Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. If nutritional deficiencies are discovered, they should be corrected before elective surgery. Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (259). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should be repeated (260). In cases of urgent or emergent surgery on patients with alcohol dependence, administration of tapered doses of benzodiazepine is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis
Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension, which ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction, however, may be somewhat quantitated by low albumin levels and prolonged prothrombin times. Surgical risk is clearly increased in patients with advanced liver disease, although it is substantially greater in emergency surgery than in elective surgery. Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child’s classification (see Table 20.20). In patients with Child’s class A cirrhosis, surgery can usually be performed without significant risk, whereas in patients with Child’s class B or C, surgery poses a major risk and requires careful preoperative consideration. Preoperative preparation should include the following measures: (i) optimizing nutritional status by enteral and parenteral nutrition and supplementation with B₁, (ii) correcting coagulopathy with administration of FFP or cryoprecipitate or both, (iii) minimizing pre-existing encephalopathy, (iv) preventing sepsis from spontaneous bacterial peritonitis by...
Section V Operative Gynecology

administering prophylactic antibiotic therapy, and (v) optimizing renal function and carefully correcting electrolyte abnormalities (261). Meticulous preoperative preparation focused on correcting abnormalities associated with advanced liver disease may improve surgical outcomes (262).

Positioning of the insufflation needle, the primary trocar, and the cannula are best accomplished with the patient in an unaltered horizontal position.

Proper patient selection is critical for laparoscopic management of ovarian cysts because of concerns about an adverse effect on prognosis with malignant tumors.

Laparoscopic myomectomy often requires laparoscopic suturing; thus, more technical skills are needed than with many other endoscopic procedures.

Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter.

Patients recovering from laparoscopic surgery usually feel better every day. Pain diminishes, gastrointestinal function improves rapidly, and fever is extremely unusual. Therefore, if a patient’s condition is not improving, possible complications of anesthesia or surgery should be considered.

The incidence of unintended electrosurgical activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use.

Endoscopy is a procedure that uses a narrow telescope to view the interior of a viscus or preformed space. Although the first medical endoscopic procedures were performed more than 100 years ago, the potential of this method has only recently been realized. Endoscopes are currently used to perform a variety of operations. In gynecology, endoscopes are used most often to diagnose conditions by direct visualization of the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).

When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery. The indications for endoscopic
surgery are outlined here and described in more detail in the appropriate chapters. The technology, potential uses, and complications of laparoscopy and hysteroscopy are summarized here.

Laparoscopy

The past three decades have witnessed rapid progress and technologic advances in laparoscopy (1–12). Operative laparoscopy was developed in the 1970s, and in the early 1980s, laparoscopy was first used to direct the application of electrical or laser energy for the treatment of advanced stages of endometriosis (6,7). The use of high-resolution, lightweight video cameras in operative laparoscopy has made it easier to view the pelvis during the performance of complex procedures (7–10). Subsequently, many other procedures that previously were performed using traditional techniques, such as hysterectomy, became feasible with the laparoscope (11). However, the endoscopic approach may have drawbacks in some patients. Although some laparoscopic procedures appear to reduce the cost and morbidity associated with surgery, others have not been shown to be effective replacements for more traditional operations. The techniques and indications for operative endoscopy are evolving.

Diagnostic Laparoscopy

The objective lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. The clarity and illumination of the optics allow a better appreciation of fine detail than is possible with the naked eye. Laparoscopy is the standard method for the diagnosis of endometriosis and adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to laparoscopy, however. The view of the operative field may be restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Also, soft tissues, intramural myomas, or the inside of a hollow viscus cannot be palpated. For assessment of these tissues, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) scans, is superior. Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be shown only by hysteroscopy or contrast imaging. Ultrasonography, in combination with serum assays of \( \beta \)-human chorionic gonadotropin (\( \beta \)-hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation (12). As a result of the advances in blood tests and imaging technology, laparoscopy is more often used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient’s problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, diagnostic laparoscopy must be performed prudently, interpreting findings in the context of the clinical problem and other diagnoses.

Therapeutic (Operative) Laparoscopy

The role of laparoscopy in the operative management of gynecologic conditions is evolving. Many procedures previously performed as traditional abdominal and vaginal operations are feasible with laparoscopy. Operative laparoscopy has the benefit of shorter hospital stays, less postoperative pain, and faster return to normal activity. In addition to
the benefits of endoscopic procedures in general, adhesions are less likely to form with laparoscopic surgery than with laparotomy. Because sponges are not used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The lack of exposure to air allows the peritoneal surface to remain more moist and, therefore, less susceptible to injury and adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced, small instruments are required and can be used only through fixed ports, the ability to manipulate the pelvic viscera is limited, and the caliber of the suture required may be larger than otherwise desired. In many cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced if a surgeon cannot adequately replicate the abdominal operation. In some patients, there is an increased risk of complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. With an adequate combination of ability, training, and experience, however, operative time and complications are comparable to those of traditional abdominal surgery.

**Tubal Surgery**

**Sterilization** Laparoscopic sterilization has been extensively used since the late 1960s and can be performed under general anesthesia. The fallopian tubes can be occluded by suture, clips, or Silastic rings, but electrosurgical desiccation with bipolar energy is the technique used most often (see Chapter 10). With operative laparoscopy, only one incision is required. Otherwise, a second port is needed for the introduction of the occluding instrument. Patients remain in the hospital for several hours, even when general anesthesia is used. Postoperative pain is usually minor and related to the effects of the anesthesia, gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate is about 5.4 per 1,000 woman-years (13,14).

**Ectopic Gestation** Medical therapy with methotrexate is considered first-line therapy for tubal pregnancies that meet the following criteria: no cardiac activity, tubal mass smaller than 5 cm confirmed by ultrasonography, and β-hCG level less than 1,000 (15). Ectopic gestation can be managed by using laparoscopy to perform the same procedures done with laparotomy, including salpingotomy, salpingectomy, and segmental resection of a portion of the oviduct (see Chapter 18) (16). Salpingotomy is performed with scissors, a laser, or an electrosurgical electrode after carefully injecting the mesosalpinx with a dilute vasopressin-containing solution (20 units per 100 mL of normal saline). For salpingectomy, the vascular pedicles are usually secured with electrosurgical desiccation, ligatures, clips, or a combination thereof. Tissue is removed from the peritoneal cavity through one of the ports of the laparoscope.

When salpingotomy is performed, regardless of the route, there is about a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with methotrexate is considered appropriate (see Chapter 18). Consequently, β-hCG levels should be measured weekly until there is confidence that complete excision has occurred (17,18).

**Ovarian Surgery**

**Ovarian Masses** Laparoscopic removal of selected ovarian masses is a well-established procedure (19,20). However, proper patient selection is critical for laparoscopic management of tumors because of its adverse effect on prognosis with malignant tumors (21). Preoperative ultrasonography is mandatory. Sonolucent lesions with thin walls
and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 levels is useful in identifying candidates for laparoscopic management (22,23). Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid), endometrioma, or hemorrhagic cyst with acute pain may also be suitable for endoscopic management (24). **Ovarian tumors should be assessed by frozen histologic section, and any malignancy should be managed expeditiously by laparotomy** (20,23).

The technique for performing laparoscopy for oophorectomy and cystectomy is similar to that used for laparotomy (17). For cystectomy, scissors are used to incise the ovarian capsule, and blunt dissection or aquadissection are used to separate the cyst from the ovary. If oophorectomy is performed, the vascular pedicles are ligated with sutures, clips, linear cutting staplers, electrosurgical desiccation, or a combination thereof. The ureter should be identified and should be clear of the pedicle to be ligated. Cysts that appear to be benign may be drained before extraction through either a laparoscopic cannula or, rarely, a posterior colpotomy. If there is concern about the impact of spilled cyst contents, the specimen should be removed in a retrieval bag inserted into the peritoneal cavity.

