cervical pregnancy in the United States ranges from 1 in 2,400 to 1 in 50,000 pregnancies (196). A variety of conditions are thought to predispose to the development of a cervical pregnancy, including previous therapeutic abortion, Asherman’s syndrome, previous cesarean delivery, diethylstilbestrol exposure, leiomyomas, and IVF (196–198).

The diagnostic criteria for cervical pregnancy were established based on histologic analysis of a hysterectomy specimen (196). Clinical criteria include the following findings (198):

1. The uterus is smaller than the surrounding distended cervix.
2. The internal os is not dilated.
3. Curettage of the endometrial cavity is nonproductive of placental tissue.
4. The external os opens earlier than in spontaneous abortion.

Ultrasonographic diagnostic criteria have also been described that are helpful in differentiating a true cervical pregnancy from an ongoing spontaneous abortion (Table 18.5). Magnetic resonance imaging of the pelvis has also been used in this situation (199). Other potential diagnoses that must be differentiated from cervical pregnancy include cervical carcinoma, cervical or prolapsed submucous leiomyomas, trophoblastic tumor, placenta previa, and low-lying placenta.
When a cervical pregnancy is diagnosed before surgery, the preoperative preparation should include blood typing and cross-matching, establishment of intravenous access, and detailed informed consent. This consent should include the possibility of hemorrhage that may require transfusion or hysterectomy.

Nonsurgical treatment, including intraamniotic and systemic methotrexate administration, has been used successfully (200,201).

The diagnosis may not be suspected until the patient is undergoing suction curettage for a presumed incomplete abortion and hemorrhage occurs. In some cases, bleeding is light, whereas in others, there is hemorrhage. Various techniques that can be used to control bleeding include uterine packing, lateral cervical suture placement to ligate the lateral cervical vessels, placement of a cerclage, and insertion of an intracervical 30-mL Foley catheter in an attempt to tamponade the bleeding. Alternatively, angiographic artery embolization can be used. If laparotomy is required, an attempt can be made to ligate the uterine or internal iliac arteries (202–204). When none of these methods is successful, hysterectomy is required.

Ovarian Pregnancy A pregnancy confined to the ovary represents 0.5% to 1% of all ectopic pregnancies and is the most common type of nontubal ectopic pregnancy. The incidence ranges from 1 in 40,000 to 1 in 7,000 deliveries (205,206). The diagnostic criteria were described in 1878 by Spiegelberg (Table 18.6). Unlike tubal gestation, ovarian pregnancy is associated with neither PID nor infertility. The only risk factor associated with the development of an ovarian pregnancy is the current use of an intrauterine device.

Patients have symptoms similar to those of ectopic pregnancies in other sites. Misdiagnosis is common because it is confused with a ruptured corpus luteum in up to 75% of cases (205). As with other types of ectopic pregnancy, an ovarian pregnancy has also been reported after hysterectomy (207). Ultrasonography has made preoperative diagnosis possible in some cases (208).

### Table 18.5 Ultrasound Criteria for Cervical Pregnancy

1. Echo-free uterine cavity or the presence of a false gestational sac only
2. Decidual transformation of the endometrium with dense echo structure
3. Diffuse uterine wall structure
4. Hourglass uterine shape
5. Ballooned cervical canal
6. Gestational sac in the endocervix
7. Placental tissue in the cervical canal
8. Closed internal os

### Table 18.6 Criteria for Ovarian Pregnancy Diagnosis

1. The fallopian tube on the affected side must be intact.
2. The fetal sac must occupy the position of the ovary.
3. The ovary must be connected to the uterus by the ovarian ligament.
4. Ovarian tissue must be located in the sac wall.

From Spiegelberg O. Casuistik der ovarialschwangerschaft. *Arch Gynaecol* 1878;13:73.
The treatment of ovarian pregnancy has changed. Whereas oophorectomy had been advocated in the past, ovarian cystectomy has become the preferred treatment (209). It is possible to perform cystectomy using laparoscopic techniques (210,211). Treatment with methotrexate or prostaglandin injection has also been reported (211).

Abdominal Pregnancy

Abdominal pregnancies are classified as primary and secondary. Listed in Table 18.7 are criteria for classifying a primary abdominal pregnancy. Secondary abdominal pregnancies are by far the most common and result from tubal abortion or rupture or, less often, from subsequent implantation within the abdomen after uterine rupture. The incidence of abdominal pregnancy varies from 1 in 372 to 1 in 9,714 live births (212).

Abdominal pregnancy is associated with high morbidity and mortality, with the risk for death 7 to 8 times greater than from tubal ectopic pregnancy and 90 times greater than from intrauterine pregnancy. There are scattered reports of term abdominal pregnancies. When this occurs, perinatal morbidity and mortality are high, usually as a result of growth restriction and congenital anomalies such as fetal pulmonary hypoplasia, pressure deformities, and facial and limb asymmetry. The incidence of congenital anomalies ranges from 20% to 40% (213).

The presentation of patients with an abdominal pregnancy varies and depends on the gestational age. In the first and early second trimester, the symptoms may be the same as with tubal ectopic gestation; in advanced abdominal pregnancy, the clinical presentation is more variable. The patient may report painful fetal movement, fetal movements high in the abdomen, or sudden cessation of movements. Physical examination may disclose persistent abnormal fetal positioning, abdominal tenderness, a displaced uterine cervix, easy palpation of fetal parts, and palpation of the uterus separate from the gestation. The diagnosis may be suspected when there are no uterine contractions after oxytocin infusion. Other diagnostic aids include abdominal radiography, abdominal ultrasonography, computed tomography scanning, and magnetic resonance imaging (214,215).

Because the pregnancy can continue to term, the potential maternal morbidity and mortality are very high. As a result, surgical intervention is recommended when an abdominal pregnancy is diagnosed. At surgery, the placenta can be removed if its vascular supply can be identified and ligated, but hemorrhage can occur, requiring abdominal packing that is left in place and removed after 24 to 48 hours. Angiographic arterial embolization has been described (216). If the vascular supply cannot be identified, the cord is ligated near the placental base, and the placenta is left in place. Placental involution can be monitored using serial ultrasonography and assessment of hCG levels. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation, and sepsis as the tissue degenerates. Methotrexate treatment appears to be contraindicated because of a high rate of complications, including sepsis and death, believed to be a result of rapid tissue necrosis (217).

Interstitial Pregnancy

Interstitial pregnancies represent about 1% of ectopic pregnancies. These patients tend to present later in gestation than those with tubal pregnancies. Interstitial pregnancies often are associated with uterine rupture; therefore, they represent a disproportionately large percentage of fatalities from ectopic pregnancy. Treatment is

---

**Table 18.7 Studdiford’s Criteria for Diagnosis of Primary Abdominal Pregnancy**

| 1. Presence of normal tubes and ovaries with no evidence of recent or past pregnancy |
| 2. No evidence of uteroplacental fistula |
| 3. The presence of a pregnancy related exclusively to the peritoneal surface and early enough to eliminate the possibility of secondary implantation after primary tubal nidation |
cornual resection by laparotomy, although laparoscopic management has also been described (218).

**Interligamentous Pregnancy**  Interligamentous pregnancy is a rare form of ectopic pregnancy that occurs in about 1 in every 300 ectopic pregnancies (219). An interligamentous pregnancy usually results from trophoblastic penetration of a tubal pregnancy through the tubal serosa and into the mesosalpinx, with secondary implantation between the leaves of the broad ligament. It can also occur if a uterine fistula develops between the endometrial cavity and the retroperitoneal space. As in abdominal pregnancy, with interligamentous pregnancy the placenta may be adherent to the uterus, bladder, and pelvic side walls. If possible, the placenta should be removed; when this is not possible, it can be left in situ and allowed to resorb. Cases of live birth have been reported with this type ectopic gestation (219).

**Heterotropic Pregnancy**  Heterotropic pregnancy occurs when intrauterine and ectopic pregnancies coexist. The reported incidence varies widely from 1 in 100 to 1 in 30,000 pregnancies (220). Patients who have undergone ovulation induction have a much higher incidence of heterotropic pregnancy than those who have a spontaneous conception. An intrauterine pregnancy is seen during ultrasonography examination, and an extrauterine pregnancy may be overlooked easily. Serial hCG levels often are not helpful because the intrauterine pregnancy causes the hCG level to rise appropriately.

The ectopic pregnancy is treated surgically; once the ectopic pregnancy has been removed, intrauterine pregnancy continues in most patients. It may be possible to treat the ectopic pregnancy using nonchemotherapeutic medical treatment, such as KCl, by transvaginal or laparoscopically directed injection.

**Multiple Ectopic Pregnancies**  Twin or multiple ectopic gestations occur less frequently than heterotropic gestations and may appear in a variety of locations and combinations. About 250 twin ectopic gestations have been reported (221). Although most reports are confined to twin tubal gestations, ovarian, interstitial, and abdominal twin pregnancies have been reported. Twin and triplet gestations have been reported following partial salpingectomy (222) and IVF (223). Management is similar to that of other types of ectopic pregnancy and is somewhat dependent on the location of the pregnancy.

**Pregnancy After Hysterectomy**  The most unusual form of ectopic pregnancy is one that occurs after vaginal or abdominal hysterectomy (224,225). Such a pregnancy may occur after supracervical hysterectomy because the patient has a cervical canal that may provide intraperitoneal access. Pregnancy may occur in the perioperative period with implantation of the fertilized ovum in the fallopian tube. Pregnancy after total hysterectomy probably occurs secondary to a vaginal mucosal defect that allows sperm into the abdominal cavity.

CHAPTER 18 Early Pregnancy Loss and Ectopic Pregnancy

SECTION IV  General Gynecology

CHAPTER 18  Early Pregnancy Loss and Ectopic Pregnancy

Early detection of breast cancer is improved by risk assessment, clinical breast examination, and screening mammography.

Triple-test concordance requires agreement between results of clinical breast examination, breast imaging, and tissue diagnosis. In the absence of concordance, further diagnostic intervention is required.

The most common benign breast problems include fibrocystic changes and mastalgia. These problems are usually best treated by reassurance. Pharmaceutical agents are available but have side effects that usually are not well tolerated.

Histologic differences exist between fibroadenomas and phyllodes tumors; phyllodes tumors require excision, whereas small asymptomatic fibroadenomas can be observed if the diagnosis is confirmed by histologic or cytologic assessment and there is no evidence of growth.

Spontaneous, unilateral, bloody discharge requires histologic evaluation to exclude malignancy, but symptoms usually are caused by a benign process such as intraductal papilloma or duct ectasia.

Breast abscesses are managed with fine needle aspiration and antibiotics, with use of incision and drainage reserved for recurrence.

Practicing gynecologists should be familiar with techniques for the diagnosis and management of common benign breast conditions, particularly those that mimic malignancy, as well as options for their treatment (1). Benign breast disease is a complex entity of its own with a range of physiologic changes and clinical manifestations that have an impact on a woman’s health independent of breast cancer risk (2).
Detection

History

Evaluation of a new breast symptom begins with assessment of symptoms based on a thorough clinical history (3). The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the symptom. **Assessment of breast problems should focus on the following points:**

- Nipple discharge
- Characteristics of discharge (spontaneous or nonspontaneous, appearance, unilateral or bilateral, single or multiple duct involvement)
- Breast mass (size and change in size, density, or texture)
- Breast pain (cyclic versus continuous)
- Association of symptoms with menstrual cycle
- Change in breast shape, size, or texture
- Previous breast biopsies

The patient should be questioned about the following risk factors for breast cancer (see Chapter 38 for more details).

- Sex
- Increasing age (approximately 50% of breast cancers occur after age 65)
- Age of menarche less than 12 years
- Nulliparity or first pregnancy at greater than 30 years of age
- Late menopause (older than 55 years of age)
- Family history of breast cancer (especially premenopausal or bilateral disease)
- Number of first-degree relatives with breast cancer and their ages when diagnosed
- Family history of male breast cancer
- Inherited conditions associated with a high risk for breast cancer, including \( BRCA1 \) and \( BRCA2 \) genes, Li-Fraumeni syndrome, Cowden’s disease, ataxia telangiectasia syndrome, and Peutz-Jeghers syndrome
- Other malignancies (ovary, colon, and prostate)
- Pathology of previous breast biopsy showing atypia or lobular or ductal carcinoma in situ
- Hormone therapy
- Alcohol consumption
- Postmenopausal weight gain
- Personal history of breast cancer

Breast cancer risk can be determined by the **Gail Risk assessment model**, which is available electronically (4). The Gail Risk assessment model calculates risk based on patient race, age, age of menarche, age of first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and presence of atypia on the biopsy.
It also is important to obtain a current list of medications used, including hormone therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility that the patient may be pregnant. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (5). The goal of breast evaluation is to determine clearly if the symptom represents a benign breast condition or may be indicative of a neoplastic process.

**Physical Examination**

Breast tumors, particularly cancerous ones, usually are asymptomatic and are discovered only by physical examination or screening mammography. Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely, these characteristics can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

**Inspection**

Inspection is performed initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 19.1). Palpable and even nonpalpable tumors that distort Cooper’s ligaments may lead to skin dimpling with these maneuvers.

**Palpation**

While the patient is seated, each breast should be palpated methodically. Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast has been covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses.

While the patient is supine with one arm over her head, the ipsilateral breast is again methodically palpated from the clavicle to the costal margin. If the breast is large, a pillow or towel should be placed beneath the scapula to elevate the side being examined; otherwise, the breast tends to fall to the side, making palpation of the lateral hemisphere more difficult. The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants, where there is more breast tissue. These benign parenchymal nodules are small, similar in size, and indistinct. By comparison, breast cancer usually occurs in the form of a nontender, firm mass with irregular margins. A cancerous mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease (6).

**Breast Self-examination**

Breast self-examination (BSE) increases breast health awareness (7,8). It helps promote early detection of cancer and may improve the survival rates for patients with breast carcinoma (9–11). Most breast cancers are detected by women themselves (48%), followed by breast imaging (41%), and by physician clinical examination in only 11%
Although young women have a low incidence of breast cancer, it is important to teach self-examination early so that it becomes habitual. Organizations such as the American Cancer Society sponsor courses in BSE. Reassurance, support, and patient education may encourage women to overcome psychologic barriers to routine BSE (13). Such instruction also available is through electronic resources (14).

The following seven “P”s represent essential components of breast examination:

- Positions
- Palpation
- Pads of fingers for palpation
- Pressure
Perimeter
Pattern of search
Patient education

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. Finally, the woman should examine her breasts while bending over and leaning forward. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. She should then lie down and again palpate each quadrant of the breast as well as the axilla using the pads of the three middle fingers with three pressures—light, medium, and deep—covering the entire breast from the clavicle to the infra-mammary fold, from sternum to latissimus dorsi laterally. The area within the perimeter of the breast should be palpated, preferably using an up-and-down method called vertical stripe, rather than the concentric circular or radial methods, in which the edges of the breast tissue often are omitted. Many women feel anxious about performing breast examination. The examination may be performed while showering; soap and water may increase the sensitivity of palpation, and the privacy of the shower may provide a less anxiety-provoking environment.

It is helpful for all women to examine their breasts at the same time each month to develop a routine. Premenopausal women should examine their breasts monthly 7 to 10 days after the onset of the menstrual cycle. For postmenopausal women, selection of a specific calendar date is a helpful way to remember to perform a monthly BSE. Women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient’s findings, the examination should be repeated in 1 month or after her next menstrual period.

Breast Imaging

Mammography

The best method for imaging of the breast is screen-film mammography (15). Full-field digital mammography, which records mammographic images on a computer, is a modification of screen-film mammography (16). Some advantages of digital mammography include lower radiation exposure, ability to manipulate a computerized image for optimal viewing, and access to distance consultations through telemammography (17). Studies comparing the sensitivity of full-field digital mammography with screen-film mammography in detecting cancer have had mixed results. Full-field digital mammography had lower detection rates than screen-film mammography in community-based programs, but a randomized trial showed full-field digital mammography to have higher detection rates and lower recall rates than screen-film mammography (16,18).

Slow-growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation. These tumors have a less aggressive biologic behavior than interval breast cancers (19–21). In fact, mammography is the only reproducible method of detecting nonpalpable breast cancer, but its use depends on the availability of state-of-the-art equipment and a dedicated breast radiologist.

Compression of the breast is necessary to obtain good images, and patients should be forewarned that breast compression is uncomfortable. With good technique and well-maintained modern equipment, exposure to radiation can be limited. For all facilities in the United States inspected under the Mammography Quality Standards Act in the first
one half of 1997, the average mean glandular radiation dose per mammographic image was 1.6 mGy (160 mrad) (22).

Indications for Mammography

The indications for mammography are as follows:

1. To screen, at regular intervals, women who are at high risk for developing breast cancer. About one third of the abnormalities detected on screening mammography prove malignant when biopsy is performed (23).

2. To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast that is detected by clinical breast examination.

3. To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.

4. To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.

5. To screen for unsuspected cancer before cosmetic operations or biopsy of a mass.

6. To monitor breast cancer patients who have been treated with a breast-conserving surgery and radiation.

Screening

Screening programs to evaluate asymptomatic, healthy women combine physical examination with mammographic screening to identify breast abnormalities. During the past 30 years, there has been an increase in the use of mammography, mammographic screening, and public awareness of breast health care. The cancer detection rate for screening mammography is 5 per 1,000 screening examinations (24). The cancer detection rate is 11-fold higher, at 55 per 1,000 examinations, when breast imaging is performed for a specific finding (i.e., diagnostic imaging) (24). Of seven randomized mammographic screening trials performed, five have demonstrated a reduction in overall mortality from breast cancer screening programs (25–32). A study from the Rhode Island Cancer Registry indicates that the institution of population-based breast cancer screening programs can result in a reduction in the median tumor size at initial detection from 2.0 to 1.5 cm, which is associated with a 25% reduction in mortality (33). Detecting breast cancer before it has spread to the axillary nodes greatly increases the chance of survival; about 85% of women with such cancer will survive at least 5 years (31,34). Because breast cancer presents first as local disease, screening mammography for breast cancer in asymptomatic women can detect small tumors that have a better prognosis. These tumors have not had the opportunity to metastasize regionally or systemically; thus women have more options for treatment with reduced toxicity.

The American Cancer Society has published an extensive review of the benefits, limitations, and potential harms of screening mammography (35). In addition, it addresses the role of physical examination, discusses screening in older and high-risk women, and reviews the role of newer technologies. A summary of the guidelines recommends that women of average risk for breast cancer begin mammographic screening at age 40. The rationale for beginning mammographic screening at age 40 is a 24% reduction in mortality in screened populations (28). For women in their 20s and 30s, a clinical breast examination is suggested at least every 3 years, and preferably annually, as part of a well-woman examination. For women older than age 40 years, annual clinical breast
examination and mammography are recommended. For older women, recommendations for mammographic screening may be individualized based on the presence of any comorbidities. Chronologic age alone should not be considered a contraindication to mammographic screening as long as a woman is in reasonable health and has a life expectancy of 3 to 5 years (35). The American Geriatrics Society recommends annual or at least biennial mammography for women up to age 75 years, and after that age, every 2 to 3 years if the woman has a life expectancy of more than 4 years (36). The reasons for liberalization of the screening interval recommendations for older women include improved biology profile, slower growth rate, and lower risk for recurrence (37–41). The natural history of the disease in older women must be balanced against life expectancy as a function of overall health (42). For high-risk women, consideration can be given to earlier initiation of screening (5–10 years earlier than the age of the index case) and shorter intervals between screening, as well as the use of additional imaging modalities such as breast ultrasonography and magnetic resonance imaging (MRI) with dedicated breast coils. No screening test is perfect, however, and false-negative imaging studies or benign clinical examinations may lead the patient to an erroneous sense of well-being only to be confronted later with a subsequent interval cancer. Likewise, a false-positive result can lead to significant anxiety and unnecessary biopsy.

**Mammographic Abnormalities**

A mammographic abnormality includes a mass (solid versus cystic), microcalcifications (benign, indeterminate, suspicious), asymmetric density, architectural distortion, and appearance of a new density. There are eight morphologic categories of mammographic abnormalities (43,44):

1. Calcification distribution
2. Number of calcifications
3. Description of calcifications
4. Mass margin
5. Shape of mass
6. Density of mass
7. Associated findings
8. Special cases

Mammographic abnormalities should be visible on two views, usually craniocaudal (CC) and mediolateral oblique (MLO). The lesion should triangulate to the same location on those two views. Calcifications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. Calcifications associated with breast cancer are clustered pleomorphic microcalcifications; typically, five to eight or more calcifications are aggregated in one part of the breast (45). These calcifications may be associated with a mammographic mass density. A mass density may appear without evidence of calcifications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction. Examples of mammographic abnormalities can be found in several electronic sources (46).
Mammographic Reports

The American College of Radiology has recommended the Breast Imaging Reporting and Data System (BI-RADS) as a standardized scheme for describing mammographic lesions (47). In the BI-RADS system, there are six categories for mammographic findings (other than incomplete) (43,44).

0. Incomplete, needs further imaging
1. Negative
2. Benign finding
3. Probably benign, short-interval follow-up recommended
4. Suspicious finding and biopsy should be considered
5. Highly suggestive of malignancy and appropriate action should be undertaken
6. Known malignancy (a category that is often used for follow-up of a lesion that is undergoing neoadjuvant treatment)

The patient should be referred to a surgeon if the report identifies a lesion as a category 4 or 5 (47). A category 0 indicates incomplete evaluation, and further diagnostic studies are required. Category 3 connotes a finding that is most likely benign; a short-interval follow-up is recommended, and breast examination by an expert should be considered.

Correlation of Findings

Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings (48). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked (Fig. 19.2). Mammography is never a substitute for biopsy because it may not reveal clinical cancer, especially when it occurs in the dense breast tissue of young women with fibrocystic changes. In fact, the sensitivity of mammography is 75%, with a specificity of 92.3% depending on the patient’s age; breast density; use of hormone therapy; and the size, location, and mammographic appearance of the tumor (49). Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts, in which mammography can detect at least 90% of malignancies (50). Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts.

Ultrasonography

Breast ultrasonography is generally used for focused scanning of a questionable finding or for evaluation of a mammographic finding (51). Reliable, portable, computer-enhanced ultrasonography with high-frequency transducers and improved imaging is now available to evaluate and treat problems of the breast (52). It is a sensitive, minimally invasive technique that is being used more frequently in evaluating some breast symptoms, especially in younger women with dense breast tissue, but is dependent on the availability of a skilled ultrasonographer (53). The reporting of findings is not standardized as with the BI-RADS system for mammography. Some lesions can be detected only with ultrasonography (54). It is the preferred modality to distinguish a solid from a cystic mass (52). Breast ultrasonography if not recommended for routine screening, but it has been used to supplement
mammographic screening in high-risk women (55). Ultrasonography has a higher false-positive rate than mammography (51,53,54).

Following are indications for breast ultrasonography:

- **Characterization:**
  - Palpable abnormality
  - Ambiguous mammographic findings
  - Silicone leak
  - Mass in woman younger than 30 years, lactating, or pregnant
- **Guidance for interventional procedures**
- **Possible role for additional imaging in high-risk individuals**

Ultrasonography is useful in distinguishing benign from malignant lesions if identified by mammography (56). Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. It may identify cancers in the dense breast tissue of premenopausal women, but it is usually used to distinguish a benign cyst from a solid tumor. Ultrasonography cannot reliably detect microcalcifications, and it is not as useful as mammography in assessing women with fatty breasts.

**Handheld or real-time ultrasonography is 95% to 100% accurate in differentiating solid masses from cysts** (57). However, this finding is of limited clinical value because a dominant mass should be evaluated by biopsy, and a cystic mass can be studied by needle aspiration, which is far less expensive than ultrasonography. If such a lesion proves to be a
simple cyst, no further evaluation is necessary. Rarely, ultrasonography may identify a small
cancer within a cyst, an intracystic carcinoma. These complex cysts warrant surgical biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging may be of value in assessing breast lesions of an indetermi-
nate nature detected by clinical and mammographic examination or occurring in patients
who have implants (58). Both MRI and positron emission tomography (PET) have been
used to identify occult lesions (59,60), and MRI is increasing in popularity as a means of
imaging the breast (58,61). It tends to be highly sensitive but not very specific, leading to
biopsies of many benign lesions. Image enhancement with gadolinium can discriminate
between benign and malignant lesions with varying degrees of accuracy.

Several roles have been proposed for breast MRI. The lack of radiation exposure makes MRI
theoretically an ideal method for screening of healthy women, but currently such widespread
use is not cost-effective. Focal asymmetry is usually benign but can represent a malignancy.
Magnetic resonance imaging may help identify those patients with focal asymmetric areas
who should undergo biopsy. Usually, a scar can easily be distinguished from recurrent tumor
based on the evaluation and diminution of the scar over time. Some scars, however, do not
resolve rapidly and are confused with cancer or, more commonly, with recurrent cancer after
breast-conserving surgery and whole breast irradiation. Ideally, such cases are evaluated with
MRI, sometimes obviating the need for biopsy. Magnetic resonance imaging is extremely
useful in identifying silicone released by ruptured breast implants in patients with augmented
breasts (Fig. 19.3). In patients with implants, MRI with gadolinium may be performed to
detect breast cancer even if silicone release is not suspected. There may be a role for MRI
in evaluation of specific conditions. It has been used for the following indications:

- Stage tumor to rule out multicentric disease
- Differentiate postoperative scar from recurrence after breast-conserving surgery
- Find a lesion seen in only one view of mammogram
- Evaluate positive axillary nodes in the presence of negative mammogram and
  clinical breast examination results
- Rule out silicone implant rupture
- Assess focal asymmetry

Potential future considerations for MRI include assessment of BRCA1 and 2 mutation-
carriers, women with personal history of breast cancer, biopsy results showing atypia or
local carcinoma in situ, young patients, or dense breasts.

A study from the Netherlands in high-risk women reported a 71% sensitivity for MRI
compared with 17.9% for clinical breast examination and 40% for mammography (62).
The International Cooperative Magnetic Resonance Mammography Study that is currently
under way will help identify the advantages and limitations of MRI. At present, MRI
should be considered only after conventional imaging is performed; it should not be used
as a screening tool or a substitute for mammography or biopsy.

Positive Emission Tomography Scan

Positive emission tomography scanning is a diagnostic modality that assesses the metabolic
activity of tumors. Radioactive fluorodeoxyglucose (FDG) is an analog of glucose that is
metabolized by tissues of high metabolic rates. In two prospective trials comparing PET
with mammography, primary breast lesions were correctly identified and lymph nodes
status was determined with a high degree of sensitivity using PET (59,63). This technique has been used to identify occult breast lesions with positive axillary lymph nodes (59).

Breast Tissue Evaluation: Histology and Cytology

The safest course is tissue or cytologic biopsy evaluation of all dominant masses found on physical examination and, in the absence of a mass, of suspicious lesions shown by mammography or ultrasonography. The diagnosis of a benign breast lesion versus breast cancer is often difficult to determine based on clinical examination and ultimately requires evaluation of tissue by fine needle aspiration cytology (FNAC), core needle biopsy (CNB), or excisional biopsy (EB). Both FNAC and CNB are accurate methods of diagnosis when compared with EB and are valuable tools in the assessment of breast lesions (64). The false-positive and false-negative rate for FNAC is 1.7% and 7.1%, and for CNB 0% and 5.7%, respectively (64). Confirmation of the accuracy of a negative FNAC result requires triple-test concordance between breast imaging studies, clinical breast examination, and cytologic assessment. Accuracy can be 100% when all three evaluations have negative results (65). Compared with CNB, FNAC is faster, simpler, and does not require anesthesia. The superiority of FNAC versus CNB has not been established, and the techniques are comparable for
most lesions. One study reported that FNAC was more sensitive than CNB (97.5% versus 90%, respectively) (66). In recent series comparing CNB with FNAC, the sensitivity was 88% versus 92%, positive predictive value for malignancy was 99% versus 100%, and inadequacy rate 7% versus 7%, respectively (67). The specificity of CNB was found to be higher than that of FNAC (90% versus 82%). Both FNAC and CNB are reasonable techniques for the evaluation of a palpable or image-identified lesion, although FNAC is more accurate when an experienced physician is performing the technique, and it allows immediate assessment of the adequacy of material and additional sampling if there is a paucity of cells (64). Collagenous lesions are more difficult to diagnose by FNAC. Distinguishing invasive from noninvasive carcinoma cannot be done reliably with FNAC. Another technique, imprint cytology from core biopsies, has been used increasingly as an alternative to FNAC.

About 30% of lesions suspected to be cancer prove on biopsy to be benign, and about 15% of lesions believed to be benign prove to be malignant (23). Dominant masses or suspicious nonpalpable mammographic findings must be evaluated by biopsy (48,68). Histologic or cytologic diagnosis should be obtained before the decision is made to monitor a breast mass (69). An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. However, an apparently fibrocystic lesion that does not completely resolve within several menstrual cycles should be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen therapy should be presumed to be malignant. Some clinicians will monitor a mass when results of the clinical diagnosis, breast imaging studies, and cytologic studies are all in agreement, such as with fibroadenoma. Many clinicians will not leave a dominant mass in the breast even when FNAC results are negative, unless perhaps if the fine-needle aspiration shows fibroadenoma. Such cases require periodic follow-up. Some surgeons excise lesions when the aspiration shows only fibrocystic disease. Presented in Figures 19.4 and 19.5 are algorithms for management of breast masses in premenopausal and postmenopausal patients.

Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and FNAC can lower the risk of missing cancer to only 1%, effectively reducing the rate of diagnostic failure and increasing the quality of patient care (70).

If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by FNAC or CNB, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results. The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient biopsy (either FNAC, CNB, or EB), followed by definitive surgery at a later date if needed. This two-step approach allows patients to adjust to the diagnosis of cancer, carefully consider alternative forms of therapy, and seek a second opinion. Studies have shown no adverse effect from the 1- to 2-week delay associated with the two-step procedure (71). Because cancer is found in the minority of patients who require biopsy for diagnosis of a breast mass, definitive treatment should not be undertaken without an unequivocal histologic diagnosis of cancer.

**Fine-needle Aspiration**

With FNAC, cells from a breast tumor are aspirated with a small (usually 22-gauge) needle and examined by a pathologist. Precise guidelines for this technique are available (72). It can be performed easily, with no morbidity, and is much less expensive than excisional or open biopsy. However, it requires the availability of a pathologist skilled in the cytologic diagnosis of breast cancer to interpret the results, and it is subject to sampling problems, particularly when lesions are deep. Cytologic diagnoses must be correlated with clinical and imaging findings to achieve triple-test concordance and to decrease the false-negative rate (73). The **triple-test concordance** (ie, concordance between fine-needle aspiration, physical examination, and mammography) is the foundation of breast evaluation. The **triple-test results are more powerful than each modality alone** (74). The incidence of false-positive diagnoses was 0% to 0.3%, and the rate of false-negative diagnoses was 1.4% to 2.3% in several recent studies (74,75).
Figure 19.4 Algorithm for management of breast masses in premenopausal women. (Revised & updated from Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. Practical gynecologic oncology. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2005:640, with permission.)
A core needle biopsy is a diagnostic alternative to surgical excision of suspicious breast lesions (77). As in the case of any needle biopsy, the main drawback is false-negative findings caused by improper positioning of the needle. False-negative findings may be reduced if core biopsy is performed with ultrasonographic guidance.

The interpretation of results from CNB is classified by categories B1–B5 (78).

- **B1**: Normal tissue
- **B2**: Benign lesions: fibroadenomas, fibrocystic change, sclerosing adenosis, duct ectasia, fat necrosis, abscess
### Open Excisional Biopsy
Open biopsy with local anesthesia as a separate procedure before deciding on definitive treatment is the most reliable means of diagnosis. It is required when the results of needle biopsy are nondiagnostic or equivocal.

### Histologic Analysis
Histologic evaluation with hematoxylin and eosin (H&E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (79). **Assessment of prognostic factors, tumor grade, estrogen, progesterone, her-2/neu receptor status, and proliferative indices is performed on paraffin-fixed tissue by immunohistochemistry** (78). Her-2/neu assessment in breast cancer by immunohistochemistry (IHC) is appropriate for patients with tumors that score 3+/H11001. **Fluorescence in situ hybridization (FISH) is recommended for 2+/H11001 IHC to more accurately assess her-2/neu amplification and provide better prognostic information** (80).

### Ductal Lavage Cytology
Ductal lavage using a microcatheter is a new modality that has been investigated in high-risk women (81). Patients undergo gentle nipple suction to elicit nipple fluid. A duct that yields fluid is then cannulated with a microcatheter, and 10 to 20 mL of saline are introduced in 2- to 4-mL increments. The **cytologic assessment of a sample obtained by ductal lavage is more sensitive than that of nipple aspiration**. Ductal lavage is a better modality to obtain a large number of cells for cytological evaluation. It is safe and well tolerated (81).

## Benign Breast Conditions

Benign breast disorders account for most breast problems. These conditions are frequently considered in the context of excluding breast cancer and often are not recognized for their own associated morbidity (82). To provide appropriate management, it is important to consider benign breast disorders from four aspects: (i) clinical picture, (ii) medical significance, (iii) treatment intervention, (iv) and pathologic etiology (83). A framework to understand benign breast problems is called Aberrations of Normal Development and Involution (ANDI) (2,82,83). It includes symptoms, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (82).

Three life cycles reflect different reproductive phases in a woman’s life and are associated with unique breast manifestations.

1. **During the early reproductive period (15–25 years), lobule and stromal formation occurs.** The ANDI conditions associated with this period are fibroadenoma (mass) and juvenile hypertrophy (excessive breast development). In this first stage, the progression from ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.

2. **During the mature reproductive period (25–40 years), cyclic hormonal changes affect glandular tissue and stroma.** In this second period, the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.
3. The third phase is involution of lobules and ducts or turnover of epithelia, which occurs during ages 35 to 55 years. The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Hughes feels that this framework allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (82).

**Fibrocystic Change**

Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs and symptoms and histologic changes (76). The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia (83). Cysts arise from the breast lobules and are an aberration of normal breast involution (82). Macroscopic cysts occur in approximately 7% of women, and microscopic, nonpalpable cysts occur in close to 40% of women (84). It is common in women 35 to 55 years of age but rare in postmenopausal women not taking hormone therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This finding is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (85). In essence, a diagnosis of fibrocystic change is of little clinical significance as long as malignancy is excluded but can lead to significant patient anxiety (86). These lesions are associated with benign changes in the breast epithelium.

**Cyst Fluid Analysis**

Investigators have examined the electrolyte and protein content of cyst fluid, but this has been of little significance in the clinical management of fibrocystic disease. The potassium-to-sodium ratio is a marker that may be used to distinguish cyst subtypes (87). Cysts are either lined by apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, CEA, CA125, and steroid hormone–binding globulin (type II) (85,87). Apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (88). The role of this serine protease in proliferative breast disease is not fully understood.

**Clinical Findings in Fibrocystic Disease**

Fibrocystic changes may produce an asymptomatic mass that is smooth and mobile that may be compressible. Fibrocystic change is more often accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides with the premenstrual phase of the cycle, when the cysts tend to enlarge. Fluctuation in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most common associated symptom of fibrocystic changes.

**Differential Diagnosis**

Pain, fluctuation in size, multiplicity of lesions, and bilaterality are the features most helpful to differentiate fibrocystic disease from carcinoma. If a dominant mass is present, however, the diagnosis of cancer should be suspected until it is disproved by complete aspiration of a cyst, or histopathologic analysis if a mass is present after aspiration, or by breast imaging. Microscopic findings associated with fibrocystic disease include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (89).
Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma based on clinical findings. Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cystic from a solid mass. Characteristic findings on ultrasonography that confirm a simple cyst include the following:

- Mass with thin walls
- Smooth round shape
- Absence of internal echoes
- Posterior acoustic enhancement

If these imaging criteria are not met, a tissue diagnosis of the mass usually requires a FNA, FNAC, or EB. The finding of a simple cyst by ultrasonography rules out carcinoma. Any lesion that is suspicious by mammography or ultrasonography should be biopsied.

When the diagnosis of fibrocystic change has been established by ultrasonography or is practically certain because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated if the patient is symptomatic, the cyst obscures visualization of breast tissue on mammography and prevents adequate imaging, or if the ultrasonographic criteria are not met.

In one study of a screened population, 1% of individuals developed a new cyst that resolved in more than 50% of cases (90). Aspiration may be performed with ultrasonographic guidance, but image guidance is usually not necessary if the cyst is palpable (91). Fine needle aspiration of a cyst is a minimally invasive procedure performed with a 21- or 22-gauge needle without local anesthesia and is not associated with significant risks or complications. There is minimal pain and little risk for infection or bleeding. Benign cyst fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (6). Injection of air into the cyst cavity has been reported to reduce the likelihood of cyst recurrence but is generally not performed (86). The patient should be reexamined at a short interval thereafter for cyst recurrence. Further cysts will occur in 30% of patients, cause anxiety, and require repeated evaluations (84). Tissue biopsy should be performed in the presence of the following findings:

- No cyst fluid is obtained
- The fluid is bloody
- The fluid is thick
- The cyst is complex
- There is an intracystic mass
- A mass persists after aspiration
- A persistent mass is noted at any time during follow-up

Even if a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve over several months should be excised. Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is not indicated for fibrocystic disease. Most patients do not require treatment for fibrocystic changes, just reassurance that fibrocystic change is a transient phenomenon of aging that is associated with hormonal effects on the breast glandular tissue that eventually subside.

Fibrocystic Change and Risk for Breast Cancer

Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia.
The common coincidence of fibrocystic disease and malignancy in the same breast reflects the fact that both processes are common events. Approximately 80% of biopsies show fibrocystic changes. In an evaluation of the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy from 1950 until 1968 and were followed for a median of 17 years, approximately 70% of the biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease (95). Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. **Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast.** Patients with carcinoma in situ have an eight- to tenfold risk of developing breast cancer. This risk is bilateral for lobular lesions and ipsilateral for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but family history plus atypia increased breast cancer risk 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk about threefold (76,92–97). Women with these risk factors (family history of breast cancer and proliferative breast disease) should be followed carefully with physical examination and mammography. For such women, age-specific probability of developing invasive breast carcinoma in the next 10 years is 1 in 2,000 (age 20), 1 in 256 (age 30), 1 in 67 (age 40), 1 in 39 (age 50), and 1 in 29 (age 60) (93). The relative risk for developing breast cancer depends on the type of proliferative lesion diagnosed.

**Management of Fibrocystic Change**

Fibrocystic change is a normal evolutionary change in breast development and does not require a specific treatment other than a good clinical breast examination and age-appropriate mammographic screening or imaging studies directed to signs and symptoms. A number of nutritional and dietary supplements have been investigated to relieve symptoms. The role of caffeine consumption in the aggravation of fibrocystic change is controversial (98–101). Results of some studies suggest that eliminating caffeine from the diet is associated with improvement of symptoms (100,101). Many patients are aware of these studies and report relief of symptoms after discontinuing intake of coffee, tea, and chocolate. Similarly, many women find vitamin E (150–600 IU daily) or $B_6$ (200–800 mg/day) helpful (102,103). However, observations about these effects have been difficult to confirm and are anecdotal (104–106). A recent review of nutritional interventions for fibrocystic breast conditions that evaluated evening primrose oil, vitamin E, or pyridoxine suggested that there are insufficient data to draw clear conclusions about their effectiveness (107). Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside unless patients are taking estrogen. A patient with fibrocystic changes should be advised to examine her own breasts each month just after menstruation and to inform her physician if a mass appears.

**Mastalgia**

Mastalgia is a recognized organic condition that has not been studied as thoroughly as other breast problems (108,109). Inflammatory cytokines have been implicated in the etiology of breast pain. A study evaluating expression of interleukin-6 and tumor necrosis factor-α in painful and nonpainful breast tissue showed lower levels of these cytokines in painful breast tissue during the luteal phase; however, these levels did not reach statistical significance (110). Elevated estrogen, low progesterone, or an imbalance in the ratio of estrogen and progesterone have been suggested as a possible cause for the symptoms (111).

**Natural History of Mastalgia**

Approximately 70% to 80% of women experience severe breast pain at some time in their lives (112,113). Mastalgia accounts for 30% to 47% of breast clinical evaluations (111,114). In 15% of the patients, the mastalgia is so severe that it alters lifestyle and
requires repeated investigations and treatment (112). Mastalgia interferes with sexual (48%), physical (37%), social (12%), and work or school activities (8%) (115).

**Types of Mastalgia**

Breast pain is a distressing constellation of symptoms that is classified as cyclic, non-cyclic, or extramammary (116). Cyclic mastalgia is related to exaggerated premenstrual symptoms beginning in the luteal phase of the menstrual cycle associated with breast engorgement, pain, ache, heaviness, and tenderness that is bilateral and can last for more than 7 days in 11% of women (116–118). Cyclical mastalgia is more prevalent in women in their third and fourth decades of life and accounts for two thirds of all breast pain symptoms (119).

Noncyclic mastalgia is independent of menstrual cycles and is described as achy, burning soreness. It may be intermittent or constant, occurs in the fourth and fifth decades, and is more difficult to treat than cyclic mastalgia (116). Extramammary pain is perceived to be located in the breast but is related to an extramammary site. Chest wall muscular pain, costal cartilage symptoms, herpes zoster, radiculopathies, and rib fractures are among some of the more common causes of extramammary pain. Costochondritis (Tietze’s syndrome) is a manifestation of chest wall pain that is frequently interpreted as breast pain.

**Management of Mastalgia**

Breast pain is an unlikely symptom of malignancy, and once malignancy has been excluded by a clinical breast examination and age-appropriate breast imaging for focal breast pain, the most important treatment is reassurance. Treatments used have included medications, such as anesthetics, diuretics, *bromocriptine*, and *tamoxifen*; vitamins and supplements, such as evening primrose oil; mechanical support with a well-fitting bra; local excision; and decreased fat intake and reduction in methylxanthines from caffeine, tea, and chocolate (108,116). Discontinuation of hormone therapy may be effective in some women. Maintenance of a pain score diary is important to understand the relationship of pain to factors such as the menstrual cycle, activities of daily living, and stress. External support may be effective for breast pain associated with generalized fibrocystic changes and is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection (120). One study evaluated resolution of symptoms in 200 women randomized either to a regimen of *danazol* (200 mg/day) or to mechanical support with a sports brassiere worn for regular activities for 12 weeks. The group using mechanical support had 85% relief of symptoms compared with 58% improvement in the *danazol* group. Symptoms recurred after discontinuance of treatment with *danazol* (113). The *danazol* group experienced drug-related side effects in 42%, which led to discontinuance of the medication in 15%. The breast has minimal structural support and is at significant risk for motion-related displacement resulting in mastalgia. The use of external support to minimize breast motion appears to be effective in reducing breast pain. The application of heat packs or cold packs and light breast massage may reduce symptoms in some individuals (116).

Hormone-modulating drugs, including *danazol*, *bromocriptine*, *tamoxifen*, and *Depo-provera*, are recognized drug treatments for mastalgia, although *tamoxifen* is not approved for this use in the United States (116,121–124). These drugs are associated with significant side effects that limit their general use (116). Withdrawal of birth control pills or hormone therapy may be all that is required to alleviate symptoms (116).

*Danazol* is a synthetic androgen that suppresses release of pituitary gonadotropin, prevents luteinizing hormone surge, and inhibits ovarian steroid formation. It is the only medication approved by the Food and Drug Administration for mastalgia (116). The androgenic effects—acne, edema, change in voice, weight gain, headaches, depression, and hirsutism—often are intolerable, and many patients stop taking *danazol* even when symptoms are improved (122). It can be initiated at doses of 100 to 200 mg twice daily orally for patients with severe pain and then tapered to a lower dose of 100 mg per day (122). A survey of surgeons in Great Britain revealed that 75% prescribed *danazol* as first-line
therapy (108). A recent study was conducted to evaluate the response to administration of danazol (200 mg daily) just during the luteal phase (125). This approach reduced the premenstrual mastalgia and resulted in virtually no side effects.

The use of oral progesterone agents has been shown to reduce cyclical breast pain by 50% (111). Further studies may be warranted to see whether medroxyprogesterone acetate suppresses cyclic mastalgia in reproductive-age women.

Breast pain is increased in some individuals who have elevated prolactin (PRL) levels induced by thyrotropin-releasing hormone (TRH) (116). Bromocriptine is a dopamine antagonist that inhibits the release of PRL. Bromocriptine (2.5 mg twice daily) given for 3 to 6 months is effective in reducing mastalgia in women who have TRH-induced elevation of PRL (123). Patients who have normal TRH levels, or are resistant to bromocriptine, or do not tolerate the side effects of nausea, vomiting, and headache, respond favorably to progesterone and systemic nonsteroidal anti-inflammatory drugs (NSAIDs).

Prolactin induces active transport of iodine in breast tissue (126,127). Iodine deficiency in rats causes hyperplasia and atypia (128). Iodine replacement is associated with improvement in subjective pain (129). A randomized, double-blind study with supraphysiologic levels of iodine in women with documented cyclic mastalgia demonstrated dose-dependent reduction in physician-assessed and self-reported pain at 3 and 6 months of treatment (130).

Goserelin is a potent synthetic analog of luteinizing-hormone releasing-hormone (LHRH) that causes reversible reduction in serum estrogen level and decrease in breast pain (131). Side effects of goserelin include vaginal dryness, hot flushes, decreased libido, oily skin and hair, and decreased breast size. A recent clinical trial randomized 147 women into goserelin versus placebo groups. The study had a 49% dropout rate. The mean breast pain score decreased by 67% in the goserelin arm and 35% in the placebo arm. The authors concluded that goserelin is an effective treatment for mastalgia with significant side effects and should be kept as second-line therapy. Hormonal blockade of the estrogen receptor is another approach to minimizing the effects of circulating estrogen on breast pain. Treatment with the selective estrogen receptor modulator tamoxifen has demonstrated reduction in breast pain at 10 and 20 mg per day, with equivalent effects compared with danazol and bromocriptine in most studies (124,132–134). Topical nonsteroidal therapy is another option for women with mastalgia (135). Gel forms of NSAIDs often are used for relief of pain. Patients were stratified by cyclic versus noncyclic pain and then randomized to treatment with NSAIDs versus placebo. There was a significant reduction in cyclic and noncyclic pain in all groups, but the magnitude of change was greater in the treatment arms and similar for cyclic and noncyclic pain. Use of NSAIDs appears to be a less toxic treatment and may be considered as an option for both cyclic and noncyclic breast pain.

Nonhormonal therapies such as dietary restrictions, vitamins and supplements, and restriction of methylxanthines have been investigated as possible treatments for mastalgia because they are less likely to be associated with adverse drug-related side effects (116). Because mastalgia is one of the symptoms associated with fibrocystic disease, the treatments described for fibrocystic disease are also relevant to mastalgia. A low-fat diet was effective in one randomized trial (136). Ninety percent of patients taking in 15% dietary fat experienced resolution of pain symptoms after 6 months compared with only 22% of those on a diet containing 36% fat ($P = 0.0023$). Evening primrose oil containing essential fatty acids (γ-linolenic acid, GLA) has been studied because of its affect on prostaglandin synthesis (137). It has been used as first-line therapy, reserving danazol and bromocriptine for treatment of more severe symptoms (112). In a small prospective mastalgia trial, women were given eight capsules of evening primrose oil daily for 4 months (320 mg GLA) (138). Those who responded had a lower level of essential fatty acids at the time of initiation when compared with poor responders, suggesting that evening primrose oil increases essential fatty acids and that this increase may be associated with the improvement in
symptoms in the responders. Two more recent trials have failed to demonstrate efficacy of
evening primrose oil capsules over placebo (139,140). In a Dutch trial, 124 women with
cyclic or noncyclic pain lasting on average 7 or more days (minimum 5 days) were
randomized to receive the following regimens: (i) fish oil and control oil, (ii) evening prim-
rose oil and control oil, (iii) fish and evening primrose oil, or (iv) both control oils for 6
months (139). There was a statistically significant reduction in the number of days per
month with pain but not in the pain score in the entire study population. There was a
greater reduction in cyclic than noncyclic pain symptoms, and this finding was true for
both the test oils and for the control oils. The authors concluded that neither fish oil nor
evening primrose oil had a better effect than the less expensive wheat germ and corn oils.
A second large double-blind randomized prospective trial was conducted in 555 women
with cyclic mastalgia of moderate to severe degree present for at least 7 days of a menstrual
cycle (140). The four groups were (i) GLA and placebo antioxidants, (ii) placebo fatty acids
and antioxidants, (iii) GLA and placebo antioxidants, and (iv) placebo fatty acids and
placebo antioxidants. The treatments were given in a blinded fashion for 4 months. All
groups had a similar 35% reduction in symptoms. This treatment was followed by open
treatment with GLA in all groups and blinded treatment with antioxidants. There was
continued improvement of symptoms in all groups with a reduction in mastalgia by 50%
over the next 12 months. This is the largest and best-controlled study to date evaluating
GLA for relief of mastalgia, and GLA was not found to be superior to placebo. The results
of this study were not consistent with those from previous smaller studies. The authors
cannot exclude a significant psychologic impact that may confound the effect of GLA.
GLA use was found to be safe, without any significant side effects, and has been
prescribed as therapy for mastalgia because of its lack of side effects. The recent random-
ized trials, however, bring into serious question the efficacy of these options.

Fibroepithelial Lesions

Fibroadenoma

**Fibroadenomas are the most common benign tumors of the breast.** In one series, they
accounted for 50% of all breast biopsies (141). They usually occur in young women (age
20–35 years) and may occur in teenagers (142). In women younger than 25 years,
fibroadenomas are more common than cysts. They rarely occur after menopause, although
occasionally they are found, often calcified, in postmenopausal women. For this reason, it
is postulated that fibroadenomas are responsive to estrogen stimulation. A recent study
reports the de novo occurrence of fibroadenoma in 51 women older than age 35 years who
had no evidence of a palpable or mammographic visualized lesion in well-documented
prior visits (143). Fibroadenomas may appear as single masses or as multiple lesions.

Clinically, a young woman usually notices a mass while showering or dressing. Most
masses are 2 to 3 cm in diameter when detected, but they can become extremely large (i.e.,
the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery.
They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of
the skin or nipple retraction. They are often bilobed, and a groove can be palpated on
examination. On mammographic and ultrasonographic imaging, the typical features are of
a well-defined, smooth, solid mass with clearly defined margins and dimensions that are
longer than wide and craniocaudal dimensions that are less than the length.

**Fibroadenoma is not associated with an increased risk for breast cancer** (144). The
natural history of fibroadenoma can be regression, growth, or no change in size. In one
study, a 50% regression was reported (145). Because transformation of a fibroadenoma into
cancer is rare and regression is frequent, current management recommendations are conser-
vative unless there is evidence of growth (141). A suspected fibroadenoma should be
confirmed by FNAC or CNB and observed for increase in size or excised based on patient
preference. Rarely will the fibroadenoma increase to more than 2 to 3 cm in size. Large or
Growing fibroadenomas must be excised. Complete excision of a fibroadenoma with local anesthesia can be performed to treat the lesion and confirm the absence of malignancy. Less invasive local treatment of a fibroadenoma is advocated by some and can be performed with either ultrasonographically guided percutaneous vacuum-assisted biopsy devices (146) or percutaneous cryoablation (147). However, a young woman with a clinical fibroadenoma can undergo needle cytology and observation of the mass (148). Acceptance of observation varies, and many women choose to have the fibroadenoma excised (149).