Although in the past the ovary has routinely been closed after cystectomy, this practice may be unnecessary and could contribute to the formation of adhesions (25). However, complete disruption of the ovarian cortex after removal of large cysts may make closure necessary, in which case the edges of the ovarian incision can be sutured.

**Other Ovarian Surgery**

Ovarian torsion, previously treated by laparotomy and oophorectomy, often can be managed laparoscopically (26,27). Even if there is apparent necrosis, the adnexa can be untwisted, usually with preservation of normal ovarian function (28). Performing a cystectomy at the same time the ovary is untwisted greatly reduces the likelihood that ovarian function will be maintained. Rarely is adnexectomy indicated.

Polycystic ovarian syndrome can be treated laparoscopically using electrosurgery and laser vaporization to perform ovarian drilling. This procedure reduces stromal tissue and may lead to a temporary return to normal ovulation (29–31). Although such procedures have been shown to be successful, postoperative adhesions form in 15% to 20% of patients, which underscores the need to first exhaust medical treatment (32,33).

**Uterine Surgery**

**Myomectomy**

Laparoscopic myomectomy, although feasible, is difficult to perform. Its efficacy is yet to be established, especially as it relates to the treatment of infertility and menorrhagia (34,35). Laparoscopic myomectomy often requires laparoscopic suturing and, thus, requires more technical skills than many other endoscopic procedures.

Unless the myoma involves the endometrial cavity, it is unlikely to contribute to heavy menstrual bleeding. Leiomyomas that cause pressure are often large and may be located in or near vital vascular structures. Myomectomy should be performed only when indicated (as opposed to expectant or medical management, which may be appropriate for some women with leiomyomas), and laparotomy should be used if there are technical limitations (36). **Patients who have pedunculated or subserosal leiomyomas that cause bothersome discomfort or pain in association with torsion are candidates for laparoscopic excision** (17,37).
Hysterectomy

For women who require hysterectomy, the appropriate route of surgery is determined by anatomical considerations, the type of pathology expected, patient preference, and physician experience and training. Laparoscopic hysterectomy offers no advantage for women in whom vaginal hysterectomy is possible because the endoscopic approach is more expensive and has a higher risk for postoperative morbidity (38,39). However, 75% of the approximately 600,000 hysterectomies performed in the United States are abdominal hysterectomies. Indications for choosing an abdominal approach are known or suspected pelvic adhesions or endometriosis, leiomyomata, the presence of adnexal pathology, the need for mandatory removal of the adnexa, or the absence of pelvic relaxation. In many patients, hysterectomy can be performed under laparoscopic direction. **Laparoscopic hysterectomy encompasses a variety of procedures, including the facilitation of vaginal hysterectomy with variable extents of endoscopic dissection, supracervical hysterectomy by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus with the assistance of the laparoscope** (40). The procedure is performed with scissors, sutures, electricity, clips, and in some instances, linear cutting and stapling devices to dissect or ligate pedicles.

There is a slightly higher risk of complications with laparoscopic hysterectomy, and operating times may be longer and procedures more costly than with abdominal hysterectomy. As experience is gained with laparoscopic hysterectomy, these outcomes approach those of abdominal hysterectomy. When reusable instruments are employed, however, laparoscopic hysterectomy is less costly than abdominal hysterectomy (41). Most studies show less postoperative pain, shorter hospital stays, and faster postoperative recovery with laparoscopic hysterectomy than with abdominal hysterectomy (42).

One study found pain scores and quality-of-life measures, including sexual activity and physical and mental functioning, were significantly better for women who underwent laparoscopic versus abdominal hysterectomy (42). These differences were present at 6 weeks following surgery and remained at the 12-month follow-up visit.

Infertility Operations

Laparoscopic treatment of infertility includes operations used to reconstruct the normal anatomic relationships altered by an inflammatory process such as fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction (43). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of pre-existing complete distal obstruction. Endometriosis associated with adnexal distortion can be treated by laparoscopic adhesiolysis. There is no known additional benefit of laparoscopic (or medical) treatment of coexistent active endometriosis. Laparoscopy has been superseded by ultrasound for the retrieval of oocytes for in vitro fertilization but is still used for procedures in which gametes (gamete intrafallopian transfer) or zygotes (zygote intrafallopian transfer) are placed into the fallopian tube.

Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, laser, ultrasonic shears, or electrosurgical electrode. These instruments are usually passed through an ancillary port; when laser energy is used, the channel of the operating laparoscope may be used for this purpose. Although there has been controversy regarding the most appropriate modality for adhesiolysis, these methods are probably equally effective in appropriately trained hands.

**Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, however, the effectiveness of all procedures is limited. Assisted reproductive technologies such as in vitro fertilization and embryo transfer are necessary in these situations** (see Chapter 30) (17,44).
SECTION V  Operative General Gynecology

Endometriosis

The laparoscopic management of endometriomas parallels that of adnexal masses, although the ultrasonographic complexity of endometriomas sometimes makes it difficult to distinguish them preoperatively from a neoplasm. The close attachment of the endometrioma to the ovarian cortex and stroma may make it difficult to find surgical dissection planes, and incomplete removal increases the risk of recurrence. There is a tendency either to compromise the function of the remaining ovary by attempting complete removal or to leave part of the endometrioma in place. Therefore, for women who want to retain their fertility, electrosurgical or laser ablative techniques may be used to treat endometriotic tissue that is adherent to the remaining ovary.

Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates about the same amount of thermal injury (45,46). Endometriosis frequently is deeper than appreciated initially, making excisional techniques valuable in many instances (17,44).

Pelvic Floor Disorders

Laparoscopy can be used to guide procedures to treat pelvic support defects, including culdoplasty, enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethropexy for urinary stress incontinence. Although these conditions can be treated vaginally, the laparoscopic approach may offer benefits, particularly with retropubic urethropexy. There is some evidence that the laparoscopic approach is effective when compared with the traditional methods (47,48). Using the same surgical principles applied during traditional pelvic floor repair, laparoscopy promises better access to key anatomical landmarks and potentially more accurate suture placement (49). Whereas apical and anterior compartment defects can be successfully corrected via laparoscopy, posterior and perineal defects are still best visualized and repaired using vaginal techniques. The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure. Because of the anatomical proximity of the pelvic ureter to the uterosacral ligament and anterolateral vagina, bilateral ureteral patency should be confirmed cystoscopically after laparoscopic vaginal vault suspension, enterocele repair, culdoplasty, cystourethropexy, or paravaginal repair.

Gynecologic Malignancies

The role of laparoscopy in the management of gynecologic malignancy has not been clearly established (50–52). A study performed by the Gynecology Oncology Group showed that laparoscopic management of presumed stage I endometrial cancer was feasible (53), whereas another study found that women with endometrial cancer and other comorbidities had fewer complications with laparoscopically assisted vaginal hysterectomy than with laparotomy (54). The potential for laparoscopic lymphadenectomy has fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is also being investigated for the staging of early ovarian malignancy and for second-look surgery.

Patient Preparation and Communication

The rationale, alternatives, risks, and potential benefits of the selected approach should be explained to the prospective patient. She should know the likely outcome of expectant management if the procedure was not performed.