On gross examination of an excised mass, the fibroadenoma appears encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, there is proliferation of both the epithelial and a stromal component. In long-standing lesions and in postmenopausal patients, calcifications may be observed within the stroma.

### Multiple Fibroadenomas

Multiple fibroadenomas occur in some women and have been reported to occur more frequently in premenopausal women undergoing immunosuppression for transplant (150–152). Excision of all lesions through separate incisions could leave significant scarring and deformity. Excision of these mobile lesions through a single periareolar incision has been suggested, but this approach can lead to significant ductal disruption (153). Another approach that has been used is through an incision in the inframammary crease. Alternatively, these lesions can be treated with observation based on triple-test concordance of results of a classic clinical examination with histologic corroboration with FNAC and ultrasonographic diagnostic criteria consistent with a fibroadenoma (151).

### Phyllodes Tumor

Phyllodes tumors are rare fibroepithelial tumors that display a spectrum of clinical and pathologic behaviors that are benign, borderline, and malignant (154,155). The distribution of phyllodes tumors demonstrates that most tumors are benign (70%) compared with malignant (23%) and borderline lesions (7%) (156). This distribution is similar to a larger, older study that reported an incidence of 64% benign, 21% malignant, and 14% borderline phyllodes tumors (157). The incidence in some studies should be viewed with caution because of variation in histologic interpretation (156). Phyllodes tumors may occur at any age but tend to be more common in women who are in their late 30s, 40s, and 50s (156,158–162). These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma. Patients often relate a long history of a previously stable nodule that suddenly increases in size. Reported sizes range from 1.0 to 50 cm (154,163,164). Size is not a dependable diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma. Whereas observation of a fibroadenoma is acceptable, excision of a phyllodes tumor is necessary for local control and for determination of benign or malignant features. To avoid unnecessary excision of benign fibroadenomas that are indistinguishable from phyllodes tumors on clinical examination, imaging criteria have been sought to aid in identifying patients who require EB for complete histopathologic evaluation and local control. Mammography may show a halo around a phyllodes tumor mass but cannot reliably distinguish a fibroadenoma from a phyllodes tumor (165–167). Ultrasonography evaluation also has limitations even when color and pulse Doppler ultrasonography are used in conjunction with it (163).

Microscopic evaluation of a lesion is important to determine the diagnosis. The histologic distinction between fibroadenoma, benign, borderline, and malignant phyllodes tumor can, however, be very difficult on minimal tissue sampling with FNAC or CNB (168,169). It may be easier to distinguish benign phyllodes from malignant phyllodes tumors than benign phyllodes tumors from fibroadenomas (170). Histologic features that stratify lesions include number of mitoses per high power field, stromal cellularity, pushing or infiltrating tumor margin, cellular atypia, tumor necrosis, and stromal overgrowth (171).
If a lesion cannot clearly be characterized as a fibroadenoma, excision may be necessary. Factors that are considered in recommending excision include older age, new mass in a well-screened individual, rapid growth, size greater than 2.5 to 3 cm, suspicious FNAC or CB, and mammographic or ultrasonographic features that demonstrate lobulation and intramural cysts. If observation is elected, repeat clinical examination and imaging in a short interval is essential to evaluate change in size.

Treatment of biopsy-proven phyllodes tumor is wide local excision, attempting to obtain a 1- to 2-cm margin (156–161). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided, and axillary lymph node dissection is not indicated. Often, however, a patient will undergo excisional biopsy of a mass believed to be fibroadenoma, and final histologic examination reveals a phyllodes tumor. Re-excision with normal breast margins is recommended for borderline and malignant phyllodes tumors (159). An expectant approach is an option for unanticipated diagnosis of benign phyllodes tumors (157).

The prognosis of benign and malignant phyllodes tumors is variable (154,155,157,162,172). Tumors judged to be benign phyllodes tumors can recur locally in up to 10% of patients (159–161). Recurrence is associated with margin involvement, whereas mortality correlates with size and grade (173). In a series reviewing only high-grade malignant phyllodes tumors, size and excision margins were associated with local recurrence and metastatic spread, and mastectomy may be required to achieve complete surgical excision (174). Malignant phyllodes tumors tend to recur locally and occasionally may metastasize to the lung, although brain, pelvic, and bone metastases also may occur (160–162). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant. Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adenocarcinoma (159). Radiation therapy has generally not been used in the treatment of phyllodes tumors. In the presence of a bulky tumor, positive margins, recurrence, or malignant histology, radiation therapy may be of some benefit (175).

### Breast Conditions Requiring Evaluation

#### Nipple Discharge

Nipple discharge is a presenting breast symptom in 4.5% of patients seeking evaluation of a breast symptom, with 48% spontaneous and 52% provoked (176). Nipple discharge that does not occur spontaneously has no pathologic significance. Provoked or self-induced nipple discharge should be managed by reassurance and instruction to discontinue manipulation. Spontaneous nipple discharge is more likely to be associated with an underlying pathologic problem than provoked discharge. **Although it is a distressing finding, spontaneous nipple discharge is infrequently found to be associated with carcinoma, ranging from 4% to 10%** (176–178). Nipple discharge can be caused by neoplastic or nonneoplastic processes (179). Nonneoplastic processes include galactorrhea, physiologic changes resulting from mechanical manipulation, parous condition, periductal mastitis, subareolar abscess, fibrocystic change, and mammary duct ectasia. Neoplastic causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, squamous metaplasia, and adenosis (176,179,180). Extramammary causes are related to hormones and drugs (179). **Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination** (180):

1. Nature of discharge (serous, bloody, or milky)
2. Association with a mass
3. Unilateral or bilateral

4. Single or multiple ducts

5. Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on entire breast

6. Relation to menses

7. Premenopausal or postmenopausal

8. Hormonal medication (contraceptive pills or estrogen)

Unilateral, spontaneous, bloody, or serosanguinous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but usually is caused by a benign papilloma in the duct. In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. MILKY discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary prolactin; serum prolactin and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, phenothiazines may cause milky discharge that disappears when the medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and disappears when the medication is stopped.

Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts. Mammography and ultrasonography are performed to rule out an associated mass. On occasion, ductography may be performed to identify a filling defect before excision of the duct system, but usually this technique is of little value (178). Ductography, however, is not a substitute for excision because it misses multiple lesions and cannot visualize the periphery (181).

A new technology, fiberoptic ductoscopy, is emerging to evaluate patients with nipple discharge (182). In 259 patients with nipple discharge, fiberoptic ductoscopy successfully detected intraductal papillary lesions in 92 patients (36%). Office-based minimally invasive breast ductoscopy with intraductal biopsy is available in some centers (183,184). It was performed for diagnosis in 83 patients with nipple discharge (183). A diagnosis of severe or malignant atypia was established in 21% of patients.

Cytologic examination of nipple discharge or cyst fluid rarely is performed. Cytologic examination usually is of no value but may identify malignant cells (178). Negative findings do not rule out cancer, which is more likely in women older than 50 years of age. In any case, the involved duct—and a mass, if present—should be excised (177,178,180,185). Complete histopathologic evaluation of the involved ductal system is the preferred method of diagnosis, and cytologic assessment should not be relied on for diagnosis.

The usual approach for nipple discharge is surgical excision through a periareolar incision adjacent to the trigger point, the pressure point that elicits nipple discharge (179). A microdochotomy of a single duct or a central duct excision of the major subareolar ducts can be performed under local or general anesthesia. The putative duct can be cannulated,
methylene blue can be injected, or a lacrimal probe can be inserted into the duct for localization. A resection of breast tissue for 3 to 5 cm, or until no bloody fluid can be identified in the ductal system, is performed. The patient must be warned of possible skin and nipple loss as a result of compromised vascularity, change in nipple sensation, deformity, inability to breastfeed, and recurrence if only a single duct if removed.

When there is a history of unilateral nipple discharge, localization is not possible, and no mass is palpable, the patient should be reexamined every week for 1 month. When unilateral discharge persists, even without definite localization or tumor, surgical exploration should be considered. The alternative is careful follow-up at intervals of 1 to 3 months. Mammography should be performed. Purulent discharge may originate in a subareolar abscess and requires excision of the related lactiferous sinus (186).

---

**Erosive Adenomatosis of the Nipple**

Erosive adenomatosis is a rare benign condition of the nipple that mimics Paget’s disease (187). Patients seek treatment for pruritus, burning, and pain. On clinical examination, the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles (188). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenocarcinoma metastatic to the skin, and unusual primary tumors of the nipple (187). Biopsy should be performed to diagnose the lesion. Local excision is curative (187).

**Fat Necrosis**

Fat necrosis of the breast is rare but clinically important because it produces a mass, often accompanied by skin or nipple retraction, which is indistinguishable from carcinoma. Fat necrosis often presents as a confusing clinical finding. Trauma is presumed to be the cause, although only about one half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the tumor. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Diagnostic imaging studies are usually insufficient (189). As a rule, the safest course is needle-core or excisional biopsy of the entire mass to rule out carcinoma (189). Fat necrosis is also common after segmental resection and radiation therapy or transverse rectus abdominis musculocutaneous (TRAM) flap (190).

**Breast Abscess**

**Lactational Abscesses**

Infection in the breast is rare unless the patient is lactating. Lactational mastitis must be distinguished from lactational abscess (191). During lactation, an area of redness, tenderness, and induration frequently develops in the breast. **Lactational mastitis is caused by transmission of bacteria during nursing and poor hygiene. The organism most commonly found in lactational mastitis and abscesses is Staphylococcus aureus** (192). If mastitis is diagnosed, manual pressure, antibiotics, and continued breastfeeding are recommended. In its early stages, the infection often can be treated while breastfeeding is continued by administering an antibiotic such as dicloxacillin 250 mg four times daily, or oxacillin, 500 mg four times daily for 7 to 10 days. **If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, and breastfeeding should be discontinued.**

**Nonlactational Abscess**

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating (193). The current approach to nonlactational abscess is conservative (194,195). A suspected abscess should be evaluated with preliminary ultrasonography to detect the
presence of an inflammatory mass, frank pus, solitary cavity, or a multiloculated abscess (196). Aspiration of pus, if present, and antibiotic therapy is instituted with reaspiration, if necessary (196). When the fluid collection is greater than 3 mL, percutaneous drain placement is an option (194). A single aspiration is sufficient in about one half of patients (194). Recurrent abscess formation is low (10%) (194). Bacteriologic analysis of 22 abscesses in nonlactating women shows a preponderance of gram-positive cocci, including *Staphylococcus epidermidis* (11 women), *Staphylococcus aureus* (3 women), *Proteus mirabilis* (3 women), *Pseudomonas aeruginosa* (1 woman), and sterile abscess (4 women) (196). **If these infections recur after multiple aspirations, incision and drainage followed by excision of the involved lactiferous duct or ducts at the base of the nipple may be necessary during a quiescent interval.** In virtually all cases, mammillary sinus (lactiferous duct fistula) can be confirmed as the cause of reinfection or persistent infection (197). Inflammatory carcinoma is a consideration when erythema of the breast is present. Patients should not undergo prolonged treatment for an apparent infection unless biopsy has eliminated the possibility of inflammatory carcinoma.

### Subareolar Abscess and Lactiferous Duct Fistula

Subareolar abscess and fistula of the lactiferous ducts secondary to squamous metaplasia can occur (198). The distal duct can be occluded with inspissated debris. Two large recent reviews report a high association of lactiferous duct fistulae in women who smoke (199,200). The definitive treatment for lactiferous duct sinus is excision of the lactiferous duct and drainage of the abscess cavity. In both studies, the recurrence rate was greater when only incision and drainage were performed. The most common organism occurring in primary subareolar abscess was *Staphylococcus aureus*, but anaerobic organisms occurred more frequently in chronic recurring abscesses (200).

### Disorders of Breast Augmentation

Estimates indicate that nearly 4 million women in the United States have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline.

The complications of breast implantation are significant. About 15% to 25% of patients develop capsule contraction or scarring around the implant, leading to a firmness and distortion of the breast that can be painful and sometimes requires removal of the implant and capsule. Implant rupture may occur in as many as 5% to 10% of women, and bleeding of gel through the capsule is even more common (201). In April 1992, the U.S. Food and Drug Administration concluded that the safety and effectiveness of silicone gel breast implants had not been established and called for additional preclinical and clinical studies (202). The agency advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms or rupture, implant removal is generally not indicated because the risks of removal are probably greater than the risk of retention. If screening ultrasonography shows no rupture, the probability of rupture is 2.2% (203). If ultrasonography shows rupture, true rupture is present in 37.8%. In this setting, a large number of women would have normal implants removed. When MRI is used in addition to ultrasonography, the probability of rupture increases to 86%.

**The suggested association between silicone gel and autoimmune disease has been poorly documented** (204,205). A retrospective cohort study from the Mayo Clinic showed no increased incidence of autoimmune disorders among women with silicone implants (206). Subsequent studies have demonstrated no clinical data proving an increased incidence of connective tissue disorders in patients with silicone gel breast implants (207–209). The data continue to reaffirm previous observations that there is no evidence of an association between breast implants and connective tissue diseases (210). In a study of Danish
women undergoing reduction mammoplasty compared with silicone implant augmentation, there was no increased incidence of antinuclear antibodies or other autoantibodies between the groups (211). The augmentation group experienced capsular contraction and more pain than the group undergoing reduction mammoplasty. Any association between implants and an increased incidence of breast cancer is unlikely (212). However, breast cancer may develop in any patient with a silicone gel prosthesis.

Preoperative Evaluation and Postoperative Management

Daniel L. Clarke-Pearson
Paula S. Lee
Monique A. Spillman
Christopher V. Lutman

• The preoperative evaluation should be complete and thorough, taking into account the essential aspects of the patient’s general medical condition and prior surgical history. The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure.

• The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status.

• Careful and meticulous fluid and electrolyte management is essential for all patients undergoing major surgical procedures.

• Although satisfactory analgesia is easily achievable with currently available methods, patients continue to suffer unnecessarily from postoperative pain.

• Prophylactic antibiotics should be employed judiciously. Prompt identification of perioperative infections and their specific treatments are critical to minimize the impact of this common morbidity.

• Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.

• Because pulmonary embolism is the leading cause of deaths following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens is an essential part of management. Calf compression during and after gynecologic surgery significantly reduces the incidence of deep venous thrombosis on a level similar to that of low-dose heparin.
Patients who are predisposed to cardiovascular, respiratory, and endocrine illnesses must be thoroughly screened preoperatively. Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. Patients with hypertension should receive medication to control their disease before surgery. Chronic obstructive pulmonary disease is the greatest risk factor for the development of postoperative pulmonary complications. Perioperative management of medical complications must be prompt and meticulous.

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. Discussed in this chapter are approaches to the general perioperative management of patients undergoing major gynecologic surgery with specific medical problems that could complicate the surgical outcome.

Medical History and Physical Examination

Gynecologic surgery should only be undertaken after gaining a thorough understanding of a patient’s medical history and performing a complete physical examination.

1. The medical history should include detailed questions to identify any medical illnesses that might be aggravated by surgery or anesthesia. Coronary artery disease and pulmonary diseases are the most common sources of postoperative complications.

2. Medications currently being taken (including nonprescription drugs) as well as those discontinued within the previous month before surgery should be recorded. In addition, information about the use of “alternative therapies,” herbs, and vitamins should be elicited. Specific instructions must be given to the patient regarding the need to discontinue any medications before surgery (e.g., aspirin, antiplatelet agents, or oral contraceptives), as well as those medications that should be continued (e.g., cardiac or antihypertensive medications).

3. The patient should be questioned regarding known allergies to medications (e.g., sulfa and penicillin), foods, or environmental agents. A history of sensitivity to shellfish may be the only clue of iodine sensitivity, which could be fatal if intravenous contrast materials are used without corticosteroid preparation.

4. Previous surgical procedures, and the patient’s course following those surgical procedures, should be reviewed to identify potential complications that might be avoided. The patient should be asked about specific complications, such as excessive bleeding, wound infection, deep venous thrombosis, peritonitis, or bowel obstruction. A history of pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy and pre-existing injury to adjacent organ systems such as small bowel adhesions or ureteral stenosis from previous periureteral scarring. In such cases, it may be prudent to identify any pre-existing abnormality by performing intravenous pyelography (IVP) or computed tomography (CT). Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous procedures should be obtained and reviewed.

5. Family history may identify familial traits that might complicate planned surgery. A family history of excessive intraoperative or postoperative bleeding,
venous thromboembolism, malignant hyperthermia, and other potentially inherited conditions should be sought.

6. A review of systems should also be detailed to identify any coexisting medical or surgical conditions. Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery because many gynecologic diseases also involve adjacent nongynecologic viscera.

7. Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other major organ systems should not be neglected in the physical examination. Identification of abnormalities, such as a heart murmur or pulmonary compromise, should lead the surgeon to obtain additional testing and consultation to minimize intraoperative and postoperative complications.

Laboratory Evaluation

The selection of appropriate preoperative laboratory studies depends on the extent of the anticipated surgical procedure and the patient’s medical status.

1. For patients undergoing general anesthesia, a blood count including hematocrit, white cell count, and platelet count should be obtained routinely.

2. Serum chemistry and liver function test results rarely are abnormal in asymptomatic patients who have no significant medical history and who are not taking medications.

3. Coagulation studies are of little value unless the patient has a significant medical history (1).

4. In women younger than 50 years of age, a chest x-ray and electrocardiography are of very low yield in identifying asymptomatic cardiopulmonary disease and thus are not be necessary (2,3).

Detailed evaluation of adjacent organ systems should be undertaken in individual cases as follows:

1. CT urography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. However, a CT urogram is not of value in the evaluation of most patients undergoing pelvic surgery (4).

2. Upper endoscopy, colonoscopy, barium enema, or upper gastrointestinal studies with small bowel assessment may be of value in evaluating some patients before undergoing pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Crohn’s disease) or, rarely, a gastric or pancreatic carcinoma. Clearly, any patient with gastrointestinal symptoms should be further evaluated.

3. Other imaging studies, including ultrasonography, CT scanning, or MRI, may be useful in selected patients.
Preoperative Discussion and Informed Consent

The preoperative discussion should include a description of the surgical procedure, its expected outcome, and risks; it is the basis for obtaining signed informed consent (5). Informed consent is an educational process for the patient and her family and fulfills the physician’s need to convey information in understandable terms. The items listed in Table 20.1 should be discussed, and, after each item, the patient and family should be invited to ask questions.

Following are components of the informed consent process:

1. A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease or condition. Printed materials, computer-based learning programs, and videotapes may assist in this process.

2. The goals of surgery should be discussed in detail. Some gynecologic surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, diagnostic laparoscopy), whereas most are aimed at correcting a specific problem. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

3. The expected outcome of the surgical procedure should be explained. If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating an anatomic deformity or disease, the expected success of the operation should be discussed, as well as the potential for failure of the operation (e.g., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues. Unanticipated findings at the time of surgery should also be mentioned. For example, if the ovaries are unexpectedly found to be diseased, the best surgical judgment may be that they should be removed.

</tr>
<tr>
<td>5. Alternative methods of therapy and the risks and results of those alternative methods of therapy</td>
</tr>
<tr>
<td>6. The results likely if the patient is not treated</td>
</tr>
</tbody>
</table>
4. The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure. For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thromboembolism, injury to adjacent viscera, and wound complications. If the patient has a preexisting medical problem (e.g., diabetes, obesity, chronic obstructive pulmonary disease [COPD], coronary artery disease) additional risks should be reviewed.

5. The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery. Information regarding the need for a suprapubic catheter or prolonged central venous monitoring helps the patient accept her postoperative course and avoids surprises to the patient that may be disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be outlined.

6. Alternative methods of therapy should be discussed, including medical management or other surgical approaches. The patient should also have an understanding of the outcome of the disease if nothing is done.

---

**General Considerations**

**Nutrition**

In general, young patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. However, all patients should have a nutritional assessment, especially elderly patients and those undergoing gynecologic cancer surgery or other major gynecologic procedures in which a prolonged postoperative recovery is expected. Nutritional status should be reassessed at regular intervals postoperatively until the patient has successfully returned to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of determining a patient’s nutritional status. In particular, information about recent weight loss, dietary history, fad diets, extreme exercise, or anorexia or bulimia should be elucidated. Physical evidence of malnutrition includes temporal wasting, muscle wasting, ascites, and edema. Accurate height and weight measurements should be obtained and an ideal body weight, percent ideal body weight, and percent usual body weight may be calculated. Many Internet-based body weight calculators are available. A variety of techniques have been developed to determine a patient’s nutritional state; however, many methods lack clinical utility outside of a research setting. Anthropometric measurements of skinfold thickness and arm-muscle circumference provide an estimate of total body fat and lean muscle mass.

The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status. The BMI is calculated as body weight in kilograms divided by the height in square centimeters. A BMI less than 22 increases the risk of malnutrition, and a BMI less than 19 gives clear evidence of malnutrition (6).

Patients who have lost less than 6% of their ideal body weight do not need preoperative nutritional intervention. However, patients who have lost more than 10% of their ideal body weight in 6 months meet the definition of severely malnourished and should be considered for preoperative intervention (7). Patients who have lost between 6% and 12% should undergo further studies to determine if preoperative intervention is needed. Laboratory assessments of albumin, transferrin, zinc, lipids, and liver function may be obtained in addition to the routine preoperative tests. The degree of malnutrition can in part
be determined by serum concentrations of albumin, transferrin, and prealbumin. The levels of these serum proteins are greatly influenced by the patient’s level of hydration. Prealbumin has the shortest half-life, at 2 to 3 days, and levels of this protein are depressed very early in comparison with serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (8). Serum albumin was determined to be a substitute for the Prognostic Nutritional Index, which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (9). A serum albumin level of 3.5 to 5.0 is in the normal range, 2.8 to 3.4 is considered to indicate mild malnutrition, 2.1 to 2.7 moderate malnutrition, and less than 2.1 severe malnutrition (10). Hypoalbuminemia is correlated with morbidity, mortality, and increased postoperative complication rates in data from the National Surgical Quality Improvement Program (11).

Decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient’s prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the severity of surgery, and the likelihood of complications. The nutritional assessment should also determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Severe malnutrition, if not corrected, can further complicate the postoperative problem by causing altered immune function, chronic anemia, impaired wound healing, and eventually multiple organ system failure and death.

The patient’s nutritional requirements are increased by surgery for several reasons. First, there is a period following surgery during which oral intake is not allowed or is very limited. In addition, the operation itself causes increased protein catabolism, increased energy requirements, and a negative nitrogen balance. If the surgery is uncomplicated and the patient is without food for less than 7 days, this response is limited and patients usually recover without the need for nutritional support. An adequate diet is defined as providing 75% of estimated caloric and protein needs. Therefore, if an adequate oral diet is not expected for 7 to 10 days, perioperative nutritional support may be required to avoid progressive malnutrition and associated complications (10). Perioperative nutritional support reduces operative morbidity and decreases the length of hospitalization when commenced early in the postoperative course. Therefore, patients with either normal nutritional indices or mild or moderate malnutrition, who will be undergoing surgical procedures likely to require a prolonged catabolic period of more than 7 to 10 days, should have enteral or parenteral nutrition instituted in the early postoperative period as soon as the patient is hemodynamically stable. This type of management should be strongly considered in patients undergoing pelvic exenterations, urinary diversions, or multiple enterectomies (12). Preoperative nutritional support is indicated for patients who have significant preexisting malnutrition or require major elective surgery. According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, evidence-based medicine supports the use of preoperative nutritional support for 7 to 14 days in moderately to severely malnourished patients undergoing major nonemergent, gastrointestinal surgery (8). A Veterans Affairs Total Parenteral Nutrition Cooperative Study found that severely malnourished patients preconditioned with total parenteral nutrition (TPN) had fewer complications than did control patients, excluding infectious complications (13). In a meta-analysis review of 22 studies of preoperative TPN use, a 10% decrease in postoperative complications occurred in TPN-supported patients (14). Although encouraging, these findings are controversial and not supported by all studies or meta-analyses (15). If preoperative TPN is prescribed, it should be tapered and stopped at midnight before surgery, restarted 24 to 72 hours after the procedure, and continued until the patient is able to meet nutritional requirements.

ASPEN guidelines do not support the routine use of nutritional support in the immediate postoperative period for patients undergoing major gastrointestinal surgery; however, the guidelines do indicate a role for nutritional support postoperatively in patients in whom
oral intake will be inadequate for 7 to 10 days (8). In summary, clinical trials have demonstrated that TPN can improve nutritional status as measured by biochemical assays, immune function, and nitrogen balance. The effect of TPN on clinical outcome, however, is less well established. Despite what would seem reasonable based on common sense as well as preoperative nutritional parameters, the data do not support TPN for mild to moderately malnourished patients. With severe malnutrition, preoperative TPN would seem to be beneficial and should be instituted.

Route of Administration

After the decision has been made that nutritional support is required, the appropriate route of administration must be determined. Enteral nutrition should be considered primarily because it is easy to deliver, associated with the fewest complications, linked to enhanced wound healing, and relatively inexpensive (16). Contraindications to this route of delivery include intestinal obstruction, gastrointestinal bleeding, and diarrhea. Many different types of preparations are commercially available and can be chosen based on their caloric content, fat content, protein content, osmolality, viscosity, and price. Depending on the patient’s problem, the route of delivery may be through a Dobhoff feeding tube, a gastrostomy tube, or a feeding jejunostomy tube (17). If the gastrointestinal tract is unusable for more than 7 days postoperatively, TPN should be implemented.

Total parenteral nutrition must be delivered through a central vein and has gained wide acceptance as a means of providing nutritional support for surgically ill patients. It must be delivered through a subclavian or internal jugular vein, and the catheter must be placed using meticulous sterile surgical technique. Only intravenous access lines in the right atrium, superior vena cava, or inferior vena cava can be truly deemed central lines (18). Proper daily care is required to avoid infectious complications. When managed by an experienced team, the most frequent complication, infection, can be reduced to a very reasonable level (19).

Composition of Total Parenteral Nutrition Solutions

1. Calories. The daily caloric requirements can be met by providing 1,000 calories more than the patient’s basal energy expenditure. Caloric requirements can be calculated based on Long’s modification of the Harrison-Benedict formula for actual energy expenditure (AEE) (20). This is the most accurate available method to calculate an individual’s AEE:

   \[
   \text{AEE (women)} = [655.10 + 9.56 \times \text{Weight (kg)} + 1.85 \times \text{Height (cm)} - 4.68 \times \text{Age (yrs)}] \times (\text{activity factor}) \times (\text{injury factor})
   \]

   Activity factor: confined to bed (1.2), out of bed (1.3).
   Injury factor: minor surgery (1.2), skeletal trauma (1.3), major sepsis (1.6), severe burn (2.1).

   Alternatively, daily caloric requirements can be met by giving the patient 35 kcal/kg/day for maintenance and 45 kcal/kg/day for anabolic states.

2. Protein. Daily nitrogen requirements may be met by providing 1 g of nitrogen (6.25 g of protein) for every 130 to 150 calories. Protein is provided by synthetic amino acids. The amino acids provide 15% to 20% of total calories (19).

3. Carbohydrates. The carbohydrate base of TPN is dextrose (glucose) in approximately 25% solution. Adults need approximately 100 g of dextrose per day at baseline. However, the maximal rate of glucose oxygenation in adults is approximately 7 g/kg/day, and glucose administration in excess of the caloric requirements can lead to fatty infiltration of the liver and other metabolic complications.
When given by TPN infusion, the dextrose tolerance in critically ill patients is 5 mg/kg/minute (19). Insulin should be used to maintain serum glucose concentration between 150 and 250 mg/dL, and it may be added directly to the TPN solution.

4. Fats. Lipids in a 10% to 20% emulsion can be given as further caloric supplement and supply the essential fatty acids, linoleic acid, and alpha-linoleic acids. More calories can be given in the form of free fatty acids, which are the major source of energy for most peripheral tissues. When lipids are used as a major source of calories, a minimum of 50 to 150 g/day of glucose should also be given to provide a substrate for the central nervous system. Most patients can tolerate up to 2 g of fat/kg/day, and daily dosages should not exceed 4 g of fat/kg/day. In critically ill patients, the lipid content should not exceed 1g/kg/day. These lipid emulsions are isotonic and can be delivered simultaneously with the protein and carbohydrate mixture in a 3-liter bag over a 24-hour infusion. In general, 30% to 50% of nonprotein calories should be supplied in lipid form. Serum triglyceride levels should be monitored to ensure that the patient can metabolize the fat.

5. Electrolytes, vitamins, and minerals. In addition to calories and protein, nutritional support should be maintained in terms of electrolytes, vitamins, and trace elements. Daily maintenance requirements for electrolytes are as follows: sodium, 40 to 50 mEq; potassium, 30 to 40 mEq; magnesium, 8 to 10 mEq; calcium, 2 to 5 mEq; and phosphate, 13 to 25 mmol (19). A number of vitamins and trace elements must also be supplied to ensure that the patient is eumetabolic.

**Fluid and Electrolytes**

Water constitutes approximately 50% to 55% of the body weight of the average woman. Two thirds of this water is contained in the intracellular compartment. One third is contained in the extracellular compartment, of which one fourth is contained in plasma, and the remaining three fourths is in the interstitium.

Osmolarity, or tonicity, is a property derived from the number of particles in a solution. Sodium and chloride are the primary electrolytes contributing to the osmolarity of the extracellular compartment. Potassium and, to a lesser extent, magnesium and phosphate are the major intracellular electrolytes. Water flows freely between the intracellular and the extracellular spaces to maintain osmotic neutrality throughout the body. Any shifts in osmolarity in any fluid spaces within the body are accompanied by corresponding shifts in free water from spaces of lower to higher osmolarity, thus maintaining equilibrium.

The average adult daily fluid maintenance requirement is approximately 30 mL/kg per day, or 2,000 to 3,000 mL/day (21). This level is offset partially by insensible losses of 1,200 mL/day, which include losses from the lungs (600 mL), skin (400 mL), and gastrointestinal tract (200 mL). Urinary output from the kidney accounts for the remainder of the fluid loss, and this output will vary depending on total body intake of water and sodium. Approximately 600 to 800 mOsm of solute are excreted by the kidney daily. Healthy kidneys can concentrate urine up to approximately 1,200 mOsm and, therefore, the minimum output can range between 500 and 700 mL/day. The maximal urine output of the kidney can be as high as 20 L/day, as seen in patients with diabetes insipidus. In healthy individuals, the kidney adjusts output commensurate with daily fluid intake.

The major extracellular buffer used in the acid-base balance is the bicarbonate-carbonic acid system: \( \text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^- \) (22). Typically, the body will maintain a bicarbonate-to-carbonic acid ratio of 20:1 to maintain an extracellular pH.
of 7.4. Both the lung and the kidney play integral roles in the maintenance of normal extracellular pH via retention or excretion of carbon dioxide and bicarbonate. Under conditions of alkalosis, minute ventilation decreases and renal excretion of bicarbonate increases to restore the normal ratio of bicarbonate to carbonic acid; the opposite occurs with acidosis.

Ultimately, the kidney plays the most important role in fluid and electrolyte balance through excretion and retention of water and solute. Circulating antidiuretic hormone and aldosterone help modulate the process. Serum osmolarity affects hypothalamic release of antidiuretic hormone and aldosterone secretion in response to renal perfusion. Under states of dehydration or hypovolemia, serum antidiuretic hormone levels increase, leading to increased resorption of water in the distal tubule of the kidney. In addition, increased aldosterone release promotes increased sodium and water retention. The opposite occurs in states of fluid excess. As a result, individuals with normal renal function and circulating antidiuretic hormone and aldosterone levels maintain normal serum osmolarity and electrolyte composition, despite daily fluctuations of fluid and electrolyte intake.

Various disease states can alter the normal fluid and electrolyte homeostatic mechanisms, making perioperative fluid and electrolyte management more difficult. Patients with intrinsic renal disease are unable to excrete solute and to maintain acid-base balance. In patients undergoing the stress of chronic starvation or severe illness, there may be an inappropriately high level of circulating antidiuretic hormone and aldosterone, resulting in fluid and sodium retention. With severe cardiac disease, secondary renal hypoperfusion can lead to increased aldosterone synthesis and, therefore, increased sodium and water retention by the kidney. Finally, patients with severe diabetes can have significant osmotic diuresis as well as acid-base dysfunction secondary to circulating keto acids. Treatment of renal, cardiac, or endocrine disorders preoperatively is imperative and often will rectify fluid and electrolyte abnormalities.

Special attention is warranted in the elderly patient undergoing surgery. Normal physiological changes associated with aging can increase the likelihood of fluid and electrolyte disorders. These changes include decreased glomerular filtration rate, decreased urinary concentrating ability, and narrowed limits for excretion of water and electrolytes (23). Fluid and electrolyte management in the preoperative and perioperative periods requires knowledge of the daily fluid and electrolyte requirements for maintenance, replacement of ongoing fluid and electrolyte losses, as well as correction of any existing abnormalities.

### Fluid and Electrolyte Maintenance Requirements

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually only necessary to replace sodium and potassium. Chloride is automatically replaced, concomitant with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mmol of sodium chloride, with smaller amounts of potassium, calcium, and magnesium, designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. The daily requirement, however, can be met by any combination of intravenous fluids. For example, 2 L of D5 (5% dextrose)/0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 liter of D5W (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.

### Fluid and Electrolyte Replacement

Fluid and electrolyte losses beyond the daily average must be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it is difficult to measure free water loss, particularly in patients who
have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient who is taking nothing by mouth (21). Any loss beyond this level, however, represents fluid loss, which should be replaced accordingly.

Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L/day. These losses should be replaced with free water in the form of D5W. Perspiration typically has one third the osmolarity of plasma and can be replaced with D5W or, if the loss is excessive, with D5/0.25 normal saline.

Patients with acute blood loss need replacement with appropriate isotonic fluid or blood or both. There is a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, that contains large-molecular-weight particles (>50 kilodaltons (kDa) molecular weight). These particles are slow to exit the intravascular space, and about one half of the particles remain after 24 hours. Controversy exists over the ideal strategy for intravascular volume replacement (24). Meta-analyses on the use of human albumin and crystalloids versus colloids in fluid resuscitation have not shown a benefit in mortality rates (25,26). However, caution is required in interpreting results from these pooled controlled trials because mortality outcome was not the end point of most of the studies, and publication bias is a limitation. Possible side effects with synthetic colloid solutions include adverse affects on hemostasis, severe anaphylactic reactions, and impairment of renal function (24). These solutions are expensive, however, and for most cases, simple replacement with 0.9 normal saline or lactated Ringer’s solution will suffice. One third of the volume of lactated Ringer’s solution or normal saline typically will remain in the intravascular space, and the remainder goes to the interstitium.

Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract. Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10–20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i.e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one third the sodium of plasma, increased amounts of hydrogen ion, and low pH.

In patients who have gastric outlet obstruction, nausea, and vomiting, or who undergo nasogastric suction, appropriate replacement of gastric secretions can be provided with a solution such as D5/0.45 normal saline with 20 mEq/L of potassium. Potassium supplementation is particularly important to prevent hypokalemia in these patients, whose kidneys attempt to conserve hydrogen ions in the distal tubule of the kidney in exchange for potassium ions.

In patients with bowel obstruction, 1 to 3 L of fluid can be sequestered daily in the gastrointestinal tract. This fluid should be replaced with isotonic saline or lactated Ringer’s solution. Similarly, patients with enterocutaneous fistulas or new ileostomies should receive replacement with isotonic fluids.

**Correction of Existing Fluid and Electrolyte Abnormalities**

Patients who have fluid or electrolyte abnormalities preoperatively can pose a diagnostic challenge. The correct diagnosis and therapy is contingent on a correct assessment of total body fluid and electrolyte status. The management of hyponatremia, for example, may be either fluid restriction or fluid replacement. The choice of treatment depends on whether there is overall extracellular fluid excess and normal body sodium stores or decreased overall total body sodium stores and extracellular fluid. A detailed history is necessary to disclose any underlying medical illness and to assess the amount and duration of any...
abnormal fluid losses or intake. Initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters to determine the overall level of hydration as well as the fluid status of the extracellular fluid compartment. The patient who has good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. Nonpitting edema is indicative of extracellular fluid excess, whereas patients with orthostasis, sunken eyes, parched mouth, and decreased skin turgor clearly have extracellular volume contraction. A patient’s overall extracellular fluid status does not always reflect the hydration status of the intravascular compartment, however. A patient can have increased interstitial fluid and yet be intravascularly dry, requiring replacement with isotonic fluid.

The laboratory workup for patients who may have pre-existing fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, blood urea nitrogen (BUN) and creatinine, urine osmolarity, and urine electrolyte levels. Serum osmolarity is mainly a function of the concentration of sodium and is given by the following equation:

\[ 2 \times \text{Na}^+ + \frac{\text{glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8} \]

Normal serum osmolarity is typically 290 to 300 mOsm. Blood hematocrit will rise or fall inversely at a rate of 1% per 500-mL alteration of extracellular fluid volume. The BUN:creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolarity will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L), indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease in which the kidney has impaired ability to retain sodium and water, urine osmolarity will be low and urine sodium will be high (>30 mEq/L). Finally, changes in sodium can give insight into the degree of extracellular fluid excess or deficit. In the average person, the serum sodium rises by 3 mmol/L for every liter of water deficit and falls by 3 mmol/L for each liter of water excess. One must be careful in making these estimates, however, because patients with prolonged water and electrolyte loss can have low serum sodium levels and marked water deficits.

### Specific Electrolyte Disorders

#### Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia, then, is usually expansion of body fluids leading to excess total body water (22, 27). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the rate of change of serum sodium than to the actual serum sodium level.

Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or cardiac failure as well as in conditions such as nephrotic syndrome, in which total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic saline to correct the hyponatremia would be inappropriate in this setting. The treatment should include, in addition to correcting the underlying disease process, water restriction with diuretic therapy. Inappropriate secretion of antidiuretic hormone (ADH) can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction...
and, if possible, correction of the underlying cause. *Demeclocycline* has been shown to be effective in this disorder via its action in the kidney.

**Inappropriate replacement of body salt losses with water alone will result in hyponatremia.** This situation will typically occur in patients who lose large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

**Hypernatremia**

Hypernatremia is an uncommon condition that can be life-threatening if severe (serum sodium greater than 160 mEq/L). The pathophysiology is extracellular fluid deficit. The resultant hyperosmolar state leads to decreased water volume in cells in the central nervous system, which, if severe, can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, have undergone tracheostomy in a dry environment, or have extensive thermal injuries; who have diabetes insipidus, either central or nephrogenic; and who have iatrogenic salt loading. The treatment involves correction of the underlying cause (correction of fever, humidification of the tracheostomy, administration of pitressin for control of central diabetes insipidus) and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypernatremia should be corrected slowly.

**Hypokalemia**

Hypokalemia may be encountered preoperatively in patients with significant gastrointestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) and marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). It can also arise from prolonged administration of potassium-free parenteral fluids in patients who are restricted from ingesting anything by mouth. The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to flaccid paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the serum potassium level is less than 3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet. If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq/hour.

**Hyperkalemia**

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment but can also be seen in patients who have adrenal insufficiency, are taking potassium-sparing diuretics, and have marked tissue breakdown such as that occurring with crush injuries, massive gastrointestinal bleeding, or hemolysis. The clinical manifestations are mainly cardiovascular. Marked hyperkalemia (potassium greater than 7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with electrocardiography. *Calcium gluconate* (10 mL of a 10% solution), given intravenously, can offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D50, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as *sodium polystyrene sulfate* (*Kayexalate*), taken orally
Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels also are increased, especially if sustained episodes of hypotension have occurred either intraoperatively or postoperatively. The elevated levels of circulating ADH and aldosterone make patients prone to sodium and water retention postoperatively.

Total body fluid volume may be altered significantly postoperatively. First, 1 mL of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water is released daily from tissue breakdown, particularly in the patient who has undergone extensive intra-abdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. The development of an ileus may result in an additional 1 to 3 L of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. In the postoperative period, the kidneys will continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores (22). If this potassium loss is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. However, beyond the first postoperative day, potassium supplementation is necessary.

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters before surgery. Postoperatively, close monitoring of daily weight, urine output, serum hematocrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The normal daily fluid and electrolyte requirements must be met and any unusual fluid and electrolyte losses, such as from the gastrointestinal tract, lungs, or skin, must be replaced. After the first few postoperative days, third-space fluid begins to mobilize back into the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained perioperatively is thus mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. Patients with inadequate cardiovascular or renal reserve are prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. The fluid excess can occur concomitantly with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal levels. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. Again, the predisposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitantly with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g/day. Clearly, the patient who is gaining weight in excess of 150 g/day...
is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary water excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily fluid losses that are not replaced. Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L/day of free water can be lost through perspiration and hyperventilation. Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid-Base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid-base homeostasis, leading to alkalosis or acidosis. Changes in the respiratory rate will directly affect the amount of carbon dioxide that is exhaled. Respiratory acidosis will result from carbon dioxide retention in patients who have hypoventilation from central nervous system depression. This condition can result from oversedation with narcotics, particularly in the presence of concurrent severe chronic obstructive pulmonary disease. Respiratory alkalosis can result from hyperventilation caused by excitation of the central nervous system by drugs, pain, or excess ventilator support. Numerous metabolic derangements can result in alkalosis or acidosis. Proper fluid and electrolyte replacement as well as maintenance of adequate tissue perfusion will help prevent most acid-base disorders that occur during the postoperative period.

Alkalosis

The most common acid-base disorder encountered in the postoperative period is alkalosis (22). Alkalosis is usually of no clinical significance and resolves spontaneously. Several etiologic factors may include hyperventilation associated with pain; posttraumatic transient hyperaldosteronism, which results in decreased renal bicarbonate excretion; nasogastric suction, which removes hydrogen ions; infusion of bicarbonate during blood transfusions in the form of citrate, which is converted to bicarbonates; administration of exogenous alkali; and use of diuretics. Alkalosis can usually be corrected easily with removal of the inciting cause, as well as with correction of extracellular fluid and potassium deficits (Table 20.2). Full correction can usually be safely achieved over 1 to 2 days.

Marked alkalosis, with serum pH higher than 7.55, can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly

pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not be sufficient to correct the alkalosis rapidly. Acetazolamide (250–500 mg), can be given orally or intravenously 2 to 4 times daily to induce renal bicarbonate diuresis. Treatment with an acidifying agent is rarely necessary and should be reserved for acutely symptomatic patients (i.e., those with cardiac or central nervous system dysfunction) or for patients with advanced renal disease. Under such conditions, hydrogen chloride (5–10 mEq/hour of a 100-mmol solution) can be given via a central intravenous line. Ammonium chloride can also be given orally or intravenously but should not be given to patients with hepatic disease.

Acidosis

Metabolic acidosis is less common than alkalosis during the postoperative period, but acidosis can potentially be serious because of its effect on the cardiovascular system. Under conditions of acidosis, there are decreased myocardial contractility, a propensity for vasodilation of the peripheral vasculature leading to hypotension, and refractoriness of the fibrillating heart to defibrillation (22). These effects promote decompensation of the cardiovascular system and can hinder attempts at resuscitation.

Metabolic acidosis results from a decrease in serum bicarbonate levels caused by the consumption and replacement of bicarbonate by circulating acids or the replacement by other anions such as chloride. The proper workup includes a measurement of the anion gap:

\[
\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-) = 10 \text{ to } 14 \text{ mEq/L (normal)}
\]

The anion gap is also composed of circulating protein, sulfate, phosphate, citrate, and lactate (28).

With metabolic acidosis, the anion gap can be increased or normal. An increase in circulating acids will consume and replace bicarbonate ion, thus increasing the anion gap. The causes include an increase in circulating lactic acid secondary to anaerobic glycolysis, such as that seen under conditions of poor tissue perfusion; increased ketoacids, as with cases of severe diabetes or starvation; exogenous toxins; and renal dysfunction, which leads to increased circulating sulfates and phosphates (29). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of an imbalance of the ions chloride and bicarbonate, which occurs under conditions leading to excess chloride and decreased bicarbonate. Hyperchloremic acidosis can be seen in patients who have undergone saline loading. Bicarbonate loss will be seen in patients with small bowel fistulas, new ileostomies, severe diarrhea, or renal tubular acidosis. Finally, in patients with marked extracellular volume expansion, which often occurs postoperatively, the relative decrease in serum sodium and bicarbonate will result in a mild acidosis. A summary of the various causes of metabolic acidosis is shown in Table 20.3.

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This state can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic infection wherever appropriate. Ketosis from diabetes can be corrected gradually with insulin therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate losses from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.
Perioperative Pain Management

Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present. Furthermore, close monitoring of serum potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks. A summary of the various acid-base abnormalities and associated therapies is shown in Table 20.4.

Perioperative Pain Although satisfactory analgesia is easily achievable with currently available methods, patients continue to suffer unnecessarily from postoperative pain. Studies have consistently shown that 30% to 40% of patients suffer moderate to severe pain in the postoperative period. There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. In a study of the perception of pain relief after surgery, 86% of patients had moderate to severe pain after surgery, but 70% felt that the pain was as severe as they had expected. Second, there is a lack of formal physician training in pain management. This lack is epitomized by the commonly written order prescribing a range of narcotic to be given intramuscularly every 3 to 4 hours as needed, leaving pain management decisions to the nursing staff, with no attempt made to titrate the dose of the prescribed narcotic commensurate with individual patient requirements. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period can result in opioid dependence. In one review, 20% of nurses responding to a staff questionnaire expressed concern that the use of opioid analgesics during the postoperative period could cause addiction. Studies have confirmed that nurses will administer less than one fourth of the total dose of narcotic that is prescribed on an as-needed basis. To facilitate acute pain management and reduce the number of adverse outcomes, the American Society of Anesthesiologists has established practice guidelines for acute pain management in the perioperative setting.

The minimal effective analgesic concentration (MEAC) refers to the serum concentration of a drug below which very little analgesia is achieved. At the MEAC, receptor and plasma concentrations of a drug are in equilibrium. Steady-state drug concentrations above the MEAC are difficult to achieve with intramuscular depot injection. In one study, patients receiving intramuscular injections with meperidine hydrochloride (Demerol) every 4 hours experienced marked intrapatient and interpatient variations in

narcotic drug peak concentrations as well as in the time required to reach these peaks. As a result, serum concentrations of drug were above the MEAC an average of only 35% of each 4-hour dosing interval (35). Variable pain control following intermittent intramuscular injections is the result of inadequate, highly variable, and unpredictable blood concentrations (36). Adequate analgesia can be achieved through intramuscular or subcutaneous modes of administration, but unpredictable absorption can make titration difficult. Small intravenous boluses can be more easily titrated but may be shorter acting, requiring more frequent injections and thus intensive nursing care, whereas larger intravenous boluses may be associated with a higher incidence of central nervous system and respiratory depression. The patient-controlled analgesia (PCA) technique, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain. This technique can provide a more thorough analgesia with maintenance of steady-state drug concentrations above the MEAC.

Irrespective of the route of administration, analgesics must be front loaded to provide prompt analgesia from the start. Without front loading, attainment of the MEAC will not occur for at least three elimination half-lives of the narcotic agent that is used. After front loading, additional small boluses of narcotic can be administered until analgesia is achieved. From the total dose of drug required to achieve analgesia, maintenance drug dosages can then be determined and administered either as a continuous infusion or on a

scheduled basis, so that the dose of drug administered offsets the amount that is cleared. Thereafter, prescribed doses of narcotic can be adjusted as needed.

**Patient-controlled Analgesia**

Devices for administering PCA are electronically controlled infusion pumps that deliver a preset dose of narcotic into a patient’s indwelling intravenous catheter upon patient request. The devices all contain delay intervals or lockout times during which patient demands for more narcotic are not met. **These devices eliminate the delay between the onset of pain and the administration of analgesic agents, a common problem inherent with on-demand analgesic orders in busy hospital wards.** Patient-controlled analgesia has enjoyed excellent patient acceptance. Compared with conventional intramuscular injections, serum narcotic levels have significantly lower variability in patients using PCA (34). Patients using PCA have been shown to have improved analgesia, a lower incidence of postoperative pulmonary complications, and less confusion than those given intramuscular narcotics (37). Furthermore, the total dose of narcotic used has been lower with PCA than with conventional intramuscular depot injection.

The use of PCA does not by any means eliminate the adverse side effects of narcotics. Potentially life-threatening respiratory depression is seen in as many as 0.5% of patients using PCA. The use of a continuous narcotic infusion in addition to demand dosing has been associated with a fourfold increase in respiratory depression. Elderly patients and those with pre-existing respiratory compromise also are at risk for respiratory depression (34).

Carefully supervised regimens using continuous infusions, on-demand intramuscular therapy, or fixed dosage schedules (every-4-hour dosing) with on-demand supplementation can have analgesic efficacy comparable with PCA. Nonetheless, the type of close supervision required to achieve adequate on-demand analgesia without PCA is difficult to maintain. **Use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control.**

**Epidural and Spinal Analgesia**

Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in one of several ways, including a single-shot dose given by epidural or intrathecal injection, intermittent injection given either on schedule or on demand, and continuous infusion.

Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. However, the risk of central nervous system and respiratory depression, as well as systemic hypotension, also is increased. Even the low doses of opioids required for intrathecal analgesia have been associated with an increased risk of respiratory depression (38). Therefore, some investigators have warned against the use of intrathecal spinal analgesia outside the intensive care setting.

**Epidural administration is the preferred approach and provides extended (greater than 24 hours) pain control during the postoperative period.** Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents have been used with excellent efficacy. Among the anesthetic agents, *bupivacaine* has been the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness,
hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, however, there is a higher incidence of nausea and vomiting, respiratory depression, and pruritus (39).

Compared with analgesics administered intramuscularly or intravenously, epidural analgesia has been shown to be associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence (39). A recent systematic review concluded that continuous epidural anesthesia is more effective than intravenous opioid PCA in reducing postoperative pain for up to 72 hours after abdominal surgery (40). Severe respiratory depression, which occurs in less than 1% of patients, is the most serious potential complication. A lower incidence of respiratory depression occurs with the more lipophilic drugs such as fentanyl, which is quickly absorbed within the spinal cord and is, therefore, less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be managed easily and usually are of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

Close monitoring by nursing staff is required for safe administration of epidural analgesia. However, an intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.

**Nonsteroidal Anti-inflammatory Drugs**

Current therapeutic strategies for perioperative pain control are largely dependent on multimodal therapy with opioid analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs). The nonselective NSAID ketorolac is a potent drug that can be given orally or parenterally. **Ketorolac has a slightly slower onset of activity than fentanyl but has an analgesic potency comparable to morphine.** The theoretical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, ketorolac has been found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements (41,42). Depending on the type of surgery, ketorolac has an opioid dose-sparing effect of a mean of 36% and improves analgesic control of moderate to severe pain 24 hours postoperatively (43). In the obstetric population, intravenous ketorolac is effective in reducing postoperative narcotic use after cesarean delivery (44). Although the U.S. Food and Drug Administration has not approved ketorolac for use during lactation, it has been quantified in breast milk and has lower levels than ibuprofen (45).

Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. The effects of ketorolac on bleeding have been inconsistent. Studies of ketorolac on healthy volunteers showed transient increases in bleeding time and decreases in platelet aggregation, but these changes were not clinically significant (46). A retrospective cohort study showed increased risk of gastrointestinal and operative site bleeding in elderly patients receiving high doses of ketorolac, between 105 mg/day and 120 mg/day (47). In addition, increased risk for all gastrointestinal bleeding was associated with use of ketorolac for more than 5 days (47). Controlled prospective studies have not shown a significant increase in blood loss in patients who receive NSAIDs perioperatively. **Ketorolac may be associated with elevated**
rates of acute renal failure when therapy exceeds 5 days (48). A meta-analyses of the use of postoperative NSAIDs in patients with normal preoperative renal function showed a clinically insignificant reduction in renal function (49). Finally, these agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to aspirin and other NSAID preparations.

With the potential advantage of less gastrointestinal toxicity, interest increased in the use of selective cyclooxygenase-2 (COX-2) inhibitors in perioperative pain management. However, in light of subsequent evidence showing increased incidence of serious cardiovascular events associated with COX-2 inhibitors, the use of these agents in the perioperative setting should be carefully assessed, especially in patients who have cardiovascular disease or who are at risk for it (50–54).

Antimicrobial Prophylaxis in Gynecologic Surgery

Gynecologic procedures often involve breaching of the reproductive and gastrointestinal tracts, which harbor endogenous flora capable of causing polymicrobial infections in the postoperative period. Despite great advances in aseptic technique and drug development, bacterial contamination of the operative site and postoperative infections are an inevitable part of the practice of gynecologic surgery. Prevention of these surgical complications includes using proper aseptic technique, minimizing tissue trauma, minimizing the amount foreign material in the surgical site, controlling diabetes, avoiding immunologic suppression, maximizing tissue oxygenization, draining blood and serum from the surgical site, and using prophylactic antibiotics. Antibiotic prophylaxis is given with the belief that antibiotics can enhance the immune mechanisms in the host tissues that would resist such infections by killing bacteria that inoculate the surgical site at the time of surgery (55).

Infections in the skin or pelvis that result from gynecologic surgery (e.g., parametritis, cuff cellulitis, pelvic abscess) typically are polymicrobial in nature. These infections are complex and often involve gram-negative rods, gram-positive cocci, and anaerobes (Table 20.5). Antibiotic prophylaxis should be sufficiently broad to cover these potential pathogens (56).

The timing of antimicrobial prophylaxis is important. There is a relatively narrow window of opportunity for affecting outcomes (57). In the United States, it is customary to give antimicrobial prophylaxis shortly before or during the induction of anesthesia. Data have revealed that a delay of 3 hours or more between the time of bacterial inoculation (i.e., skin incision) and administration of antibiotics may result in ineffective

</table>
prophylaxis. Evidence indicates that for prophylaxis, one dose of antibiotic is appropriate. When the surgical procedure proceeds longer than 1 to 2 times the half-life of the drug or blood loss is greater than 1.5 liters, additional intraoperative doses of antibiotics should be administered to maintain adequate levels of medication in serum and tissues. There are no data to support the continuation of prophylactic antimicrobial agents into the postoperative period for routine gynecologic procedures.

The cephalosporins have emerged as the most important class of antimicrobial agents for prophylaxis. These drugs have a broad spectrum and relatively low incidence of adverse reactions. Cefazolin (1 g) appears to be most widely used in the United States by gynecologic surgeons because of its relatively low cost and long half-life. Other cephalosporins such as cefoxitin, cefotaxime, and cefotetan also commonly are used for prophylaxis. These agents appear to have a broader spectrum of activity against anaerobic bacteria; however, there is little evidence to indicate that there is a clinically relevant distinction between cefazolin and the other agents.

Antimicrobial prophylaxis, although usually beneficial, is not without risk. Anaphylaxis is the most life-threatening complication from antibiotic use. Anaphylactic reactions to penicillins are reported to occur in 0.2% courses of treatment. The fatality rate is 0.0001%. Data indicate that it generally is safe to administer cephalosporins to women who report a history of adverse reactions to penicillins. The incidence of adverse reactions (e.g., skin flushing, itching) in women with a history of penicillin allergy who are given cephalosporins is 1% to 10%. The incidence of anaphylaxis in this setting is less than 0.02% (58).

A single dose of broad-spectrum antibiotics can result in pseudomembranous colitis, caused by Clostridium difficile. Diarrhea may develop in as many as 15% of hospitalized patients treated with beta-lactam antibiotics. In patients receiving clindamycin, the rate of diarrhea is nearly 30%. These gastrointestinal complications from antibiotics may cause serious morbidity in the surgical patient, and the surgeon should be familiar with recognizing and managing these problems (59).

Not all gynecologic surgery patients need to receive prophylactic antibiotics. The surgeon should choose agents to cover procedures based on available data, thereby avoiding the potential for adverse reactions and minimizing the unnecessary use of antibiotics, which may contribute to increased rates of antimicrobial resistance. In patients reporting adverse reactions to the aforementioned agents, other drugs or combinations should be chosen that will provide adequate prophylactic coverage. For example, metronidazole and levofloxacin or clindamycin and gentamicin are two alternative broad-spectrum prophylactic regimens that can be used patients undergoing hysterectomy to cover anaerobes, gram-positive cocci, and gram-negative rods (60). Some commonly used recommendations are listed in Table 20.6.

Subacute Bacterial Endocarditis Prophylaxis

Often, the gynecologic surgeon encounters the issue of endocarditis prophylaxis. Most commonly, a woman will report a history of a murmur or mitral valve prolapse to the surgeon during the preoperative interview. Data clearly indicate that surgeons and dentists in the United States overtreat these women with prophylactic antibiotics meant to prevent endocarditis. It appears that most patients who report these cardiac conditions are at no increased risk for endocarditis. For example, most patients with mitral valve prolapse or benign murmurs do not require endocarditis prophylaxis at the time of gynecologic surgery. A thorough history and physical examination, coupled with a preoperative echocardiography and consultation with a cardiologist, will provide a detailed assessment of the risk of endocarditis in these patients. The American Heart Association (AHA) has published guidelines for physicians and dentists to use in selecting patients and procedures for endocarditis prophylaxis. If the surgeon is uncertain, consultation with a cardiologist is appropriate. If it appears that the patient would benefit from endocarditis
prophylaxis, based on the cardiac lesion and the procedure she will undergo, the risk is stratified as high or moderate. High-risk patients should receive **ampicillin** or **vancomycin** plus **gentamycin** in a multidose regimen. Moderate-risk patients receive **amoxicillin** or **ampicillin** or **vancomycin** as prophylaxis in a single-dose regimen. Of note, low-risk patients require no subacute bacterial endocarditis (SBE) prophylaxis regardless of the procedure.

Antibiotics administered to prevent surgical site infection are not sufficient for endocarditis prophylaxis; however, some experts feel that antibiotics given for endocarditis prophylaxis may provide adequate coverage against postoperative infections. This claim may be suspect, however, in patients undergoing gynecologic surgery. Some of the regimens (e.g., single-dose oral **amoxicillin**) prescribed for endocarditis prophylaxis in some patients may not provide adequate coverage for flora (gram-negative rods and anaerobes) found in the reproductive or gastrointestinal tracts. The AHA guidelines provide detailed dosing and schedule information for endocarditis prophylaxis (Table 20.7) (61).

### Postoperative Infections

**Infections are a major source of morbidity in the postoperative period.** Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and pre-existing focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic side wall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome for these potentially serious complications.

**Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures.** In cases that involve transection of the large bowel, spillage of fecal contents inevitably occurs. A thorough preoperative mechanical and antibiotic bowel preparation in combination with systemic antibiotic prophylaxis will help decrease the incidence of postoperative
pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. In cases in which there is higher-than-usual potential for serum and blood to collect in spaces that have been contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intra-abdominal infection or pus. Elective surgical procedures should be postponed in patients who have infections preoperatively. In an epidemiologic study conducted by the Centers for Disease Control and Prevention, the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals (62). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the skin and wound accounted for approximately one third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection before surgery, the risk of infection at the surgical wound site was increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay before surgery. The relative risk was 3 times higher in patients with a community-acquired infection before surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients has been the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. However, other sources have defined fever as two consecutive temperature elevations greater than 101.0°F (38.3°C) (63,64). Febrile morbidity has been estimated to occur in as many as one half of patients; however, it is often self-limited, resolves without therapy, and is usually noninfectious in origin (65). Overzealous evaluations of postoperative fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (64). The value of 101.0°F is more useful than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever.
The assessment of a febrile surgical patient should include a review of the patient’s history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection (Table 20.8). The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis or thrombophlebitis. In gynecologic patients, an appropriate workup may also include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should also be performed to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

Patients with fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry (64). If the fever persists beyond 72 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. In one study, a routine urine culture had a yield of only 9%; therefore, cultures should not be analyzed unless indicated by the urinalysis results or symptoms (63). Routine chest radiography has a yield of 12.5% and should be performed in asymptomatic patients as well as those with signs and symptoms localizing to the lung (63). Blood cultures can also be obtained but will most likely be of little yield unless the patient has a high fever (102°F). In patients with costovertebral angle tenderness, IVP may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of urinary tract infection. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intra-abdominal abscess. Finally, if fever persists in patients who have had gastrointestinal surgery, a barium enema or upper gastrointestinal studies with small bowel assessment may be indicated late in the course of the first postoperative week to rule out an anastomotic leak or fistula.

**Urinary Tract Infections**

Historically, the urinary tract has been the most common site of infection in surgical patients (62). However, the incidence reported in the more recent gynecologic literature has been less than 4% (65,66). This decrease in urinary tract infections is most likely the result of increased perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics has been confirmed to be as high as 40% (67), and even a single dose...
of perioperative prophylactic antibiotic has been shown to decrease the incidence of postoperative urinary tract infection from 35% to 4% (68).

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and has been defined as the growth of $10^5$ organisms/mL of urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include *Klebsiella*, *Proteus*, and *Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (69). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, has been implicated as a main cause of urinary tract contamination (70). In fact, more than one million catheter-associated urinary tract infections occur yearly in the United States, and *catheter-associated bacteria remains the most common etiology of gram-negative bacteremia in hospitalized patients*. Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making treatment less effective. Therefore, the use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

The treatment of urinary tract infection includes hydration and antibiotic therapy. Commonly prescribed and effective antibiotics include *penicillin*, *sulfonamides*, *cephalosporins*, *fluoroquinolones*, and *nitrofurantoin*. The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to *ampicillin*. For uncomplicated urinary tract infections, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as *Klebsiella* and *Pseudomonas*. Chronic use of *fluoroquinolones* for prophylaxis is not advised because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

**Pulmonary Infections**

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. In one study only six cases of pneumonia occurred in more than 4,000 women who underwent elective hysterectomy (65). This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (71). Risk factors include extensive or prolonged atelectasis, preexistent COPD, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, and nasogastric suction (71). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures. The role of prophylactic antibiotics remains unclear.

A significant percentage (40%–50%) of cases of hospital-acquired pneumonia is caused by *gram-negative organisms*. These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx has been shown to be increased in patients in acute care facilities and has been associated with the presence
of nasogastric tubes, pre-existing respiratory disease, mechanical ventilation, tracheal intubation, and paralytic ileus as a result of microbial overgrowth in the stomach (72). Interestingly, the use of antimicrobial drugs seems to significantly increase the frequency of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, chest radiography is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, chest radiography should be performed. A sputum sample should also be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both gram-positive and gram-negative organisms. In patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

### Phlebitis

Intravenous catheter-related infections are common; the reported incidence is 25% to 35% (73). The intravenous site should be inspected daily, and the catheter should be removed if there is any associated pain, redness, or induration. Unfortunately, phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (74). In addition, less than one third of patients had symptoms related to the intravenous catheter site 24 hours before the diagnosis of phlebitis.

**Intravenous catheters should be inserted using sterile technique, and they should be changed frequently.** The institution of intravenous therapy teams has decreased the incidence of phlebitis by as much as 50% (73). This decrease is related not so much to surveillance of the intravenous catheter site as it is to frequent changing of intravenous catheters. The incidence of catheter-related phlebitis increases significantly after 72 hours. Therefore, intravenous catheters should be changed at least every 3 days.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or a palpable venous cord. Occasionally, suppurative will be present. Phlebitis is usually self-limited and resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antistaphylococcal agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein rarely is necessary.

### Wound Infections

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (75). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with hexachlorophene slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the infection rate. A 5-minute wound preparation immediately before surgery was as effective as preparation for 10 minutes. The wound infection rate increased with the duration of preoperative hospital stay as well as with the duration of surgery. In addition, incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that the incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers before surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates. A program instituting
these conclusions led to a decrease in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. The wound infection rate in most gynecologic services has been lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections that occur on postoperative days 1 through 3 are generally caused by streptococcal and *Clostridia* infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and debridement of the wound edges as necessary. Wound care, consisting of debridement and dressing changes 2 to 3 times daily with mesh gauze, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. Clean, granulating wounds can often be secondarily closed with good success, shortening the time required for complete wound healing.

The technique of delayed primary wound closure can be used in contaminated surgical cases to lower the incidence of wound infection. Briefly, this technique involves leaving the wound open above the fascia at the time of the initial surgical procedure. Vertical interrupted mattress sutures through the skin and subcutaneous layers are placed 3 cm apart but are not tied. Wound care is instituted immediately after surgery and continued until the wound is noted to be granulating well. Sutures may then be tied and the skin edges further approximated using sutures or staples. Using this technique of delayed primary wound closure, the overall wound infection rate has been shown to be decreased from 23% to 2.1% in high-risk patients (76).

**Pelvic Cellulitis**

Vaginal cuff cellulitis is present to some extent in most patients who have undergone hysterectomy. It is characterized by erythema, induration, and tenderness at the vaginal cuff. Occasionally, a purulent discharge from the apex of the vagina may also be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for gram-negative, gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can then be left open for dependent drainage or, alternatively, a drain can be placed into the lower pelvis through the cuff and removed when drainage, fever, and symptoms in the lower pelvic region have resolved.

**Intraabdominal and Pelvic Abscess**

The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is most likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of hematomas. The causative pathogens in patients who have intra-abdominal abscesses are usually polymicrobial in nature. The aerobes most commonly identified include *E. coli*, *Klebsiella*, *Streptococcus*, *Proteus*, and *Enterobacter*. Anaerobic isolates are also common, usually from the *Bacteroides* group. These pathogens arise mainly from the vaginal tract but also can be derived from the gastrointestinal tract, particularly when the colon has been entered at the time of surgery.

**Intra-abdominal abscess is sometimes difficult to diagnose.** The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, the diagnosis will depend on radiologic confirmation.
Ultrasonography can occasionally delineate fluid collections in the upper abdomen as well as in the pelvis. However, bowel gas interference makes visualization of fluid collections or abscesses in the midabdomen difficult to distinguish. Computed tomography scanning is, therefore, much more sensitive and specific for diagnosing intra-abdominal abscesses and often is the radiologic procedure of choice. Occasionally, if conventional radiologic methods fail to identify an abscess and the index of suspicion for an abscess remains high, labeled leukocyte scanning may be useful for locating the infected focus.

Standard therapy for intra-abdominal abscess is evacuation and drainage combined with appropriate parenteral administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can often be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance has obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage decreases. Transperineal and transrectal drainage of deep pelvic abscesses has been successful in 90% to 93% of patients, obviating the need for surgical management (77,78). For those patients in whom radiologic drainage is not successful, however, surgical exploration and evacuation are indicated. The standard approach to initial antibiotic therapy has been the combination of ampicillin, gentamicin, and clindamycin. Adequate treatment can also be achieved with currently available broad-spectrum single agents (including the broad-spectrum penicillin), second- and third-generation cephalosporins, levofloxacin and metronidazole, and the sulbactam-clavulanic acid–containing preparations (79–81).

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon infectious disorder; approximately 1,000 cases occur annually in the United States (82). The disorder is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, disseminated intravascular coagulation, and multiple organ system failure.

The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Hemolytic streptococcus was initially believed to be the primary pathogen responsible for the infection in necrotizing fasciitis (83). However, it is now evident that numerous other organisms are often cultured in addition to streptococcus, including other gram-positive organisms, coliforms, and anaerobes (83–87). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. In addition, noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin (86,87). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can cause septic shock, acid-base disturbances, and multiple organ impairment.

The diagnostic criteria for necrotizing fasciitis include extensive necrosis of the superficial fascia and subcutaneous tissue with peripheral undermining of the normal skin, a moderate to severe systemic toxic reaction, the absence of muscle involvement, Clostridia in wound and blood culture, major vascular occlusion, intensive leukocytic infiltration, and necrosis of subcutaneous tissue (88).

Most patients with necrotizing fasciitis suffer pain, which in the early stages of the disease is often disproportionately greater than that expected from the degree of...
cellulitis present. Late in the course of the infection, the involved skin may actually be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are common concomitant with the release of bacterial toxins as well as with bacterial sepsis, which is present in up to 40% of patients (89). The involved skin is initially tender, erythematous, and warm. Edema develops, and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. Eventually, as necrosis develops, the skin becomes gangrenous and may slough spontaneously. Most patients will have leukocytosis and acid-base abnormalities. Finally, subcutaneous gas may develop, which can be identified by palpation and by radiography. The finding of subcutaneous gas by radiography is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include Enterobacter, Pseudomonas, anaerobic streptococci, and Bacteroides, which, unlike clostridial infections, spare the muscles underlying the affected area (90). A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion to identify the etiologic organisms (87). Although necrotizing fasciitis often is diagnosed during surgery, a high index of suspicion as well as liberal use of frozen-section biopsy can often provide an early life-saving diagnosis and minimize morbidity (91).

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, intravenous drug abuse, and obesity (82,85,86,90,92). The most frequent site of infection has been in the extremities (87), but the infection can occur anywhere in the subcutaneous tissues, including the head and neck, trunk, and perineum. Necrotizing fasciitis has been known to occur after trauma, surgery, burns, and lacerations; as a secondary complication in perirectal infections or Bartholin duct abscesses; and de novo (82,83,86 87,91). Increased age, delay in diagnosis, inadequate debridement during initial surgery, extensive disease at the time of diagnosis, and the presence of diabetes mellitus are all factors that have been associated with an increased likelihood of mortality from necrotizing fasciitis (82,89). Early diagnosis and aggressive management of this lethal disease have led to improved survival. In an earlier series, the mortality rate was consistently higher than 30%; in more recent series, the mortality rate has decreased to less than 10% (90,93,94).

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid-base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and redebridement as necessary, and broad-spectrum antibiotic therapy. Many patients will benefit from central venous monitoring, as well as from high-caloric nutritional support.

During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can then be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins. Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms. Retrospective nonrandomized studies have demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appear to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis (82,95). The benefit of hyperbaric therapy shown in one study was remarkable, given that patients
receiving hyperbaric oxygen were sicker and had a higher incidence of diabetes mellitus, leukocytosis, and shock (82).

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Interestingly, temporary biologic closure of open wounds also seems to decrease bacterial growth (96). Amniotic membranes have also been shown to be an effective wound covering in patients with necrotizing fasciitis (92). A new technology that has been demonstrated in laboratory and clinical studies to significantly improve wound healing is a vacuum-assisted closure (VAC) method that uses a subatmospheric pressure technique (97,98). In situations in which spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Finally, skin flaps can be mobilized to help cover open wounds once the infections have resolved and granulation has begun.

Gastrointestinal Preparation

Preparation of the lower gastrointestinal tract before elective gynecologic surgery has several goals. In most gynecologic surgery, when the gastrointestinal tract is not entered, mechanical preparation of the bowel reduces gastrointestinal contents and thus allows more room in the abdomen and pelvis, facilitating the surgical procedure. If a rectosigmoid colon enterotomy occurs, the mechanical bowel preparation eliminates formed stool and reduces the risk of bacterial contamination, thus reducing infectious complications. Mechanical bowel preparation may be accomplished as presented in (Table 20.9). The traditional use of laxatives and enemas requires at least 12 to 24 hours and generally causes moderate abdominal distention and crampy pain. Randomized trials comparing traditional mechanical bowel preparation with oral gut lavage (PEG electrolyte solution, GoLYTELY) have found that the use of approximately 4 L of GoLYTELY (administered until the rectal effluent is clear) provides more complete, faster, and more comfortable bowel preparation (99). However, the ingestion of 4 L of fluid is problematic for many patients. An alternative mechanical preparation method is the use of oral sodium phosphate (Phospho-Soda). When evaluated in a randomized trial comparing the 4 L of GoLYTELY with oral sodium phosphate, colonoscopic examination disclosed that both methods were equally effective in colonic cleansing, and more patients preferred the sodium phosphate method (100).

High infection rates after colonic surgery have led to investigation of methods aimed at reducing these significant complications. Although mechanical bowel preparation is an essential part of all colonic surgery preparation regimens, it does not reduce the infection rate satisfactorily. Reduction of the number of pathogenic flora in the colon is the primary strategy to reduce infection after colonic surgery. The colon has the greatest concentration of bacteria in the body, including both aerobes and anaerobes. Anaerobes outnumber aerobes by 1,000:1. After reducing the bacterial load by mechanical preparation, the administration of antibiotics can further reduce the bacterial count in the colon. Of the many trials reported, the most widely accepted regimen combines erythromycin base and neomycin administered orally (see Table 20.9) (101–103). Many surgeons substitute metronidazole for the erythromycin; there is no significant difference in infection rates, but patients tolerate metronidazole better than erythromycin. The use of oral antibiotics 24 hours before colonic resection has reduced the infection rate from approximately 40% to 5% to 10% in randomized trials. Because these oral antibiotics are poorly absorbed and many do little to reduce infection from vaginal contamination, an intravenous antibiotic (first-generation cephalosporin) can be added to the preoperative regimen. Antibiotic bowel prophylaxis should be used for patients who are likely to undergo colorectal surgery (pelvic exenteration, ovarian cancer debulking) and those who are at high risk for rectal injury (such as severe cases of endometriosis or pelvic inflammatory disease).

Postoperative Gastrointestinal Complications

Ileus

Following abdominal or pelvic surgery, most patients will experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. Infection, peritonitis, and electrolyte disturbances may also result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus is minimal, and gastrointestinal function returns relatively rapidly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management.

Ileus is usually manifested by abdominal distention and should be evaluated initially by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of tenderness or rebound. The possibility that the patient’s signs and symptoms may be associated with a more serious intestinal obstruction or other intestinal complication must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. Abdominal radiography to evaluate the abdomen in the flat (supine) position as well as in the upright position usually will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel as well as air-fluid levels while the patient is in the upright position. Sometimes, massive dilation of the colon or stomach may be noted. The remote possibility of distal colonic obstruction suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, or barium enema. In the postoperative gynecology patient, especially in the upright position, the flat plate of the abdomen may also show evidence of free air. This common finding following surgery lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients.
The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravenous replacement fluids and electrolytes.

1. **A nasogastric tube should be used to evacuate the stomach of its fluid and gaseous contents.** Prolonged nasogastric suction continues to remove swallowed air, which is the most common source of air in the small bowel. Some clinicians prefer to use a longer small intestinal tube (Cantor or Miller-Abbott tube) (103). This tube, which usually has a mercury-filled bag on its distal tip, may be propelled by peristalsis through the pylorus and into the small bowel, thus allowing better evacuation of the small bowel. The disadvantage of long tubes is that they take a longer time to become positioned and may not enter the small bowel as a result of the decreased intestinal motility associated with ileus.

2. **Fluid and electrolyte replacement must be adequate to keep the patient well perfused.** Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. Gastrointestinal fluid losses from the stomach may lead to a metabolic alkalosis and depletion of other electrolytes as well. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.

3. **Most cases of severe ileus will begin to improve over a period of several days.** In general, this improvement is recognized by reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Follow-up abdominal radiographs should be obtained as necessary for further monitoring.

4. **When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet may be instituted.**

5. **If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought.** Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies may assist in the resolution, but prospective randomized data regarding this maneuver are lacking.

---

**Small Bowel Obstruction**

Obstruction of the small bowel following major gynecologic surgery occurs in approximately 1% to 2% of patients (104). The most common cause of small bowel obstruction is adhesions to the operative site. If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or large bowel mesentery. Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate. Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstruction following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

1. **Further evaluation after several days of conservative management may be necessary.** Evaluation of the gastrointestinal tract with barium enema and an
upper gastrointestinal study with small bowel assessment are appropriate. In most cases, complete obstruction is not documented, although a narrowing or tethering of the segment of small bowel may indicate the site of the problem.

2. **Further conservative management with nasogastric decompression and intravenous fluid replacement** may allow time for bowel wall edema or torsion of the mesentery to resolve.

3. **If resolution is prolonged and the patient’s nutritional status is marginal, the use of TPN may be necessary.**

4. **Conservative medical management of postoperative small bowel obstruction usually results in complete resolution.** However, if persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to evaluate surgically and manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

### Colonic Obstruction

Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is almost always associated with a pelvic malignancy, which in most cases will have been known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distention and abdominal radiography reveals a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. **Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiography requires immediate evaluation and surgical decompression by performing colectomy or colostomy.** Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complication of colonic perforation has an exceedingly high mortality rate.