The expectations and risks of diagnostic laparoscopy, as well as those of any other procedures that may be needed, must be explained. It may be helpful to compare risks and recovery with the same procedure performed via abdominal surgery. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the
abdominal and pelvic viscera. The possibility of conversion to laparotomy if a complication should occur or if the procedure cannot be completed via laparoscopic surgery should also be discussed. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. The potential for these risks should be clearly presented. The patient should be given realistic expectations regarding postoperative disability. Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery. After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours off work or school. If extensive dissection—a major surgical procedure performed laparoscopically—is necessary, or if the surgery lasts longer than 2 hours, hospital admission may be necessary, and the period of disability may be as long as 10 to 14 days.

If the procedure may involve the colon, mechanical bowel preparation should be performed to help improve visualization and minimize the likelihood of fecal spillage if the colon is entered. The patient should arrange for a friend or family member to be present to discuss the results of the procedure with the physician and to drive her home if she is discharged the same day. Mild analgesia often is necessary.

Equipment and Technique

To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into “core competencies,” which are as follows:

1. Patient positioning
2. Operating room organization
3. Peritoneal access
4. Visualization
5. Manipulation of tissue and fluid
6. Cutting, hemostasis, and tissue fastening
7. Tissue extraction
8. Incision management

Patient Positioning

Proper positioning of the patient is essential for patient safety, comfort of the operator, and optimal visualization of the pelvic organs. Laparoscopy is performed on an operating table that can be tipped to create a steep, head-down (Trendelenburg) position that allows the bowel to move out of the pelvis after the first trocar has been placed. The footrest can be dropped to allow access to the perineum. The patient is placed in the low lithotomy position, with the legs supported in stirrups and the buttocks protruding slightly from the lower edge of the table (Fig. 21.1). The thighs are usually kept in the neutral position to preserve the sacroiliac angle, reducing the tendency of bowel to slide into the peritoneal cavity. The feet should rest flat, and the lateral aspect of the knee should be protected with padding or a special stirrup to avoid peroneal nerve injury. The knees should be kept in at least slight flexion to minimize stretching of the sciatic nerve and to provide more stability in the Trendelenburg position. The arms are positioned at the patient’s side by adduction and pronation to allow freedom of movement for the surgeon and to lower the risk for brachial plexus injury (Fig. 21.2). Care must be exercised to protect the patient’s fingers and hands from injury when the foot of the table is...
SECTION V Operative General Gynecology

The patient’s buttocks are positioned so that the perineum is at the edge of the table. The legs are well supported with stirrups, with the thighs in slight flexion. Too much flexion may impede the manipulation of laparoscopic instruments while in the Trendelenburg (head-down) position.

Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in Figure 21.2.

For pelvic surgery, the monitor may be placed at the foot of the table within the angle formed by the patient’s legs. If a second monitor is used, one may be positioned at each foot of the patient.

The surgeon usually stands by the patient’s left side, at an angle facing the patient’s contralateral foot. The nurse or technician and instrument table are positioned near the foot of the operating table to avoid obscuring the video monitor. The insufflator may be placed on the patient’s right side, in front of the surgeon, to allow continuous monitoring of the inflation rate and intra-abdominal pressure. The electrosurgical generator may also be positioned on the patient’s right side to permit visualization of the power output. When a laser is used through a second puncture site, it may also be placed to the patient’s right.
When the laser is passed through the channel of an operating laparoscope, however, it may be situated on the patient’s left side, beside the surgeon.

Peritoneal Access

Before inserting the laparoscope, a cannula or port must be positioned in the abdominal wall to establish access to the peritoneal cavity. The closed technique is a blind approach in which the cannula is introduced with a sharp trocar used to penetrate the abdominal layers. In open laparoscopy, entry into the peritoneal cavity is achieved with minilaparotomy using either a transverse subumbilical or midline infraumbilical incision down to the rectus fascia, to which the cannula is fixed into position with sutures or other suitable techniques. Gynecologists have generally favored a closed technique, preinflating the peritoneal cavity with CO₂ through a hollow insufflation needle. In either case, additional cannulas are subsequently inserted by sharp trocars under direct vision to allow the use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices.
Insertion of the insufflation needle and primary cannula is aided by an understanding of the normal underlying anatomy, especially the location of the larger retroperitoneal vessels (Fig. 21.3). A “safety zone” exists inferior to the sacral promontory in the area bounded cephalad by the bifurcation of the aorta, posteriorly by the sacrum, and laterally by the iliac vessels (49). In women placed in the Trendelenburg position, the great vessels are situated more cephalad and anterior, making them more vulnerable to injury unless appropriate adjustments are made in the angle of insertion (Fig. 21.4) (55). Therefore, positioning of the insufflation needle, the primary trocar,
CHAPTER 21  Gynecologic Endoscopy

and the cannula are best accomplished with the patient in an unaltered horizontal position. This approach also facilitates the evaluation of the upper abdomen, which is limited if the intraperitoneal contents are shifted cephalad by the head-down position.

**Insufflation Needles**

Virtually all insufflation needles are modifications of the hollow needle designed by Verres (Fig. 21.5). In cases uncomplicated by previous pelvic surgery, the preferred site for insertion is the base of the umbilicus, where the abdominal wall is the thinnest and usually avascular.

1. A midline infraumbilical incision adequate for the needle is made at the base of the umbilicus with a small scalpel, and the abdominal wall is maximally lifted, either manually or with instruments. Elevation is accomplished manually by grasping on either side lateral to the umbilicus or midway between the umbilicus and mons pubis. Instrumentally, elevation can be achieved by affixing towel clips to the abdominal wall on either side lateral to the umbilicus or opposite one another within the edge of the umbilical incision itself (56).

Safe insertion of the insufflation needle mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Because the sacral promontory is commonly covered in part by the left common iliac vein, vascular injury may still occur in the midline below the bifurcation (57).

To reduce the risk of retroperitoneal vascular injury while minimizing the chance of inadvertent preperitoneal insufflation, in women of average weight, the insufflation needle is directed to the patient’s spine at a 45-degree angle. In heavy to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth (58). The needle’s shaft is held by the tips of the fingers and steadily but purposefully guided into position only far enough to allow the tip’s entry into the peritoneal cavity. The tactile and visual feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may
provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Verres needle. With the former, the surgeon must listen to the “clicks” as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The needle should never be forced. Regardless of technique, the underlying retroperitoneal vessels are protected ultimately by limiting the depth of insertion of the insufflation needle and umbilical cannula.

2. In instances in which known or suspected intra-abdominal adhesions surround the umbilicus, alternative sites should be used for insufflation needle insertion. These sites include the left upper quadrant, most often at the left costal margin, the pouch of Douglas, and the fundus of the uterus (Fig. 21.6). The left upper quadrant is preferred if hepatosplenomegaly is not present and the patient has not previously had surgery in this area. In such patients, the stomach must be decompressed with a nasogastric or orogastric tube before the needle is inserted (59).

3. Before insufflation, the operator should try to detect whether the insufflation needle has been malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel. Using a syringe attached to the

**Figure 21.6.** Insufflation needle and cannula insertion sites. In most instances, both the insufflation needle, if used, and the primary cannula are inserted through the umbilicus. When subumbilical adhesions are known or suspected, the insufflation needle may be placed through the pouch of Douglas or in the left upper quadrant after evacuation of the gastric contents with an orogastric tube.
insufflation needle, blood or gastrointestinal contents may be aspirated. To facilitate this examination, a small amount of saline may be injected into the syringe. If the needle is appropriately positioned, negative intra-abdominal pressure is created by lifting the abdominal wall. This negative pressure may be demonstrated by aspiration of a drop of saline placed over the open, proximal end of the needle or, preferably, by using the digital pressure gauge on the insufflator.

4. **Additional signs of proper placement may be sought after starting insufflation.** The intra-abdominal pressure reading should be low, reflecting only systemic resistance to the flow of CO₂. Consequently, there should be little deviation from a baseline measurement, generally less than 10 mm Hg. The pressure varies with respiration and is slightly higher in obese patients. The earliest reassuring sign is the loss of liver “dullness” over the lateral aspect of the right costal margin. However, this sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can also be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.

5. **The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated.** Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 25 mm Hg for positioning of the cannulas. This level usually provides extra volume and enough counterpressure against the peritoneum, facilitating trocar introduction and potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. After placement of the cannulas, the pressure should be dropped to 10 to 12 mm Hg, which reduces the risk of subcutaneous insufflation leading to crepitus and essentially eliminates hypercarbia or decreased venous return of blood to the heart (59–61).

### Laparoscopic Cannulas

Laparoscopic cannulas allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (Figs. 21.7 and 21.8). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows attachment to tubing connected with the CO₂ insufflator. Larger-diameter cannulas (8–12 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

The trocar is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most trocars have sharp tips, allowing penetration of the abdominal wall after a small skin incision. Many disposable trocar-cannula systems are designed with a “safety mechanism”—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices has been shown to make insertion safer, however, and they all increase the cost of the equipment.

**Following open laparoscopy, cannulas can be inserted either after the successful creation of a pneumoperitoneum (secondary puncture) or without previously instilling intraperitoneal gas (primary puncture).** With open laparoscopy, there is less risk of injury to blood vessels. However, open laparoscopy cannot prevent all insertion accidents because intestine can be entered inadvertently no matter how small the incision. There is little evidence that a pneumoperitoneum is necessary, at least in the absence of pre-existing abdominal wall adhesions. Therefore, **in women with no previous surgery, the primary puncture can be performed with a sharp-tipped trocar-cannula system, which reduces operating time.** The first, or primary, cannula must be of sufficient caliber to permit passage of the
**Figure 21.7** Disposable access systems. These instruments are designed for single use. A 12-mm internal diameter blunt access system is shown in A. The next device (B) also has a 12 mm internal diameter, but has a deployable blade that is used to cut through the abdominal wall. A smaller diameter blunt conical device is shown in C while a sharp conical access system is presented in D. Both C and D have a 5 mm inside diameter. A narrow, 2.7-mm diameter cannula is shown in E. The trocar for this system is a long insufflation needle with a spring deployable obturator.

**laparoscope and usually is inserted in or at the lower border of the umbilicus.** The incision should be extended only enough to allow insertion of the cannula; otherwise, leakage of gas may occur around the sheath. The patient should be in an unaltered supine position during placement of the primary cannula. For the primary puncture, either the surgeon or an assistant should elevate the abdominal wall as described previously. Both
hands can be positioned on the device, using one to provide counterpressure and control to prevent “overshoot” and resultant injury to bowel or vessels. The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient’s weight and body habitus. The laparoscope should be inserted to confirm proper intraperitoneal placement before the insufflation gas is allowed to flow. Previous abdominal surgery increases the incidence of adhesions of the bowel to the anterior abdominal wall, frequently near the umbilicus and in the path of the primary trocar (8,62). In such patients, another primary insertion site, such as the left upper quadrant, should be selected, even if it is used solely for conveying a narrow “scout” laparoscope, some types of which can be inserted through an insufflation needle (Fig. 21.10). Using such a laparoscope, the presence of adhesions under the incision can be excluded and the umbilical cannula can be inserted under direct vision. If adhesions are noted under the incision, appropriate placement of secondary cannulas may be used to introduce instruments for adhesiolysis. Alternate insertion sites for primary cannulas are shown in Figure 21.6.

Ancillary Cannulas

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures. Most currently available disposable ancillary cannulas are identical to those designed for insertion of the primary cannula; however, simple cannulas without safety sheaths and insufflation ports are sufficient (Figs. 21.7D and 21.8D).

Proper positioning of these cannulas depends on a sound knowledge of the abdominal wall vascular anatomy. For the secondary puncture, the patient should be tipped head
down (Trendelenburg), allowing the abdominal contents to move away from the sites for secondary puncture, and thus making it unnecessary to lift the abdominal wall during secondary cannula insertion. Ancillary cannulas should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a urethral catheter. The insertion sites depend on the procedure, the disease, the patient’s body habitus, and the surgeon’s preference. For diagnostic laparoscopy, the most useful and cosmetically acceptable site for insertion of an ancillary cannula is in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac. Laparoscope cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannula attachments, called grippers, designed to prevent slippage.

Lateral placement of lower-quadrant cannulas are useful for operative laparoscopy, but the superficial and inferior epigastric vessels must be located to avoid injury (Fig. 21.3). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. However, the deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal. At the pubic crest, the deep inferior epigastric vessels can often be visualized between the medially located umbilical ligament and the laterally positioned exit point of the round ligament. The trocar should be inserted medial or lateral to the vessels if they are visualized. If the vessels cannot be seen and it is necessary to position the cannula laterally, the cannula should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle. If the insertion is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk of injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, directly observing the entry through the laparoscope. This provides reassurance that a safe location has been identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the trocar.

Even after a proper incision, the abdominal wall vessels can be injured if the trocar slides medially during placement. Large-diameter trocars are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this results in hindrance of the hand instruments, which compromises access and maneuverability.

Visualization

During endoscopy, the image must be transferred through an optical system. Although direct optical viewing is feasible and often used for diagnostic purposes, virtually all operative laparoscopy is performed using video guidance.

Operative versus Diagnostic Equipment

Laparoscopes used for operative purposes have a straight channel, parallel to the optical axis, for the introduction of operating instruments. This provides an additional port for the insertion of instruments and the tangential application of laser energy. However, operative endoscopes are of relatively larger caliber than diagnostic laparoscopes and have smaller fields of view and increased electrosurgical risks. Diagnostic laparoscopes permit better visualization at a given diameter and are associated with fewer electrosurgical risks.

Diameter

Narrow-diameter laparoscopes allow limited transfer of light both into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light

SECTION V Operative General Gynecology
CHAPTER 21  Gynecologic Endoscopy

source for adequate illumination. Ideal illumination is provided by 10-mm diagnostic laparoscopes, but improvements in optics are making more procedures feasible with smaller-caliber devices (Fig. 21.9).

Viewing Angle

The viewing angle depicts the relationship of the visual field to the axis of the endoscope and is usually either zero or 30 degrees to the horizontal. The zero-degree scope is the standard for gynecologic surgery. However, the 30-degree angle provides some advantage in difficult situations, such as the performance of retropubic urethropexy or adhesiolysis or for surgery in the presence of large myomas.

Imaging Systems

The video camera captures the image transmitted by the endoscope and the image is transmitted to the body of the camera located outside the operative field, where it is processed and sent to a monitor and, if desired, a recording device (Fig. 21.11). The resolution capability of the monitor should be at least equal to that provided by the camera. Most monitors have the potential to display about 800 horizontal lines of resolution. The more light transmitted through the endoscope, the better the visualization. The best currently available output is achieved from 250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required. Light guides or cables transmit light from the source to the endoscope via a bundle densely packed optical fibers (fiberoptic). Fiberoptic cables lose function over time, particularly if they are mishandled, which may break the fibers.
Figure 21.11 Laparoscopic Tower. This tower comprises a monitor (A), a camera body or base unit (B) attached to a camera sensor; a light source (C) attached to a cable, which in turn will be connected with the endoscope; a still-image printer (D) and an insufflation machine (E). A video recorder is shown in (F).
Intraperitoneal Distention

**Insufflation Machines**

The insufflator delivers CO₂ from a gas cylinder to the patient through tubing connected to one of the ports on the laparoscope. Most insufflators can be set to maintain a predetermined intra-abdominal pressure. High flow rates (9–20 L/min) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

**Laparoscopic Lifting Systems**

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent. This “gasless” or “apneumic” technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease. Airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions.