### Diarrhea

Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. However, prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiography and stool samples tested for the presence of ova and parasites, bacterial culture, and *Clostridium difficile* toxin. Proctoscopy and colonoscopy may also be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics as well as fluid and electrolyte replacement. **C. difficile–associated pseudomembranous colitis may result from exposure to any antibiotic.** Discontinuation of these antibiotics (unless they are needed to treat another severe infection) is advisable, along with the institution of appropriate therapy. Oral *metronidazole* is a suitable agent for instituting therapy and is less expensive than *vancomycin*. Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required to obtain complete resolution of the pseudomembranous colitis.

### Fistula

Gastrointestinal fistulas are relatively rare following gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, or surgical injury to the large or
small bowel that was improperly repaired or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or ileus, except that a fever is usually a more prominent component of the patient’s symptoms. When fever is associated with gastrointestinal dysfunction postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis. Evaluation with abdominal pelvic CT scan may also assist in identification of a fistula and associated abscess. Recognition of an intraperitoneal gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula has drained spontaneously through the abdominal wall or vaginal cuff.

An enterocutaneous fistula arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy. Therapy should include nasogastric decompression, replacement of intravenous fluids as well as TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors have suggested the use of somatostatin to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A rectovaginal fistula that occurs following gynecologic surgery is usually the result of surgical trauma that may have been aggravated by the presence of extensive adhesions in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula. A small fistula that allows continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there is no hope of spontaneous closure are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation has resolved. After the fistula closure is healed and deemed successful, the colostomy can be closed.

Thromboembolism

Risk Factors

Deep venous thrombosis and pulmonary embolism are largely preventable, yet remain a significant complication in postoperative patients. The magnitude of this problem is relevant to the gynecologist, because 40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli (105), and it is the most frequent cause of postoperative death in patients with uterine or cervical carcinoma (106).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include a hypercoagulable state, venous stasis, and vessel endothelial injury. Risk factors include major surgery; advanced age; nonwhite race; malignancy; history of deep venous thrombosis, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Lieden, pregnancy, use of oral contraceptives, estrogens, or tamoxifen. Intraoperative factors associated with postoperative deep venous thrombosis included increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors to provide the appropriate level
A general outline of levels of thromboembolism risk are listed in Table 20.10.

*Risk factors: obesity, varicose veins, history of deep venous thrombosis or pulmonary embolism, current estrogen, tamoxifen, or oral contraceptive use.

A number of prophylactic methods have been shown to significantly reduce the incidence of deep venous thrombosis, and a few studies have included a large enough patient population to show a reduction in fatal pulmonary emboli. The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive.

#### Low-Dose Heparin

The use of small doses of subcutaneously administered heparin for the prevention of deep venous thrombosis and pulmonary embolism is the most widely studied of all prophylactic methods. More than 25 controlled trials have demonstrated that heparin given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively is effective in reducing the incidence of deep venous thrombosis. The value of low-dose heparin in preventing fatal pulmonary emboli was established by a randomized, controlled, multicenter international trial, which demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose heparin every 8 hours postoperatively (109). Trials of low-dose heparin in gynecologic surgery patients have shown a significant reduction in postoperative deep venous thrombosis.

Although low-dose heparin is considered to have no measurable effect on coagulation, most large series have noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma (110). Although relatively rare, thrombocytopenia is associated with low-dose heparin use and has been found in 6% of patients after gynecologic surgery (110). If patients remain on low-dose heparin for more than 4 days, it is reasonable to check their platelet count to assess the possibility of heparin-induced thrombocytopenia.
Low-Molecular-Weight Heparin

Low-molecular-weight heparins (LMWH) are fragments of heparin that vary in size from 4,500 to 6,500 daltons. When compared with unfractionated heparin, LMWH have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time and possibly also leading to fewer bleeding complications (111). An increased half-life of 4 hours results in increased bioavailability when compared with unfractionated heparin. The increase in half-life of LMWH also allows the convenience of once-a-day dosing.

Randomized controlled trials have compared LMWH with unfractionated heparin in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of deep venous thrombosis (DVT). Bleeding complications were also similar between the unfractionated heparin and LMWH groups (112). A meta-analysis of general surgery and gynecological surgery patients from 32 trials likewise indicated that daily LMWH administration is as effective as unfractionated heparin in DVT prophylaxis without any difference in hemorrhagic complications (113).

Mechanical Methods

Stasis in the veins of the legs occurs while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, plus the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative DVT have shown that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery (114).

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

Elastic Stocking

Controlled studies of graduated pressure stockings are limited but do suggest modest benefit when they are carefully fitted (115). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or midthigh (106). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. The simplicity of elastic stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care.

External Pneumatic Compression

The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent external compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and the current literature has not demonstrated superiority of one system over another. Calf compression during and after gynecologic surgery significantly reduces the incidence of DVT on a level similar to that of low-dose heparin. In addition to increasing venous flow and pulsatile emptying of the calf veins, external pneumatic compression also appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant (116).

The duration of postoperative external pneumatic compression has differed in various trials. External pneumatic compression may be effective when used in the operating room and for the first 24 hours postoperatively in patients with benign conditions who will ambulate on the first postoperative day (116,117).
External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy has been found to reduce the incidence of postoperative venous thromboembolic complications by nearly threefold (118), but only if calf compression was applied intraoperatively and for the first 5 postoperative days (119). Patients with gynecologic malignancies may remain at risk for a longer period than general surgical patients because of stasis and hypercoagulable states; therefore, these patients appear to benefit from longer use of external pneumatic compression.

External pneumatic leg compression has no significant side effects or risks and is considered slightly more cost-effective when compared with pharmacologic methods of prophylaxis (120). Of course, compliance in wearing the leg compression while in bed is of utmost importance, and the patient and nursing staff should be educated to the proper regimen for maximum benefit.

Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism

Because pulmonary embolism is the leading cause of deaths following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens is an essential part of management (105,106,121). In addition, the early recognition of DVT and pulmonary embolism and immediate treatment are critical. Most pulmonary emboli arise from the deep venous system of the leg following gynecologic surgery; the pelvic veins are a known source of fatal pulmonary emboli as well.

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not actually have DVT (122). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities (123). Because of the lack of specificity when signs and symptoms are recognized, additional tests should be performed to establish the diagnosis of DVT.

Diagnosis

Doppler Ultrasound  B-mode duplex Doppler imaging is currently the most common technique for the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly (124). Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. It should be recognized that Doppler imaging is less accurate when evaluating the calf and the pelvic veins.

Venography  Although venography has been the standard technique for diagnosis of DVT, other diagnostic studies are accurate when performed by a skilled technologist and, in most patients, may replace the need for routine contrast venography. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients (125). However, if the results of noninvasive imaging are normal or inconclusive and the clinician remains concerned given clinical symptoms, venography should be performed to obtain a definitive answer.

Magnetic Resonance Venography (MRV)  In addition to having a sensitivity and specificity comparable to venography, MRV may detect thrombi in pelvic veins that are not imaged by venography (126). The primary drawback to MRV is the time involved in examining the lower extremity and pelvis as well as the expense of this technology.
Treatment

Deep Venous Thrombosis

The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy. Treatment may be with either unfractionated heparin or LMWH, followed by 6 months of oral anticoagulant therapy with warfarin (Coumadin).

Unfractionated Heparin  After venous thromboembolism is diagnosed, unfractionated heparin should be initiated to prevent proximal propagation of the thrombus and allow physiological thrombolytic pathways to dissolve the clot. An initial bolus of 80 units per kilogram is given intravenously, followed by a continuous infusion of 1,000 to 2,000 units per hour (18 units/kg/hour). Heparin dosage is adjusted to maintain activated partial thromboplastin time (APTT) levels at a therapeutic level 1.5 to 2.5 times the control value. Initial APTT should be measured after 6 hours of heparin administration and the dose adjusted as necessary. Patients having subtherapeutic APTT levels in the first 24 hours have a risk of recurrent thromboembolism 15 times the risk of patients with appropriate levels. Patients, therefore, should be managed aggressively using intravenous heparin to achieve prompt anticoagulation. A weight-based nomogram is helpful in achieving a therapeutic APTT level (Table 20.11) (127). Oral anticoagulant (warfarin) administration should be started on the first day of heparin infusion. The international normalized ration (INR) should be monitored daily until a therapeutic level is achieved (2.0–3.0). The change in the INR resulting from warfarin administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, heparin should be administered until the INR has been maintained in a therapeutic range for at least 2 days, confirming proper warfarin dose. Intravenous heparin may be discontinued in 5 days if an adequate INR level has been established.

Low-Molecular-Weight Heparin  Two LMWH preparations (exoxaparin and dalteparin) have been shown to be effective in the treatment of venous thromboembolism and have a cost-effective advantage over intravenous heparin in that they may be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight-adjusted according to each LMWH preparation. Because LMWH have a minimal effect on APPT, serial laboratory monitoring of these levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases or those with renal impairment) has not been shown to be of significant benefit in a dose adjustment of

<table>

<tr>
<th>Time of Administration</th>
<th>Dose</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial dose</td>
<td>80-U/kg bolus, then 18 U/kg/h</td>
</tr>
</tbody>
</table>

The APTT* should be measured every 6 h and the heparin dose adjusted as follows:

- APTT <35 seconds (<1.2 × control): 80-U/kg bolus, then 4 U/kg/h
- APTT 35–45 seconds (1.2–1.5 × control): 40-U/kg bolus, then 2 U/kg/h
- APTT 46–70 seconds (1.5–2.3 × control): No change
- APTT 71–90 seconds (2.3–3 × control): Decrease infusion rate by 2 U/kg/h
- APTT >90 seconds (>3 × control): Hold infusion for 1 h, then decrease infusion rate by 3 U/kg/h

*APTT, activated partial thromboplastin time.

LMWH. The increased bioavailability associated with LMWH allows for twice-a-day dosing, potentially making outpatient management for a subset of patients an option. A meta-analysis involving more than 4,000 patients from 22 trials suggests that LMWH is more effective, safer, and less costly when compared with unfractionated heparin in preventing recurrent thromboembolism (128).

Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism. Many times, however, the signs are much more subtle and may be suggested only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest x-ray, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by ventilation-perfusion lung scan, or a spiral CT scan of the chest. Unfortunately, a high percentage of lung scans may be interpreted as “indeterminate.” In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be performed to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is as follows:

1. Immediate anticoagulant therapy, identical to that outlined for the treatment of DVT, should be initiated.

2. Respiratory support, including oxygen and bronchodilators and an intensive care setting, may be necessary.

3. Although massive pulmonary emboli are usually quickly fatal, pulmonary embolectomy has been performed successfully on rare occasions.

4. Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.

5. Vena cava interruption may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava umbrella or filter may be inserted percutaneously above the level of the thrombosis and caudad to the renal veins. In most cases, however, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient’s own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

Management of Medical Problems

Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus, thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

Diabetes Mellitus

According to the American Diabetes Association, 9.3 million American women, or 8.7% of all women older than 20 years, suffer from diabetes (129). Approximately 50% of
individuals with diabetes mellitus (DM) will have surgery during their life (130). Many of these procedures are a direct result of the complications of DM: retinopathy, nephropathy, large- and small-vessel occlusive disease, and coronary artery disease. It is the direct effect of DM on the end organs that determines the risk of surgery rather than the type or duration or the control of the condition itself. Diabetes mellitus is a complicated medical disorder of glucose metabolism that is related to a lack of production of or resistance to insulin.

Patients with DM experience exaggerated hyperglycemia during surgery. This hyperglycemia is multifactorial in origin and is secondary to increased catecholamine production, which inhibits pancreatic release of insulin and causes increased insulin resistance at the end organs. Elevations in instrumental hormones, such as cortisol, growth hormone, and glucagon, also enhance gluconeogenesis and glycogenolysis (131). Goals of the preoperative assessment and perioperative management are to ensure metabolic homeostasis and to anticipate problems arising from pre-existing complications.

Preoperative Risk Assessment

Preoperative risk assessment for diabetes should begin with a review of systems. Nocturia, polyuria, polydipsia, glucosuria, obesity, previous gestational diabetes, ethnicity, and family history are relevant aspects of the history. The current recommendations for establishing a diagnosis of diabetes are as follows (132):

1. Polyuria, polydipsia, unexplained weight loss with a random nonfasting glucose of >200 mg/dL, or

2. Fasting glucose >126 mg/dL, or

3. Two-hour postprandial 75 g glucose drink with serum glucose >200 mg/dL

Confirmation of the diagnosis requires a second test on a different day.

Preoperative risk assessment in the previously diagnosed individual with diabetes should begin with the knowledge of the patient’s routine glucose management strategies, medications, and baseline hemoglobin A1c (133). The presence of end-organ complications of diabetes should also be documented.

Large- and small-vessel arterial occlusive disease is the single most important risk factor in the preoperative setting. A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease (130). When extended surgery is possible, as with surgery for gynecologic cancer, exercise stress testing or dipyridamole-thallium imaging should be considered to rule out occult coronary artery disease. Preoperative and intraoperative administration of beta-blockers should be considered for patients undergoing surgery (134). Assessment of end-organ disease in the retina, kidney, and carotid arteries or evidence of peripheral vascular disease by the presence of foot ulcers should alert the clinician to the presence of small- or large-vessel disease. Diabetic nephropathy should be documented carefully preoperatively. Imaging studies using contrast dye should be avoided and alternative testing should be performed to reduce the incidence of acute tubular necrosis. If a contrast study must be performed, adequate hydration both before and after the procedure is essential, and oral metformin should be withheld for 24 to 48 hours after the procedure.

Preoperative evaluation should include examination of the skin and urine sediment to detect asymptomatic infection. Wound infections, skin infections, pneumonia, and urinary tract infections account for two thirds of the postoperative complications in patients with diabetes (131). There is a known predisposition for patients with DM to have gram-negative and staphylococcal pneumonia as well as an increased incidence of gram-negative and
group B streptococcal sepsis (135). Seven percent of individuals with diabetes will have postoperative gram-negative sepsis, a rate approximately seven times higher than of the nondiabetic population. These complications occur more often in patients with poor glucose control, probably caused by impaired leukocyte function in the presence of hyperglycemia (136,137). Individuals with DM have an increased risk of wound dehiscence and wound infection, as well as decreased amounts of collagen formation, fibroblast growth, and capillary growth, presumably secondary to the pathophysiology of small-vessel disease (138–140). Autonomic neuropathy has been documented in patients with DM, and these autonomic impairments can lead to intraoperative hypotension, cardiac arrhythmias, and sudden death as well as abnormal motility of the esophagus, stomach, and small intestine (131). Peripheral sensory and motor neuropathies may or may not be present. The presence of any manifestations of autonomic neuropathy intraoperatively should prompt close monitoring of the affected organ system in the postoperative period.

The traditional goal for glucose control during surgery is to maintain the glucose level between 150 mg/dL and 200 mg/dL. Perioperative hyperglycemia (greater than 250 mg/dL) is associated with increased susceptibility to infection and poor wound healing. Extreme hyperglycemia predisposes type I DM patients to metabolic acidosis, and surgery should be canceled until normal acid-base balance has been documented. Hyperosmolar hyperglycemic nonketotic states must be recognized before surgery. Electrolyte disturbances, especially those related to sodium and potassium, should be corrected preoperatively. Hypoglycemia should be avoided during the perioperative period.

The history and type of DM are important factors to consider when devising a perioperative management plan. Patients with noninsulin-dependent diabetes (type II) whose condition is controlled with oral hypoglycemic agents or diet are best treated with intravenous fluids containing no dextrose and generally should not be given insulin intraoperatively. Oral administration of hypoglycemic agents should be discontinued approximately 24 hours before the surgery, and hyperglycemic episodes in the perioperative period are treated with sliding-scale regular insulin only for blood sugar levels in excess of 250 mg/dL.

Insulin-dependent or type I diabetes poses a more difficult problem. Preoperatively, the goals include avoiding ketoacidosis and hypoglycemia, as well as, to a lesser extent, hyperglycemia. Traditionally, approximately one third to one half of the patient’s usual daily dose of NPH insulin (intermediate acting) is given subcutaneously the morning of surgery. An infusion of 5% dextrose is then given intraoperatively and additional regular insulin can be administered in the operating room. Alternatively, a continuous infusion of insulin and glucose in a fixed ratio has been advocated (130). The patient is much more prone to significant hypoglycemia, however, when a continuous infusion of insulin is given. Because of the severe implications associated with intraoperative hypoglycemia, this method may pose additional risks. There is no single regimen that is clearly superior for the intraoperative management of type I diabetic patients. However, a continuous intravenous insulin infusion is indicated for patients with unstable type I diabetes, those who require emergency surgery while in ketoacidosis, and those undergoing long, complex procedures (136). Consultation with endocrine and anesthesia colleagues can be helpful in managing these complex regimens.

Postoperative Management Postoperative monitoring of patients with DM includes careful monitoring of serum glucose levels. If an intravenous insulin regimen has been used, blood glucose levels must be checked every 1 to 2 hours. If a sliding-scale insulin administration is to be used, blood glucose should be checked and documented approximately every 6 hours until the patient is eating and stable on her preoperative regimen. The serum glucose level should be maintained at less than 250 mg/dL, and ideally in the “inpatient glycemic ‘hot spot’” between 100 and 200 mg/dL (130).
It is essential to prevent the development of severe hypoglycemia or hyperglycemia and the associated complications of diabetic ketoacidosis or a hyperosmolar state. Rigorous perioperative management may obviate some of the infectious and wound-healing complications that are more common in these patients (138). In one study, compulsive control of blood glucose contributed to a decreased overall mortality in myocardial infarction patients (141).

**Thyroid Syndromes**

Thyroid dysfunction should be suspected in any patient with a history of hyperthyroidism, use of thyroid replacement medication or antithyroid medication, prior thyroid surgery, or radioactive iodine therapy.

**Hyperthyroidism**

Diffuse toxic goiter (Grave’s disease) is the most common cause of hyperthyroidism and results from abnormal stimulation of the thyroid gland by antithyroid antibodies. Any signs or symptoms suggestive of weight loss, tachycardia, atrial fibrillation, goiter, or proptosis should initiate a more extensive laboratory evaluation of thyroid function. Total thyroxin, free T₄, free thyroxin (T₃), and thyroid-stimulating hormone (TSH) tests are useful in diagnosis. In hyperthyroidism, the free T₄ level will be elevated, and the TSH level will be suppressed (134). A new diagnosis of hyperthyroidism necessitates postponement of elective surgery until adequate treatment with antithyroid medication because of the risk of thyroid storm. Ideally, an euthyroid state should be maintained for 3 months before elective surgery. In emergent situations, beta-blockers can be used to counter sympathomimetic drive such as palpitations, diaphoresis, and anxiety. Antithyroid medications such as propylthiouracil (PTU) or radioactive iodine do not render patients euthyroid quickly enough for urgent surgery. Radioactive iodine requires 6 to 18 weeks to establish a euthyroid state (134). When thyroid dysfunction is corrected and maintained for several months, elective surgery can proceed without additional perioperative monitoring. Antithyroid medications should be resumed with return of bowel function. If a prolonged delay in resumption of oral intake is encountered, PTU and methimazole can be administered rectally (142). When time does not permit establishment of a euthyroid state preoperatively, oral administration of PTU and a beta-blocker can be implemented for 2 weeks before surgery, and with careful monitoring, optimal results can be achieved (140). Alternatively, oral beta-blockers, glucocorticoids, and sodium iopanoate can be used for 5 days, followed by surgery on the day 6 (142). In the emergent setting, however, close monitoring of the patient for tachycardia, arrhythmias, and hypertension is necessary. Beta-blockers can control these symptoms until definitive therapy can be initiated after recovery from surgery. Any signs suggestive of the development of thyroid storm—including hemodynamic instability, tachycardia, arrhythmias, hyperreflexia, diarrhea, fever, delirium, or congestive heart failure—mandate transfer to an intensive care setting for optimal monitoring and management in consultation with a medical endocrinologist. Such thyroid instability can be triggered by underlying infection, which requires diagnosis and treatment to facilitate management of this medical emergency. The mortality rate from thyroid storm has been reported to be between 10% and 75% (142). Treatment of thyroid storm consists of beta-blockers, thioamides, iodine, iodinated contrast agents, and corticosteroids (131). Aspirin should not be given for fever in the patient with thyroid storm because it may interfere with the protein binding of T₄ and T₃, resulting in increased free serum concentrations (131).

**Hypothyroidism**

The incidence of hypothyroidism is approximately 1% in the adult population, and 5% in adults older than 50 years (134). In women older than 60 years, the incidence of hypothyroidism may approach 6% (143). Hypothyroidism is 10 times more common in women than in men (134). Many such cases are secondary to previous antithyroid
therapy (radioactive iodine or thyroidectomy) for hyperthyroidism. The most common primary cause of hypothyroidism is Hashimoto’s thyroiditis, an autoimmune condition (134). A history of lethargy, cold intolerance, lassitude, weight gain, fluid retention, constipation, dry skin, hoarseness, periorbital edema, and brittle hair can be indicative of inadequate thyroid function. In this setting, physical findings of increased relaxation phase of deep tendon reflexes, cardiomegaly, pleural or pericardial effusions, or peripheral edema should stimulate further investigation of thyroid function by assessment of TSH and free T 4 levels. Hypothyroidism decreases cardiac output by 30% to 50% as a result of decreased stroke volume and heart rate (144). Hyponatremia may also be associated with hypothyroidism because of the inability to the kidney to excrete water (144). When elective surgery is planned for severely hypothyroid patients, surgery should be postponed until thyroid replacement therapy has been initiated (134). In patients with mild or moderate hypothyroidism, the delay of surgery is controversial (134).

For young patients with mild to moderate hypothyroidism, a starting dose of 1.6 µg/kg of thyroid hormone replacement can be given. In elderly patients, thyroxin dosage (0.025 mg once a day) should be doubled every 2 weeks until the patient is taking a dose of 0.15 mg daily (143). Dosage levels can ultimately be titrated against TSH levels. In severely hypothyroid patients requiring urgent or emergent surgery, intravenous T 3 or T 4 may be given, along with intravenous corticosteroids to avoid consequences of unrecognized adrenal insufficiency (131,134).

In the immediate postoperative setting, T 4 therapy can be held for 5 to 7 days while waiting for return of bowel function because the half-life of circulating T 4 is approximately 5 to 9 days (131). If more than 5 to 7 days of decreased bowel function are expected, T 4 can be given by the intramuscular or intravenous route at approximately 80% of the oral dose (143,144).

**Adrenal Insufficiency**

Adrenal insufficiency may result in catastrophic postoperative complications, including death. The most common cause of adrenal insufficiency in the surgical patient is secondary to the exogenous use of corticosteroids. Therefore, the physician should ascertain whether a patient has used exogenous steroids for asthma, malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The type of surgical procedure and its associated stress should also be taken into consideration. The use of high doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on wound healing and immunocompetence.

The daily replacement dose of cortisol is approximately 5 to 7.5 mg of prednisone. **Suppression of the hypothalamic–pituitary–adrenal axis by exogenous steroids for more than a few weeks may produce relative adrenal insufficiency.** When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year. Short courses of low-dose oral steroids (less than 5 mg of prednisone in a single morning dose for any duration of time, alternate-day dosing of short-acting glucocorticoids, and any dose of corticosteroids given for less than 3 weeks) are not thought to cause clinically significant suppression of the hypothalamic–pituitary–adrenal axis (131).

If either the dose or duration of glucocorticoid administration exceeds the preceding regimen, biochemical tests have been recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess hypothalamic–pituitary–adrenal function is the cosyntropin stimulation test. **Cosyntropin**, a synthetic analog of adrenocorticotropic hormone, is given in a dose of 250 µg (0.25 mg) intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of greater than 18 to 20 µg/dL indicates adequate adrenal function (134). If the history regarding exogenous steroid use is unclear, the cosyntropin stimulation test should
be considered as a preoperative test to determine if the patient will need perioperative glucocorticoid coverage. The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress (Table 20.12) (145).

For minor surgical stress, such as colonoscopy, the glucocorticoid target is approximately 25 mg of hydrocortisone equivalent on the day of the procedure (145). For moderate surgical stress, for example, open cholecystectomy, the glucocorticoid target is 50 to 75 mg of hydrocortisone equivalent on the day of the procedure and tapered quickly for 1 to 2 days (145). The patient should receive her normal daily dose preoperatively, followed by 50 mg of hydrocortisone intravenously administered intraoperatively. For major surgical stress, such as liver resection, the glucocorticoid target range is 100 to 150 mg hydrocortisone equivalent on the day of the procedure, tapering rapidly over the next 1 to 2 days to the usual dosage (145). The patient should receive her normal daily dose preoperatively.

**Administration of high-dose steroids should be stopped as soon as possible postoperatively because they can inhibit wound healing and promote infection.** Hypertension and glucose intolerance also can develop. When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering may be required. The previously recommended approach was to halve the dose of hydrocortisone on a daily basis until a dose of 25 mg is reached. Eliminating one daily dose each day until the drug has been stopped has been considered the safest method of withdrawal; however, no

IV, intravenously.

*Patients receiving 5 mg/d or less of prednisone should receive their normal daily replacement but do not require supplementation. Patients who receive greater than 5 mg/d of prednisone should receive the above therapy in addition to their maintenance therapy.

Consensus on the timing or duration of steroid tapering currently exists. Addison’s disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension after steroids are withdrawn. In addition to blood and isotonic fluid replacement, a “stress” dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia have been excluded.

Cardiovascular Diseases

The incidence of perioperative cardiovascular complications has decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (146).