**Fluid Management**

Fluid may be instilled into the peritoneal cavity through wide-caliber arthroscopy or cystoscopy tubing using pressure provided by gravity, an infusion cuff, or a high-pressure mechanical pump. The pumps deliver fluid faster than the other techniques, and the highly pressurized stream of fluid may facilitate blunt dissection (hydro- or aquadissection). Small volumes of fluid can be removed with a syringe attached to a cannula; for large volumes, it is necessary to use suction generated by a machine or a wall source.

The cannulas used for suction and irrigation depend on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7–10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection.

If large volumes of fluid are required, isotonic fluids should be used to avoid fluid overload and electrolyte imbalance. If electrosurgery is to be performed, however, small volumes of a nonelectrolyte-containing solution such as glycine or sorbitol can be used for hemostasis and irrigation. Heparin (1,000–5,000 U/L) can be added to irrigating solution to prevent blood from clotting, thus allowing it to be removed more easily.

**Tissue Manipulation**

**Uterine Manipulators**

A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for fixation of the device to the uterus. Articulation of the instrument permits acute anteversion or retroversion, both of which are extremely useful maneuvers. If the uterus is large, longer and wider obturators are used so that the manipulations can be performed more effectively. Two types of uterine manipulators are shown in Figure 21.12. A hollow obturator attached to a port allows intraoperative instillation of liquid dye to demonstrate tubal patency.

**Grasping Forceps**

The forceps used during laparoscopy should replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, and precision of nondisposable forceps (Fig. 21.13). Instruments with teeth (toothed forceps) are necessary to grasp the peritoneum or the edge of ovary securely to remove an ovarian cyst. Minimally traumatic instruments designed like Babcock clamps are needed to retract the fallopian
**Figure 21.12** Uterine Manipulators. *(Top)* is the disposable “V-Care” device. At the tip is a balloon inflated to maintain the device in the endometrial cavity. Next to the tip is a cervical collar that serves to facilitate identification of the vaginal fornices and cutting of the vagina in laparoscopic total hysterectomy. The blue truncated cone maintains a seal so that gas won’t leak out when culdotomy is performed. *(Bottom)* is the reusable Pelosi manipulator. The ring handle allows the surgeon to antevert the uterus.

**Figure 21.13** Laparoscopic Instruments for Grasping and Manipulating Tissue. *A:* *(top and inset)* are 5-mm diameter graspers with a curved tip, often called “Maryland” graspers. Other reusable tips *(B)* and *(C)* may be positioned in the same handle as is shown for *A.* *D:* is a 10-mm claw grasper while *(E)* and *(F)* are 5- and 2-mm manipulating probes respectively. *G:* is a 2-mm grasper forceps.
Cutting can be achieved by mechanical means or by using radiofrequency electrical current, laser energy, or ultrasonic energy. The methods for maintaining or securing hemostasis include sutures, clips, linear staplers, energy sources, and topical or injectable substances. Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. With appropriate training, a skilled surgeon can obtain good results with any combination of these techniques for cutting, hemostasis, and tissue fixation. Studies in animals have not demonstrated any difference in injury characteristics when cutting is performed with either laser or radiofrequency energy (44,45,63), and randomized controlled studies have shown no differences in fertility outcomes (64). Therefore, differences in results are more likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise.

Cutting

The most useful cutting instruments are scissors (21.14 Bottom). Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that can be used until dull and then discarded. Another mechanical cutting tool is the linear stapler–cutter that can simultaneously cut and hemostatically staple the edges of the incision. The cost and large dimensions of the instruments limit their practical use to only a few highly selected situations, such as separation of the uterus from the ovary and fallopian tube during laparoscopic hysterectomy.

Laser and electrical sources of energy manifest their effect by conversion of electromagnetic energy generated by a special electrosurgical unit (ESU) (Fig. 21.15) to mechanical energy which is then transformed to thermal energy. Highly focused radiofrequency energy produces vaporization or cutting, whereas less focused energy (high-current density) raises the intracellular temperature above 100°C and results in tissue vaporization or, if the instrument is moved in a linear fashion, tissue cutting. Less focused radiofrequency energy (moderate current density) elevates intracellular temperature, causing desiccation and tissue coagulation, but vaporization and cutting does not occur. Electrosurgical instruments that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue. Continuous or modulated, usually unipolar, outputs are used. For optimal results, they should be used in a noncontact fashion, following (not leading) the energy. Specially designed bipolar cutting probes are available that have one integrated electrode shaped as a needle and the other band-shaped electrode designed to be dispersive (Fig. 21.14 Top). Laparoscopic scissors with unipolar or bipolar electrosurgical attachments are designed to cut mechanically, and energy may be applied simultaneously for desiccation and hemostasis when cutting tissue that contains small blood vessels (Fig. 21.14 Bottom).

Laser energy can be focused to vaporize and cut tissue. The most efficient laser-based cutting instrument is the CO2 laser, which has the drawback of requiring linear transmission because light cannot be conducted effectively along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium, aluminum, garnet (Nd:YAG) lasers are also effective cutting tools. They are capable of propagating energy along bendable quartz fibers but have a slightly greater thermal injury risk than electrical or CO2 laser energy. Because of such limitations and their additional expense, these lasers are of limited value.

Ultrasonic cutting is largely accomplished mechanically using a blade that oscillates back and forth in a linear fashion (Fig. 21.14 Center). The oscillation is achieved using a vibrating element located in a handle that vibrates the blade, hook, or clamp 55,000 times per second (55 kHz). The distance of the oscillation can be varied and determines the rapidity...
**Figure 21.14** Laparoscopic Cutting Devices. *Top and inset left* is a bipolar electrosurgical spatula. *Middle and center inset* is a harmonic scalpel. This device oscillates at 55,000 Hz to cut tissue. *Bottom and inset right* are laparoscopic scissors. They may be connected if desired to an electrosurgical generator to act as a unipolar electrode.

**Figure 21.15** Radiofrequency Electrosurgical Generator. Displayed is the Force FX generator with unipolar laparoscopic electrodes. The device is capable of outputting high-voltage (“coagulation”) and low-voltage (“cut”) waveforms for unipolar instruments as well as a low-voltage bipolar circuit for bipolar instruments.
of the cutting process. The tip of the device cuts mechanically, but there is a degree of collateral thermal tissue coagulation injury that can be used for hemostasis. In low-density tissue, the process of mechanical cutting is augmented by the process of cavitation, in which reduction of local atmospheric pressure allows vaporization of intracellular water at body temperature.

**Hemostasis**

Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important for efficient, effective, and safe procedures. Radiofrequency electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy and can be applied with either monopolar or bipolar instruments. Regardless of the type of system, the process of electrical desiccation and coagulation is best achieved by contacting the tissue and activating the electrode using continuous low-voltage or “cutting” current. With adequate power, typically 25 watts, tissue will be heated and coagulated. Blood vessels should be compressed with the blades of the forceps before the electrode is activated so that the “heat sink” effect of flowing blood is eliminated. This also allows the opposing walls of the vessel to bond together, forming a strong tissue seal in a process called coaptive coagulation. Bipolar devices can be fitted with a serial ammeter that measures the current flowing through the system. When the tissue between the blades of the forceps is completely desiccated, the device is no longer able to conduct electricity, which can trigger a visual or auditory cue for the surgeon. Alternatively, the generator can be designed to stop automatically when current is no longer being conducted by the tissue between the blades of the forceps. The surgeon can reduce lateral thermal spread of radiofrequency energy by manually pulsing delivery or by simultaneously running irrigation fluid over the pedicle. Automated generators that pulse energy automatically are available and such bipolar systems can include mechanical blades to cut tissues following coagulation of the tissue (Fig. 21.16).