Preoperative Evaluation

The goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Patients with a history of cardiac disease should be evaluated for worsening of symptoms, which indicates progressive or poorly controlled disease. Records of previous treatment should be obtained. Prescriptions for antihypertensive, anticoagulant, antiarhythmic, antilipid, or antianginal medications may be the only indication of cardiac problems. In patients without known heart disease, the presence of DM, hyperlipidemia, hypertension, tobacco use, or a family history of heart disease identifies patients at higher risk for heart disease who should be more carefully screened.

On physical examination, the presence of findings such as hypertension, jugular venous distention, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruits should prompt a more complete evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels are particularly important in patients taking diuretics and digitalis. Blood urea nitrogen and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM. Chest radiography and electrocardiography are mandatory as part of the preoperative evaluation, and the results may be particularly helpful when compared with those of previous studies.

Coronary Artery Disease

Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (147). In patients who have had a prior myocardial infarction, however, the reinfarction rate is 2.8% to 7% (148). The risk of reinfarction is inversely proportional to the length of time between infarction and surgery. At 3 months or less, the risk of reinfarction is 5.7%, and from 3 to 6 months, the rate falls to 2.3%. Six months after myocardial infarction, the reinfarction rate is 1.5% (147). Fortunately, careful perioperative management can lower the reinfarction rate even in patients who have had recent infarctions. Perioperative myocardial infarction is associated with a mortality rate of 26% to 70% (149).

Because of the high mortality and morbidity associated with perioperative myocardial infarction, much effort has been made to predict perioperative cardiac risk. A prospective evaluation of preoperative cardiac risk factors using a multivariate analysis identified independent cardiac risk factors for patients undergoing noncardiac surgery (149). Using these factors, a cardiac risk index was created that placed a patient in one of four risk classes. This cardiac risk index was then further modified and validated prospectively, resulting in the most current tool for clinical risk assessment in nonemergent major
noncardiac surgery, the Revised Cardiac Risk Index (150). Risk factors include high-risk surgical procedures, history of ischemic heart disease, history of congestive heart failure, history of transient ischemic attack or stroke, preoperative insulin therapy, and preoperative serum creatinine levels greater than 2.0 mg/dL. Depending on the number of risk factors, the risk of major cardiac events (myocardial infarction, cardiac arrest, pulmonary edema, and complete heart block) range from 0.5% to 9.1% (Table 20.13).

Risk assessment is stratified into three major categories: (i) clinical predictors, (ii) functional capacity, and (iii) surgery-specific risk (151). Clinical predictors of increased perioperative cardiac risk are divided into major, intermediate, and minor factors (Table 20.14). The patient’s functional status is assessed by a thorough history (Table 20.15), and self-reported exercise tolerance can be used to predict perioperative risk (152). Patients with

### Table 20.14 Clinical Predictors of Increased Perioperative Cardiovascular Risk

#### Major
- Unstable coronary syndromes (acute or recent MI, unstable or severe angina)
- Decompensated congestive heart failure
- Significant arrhythmias (high-grade AV block, symptomatic ventricular arrhythmias, supraventricular arrhythmias with uncontrolled ventricular rate)
- Severe valvular disease

#### Intermediate
- Mild angina
- Prior myocardial infarction (more than 1 month before planned surgery)
- Compensated or prior congestive heart failure
- Diabetes mellitus
- Renal insufficiency

#### Minor
- Advanced age
- Abnormal ECG (LVH, LBBB, ST-T abnormalities)
- Rhythm other than sinus
- Low functional capacity
- History of stroke
- Uncontrolled systemic hypertension

MI, myocardial infarction; AV, atrioventricular; ECG, electrocardiogram; LVH, left ventricular hypertrophy; LBBB, left bundle branch block.
Poor functional capacity have higher perioperative cardiac risk and should be considered for preoperative cardiac function testing (148). Surgery-specific risk is subdivided into high-risk procedures (emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss), intermediate-risk procedures (other intraperitoneal operations), and low-risk procedures (endoscopic surgery, breast surgery, and superficial procedures).

In an effort to quantitate preoperative cardiac risk, several tests have been used to assess cardiovascular function. *Exercise stress testing before surgery can identify patients who have ischemic heart disease not apparent at rest.* These patients have been shown to be at increased risk of developing cardiac complications in the perioperative period. In a study of patients undergoing peripheral vascular surgery, a high-risk group of patients was identified who had ischemic electrocardiographic changes when they exercised to less than 75% of their maximal predicted heart rate. In this group, the incidence of perioperative myocardial infarction was 25%, and the overall cardiac mortality rate was 18.5%. Conversely, no perioperative infarctions occurred in patients who were able to exercise to more than 75% of their maximal predicted heart rate and who had no electrocardiographic evidence of ischemia (153). However, the prognostic value of stress testing was not supported in another prospective study that found that only an abnormal preoperative resting electrocardiography result was an independent risk factor (154). The exercise stress test must be selectively applied to a high-risk population because its predictive value depends on the prevalence of the disease. Therefore, it is not prudent to screen all patients preoperatively; it is preferable to rely on a careful history to identify patients with symptoms of cardiac disease for whom the test would be most predictive.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. *Dipyridamole-thallium scanning* may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity, and it relies on the ability of dipyridamole to dilate normal coronary arteries but not stenotic vessels. Normally perfused myocardium readily takes up thallium when it is given intravenously. Conversely, hypoperfused myocardium does not show good uptake of thallium when scanned 5 minutes after injection. Reperfusion and uptake of thallium 3 hours after injection identify viable but high-risk
myocardium. Old infarctions are identified as areas without uptake. Several studies have shown a risk of perioperative myocardial infarction in patients with areas of reperfusion of thallium uptake ranging from 20% to 33% (155,156). The dipyridamole-thallium scan is applicable to patients who are unable to exercise because it uses a medically induced “stress.”

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after dobutamine infusion to identify patients at high risk for cardiac events. Positive and negative predictive values are similar to those of dipyridamole-thallium testing (157,158). Coronary angiography should be considered only in patients who have an indication for angiography independent of the planned surgery, such as patients with acute coronary syndromes, unstable angina, angina refractory to medical therapy, or high-risk results on noninvasive testing.

Preoperative testing should be used discriminately in intermediate-risk patients. Controversy exists regarding the accuracy of these tests to provide prognostic information beyond what is obtained from clinical risk stratification for nonvascular procedures. Diagnostic testing should not lead to unnecessary additional testing or harmful delays in surgery. The American College of Cardiology and the American Heart Association present an updated detailed algorithm that incorporates risk-factor stratification to guide clinicians to proceed directly to surgery, obtain noninvasive testing, consider coronary angiography, or consider delay of surgery and risk-factor modification (151).

It is rare for patients who are younger than 50 years and who do not have diabetes, hypertension, hypercholesterolemia, or coronary artery disease to suffer a perioperative myocardial infarction. However, patients with coronary artery disease are at increased risk of myocardial infarction in the postoperative period. Prevention, early recognition, and treatment are important because myocardial infarctions that occur in the postoperative period have mortality rates of approximately 50% and are more lethal than those that are not associated with surgery.

Nearly two thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively. Although the pathophysiologic factors are complex, the causes of postoperative myocardial ischemia and infarction are related to decreased myocardial oxygen supply coupled with increased myocardial oxygen requirements. In postoperative patients, conditions that decrease oxygen supply to the myocardium include tachycardia, increased preload, hypotension, anemia, and hypoxia (159). Conditions that increase myocardial oxygen consumption are tachycardia, increased preload, increased afterload, and increased contractility. Tachycardia and increased preload are the most important causes of ischemia, because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen demand. Tachycardia decreases the diastolic time, which, when the coronary arteries are perfused, decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or intra-arterial line placement, emergence from anesthesia, pain, and anxiety. This stress results in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can also induce ischemia.

Postoperative myocardial infarction is often difficult to diagnose. Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only
50% of patients with postoperative infarction because myocardial pain may be masked by coexisting surgical pain and the use of analgesia (147). Thus, it is important to maintain a high level of suspicion for postoperative infarction in patients with coronary artery disease. The presence of arrhythmia, congestive heart failure, hypotension, dyspnea, or elevations of pulmonary artery pressure may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. Measurement of creatinine phosphokinase myocardial band (CPK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction.

Despite the high incidence of silent myocardial infarction, routine use of postoperative electrocardiography (ECG) for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. Currently, the American College of Cardiology and American Heart Association recommend postoperative surveillance of perioperative myocardial infarction in patients with known or suspected coronary artery disease (151). A recent study of patients older than 50 years undergoing major noncardiac surgery found that immediate postoperative ECG may be a valuable tool in patients who have lower risks when undergoing major noncardiac surgery (160). However, this is a preliminary study, and further investigation is warranted. If routine screening of asymptomatic patients is desired, ECG should be performed 24 hours following surgery because significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium as well as decreasing myocardial oxygen utilization. Most patients benefit from supplemental oxygen in the postoperative period, although special care should be exercised in patients with COPD. Oxygenation can easily be monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity as well as resultant tachycardia and should, therefore, be carefully corrected in high-risk patients.

Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production. Beta-blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. Perioperative use of β₁-selective beta-blocker has been shown to significantly reduce perioperative ischemia, myocardial infarction, and overall mortality caused by cardiac death and congestive heart failure in the perioperative period (161–163). Perioperative beta-blocker therapy is recommended for patients with at least two of the following minor risk factors: age 65 years or older, hypertension, current smoker, serum cholesterol at least 240 mg/dL, or DM not requiring insulin therapy (162). Therapy also is recommended for patients having any one of the risk factors defined by the Revised Cardiac Risk Index (150). The timing and optimal duration of beta-blocker therapy remains an area of uncertainty. Current evidence suggests initiating therapy at least 1 week before surgery and continuing throughout the hospitalization. For patients receiving beta-blockade therapy before surgery, therapy should be continued in the perioperative period because abrupt withdrawal results in a rebound hyperadrenergic state.

Although prophylactic nitrates have been used in the perioperative period for many years, this practice remains controversial. Nitroglycerin enhances blood flow to ischemic areas, increases collateral flow, increases myocardial oxygenation, and reduces angina (164–167). The route of administration, dosage, and duration of therapy are controversial; thus, perioperative treatment with nitrates should be initiated in consultation with a cardiologist. Likewise, calcium-channel blockers have not proved useful in the prophylaxis of perioperative myocardial ischemia (168).
Congestive Heart Failure patients with congestive heart failure (CHF) face a substantially increased risk of myocardial infarction during and after surgery (149). The postoperative development of pulmonary edema is a grave prognostic sign and results in death in a high percentage of patients (169). Because patients with heart failure at the time of surgery are significantly more likely to develop pulmonary edema perioperatively, every effort should be made to diagnose and treat CHF before surgery (170). The signs and symptoms of CHF are listed in Table 20.16 and should be assessed based on preoperative history and physical examination. Patients who are able to perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

To prevent severe postoperative complications, CHF must be corrected preoperatively. Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are also taking digitalis. In addition to diuretics and digitalis, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. In general, it is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period.

Postoperative CHF results most frequently from excessive administration of intravenous fluids and blood products. Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause. Postoperative diagnosis of CHF is often more difficult than preoperative diagnosis because the signs and symptoms of CHF are not specific and may result from other causes. The most reliable method of detecting CHF is chest radiography, in which the presence of cardiomegaly or evidence of pulmonary edema is a helpful diagnostic feature.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of pulmonary edema may include the use of intravenous furosemide, supplemental oxygen, morphine sulfate, and elevation of the head of the bed. Intravenous aminophylline may be useful if cardiogenic asthma is present. Electrocardiography, in addition to laboratory evaluation, including arterial blood gas, serum electrolyte, and renal function chemistry measurements, should be obtained expediently. If the patient’s condition does not improve rapidly, she should be transferred to an intensive care unit.

Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even
brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents as well as surgical stress contribute to the development or worsening of arrhythmias. In patients undergoing continuous electrocardiographic monitoring during surgery, a 60% incidence of arrhythmias, excluding sinus tachycardia, has been reported (171). Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias (171). Conversely, patients without cardiac disease are more likely to develop supraventricular arrhythmias during surgery. Patients taking antiarrhythmic medications before surgery should continue taking those drugs during the perioperative period. Initiation of antiarrhythmic medications is rarely indicated preoperatively, but consultation with a cardiologist is recommended for patients in whom arrhythmias are detected before surgery.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. Conversely, a pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery (172). In emergency situations, a pacing pulmonary artery catheter can be used. Before performing surgery on patients with a permanent pacemaker, the type and location of the pacemaker should be determined because electrocautery units may interfere with demand-type pacemakers (173). When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg to minimize interference. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate mode.

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease (174–176). However, the presence of a left bundle branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

Valvular Heart Disease

Although there are many forms of valvular heart disease, primarily two types— aortic and mitral stenosis—are associated with significantly increased operative risk (177). Patients with significant aortic stenosis appear to be at greatest risk, which is further increased in the presence of atrial fibrillation, congestive heart failure, or coronary artery disease. Significant stenosis of aortic or mitral valves should be repaired before elective gynecologic surgery (148).

Severe valvular heart disease usually is evident during physical exertion. Common findings in such patients are listed in Table 20.17. The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptyis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm², and diagnosis can be confirmed by echocardiography or cardiac catheterization.

Patients with valvular abnormalities have been subdivided by the American Heart Association into risk groups for the development of subacute bacterial endocarditis following surgery (61). Patients with prosthetic valves are classified as high risk, whereas patients with mitral valve prolapse with regurgitation, history of rheumatic heart disease, or bicuspid aortic valve are considered at moderate risk. Patients in both high- and moderate-risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis (see Table 20.7).
Patients with aortic and mitral stenosis tolerate sinus tachycardia and other tachyarrhythmias poorly. In patients with aortic stenosis, sufficient levels of *digitalis* should be provided to correct preoperative tachyarrhythmias, and *propranolol* may be used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, *digitalis* should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (178). These patients should receive antibiotic prophylaxis (see Table 20.7), and anticoagulant therapy should be discontinued during the perioperative period. If the patient is taking *aspirin* therapy, it should be discontinued 1 week before the procedure and restarted as soon as it is considered safe by the surgeon. Usually, *warfarin* (*Coumadin*) is withheld 72 hours before surgery, and anticoagulation is obtained by intravenous administration of *heparin* once the INR falls below 2.0 (179,180). *Heparin* is discontinued 6 to 8 hours before surgery and resumed when the risk of bleeding is low and continued until the patient is returned to *warfarin* maintenance therapy (180,181). Alternatively, *warfarin* can be stopped 72 hours before the procedure and restarted within 24 hours of the procedure (182). The American College of Cardiology and American Heart Association Guidelines recommend perioperative heparinization in patients who have more thrombogenic valves, recent thrombosis, or embolus (arbitrarily within 1 year); those with more than three of the following risk factors: atrial fibrillation, previous thromboembolism, hypercoagulable condition, and mechanical prosthesis; or those with one risk factor and a mechanical valve in the mitral position (180). Both methods of management have essentially no risk of thromboembolic complications and bleeding complication rates of approximately 15%.

In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Patients with mitral stenosis also frequently have pulmonary hypertension and decreased airway compliance. Therefore, they may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period. Even sinus tachycardia can be deleterious.
because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with atropine. Supraventricular dysrhythmias may be controlled with verapamil or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

**Hypertension**

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality (170). However, patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiography, blood count, urinalysis, and serum electrolytes and creatinine measurement. Antihypertensive medications should be continued perioperatively. Of note, beta-blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension.

Patients with diastolic pressures higher than 110 mm Hg or systolic pressures higher than 180 mm Hg should receive medication to control their hypertension before surgery. Chronically hypertensive patients are very susceptible to intraoperative hypotension because of impaired autoregulation of blood flow to the brain and, therefore, require a higher mean arterial pressure to maintain adequate perfusion (183). Conversely, during induction of anesthesia, episodes of hypertension occur, and such episodes are seen more frequently in patients with baseline hypertension.

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 20.18.

**Hemodynamic Monitoring**

Hemodynamic monitoring has become integral to the perioperative management of patients with cardiovascular and pulmonary disease. The major impetus for this advancement resides in the need for the quantitative estimate of cardiac function, resulting in the development of bedside pulmonary artery catheterization. The impact of monitoring of cardiac function is demonstrated by the significant reduction of myocardial infarctions in high-risk patients who are aggressively monitored for 72 to 96 hours postoperatively (147).

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava. A water manometer or a calibrated pressure transducer is connected to the CVP line, thus allowing an estimation of right atrial pressure to be obtained. Right atrial pressure is determined by the balance between cardiac output and venous return.

IV, intravenous.
Cardiac output is determined by heart rate, myocardial contractility, preload, and afterload. Thus, if the pulmonary vascularity and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and has been considered the standard estimator of left ventricular pump function. Venous return is determined primarily by the mean systemic pressure, which propels blood toward the heart, balanced against resistance to venous return, which acts in the opposite direction. Thus, if right ventricular function is normal, the CVP accurately reflects intravascular volume.

Left and right ventricular function is frequently abnormal or discordant; therefore, the relationship of CVP to cardiac function and to intravascular volume is not maintained. When this occurs, measurement of pulmonary artery occlusion pressure is required to accurately assess volume status and cardiovascular function. The use of a pulmonary artery catheter also allows detection of changes in cardiovascular function with more sensitivity and rapidity than clinical observation.

The balloon-tipped pulmonary artery catheter (Swan-Ganz catheter) can measure pulmonary artery and pulmonary artery occlusion pressures (184). The catheter can measure cardiac output, be used to perform intracavitary electrocardiography, and provide temporary cardiac pacing. The standard pulmonary artery occlusion catheter is a 7-French, radiopaque, flexible, polyvinyl chloride, 4-lumen catheter with a 1.5-mL latex balloon at its distal tip. Most often, a right internal jugular cannulation is used for placement of the catheter, because this site provides the most direct access into the right atrium and has fewer complications when compared with a subclavian route of placement. After the catheter is placed into the right atrium, the balloon is inflated, and the catheter is pulled by blood flow through the right ventricle into the pulmonary artery. The position of the catheter can be identified and followed by the various pressure waveforms generated by the right atrium, right ventricle, and pulmonary artery. As the catheter passes through increasingly smaller branches of the pulmonary artery, the inflated balloon eventually occludes the pulmonary artery.

The distal lumen of the catheter, which is beyond the balloon, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Thus, pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg. Additionally, because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. This thermodilution method is performed by injecting cold 5% dextrose in water through the proximal port of the catheter, which cools the blood entering the right atrium. The change in temperature measured at the more distal thermistor (4 cm from the catheter tip) generates a curve proportional to cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-to-normal wedge pressure, and a cardiac output of 3 L/minute is most likely hypovolemic. Conversely, the same patient with a cardiac output of 8 L/minute is probably septic with resultant low systemic vascular resistance.

Pulmonary artery catheters are associated with a small but significant complication rate. The complications can be grouped into those occurring during venous cannulation and those resulting from the catheter or its placement. The most common problems encountered during venous access are cannulation of the carotid or subclavian artery and introduction of a pneumothorax. Problems resulting from the catheter itself include dysrhythmias, sepsis, and disruption of the pulmonary artery. Pulmonary artery catheters should be placed under the supervision of experienced personnel in a setting in which complications can be rapidly diagnosed and treated.

The effect of pulmonary artery catheter use on patient outcome has become controversial. In 1996, a reevaluation of pulmonary artery catheters and initiation of randomized clinical
trials to assess their benefit was recommended (185). At that time, others published a large study demonstrating a higher mortality rate in patients who received a pulmonary artery catheter than those that did not have a pulmonary artery catheter (186). The design of this study was questionable, however, and it was retrospective and not randomized. A meta-analysis evaluating 12 randomized clinical trials showed a statistically significant reduction in morbidity (63% versus 74%, P < 0.01) in the pulmonary artery catheter group, but no significant difference in mortality (187). Finally, in a recent randomized blinded controlled trial of 1,994 high-risk (American Society of Anesthesiologists class III or IV risk) subjects 60 years of age or older undergoing urgent or elective major noncardiac surgery, therapy guided by pulmonary artery catheters showed no benefit over standard care with central venous catheters (188). Therefore, routine preoperative use of pulmonary artery catheters in noncardiac surgery patients is no longer indicated.

### Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and, therefore, should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

### Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. Current anesthetic and surgical practice ideally recommend a hemoglobin level of greater than 10 g/dL or a hematocrit of greater than 30%. Such numbers are only guidelines and should be applied on an individual basis. Oxygen-carrying capacity and tissue oxygenation is provided by the circulating blood volume. Usually this capacity is reflected by the hemoglobin level and hematocrit. Under certain circumstances, however, this is not the case. After an acute blood loss or before plasma expansion by extracellular fluid has occurred, hematocrit measurements may be normal despite a low circulating blood volume. Conversely, overhydration may result in low hematocrit and hemoglobin levels despite adequate red blood cell mass.

Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. The effects of anemia depend on its magnitude, the rate at which it occurs, the oxygen requirement of the patient, and the ability of physiologic mechanisms to compensate (189). Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls (190). A patient with ischemic heart disease will not tolerate anemia as well as a healthy young patient. Therefore, the presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Conversely, patients with long-standing anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality (191).

Patients with normal hematocrit levels may store three or more units of autologous blood preoperatively to reduce the need for allogeneic blood transfusion and minimize the risk of infections and immunologic problems (192). Recombinant human erythropoietin may increase collection and reduce preoperative anemia in these patients (193,194). Further, intraoperative blood collection and homologous transfusion can be employed to limit the need for allogeneic blood transfusion.

Autologous blood donation has been advocated as a safer alternative for the patient; however, the use of preoperative autologous blood donation has come under scrutiny (195). Preoperative autologous blood may lead to more liberal blood transfusion, iatrogenic anemia, volume overload, and bacterial contamination (196). Furthermore,
preoperative autologous blood donation is poorly cost-effective (197). The National Heart, Lung, and Blood Institute does not recommend collection of autologous blood for procedures with a likelihood of transfusion less than 10%, such as uncomplicated abdominal and vaginal hysterectomies (198).

**Platelet and Coagulation Disorders**

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Thus, functional platelets and coagulation pathways are necessary to prevent excessive surgical bleeding. Platelet dysfunction is encountered preoperatively more frequently than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm$^3$, and the normal life span of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than 100,000/mm$^3$ and the platelets are functioning normally, there is little chance of bleeding during surgical procedures. Patients with a platelet count higher than 75,000/mm$^3$ almost always have normal bleeding times, and a platelet count higher than 50,000/mm$^3$ is probably adequate. **A platelet count lower than 20,000/mm$^3$ will often be associated with severe and spontaneous bleeding.** Platelet counts higher than 1,000,000/mm$^3$ are often, paradoxically, associated with bleeding.

If the patient’s platelet count is lower than 100,000/mm$^3$, an assessment of bleeding time should be obtained. If the bleeding time is abnormal and surgery must be performed, an attempt should be made to raise the platelet count by administering platelet transfusions immediately before surgery. In patients with immune destruction of platelets, human leukocyte antigen (HLA)–matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematology consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. **Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon.** Decreased platelet production may be drug induced and has been associated with the use of sulfaonamides, cinchona alkaloids, thiazide diuretics, NSAIDs, gold salts, penicillamine, anticonvulsants, and heparins (199). Decreased platelet count is a feature of several diseases, including vitamin B$_{12}$ and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by diseases such as idiopathic thrombocytopenia purpura and collagen vascular disorders. **Consumptive thrombocytopenia is a feature of disseminated intravascular coagulation, which is encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.**

Platelet dysfunction most often is acquired, but may be inherited. Occasionally, a patient with von Willebrand’s disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. More commonly, however, platelet dysfunction results from the use of drugs (e.g., aspirin and amitriptyline), and in patients with resulting prolonged bleeding times, the drug should be withheld for 7 to 10 days before surgery. Uremia and hepatic diseases can also affect platelet function.

Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of
the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy has been instituted.

Similarly, disorders of the coagulation cascade often are diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Many women with menorrhagia are referred for surgical intervention and require a thorough preoperative evaluation for possible inherited disorders of hemostasis, such as factor VIII (hemophilia), factor IX (Christmas disease), factor XI deficiencies, and von Willebrand’s disease. Von Willebrand’s disease is the most common hereditary bleeding disorder, with prevalence in the general population of 0.8% to 1.3% (200,201). In women with menorrhagia, the prevalence of von Willebrand’s disease increases to 13% to 20% (202,203). Identified women can potentially be treated effectively with desmopressin nasal spray, thus avoiding unanticipated or excessive bleeding during surgery. In the absence of a genetic diagnosis, the diagnosis of von Willebrand’s disease is difficult and involves a combination of clinical and laboratory assessments, including von Willebrand factor antigen and von Willebrand factor functional activity or ristocetin cofactor assay. Physiologic fluctuations occur with von Willebrand factor levels, requiring repeat testing and consultation or referral to a hematologist. Nevertheless, it is recommended that women presenting with menorrhagia without obvious pelvic abnormalities should be routinely screened for inherited bleeding disorders before undergoing invasive procedures.

There are few commonly prescribed drugs that affect coagulation factors, the exceptions being warfarin and heparin. Disease states that may be associated with decreased coagulation factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and disseminated intravascular coagulation.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening is not warranted in patients who do not have historical evidence of a bleeding problem (204). However, patients who are seriously ill or who will be undergoing extensive surgical procedures should undergo testing preoperatively to determine prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count.

| White Blood Cells and Immune Function | Abnormally high or low white blood cell counts are not an absolute contraindication to surgery; however, they should be considered relative to the need for surgery. Evaluation of an elevated or decreased white blood cell count should be undertaken before elective surgery. Clearly, patients with absolute granulocyte counts lower than 1,000/mm³ are at increased risk of severe infection and perioperative morbidity and mortality and should undergo surgery only for life-threatening indications (205). |
| Blood Component Replacement | Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be due to dilution of platelets and labile coagulation factors by platelet- and factor-poor packed red blood cells (PRBCs), fibrinolysis, and disseminated intravascular coagulation. Reports of massive transfusions in soldiers reveal that for those in whom thrombocytopenia developed following red blood cell replacement, bleeding diatheses that responded to infusion of fresh blood but not fresh-frozen plasma (FFP) also developed (206). The investigators concluded that dilutional thrombocytopenia is a major cause of posttransfusion bleeding. However, more recently, in a prospective, randomized, double-blind study, prophylactic platelet administration during massive transfusion was not helpful (207). |
Although it seems that these studies are contradictory, they demonstrate the need for obtaining platelet counts during transfusion of large amounts of blood. If clinical evidence of excessive bleeding exists and the platelet count is lower than 100,000/mm³, platelets should be transfused because they are consumed during surgery, and higher levels are required to maintain hemostasis following surgery.

Packed red blood cells, which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Despite this loss, these factors rarely decrease below levels required for hemostasis. In 1985, a National Institutes of Health consensus conference concluded that there was little or no scientific evidence to support the use of FFP for bleeding diatheses following multiple blood transfusions except in the presence of clinical bleeding, platelet count higher than 100,000/mm³, and a partial thromboplastin time greater than 1.5 times control. A task force of the American Society of Anesthesiologists (208) recently recommended critical values for replacement in patients with massive transfusion and microvascular bleeding:

1. Platelet transfusion usually is indicated for counts less than 50,000/mm³ (with intermediate platelet counts, i.e., 50,000/mm³–100,000/mm³, the transfusion of platelet concentrates should be based on the risk of more significant bleeding).

2. Fresh frozen plasma therapy is indicated if the prothrombin or activated partial thromboplastin time values exceed 1.5 times the normal values.

3. Cryoprecipitate transfusion is indicated if fibrinogen concentrations decrease to less than 80 to 100 mg/dL.

Cryoprecipitate transfusions are recommended for prophylaxis in nonbleeding perioperative patients with fibrinogen deficiencies or von Willebrand’s disease refractory to DDAVP, and bleeding patients with von Willebrand’s disease (208).

Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, increasing the theoretical risk of hypocalcemia following massive transfusion. However, citrate is metabolized at a rate equivalent to 20 units of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

**Pulmonary Disease**

In patients undergoing abdominal surgery, several pulmonary physiologic changes manifest secondary to immobilization, anesthetic irritation of the airways, and the splinting of breathing that inevitably occurs secondary to incisional pain. Pulmonary physiologic changes include a decrease in the functional residual capacity (FRC), an increase in ventilation perfusion mismatching, and impaired mucociliary clearance of secretions from the tracheobronchial tree (209). In multivariate regression analyses, definite risk factors for postoperative pulmonary complications include the following (210):

- Upper abdominal, thoracic, or abdominal aortic aneurysm surgery
- Surgical procedure time longer than 3 hours
- American Society of Anesthesiologists class greater than 2
- Previous COPD
• Smoking within 2 months of surgery

• Use of pancuronium for general anesthetic

Probable risk factors include general anesthesia, preoperative PaCO₂ greater than 45 mm Hg, and emergency surgery. Risk factors that could possibly increase the postoperative risk are upper respiratory infection, abnormal chest x-ray, and elderly age (older than 70 years). Preoperative spirometry is of unproven value in patients in whom the risk of postoperative pulmonary complications is low. In high-risk patients, preoperative spirometry should be performed with and without bronchodilators to identify patients who may benefit from preoperative treatment with inhaled β₂ agonists and steroids. These patients include those with a history of chronic cough or dyspnea, evidence of pulmonary abnormalities by either physical examination or chest x-ray, and a history of COPD, as well as patients with a significant history of smoking. The spirometric abnormalities most often associated with postoperative atelectasis and pneumonia are shown in Table 20.19. Reduction of the forced expiratory volume in 1 second (FEV₁) is an important parameter to note on pulmonary function tests (209). The routine performance of preoperative arterial blood gas measurements does not improve assessment of risk (209). Noninvasive pulse-oximetry measurements can detect patients with hypoxemia (209). The presence of hypercapnia on arterial blood gas measurements also does not predict postoperative pulmonary complications (211).

Young, healthy patients rarely have abnormal chest x-rays. Therefore, chest x-rays should not be performed routinely in these patients. Most patients with abnormal chest x-rays have history or physical examination findings suggestive of pulmonary disease. Chest x-rays should be limited to patients older than 40 years of age, with a history of smoking or of pulmonary disease, who have evidence of cardiopulmonary disease, and in whom a metastatic malignancy is suspected. Although they have limited usefulness in predicting postoperative pulmonary complications, chest x-rays provide a valuable baseline in elderly patients, patients with chronic pulmonary diseases (209), and those with known lung metastases.

Asthma

Asthma affects approximately 5% to 7% of individuals in the United States (212). It is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa. Asthma is not a disease of airway physiology in which hypertrophy and increased contractility of bronchial smooth muscle is the dominant lesion; rather, it is an inflammatory disease

affecting the airways that secondarily results in epithelial damage, leukocytic infiltration, and increased sensitivity of the airways to a number of different stimuli. The treatment of asthma is directed toward relaxing the airways and alleviating inflammation with corticosteroids (212).

Multiple stimuli have been noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress, nonselective beta-adrenergic blockers, and aspirin (213). Management of asthma includes removal of the inciting stimuli as well as use of appropriate pharmacologic therapy. The optimal therapy for asthma involves not only managing the acute symptoms but also long-term management of the inflammatory component of the disease.

**Pharmacotherapy of Asthma**

The recognition of asthma as an inflammatory condition that should be treated with anti-inflammatory agents has led to the use of corticosteroids for treatment. Because corticosteroids inhibit mediator release from eosinophils and macrophages, inhibit the late response to allergens, and reduce hyperresponsiveness of the bronchioles, they have become the first-line therapy for chronic asthma (214). **Inhaled steroids have greatly reduced the steroid dose required to achieve optimal results.** The steroid effect is dose related, but many patients with asthma can achieve control using low-dose inhaled steroids. Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute bronchospasm, steroid treatment can enhance the beneficial effect of beta-adrenergic treatment. During acute exacerbations of asthma, a short course of oral steroids, in addition to inhaled steroids, may be necessary. For adults with chronic asthma, however, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support perioperatively to avoid adrenal insufficiency.

**Beta_2-adrenergic agonists remain the first-line drugs for acute asthma attacks.** These drugs, inhaled 4 to 6 times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of beta_2 agonists in chronic asthma, however, have failed to show any influence of these agents on the inflammatory component of asthma. Furthermore, it has been suggested that the long-term use of this class of drugs can lead to a worsening of asthma (214). Thus, beta_2 agonists are now recommended for use for short-term relief of bronchospasm (“rescue inhalers”) or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise (215).

Methylxanthines, such as theophylline, have been relegated to third-line status in the management of asthma. It is doubtful whether these drugs have any additional benefit in patients who are using maximal inhaler therapy. Theophylline toxicity can develop when other drugs such as ciprofloxacin, erythromycin, allopurinol, inderal, or cimetidine are concomitantly administered (212).

Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives such as ipratropium bromide (Atrovent) are available in an inhaled form that is not absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an anti-inflammatory effect.

Cromolyn sodium is highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not allergic in nature (215). The drug is taken by inhalation but has a relatively
short duration of action (3–4 hours). It has a mild anti-inflammatory effect but is less effective than inhaled cortical steroids, and its role as a single agent is limited.

**Perioperative Management of Asthma**

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized. The preoperative evaluation may include pulmonary function testing and arterial blood gases depending on the severity of the symptoms and concern regarding ventilation and oxygenation. Preoperative chest physiotherapy, bronchodilator therapy, systemic hydration, and appropriate antibiotics will improve the reversible components of asthma (216). For mild asthma, the use of inhaled beta-adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease alveolar inflammation and bronchiolar hyperresponsiveness. Inhaled beta₂ agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. For patients undergoing emergent surgery who have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy, intravenous amiphylline, as well as steroid therapy. Ideally, steroid therapy can be instituted 3 to 6 days preoperatively. In all patients with asthma, pharmacotherapeutic response can be monitored with pulmonary function testing as demonstrated by an improvement in the peak expiratory flow rate (215).

**Chronic Obstructive Pulmonary Disease**

Chronic obstructive pulmonary disease is the greatest risk factor for the development of postoperative pulmonary complications. The term COPD has been used to encompass both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any treatment plan must include cessation of smoking (217). Chronic bronchitis is defined as the presence of productive cough on most days for at least 3 months per year and for at least 2 successive years (218). It is characterized by chronic airway inflammation and excessive mucus production. The histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, significant ventilation-perfusion mismatching, and ineffective cough (219). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

Patients with COPD and a history of heavy smoking account for most postoperative pulmonary complications in gynecologic surgical patients. The severity of COPD can be determined preoperatively via a thorough history, physical examination, pulmonary function tests, and arterial blood gas assessment. Preoperative evaluation should be performed to assess reversible components of COPD, such as bronchospasm or infection.

The severity of COPD can be quantitated with pulmonary function testing (217). Typically, patients with COPD will demonstrate impaired expiratory air flow, manifested by diminished forced expiratory volume (FEV₁), forced vital capacity (FVC), FEV₁/FVC. In patients considered to be at high risk, the incidence of complications was highest in those undergoing abdominal surgery (92%) or thoracic surgery (78%) and lowest in those undergoing surgery outside the abdomen (26%). The current American College of Physicians guidelines list the following indications for preoperative spirometry: lung resection; coronary artery bypass or upper abdominal surgery in a patient with a positive smoking history or dyspnea; and lower abdominal surgery in a patient with uncharacterized pulmonary symptoms or history of pulmonary disease without recent spirometry within 60 days, especially if the surgery will be extensive, prolonged, or require strenuous postoperative rehabilitation (220).
Older data suggest that arterial blood gas measurements may show varying degrees of hypoxemia and hypercapnia and can be used for prognostic purposes; \( \text{PaO}_2 \) levels lower than 70 mm Hg and \( \text{PaCO}_2 \) levels higher than 45 mm Hg are associated with an increase in the risk of postoperative pulmonary complications and the need for mechanical ventilation postoperatively (221). \( \text{PaCO}_2 \) levels higher than 50 mm Hg are associated with increased postoperative respiratory failure and should caution against elective surgery (216).

The preoperative preparation of the patient at risk for postoperative pulmonary complications should include cessation of smoking for as long as possible preoperatively; whereas 2 to 3 days of smoking abstinence are sufficient for carboxyhemoglobin levels to return to normal (209). One to two weeks of cessation decreases sputum volume (209). Two months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (209). Longer periods of abstinence can thus be counseled in patients undergoing elective surgery.

In patients with severe COPD, maximum improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral corticosteroids followed by a 2-week trial of high-dose inhaled steroid (beclomethasone 1.5 mg/day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and then tapered postoperatively. Beta-adrenergic agonist therapy can be initiated at least 72 hours preoperatively and is beneficial in patients who have demonstrated either clinical or spirometric improvement on bronchodilators.

Patients with COPD and an active bacterial infection suggested by purulent sputum should undergo a full course of antibiotic therapy before surgery. The antibiotic used should cover the most likely etiologic organisms, *Streptococcus pneumoniae* and *Haemophilus influenzae*. In any patient with acute upper respiratory infection, surgery should be delayed if possible. The use of antibiotics to sterilize the sputum in the absence of evidence of an acute infection should be avoided because this practice may lead to bacterial resistance.

Instruction in deep breathing maneuvers and chest physical therapy are easily instituted, and these measures can be started the evening before surgery (222). These prophylactic measures (smoking cessation, pharmacotherapies, and aggressive pulmonary toilet) should be instituted preoperatively and continued postoperatively to minimize the incidence of atelectasis and pneumonia.

**Postoperative Pulmonary Management**

**Atelectasis**

Atelectasis accounts for more than 90% of all postoperative pulmonary complications. The pathophysiology involves a collapse of the alveoli, resulting in ventilation-perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the \( \text{PaO}_2 \). Collapsed alveoli are susceptible to superimposed infection, and if managed improperly, atelectasis will progress to pneumonia. Patients with atelectasis have a decreased FRC as well as decreased lung compliance, resulting in increased work during breathing. Despite the decrease in \( \text{PaO}_2 \), the \( \text{PCO}_2 \) remains unaffected unless atelectatic changes progress to large volumes of the lung or pre-existing lung disease is present.
Physical findings associated with atelectasis may include a low-grade fever. Auscultation of the chest may reveal decreased breath sounds at the bases or dry rales upon inspiration. Percussion of the posterior thorax may suggest elevation of the diaphragm. Radiologic findings include the presence of horizontal lines or plates on posteroanterior chest x-rays, occasionally with adjacent areas containing hyperinflation. These changes are most pronounced during the first 3 postoperative days.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the FRC. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. This exercise promotes not only an expansion of the alveoli but also secretion of surfactant, which stabilizes alveoli. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing, and in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Oversedation should be avoided, and patients should be encouraged to ambulate and change positions frequently. Fiberoptic bronchoscopy for removal of mucopurulent plugs should be reserved for patients who fail to improve with the usual measures.

Cardiogenic (High-Pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve or renal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance, impairment of the oxygen diffusion capacity, and an increase in the arteriolar–alveolar oxygen gradient. Ventilation-perfusion mismatching in the lung results in a decrease in the PaO₂, resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distention of the jugular veins, peripheral edema, rales upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchiolar cuffing, as well as increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be further confirmed with the use of central hemodynamic monitoring, which will denote an elevated central venous pressure and, more specifically, an elevation in the pulmonary capillary wedge pressure.

The patient’s volume status should be evaluated thoroughly. In addition, myocardial ischemia or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)

In contrast with cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the capillaries to the pulmonary parenchyma and alveoli. Lung compliance decreases and oxygen diffusion capacity is impaired, resulting in hypoxemia. If not managed aggressively, respiratory failure may result. Even when managed aggressively, the mortality rate
associated with ARDS is high. There are a number of causes as well as several distinct states of ARDS. The causes of ARDS include shock, sepsis, massive nonlung trauma (as from fractures or burns), multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, disseminated intravascular coagulation, and fat emboli (216). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical picture and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest x-ray. Chest x-rays will eventually reveal bilateral diffuse pulmonary infiltrates. As lung compliance becomes impaired, functional residual capacity, tidal volume, and vital capacity decrease. The PaO₂ decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above 90%. This may be achievable initially by administering oxygen by mask. For patients with severe hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted. Guidelines for initial ventilatory support are changing, and new lung-protective ventilation strategies are being advocated. One strategy advocates the use of high positive end-expiratory pressure (PEEP), low tidal volume, permissive hypercapnia, and pressure-limited ventilatory modes. The low tidal volume strategy may confer a survival advantage, and available data support its use in patients with ARDS (223). Multicenter ARDSNet trials are currently under way to assess differences in PEEP and FIO₂ levels and the use of corticosteroids. Analysis of a recent ARDSNet trial found no difference in the application of high or low levels of PEEP, holding tidal volume and end-inspiratory pressure stable at 30 cm of water (224). Attempts to manage and treat the cause of ARDS must also include aggressive efforts toward hemodynamic and circulatory resuscitation in patients with shock. Nosocomial pneumonia is present in 50% of patients with ARDS, and broad-spectrum antibiotic therapy should be administered appropriately for patients with suspected pneumonia or sepsis. Patients who have disseminated intravascular coagulopathy may require replacement with cryoprecipitate or FFP. Other measures for general care should include the placement of a nasogastric tube, gastric acid suppression with H₂ blockers, and administration of steroids in patients with the fat emboli syndrome.

Hemodynamic monitoring is invaluable and should be initiated early in the course of the disease process in the appropriate intensive care unit setting. Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the pulmonary-capillary wedge pressure is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. The goal of management is to maintain the lowest pulmonary–capillary wedge pressure, with acceptable cardiac output and blood pressure. In the setting of hypotension and oliguria, inotropic support with dopamine or dobutamine or both is helpful.

With aggressive management, particularly if the inciting cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae. After the first 48 hours, however, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. With progression beyond 10 days, multiorgan system failure occurs, and mortality is higher than 80% (223).

Renal Disease

The need for surgical intervention in patients with renal impairment has resulted in the development of a very specialized medical approach to their care. Special precautions are necessary to compensate for the kidney’s impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a
propensity to develop specific acid-base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and often are difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Patients undergoing dialysis in whom major abdominal or pelvic surgery is contemplated should be treated using a Swan-Ganz catheter intraoperatively and postoperatively. The results of physical examination and CVP monitoring correlate poorly with left cardiac filling pressures. Swan-Ganz catheter measurements will help guide fluid replacement and avoid volume overload. Invasive hemodynamic monitoring should be continued as needed throughout the first postoperative week because third spacing will occur during this period.

Postoperative dialysis usually is necessary to avoid problems associated with fluid overload and hyperkalemia. Dialysis-dependent patients should undergo dialysis approximately 24 hours following surgery. A short-lived but rather significant fall in the number of platelets occurs during dialysis, and heparin is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. Although ischemic heart disease is the most common cause of death in patients with renal insufficiency, it is not a major cause of perioperative mortality (225). A large percentage of perioperative deaths of patients with renal insufficiency are associated with hyperkalemia that is controlled most effectively by dialysis (226).

Patients with chronic renal failure are at an increased risk for postoperative infections resulting from abnormalities in neutrophil and monocyte function (227). Appropriate preoperative antibiotic prophylaxis and accurate assessment of nutritional status help lower the incidence of postoperative infectious complications.

The major hematologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet function related to a decreased amount of factor VIII and von Willebrand antigen in the serum of uremic patients. Anemia, which is common in patients with renal insufficiency, can contribute to prolonged bleeding times (228). Abnormalities in arachidonic acid metabolism, acquired platelet storage pool deficienc, and disturbed regulation of platelet calcium content all contribute to an increased tendency for uremic patients to have significant bleeding during surgery (229). Therefore, the bleeding time should be routinely checked preoperatively in these patients, and abnormalities should be corrected before surgery. Options for the correction of bleeding time in uremic patients include infusion of desmopressin or cryoprecipitate, both of which act to increase plasma levels of factor VIII and von Willebrand antigen (230,231).

Normal renal function is essential for maintenance of acid-base balance in the body. Patients with renal insufficiency can have a normal anion gap or an elevated anion gap acidosis. When mild renal insufficiency develops, a normal anion gap is present, whereas in more significant and severe renal dysfunction, an elevated anion gap acidosis occurs. Hemodialysis corrects metabolic acidosis. If a patient is severely acidic (pH <7.15) and emergency surgery is planned, correction of the blood pH to 7.25 using intravenous sodium bicarbonate is indicated. However, correction of metabolic acidosis should be carried out slowly, because in patients with hypocalcemia, seizures may be precipitated (231). It is also important to exclude other causes of elevated anion gap acidosis, such as ketoacidosis.
secondary to diabetes, lactic acidosis secondary to infection, or in rare instances, poisoning with ethylene glycol, methanol, or aspirin.

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic acidosis increases the level of ionized calcium. Oral phosphate binders, such as aluminum hydroxide (1–2 g per meal), and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia–hyperphosphatemia in patients with renal insufficiency. In chronic situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia–hyperphosphatemia with large doses of calcium carbonate (6–12 g per day) rather than with the standard aluminum-containing antacids (232).

Approximately 20% of patients with renal insufficiency will exhibit clinical evidence of protein calorie malnutrition. Vitamin deficiencies, most notably with water-soluble vitamins, also occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies have shown that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (233). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (233).

Wound healing is impaired in patients with chronic renal failure, and wound dehiscence and evisceration are potential problems. Wound healing is most appropriately aided by nutritional assessment preoperatively and maintenance of adequate caloric and protein intake in the perioperative setting. Antibiotic prophylaxis should be used in these patients, and uremia should be treated with dialysis as indicated. A running mass-closure of the midline vertical incision with continuous monofilament sutures should be used to further decrease the risk of wound dehiscence and evisceration (234).

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, as well as the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Of particular note is the inability of patients with renal insufficiency to clear the neuromuscular blockade caused by pancuronium (235). Care must be taken with D-tubocurarine, especially if repeated doses are given (236). Midazolam, propofol, vecuronium, and atracurium have been used safely in patients with renal failure (231). Succinylcholine has been reported to cause significant hyperkalemic responses in patients with renal failure (237). When succinylcholine is used in patients with chronic renal insufficiency, careful monitoring of the serum potassium level is necessary (238).

Perioperative acute renal failure in previously normal patients may be caused by decreased renal perfusion, nephrotoxins, or both. Patients with impaired cardiac function, intravascular volume depletion, sepsis, or hypotension fall under the first category. Nephrotoxic medications such as aminoglycosides, chemotherapeutic agents such as cisplatin, or iodinated contrast agents fall under the second category (239–241). The risk of renal impairment becomes cumulative if more than one of these factors exist at the same time, and especially if a variety of factors are associated with intervascular volume depletion (242). Several measurements should be used to avoid acute renal failure. All nephrotoxic drugs should be discontinued when possible. When it is not practical to withdraw medication, strict attention should be paid to the pharmacokinetic characteristics of each drug as well as to the regular measurements of serum creatinine levels. Patients with diabetes should be
given reduced doses of radiocontrast agents and should be well hydrated because they are particularly susceptible to renal injury from these materials (243). Volume repletion is essential to lower the incidence of renal impairment (244).

Liver Disease

Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. **Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.**

History and Physical Examination

Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wastage, ascites, right upper quadrant tenderness, or hepatomegaly.

Laboratory Testing

The biochemical profile (alkaline phosphatase, calcium, lactacid dehydrogenase, bilirubin, serum glutamic–oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) has not been shown to be useful for routine preoperative evaluation (245). Mild abnormalities can result in further extensive testing that requires consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child’s risk classification (Table 20.20). This system was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of prothrombin time may also be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, and albumin levels. Serologic documentation of hepatitis is also important. If a patient has a known malignancy, biochemical testing of the liver may be of some benefit as a screen for metastatic disease, although this has not been proved conclusively.

Anesthesia

With few exceptions, most anesthetic agents, including those administered by epidural or spinal routes, reduce hepatic blood flow and decrease oxygenation of the liver. Other perioperative factors—hemorrhage, intraoperative hypotension, hypercarbia, congestive heart failure, and intermittent positive pressure ventilation, especially in critically ill patients—lead to decreased hepatic perfusion and hypoxia (246).

**Drug Metabolism**

Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication being considered. For inhalation anesthetics, isoflurane is preferred because it undergoes minimal hepatic metabolism in comparison with halothane or enflurane. Narcotics, induction agents, sedatives, and neuromuscular blocking agents all undergo abnormal metabolism in patients with decompensated liver disease. Diazepam, meperidine, and phenobarbital cause prolonged depression of consciousness and may precipitate hepatic encephalopathy because of their altered rates of clearance. Sufentanil and oxazepam are the preferred narcotics, and benzodiazepine should be used for patients with altered liver function. Muscle relaxants, such as D-tubocurarine, pancuronium, and vecuronium, cause prolonged neuromuscular blockade in patients with impaired liver function and are not ideal drugs to use in this situation. Atracurium is not metabolized by the liver and, therefore, is the preferred muscle relaxant for patients with abnormal hepatic function. Succinylcholine metabolism is prolonged in patients with hepatic dysfunction and must be used with great caution (247).

**Determination of Operative Risk**

Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is difficult based on the history and physical examination. The most accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child's classification (see Table 20.20). Using this system, accurate assessment of morbidity and mortality can be directly related to the degree of liver dysfunction (248). The Child’s classification has been shown to be useful for patients undergoing a variety of different types of abdominal surgery. Operative mortalities of 10%, 31%, and 76% have been reported for each of the three Child’s classifications, respectively (249). The major cause of perioperative death was sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis.

**Acute Viral Hepatitis**

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and, therefore, elective surgery is contraindicated (250). Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (251). In patients with ectopic pregnancy, hemorrhage, or bowel obstruction secondary to malignancy, however, surgical intervention must take place before normalization of serum transaminase levels (250). In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (247).

**Chronic Hepatitis**

Chronic hepatitis is a group of disorders characterized by inflammation of the liver for at least 6 months. The disease is divided by morphologic and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the severity of disease. The risk of surgery in patients with asymptomatic or mild disease is minimal in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis (252). Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (251). In the nonelective situation, patients taking long-term glucocorticoid therapy should be given appropriate stress coverage with a higher dose of glucocorticoids during the perioperative period. Preoperatively, patients who are not taking steroids should receive prednisone and azathioprine, which have been shown to reduce the perioperative
risk of complications and may result in remission in as many as 80% of patients (253). More recently, a controlled randomized trial of prednisone and interferon-α has shown regression of the hepatitis B (HBV) core antigen and HBV viral DNA replication in approximately 30% of patients (254). Current strategies for treating chronic HBV also include the use of nucleoside analogs such as lamivudine and adefovir (255,256). Pegylated interferon and ribavirin are used in the standard treatment of hepatitis C (HCV) (257). Consideration should be given to using these medications for patients in whom surgery cannot be avoided but is not emergent.

Asymptomatic carriers of the HBV (individuals who test positive for the HBV surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation. There is, however, a significant risk to the health care professional operating on these individuals. In cases of needle-stick in which the patient’s hepatitis status is unknown, both the health care worker and the patient should be tested for HCV antibody and HBV serologic markers. If markers for HBV infection are present, hepatitis B immune globulin should be administered to unvaccinated medical personnel. A vaccination series should then be initiated during the early postoperative period. If the health care worker is immune (surface antibody positive), no treatment is necessary (247). All medical personnel, and especially those in the surgical subspecialties, should receive a full course of recombinant hepatitis B vaccine as recommended by the Centers for Disease Control and Prevention (258).