![Figure 21.16](image)

**Figure 21.16** Displayed are two devices that both cut and coagulate or seal tissue. Top (A–C) are the ligating cutting shears (LCS) that are based on the same technology as the harmonic scalpel displayed in Figure 21.13. The bottom blade oscillates (C) while the top blade is opened to grasp the tissue and then used by the surgeon to slowly transect and seal the blood vessels in the tissue being transected. The PlasmaKinetic (D–F) is a bipolar radiofrequency device that, using electrical impedance, tells the surgeon when the tissue is coagulated. Then the orange trigger (top) is pushed deploying the blade (F), thereby cutting the coagulated tissue.
Control of superficial bleeding can be achieved with fulguration, the near-contact spraying of tissue with unipolar, high-voltage radiofrequency energy from the “coagulation” side of the electrosurgical generator. Care must be taken to perform laparoscopic fulguration carefully, ensuring that the entire shaft of the laparoscopic instrument is well away from bowel.

Ultrasonic instruments can be used for hemostasis as well. Those with a forceps-like end disperse the mechanical energy in a way that allows the tissue to be heated and coagulated. These so-called “ligating-cutting” shears also cut when high pressure is exerted in the handle by the surgeon (Fig. 21.16 A–C).

**Clips may be used with specially designed laparoscopic instruments.** Nonabsorbable clips made of titanium are useful for relatively narrow vessels, and longer, self-retaining clips are generally preferred for larger vessels. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing is a method of maintaining hemostasis (65). Compared with clips or linear staplers, suturing has a relatively low cost of materials, although operating time may be longer. **The two basic methods for securing a ligature around a blood vessel are intracorporeal and extracorporeal knots, depending on where the suture is tied.** Intracorporeal knots replicate the standard instrument-tied knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and then transferred into the peritoneal cavity by knot manipulators (see Fig. 21.17) (66). Pretied knotted suture loops attached to long introducers, called endoloops, may also be used to secure vascular pedicles. However, care should be taken to make sure that they are tightly secured and that no other tissue is incorporated in the loop.

Topical agents such as microfibrillar collagen are available in 5-mm and 10-mm diameter laparoscopic applicators (see Fig. 21.13). Local injection of diluted vasopressin may be used to maintain hemostasis for myomectomy or removal of ectopic pregnancy.
After excising tissue, it is usually necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. If there is any concern for malignancy, an alternative is to place the specimen in an endoscopic retrieval bag before drainage to prevent spillage (Fig. 21.18). More solid tissue may be morcellated with scissors, ultrasonic equipment, or electrosurgery. If monopolar radiofrequency instruments are used for electrosurgical morcellation, the specimen must remain attached to the patient to preserve the integrity of the electrical circuit. Alternatively, special bipolar needles are available that do not require a dispersive electrode.

Larger specimens may be removed by inserting a larger cannula through an incision in the cul-de-sac (posterior culdotomy) or by extending one of the laparoscopy incisions. With the exception of colpotomy, extension of the umbilical incision may be the most cosmetic approach because removal of the tissue can be directed from an endoscope positioned in

**Figure 21.18** Specimen Removal Bag. This 10-mm diameter bag is positioned in the peritoneal cavity. Then, the bag is deployed (insets), allowing the surgeon to place specimens for removal.
Operative General Gynecology

Electronic morcellators are available to remove large tissue specimens by reducing them to smaller sections (Fig. 21.19). These are especially useful for laparoscopic myomectomy and laparoscopic supracervical hysterectomy.

Incision Management

Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter (67). Closure of the fascia should take place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions, and the peritoneum should be included to reduce the risk of Richter’s hernia. A small-caliber laparoscope passed through one of the narrow cannulas can be used to direct the fascial closure using curved needles or a ligature carrier especially designed for this purpose.

Complications

Patients recovering from laparoscopic surgery usually feel better every day. Pain diminishes, gastrointestinal function improves rapidly, and fever is extremely unusual. Therefore, if a patient’s condition is not improving, possible complications of anesthesia or surgery should be considered. Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, as well as by problems associated with anesthetic use. The incidence of infection is lower than with procedures performed by laparotomy. Conversely, problems associated with visualization in conjunction with the change in anatomic perspective may increase the risk of damage to blood vessels or vital structures such as the bowel, ureter, or bladder.

Anesthetic and Cardiopulmonary Complications

A recent review of laparoscopic tubal sterilization in 9,475 women found no deaths from complications of anesthesia (68). However, the potential risks of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest. These risks can
be enhanced by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater pressure on the diaphragm, increasing the risk of hypoventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which in turn can lead to aspiration, bronchospasm, pneumonitis, and pneumonia. Parameters of cardiopulmonary function associated with both CO\textsubscript{2} and N\textsubscript{2}O insufflation include reduced PO\textsubscript{2}, O\textsubscript{2} saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO\textsubscript{2} as a distention medium is associated with an increase in PCO\textsubscript{2} and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and a ventilation–perfusion mismatch (69).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because the rapid absorption of CO\textsubscript{2} in blood reduces the significance of gas emboli. However, if large amounts of CO\textsubscript{2} gain access to the central venous circulation, if peripheral vasoconstriction occurs, or if the splanchnic blood flow is decreased by excessively high intraperitoneal pressure, severe cardiorespiratory compromise may result.

The signs of CO\textsubscript{2} embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO\textsubscript{2} level may increase, and findings consistent with pulmonary edema may manifest. Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.

Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the insufflation needle, if used, must be ensured. Although the initial intraperitoneal pressure may be set at 20 to 30 mm Hg for port placement, it should be maintained at 8 to 12 mm for the rest of the case. The risk of CO\textsubscript{2} embolus also is reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor the patient’s color, blood pressure, heart sounds, heartbeat, and end-tidal CO\textsubscript{2} to allow early recognition of the signs of CO\textsubscript{2} embolus.

If CO\textsubscript{2} embolus is suspected or diagnosed, the surgeon must evacuate the CO\textsubscript{2} from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, the patient should be evaluated for other causes of cardiovascular collapse.

Cardiovascular Complications

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists have adopted the practice of mechanical ventilation during laparoscopic surgery. The incidence of hypercarbia is reduced by operating with intraperitoneal pressures at levels less than 12 mm Hg (70).

The risk of cardiac arrhythmia also may be reduced by using NO\textsubscript{2} as a distending medium (see the preceding discussion on Access). Although NO\textsubscript{2} is associated with a decreased incidence of arrhythmia, it also is insoluble in blood and, therefore, its use may increase the risk of gas embolus. External lifting systems avoid the complication of hypercarbia and can also provide protection against cardiac arrhythmia.
Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (71). All of these side effects should be considered when performing surgery on patients with pre-existing cardiovascular disease.

**Gastric Reflux**

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk of aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of metoclopramide, H2-blocking agents, and nonparticulate antacids also reduces the risk of aspiration.

**Extraperitoneal Insufflation**

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO₂ around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema can become extensive, involving the extremities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. Such a finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (72–74).

The risk of subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation has occurred extraperitoneally, the laparoscope can be removed and the procedure can be repeated. However, difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudal to the tip of the laparoscope (75).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result. Following termination of the procedure, it is prudent to obtain a chest x-ray. The patient’s condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14–16 gauge) inserted in the second intercostal space in the midclavicular line.

**Electrosurgical Complications**

Complications of electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode, current diversion to an undesirable path,
and injury at the site of the dispersive electrode. Such complications may occur with the use of these instruments during laparoscopic, abdominal, or vaginal surgery. Active electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion and dispersive electrode accidents occur only with unipolar devices. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (17).

Active Electrode Trauma

If the foot pedal is accidentally depressed, tissue adjacent to the electrode will be traumatized. Potential sites of injury include the bowel, ureter, or, if the electrode lies on the abdomen, the skin. Injury from direct extension of thermal effect can occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar instruments may reduce but do not eliminate the risk of thermal injury to adjacent tissue (76). Therefore, blood vessels should be isolated before desiccation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noncoagulated tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of its activation. The diagnosis of visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately, taking into consideration the potential extent of the zone of coagulative necrosis (77). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce thermal necrosis that extends several centimeters. In such cases, wide excision or resection will be necessary. The choice of route of access for any required surgical repairs depends in part on the nature of the injury and on the skills and training of the surgeon.

The incidence of unintended activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient’s skin if the electrode is accidentally activated.

Current Diversion

Current diversion occurs when the radiofrequency circuit follows an unintended path between the active electrode and the electrosurgical generator. This may occur with insulation defects, direct coupling, or capacitative coupling. In older, grounded systems, current can be diverted if any part of the patient’s body touches a conductive and grounded object. In any of these situations, if the power density becomes high enough, unintended and severe thermal injury can result.

Insulation Defects

If the insulation coating the shaft of an electrosurgical electrode becomes defective, it can allow current diversion to adjacent tissue, often bowel, potentially resulting in significant
injury (Fig 21.20A). Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. **When using monopolar laparoscopic instruments, the shaft of the device should be kept away from vital structures and, if possible, totally visible in the operative field.**

**Direct Coupling**

Direct coupling occurs when an activated electrode touches and energizes another uninsulated metal conductor such as a laparoscope, cannula, or other instrument. Direct coupling is often used for hemostasis when a grasping instrument is used to occlude a blood vessel while a separate activated electrode is used to provide the energy for desiccation and coagulation. If this occurs while the noninsulated device rests against structures such as bowel or the urinary tract, however, unintended injury may occur (Fig 21.20B). The risk of direct coupling can be reduced by eliminating the simultaneous use of noninsulated instruments and monopolar electrodes. Furthermore, the surgeon should visually confirm that there is no contact with other conductive instruments before activating a monopolar electrode.

**Capacitive Coupling**

**Capacitance** is the ability of a conductor to establish an electrical current in an unconnected but nearby circuit. An electrical field is established around the shaft of any activated unipolar electrode (including the cord), a circumstance that makes the electrode a potential capacitor. This field is harmless if the circuit is completed through a dispersive, low-power density pathway (Fig. 21.21). For example, if capacitative coupling occurs between a laparoscopic electrode and a metal cannula positioned in the abdominal wall, the current is harmlessly dispersed in the abdominal wall at the point where it connects with the dispersive electrode (Fig. 21.21A). However, if the metal cannula is anchored to the skin by a nonconductive plastic retaining sleeve or “gripper” (a hybrid system), the current cannot return to the abdominal wall because the sleeve acts as an insulator (Fig. 21.21B). Instead, the capacitor will have to “look” elsewhere to complete the circuit. Therefore, bowel or any other nearby conductor can become the target of a relatively high-power density discharge (Fig. 21.21C).

Capacitive coupling can be prevented by avoiding the use of hybrid laparoscope-cannula systems that contain a mixture of conductive and nonconductive elements. Instead, the use of all-plastic or all-metal cannula systems is preferred. When operating laparoscopes are used, all-metal cannula systems should be the rule unless there is no intent to perform unipolar electrosurgical procedures through the operating channel.

**Dispersive Electrode Burns**

Modern electrosurgical units are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode detachment (“patient pad”) occurs. The use of isolated-circuit electrosurgical generators with dispersive electrode monitors has virtually eliminated dispersive electrode–related thermal injury. Dispersive electrode monitoring is actually accomplished by measuring the impedance in the dispersive electrode, which should always be low because of the large surface area. Without such devices, partial detachment of the dispersive electrode could result in a thermal injury because reducing the surface area of the electrode raises the current density (Fig. 21.22).

Because ground-referenced machines without such safeguards are still in use, it is important to know the type of electrosurgical unit used in the operating room. If the electrosurgical generator is ground referenced and if the dispersive electrode becomes detached,
These events may occur with the use of monopolar instrumentation when there is a defect in the insulation (A) or, classically, to contact a conductive instrument that, in turn, touches other intraperitoneal structures. In the example depicted (B), the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.

unplugged, or otherwise ineffective, the current seeks any grounded conductor, such as electrocardiograph patch electrodes or the conductive metal components of the operating table (Fig. 21.23). If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury (Fig. 21.24).

**Figure 21.20** Current Diversion Secondary to Insulation Defects and Direct Coupling. These events may occur with the use of monopolar instrumentation when there is a defect in the insulation (A) or, classically, to contact a conductive instrument that, in turn, touches other intraperitoneal structures. In the example depicted (B), the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.

**Hemorrhagic Complications**

**Great Vessel Injury**

The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches,
Figure 21.21 Capacitative coupling. **A:** All activated monopolar electrodes emit a surrounding charge, proportional to the voltage of the current. This makes the electrode a potential capacitor. **B:** Generally, as long as the charge is allowed to disperse through the abdominal wall, no sequelae result. However, if the “return” to the dispersive electrode is blocked by insulation, such as a plastic anchor **(C),** the current can couple to a conductive cannula or directly to bowel.
Figure 21.22  Dispersive electrode burns. If the dispersive electrode becomes partially detached, the current density may increase to the point that a skin burn results.

Figure 21.23  Risk of ground-referenced generators. Current diversion along alternate pathways is a risk associated with ground-referenced electrosurgical generators, particularly if the dispersive electrode is detached. In the example depicted, the relatively high current density at the electrocardiogram electrode site may result in a skin burn.
and the internal and external iliac arteries and veins. The most catastrophic injuries occur secondary to insertion of an insufflation needle or the tip of the trocars used to position the primary or ancillary cannulas. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (79). After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some instances, blood is aspirated through the insufflation needle before the introduction of the distending gas. In such instances, the needle should be left in place while immediate preparations are made to obtain blood products and perform laparotomy. The bleeding frequently will be contained in the retroperitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop. To avoid late recognition, the course of each great vessel must be identified before completing the procedure. Because it is difficult to assess the volume of blood filling the retroperitoneal space, immediate laparotomy is indicated if retroperitoneal bleeding is suspected. A midline incision should be made to allow access to the great vessels. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury. Vascular or general surgery consultation may be necessary to evaluate and repair significant vascular injuries. Although most of these injuries are small and amenable to repair with suture, some are larger and require the insertion of a vascular graft. Deaths have occurred as a result of these injuries.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar or by the introduction of a wider device later in the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles (Fig. 21.3). More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.

Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops bleeding spontaneously; therefore, expectant management is appropriate. A straight ligature carrier can be used to repair lacerated deep inferior epigastric vessels. Alternatively, a Foley catheter may be inserted through the cannula, inflated, put on traction, and held in place with a clamp for 24 hours. If a postoperative hematoma develops, local compression should be used initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk of abscess. However, if the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.
Intraperitoneal Vessel Injury

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO₂ in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined. Carbon dioxide should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

Gastrointestinal Complications

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured (80,81).

Insufflation Needle Injuries

Needle entry into the gastrointestinal tract may be more common than reported because it often occurs unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury can be identified. Defects must be repaired immediately by laparoscopy or laparotomy.

Trocar Injuries

Damage caused by a sharp trocar is usually more serious than needle injury. Inadvertent gastric entry usually results from stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often, the injury is created by the primary trocar. Ancillary cannulas may also result in visceral injury, although placement of these cannulas under direct vision helps to reduce the risk of injury. The risk of gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper-quadrant entries are used or when the intubation was difficult. Open laparoscopy likely has little impact on the risk for gastrointestinal complications, particularly those related to adhesions to the anterior abdominal wall from previous surgery. For high-risk patients, left upper quadrant needle and trocar insertion with a properly decompressed stomach may be preferable (82–84).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be immediately recognized because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess,
enterocutaneous fistula, or death occurs (85,86). Therefore, at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.

Trocar injuries to the stomach and bowel require repair as soon as they are recognized. If the injury is small, a trained operator can repair the defect by laparoscopy using a double layer of running 2-0 or 3-0 absorbable sutures. Extensive lesions may require resection and reanastomosis, which in most instances requires laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy.

Dissection and Thermal Injury

When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. Should the injury involve radiofrequency electrical energy, it is important to recognize that the zone of desiccation may exceed the area of visual damage. This is especially true if the exact mechanism of the thermal injury is unknown or if injury results from contact with a relatively large surface area electrode that would be more likely to create a large coagulation injury. Conversely, bowel injury created under direct vision with a radiofrequency needle or blade electrode is associated with little collateral coagulation effect and, therefore, can be managed similar to a mechanically induced lesion. Consequently, surgical repair should be implemented considering these factors, and should include, if necessary, resection of ample margins around the injury. Thermal injury may be handled expectantly if the lesion seems superficial and confined, such as is the case when fulguration (noncontact arcing of high-voltage current) involves bowel. In such instances, the depth of injury is generally less than half a millimeter. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for repair of perforation (87).

Urologic Injury

Damage to the bladder or ureter may occur secondary to mechanical or thermal trauma during laparoscopic procedures. Ideally, such injury should be prevented; otherwise, as is the case for most complications, it is preferable to identify the trauma intraoperatively.

Bladder Injury

Bladder injury can result from the perforation of the undrained bladder by a trocar, but it also may occur while the bladder is being dissected from adherent structures or from the anterior uterus (88,89). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO₂ in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be apparent initially and, if missed, can present as peritonitis or a fistula.

Routine preoperative bladder drainage usually prevents trocar-related cystotomies. Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

Very small-caliber injuries to the bladder (1–2 mm) may be treated with bladder catheterization for 3 to 7 days. If repair is undertaken immediately, catheterization is unnecessary. When a larger injury is identified, it can be repaired laparoscopically.
If the laceration is near the trigone or involves the trigone, however, an open procedure should be used. The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. If thermal injury occurred, the coagulated portion should be excised. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. Cystography should be considered before the urinary catheter is removed.

**Ureteral Injury**

The most common cause of ureteral injury during laparoscopy is electrosurgical trauma (76,91). However, ureteral injury also can occur after mechanical dissection including linear cutting and stapling devices (92,93). Although intraoperative recognition of ureteral injury is possible, the diagnosis is usually delayed (91). Ureteral lacerations may be confirmed intraoperatively visually or with the intravenous injection of indigo carmine. Thermal injury presents up to 14 days after surgery with fever, abdominal or flank pain, and peritonitis. Leukocytosis may be present, and intravenous pyelography shows extravasation of urine or urinoma. Mechanical obstruction from staples or a suture may be recognized intraoperatively by direct visualization. Cystoscopy following the intravenous injection of indigo carmine may be used to confirm failure of the dye to pass through the ureter. Abdominal ultrasound may be helpful, but a CT urogram can more precisely identify the site and degree of the obstruction. Unrecognized ureteral obstruction may present a few days to 1 week after surgery with flank pain and often fever (93).

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistulas. A bladder fistula can be confirmed by detecting dye on a tampon previously placed in the vagina after filling the bladder with methylene blue. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk of injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. Because of variation from one patient to another or the presence of disease, however, the location of the ureter can become obscured, making it necessary to enter the retroperitoneal space. The techniques used for retroperitoneal dissection are also important factors in reducing the risk of ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used (94). The selective placement of ureteral stents may also be helpful in preventing injury.

Ureteral injury can be treated immediately if it is diagnosed intraoperatively. Although limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Although laparoscopic repair of ureteric lacerations and transections has been performed, most injuries require laparotomy (91,95).

When the diagnosis of ureteral injury is delayed, the bladder should be drained with a catheter. Incomplete or small obstructions or lacerations may be treated successfully with either a retrograde or antegrade ureteral stent. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken.
Neurologic Injury

Peripheral nerve injury is usually related either to poor positioning of the patient or to excessive pressure exerted by the surgeons. Nerve injury may also occur as a result of the surgical dissection.

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against the stirrups. The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by excessive flexion or external rotation of the hips. The peroneal nerve may be injured by compression if the lateral head of the fibula rests against the stirrups (96–98). Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against the abducted arm during the procedure. If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint. In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient’s arms in an adducted position.

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be hastened by the use of physical therapy, appropriate braces, and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intrapelvic nerves.

Incisional Hernia and Wound Dehiscence

Incisional hernia after laparoscopy has been reported in more than 900 cases (66,99). The most common defect is dehiscence that develops in the immediate postoperative period. Hernias may be asymptomatic or may cause pain, fever, periumbilical mass, obvious evisceration, and the symptoms and signs of mechanical bowel obstruction. Although no incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable (99–101).

Richter’s hernias contain only a portion of the intestine in the defect, and the diagnosis is often delayed because the typical symptoms and findings of mechanical bowel obstruction may be absent. The initial symptom is usually pain. These hernias most often occur in incisions lateral to the midline where there is a greater amount of preperitoneal fat creating a potential space for incarceration. Fever can be present if incarceration occurs, and peritonitis may result from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with ultrasonography or computed tomography (102).

In most cases, these occurrences can be prevented by using small-caliber cannulas, where possible, and with routine fascial and peritoneal closure of defects made by peritoneal access. The risk of inadvertent incorporation of the intestine into the wound can be reduced by viewing the closure with the laparoscope. A small-diameter laparoscope should be used through a narrow cannula to facilitate incisional closure. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision and that no active bleeding is present in the incision.

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced into the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk of perforation, laparotomy is necessary to repair or resect the intestine.
CHAPTER 21  Gynecologic Endoscopy

Infection

Wound infections after laparoscopy are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics (103). Severe necrotizing fasciitis can occur rarely (103). Bladder infection, pelvic cellulitis, and pelvic abscess have been reported (104).

Laparoscopy is associated with a much lower risk of infection than open abdominal or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.

Hysteroscopy

The hysteroscope can be used to aid diagnosis or to direct the performance of a variety of intrauterine procedures. Hysteroscopic lysis of intrauterine adhesions was first described in 1973 (105). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology for the removal of uterine leiomyomas (106). Hysteroscopic division of uterine septa was originally developed using a mechanical technique with specially designed scissors (107). Hysteroscopic destruction of the endometrium has been reported using Nd:YAG laser vaporization, and using electrosurgical desiccation or resection, and vaporization. More recently, hysteroscopically guided thermal ablation with heated fluid has been described (108–110).

Developments in the design of endoscopes have resulted in smaller-diameter instruments that retain the ability to provide a high-quality image. Such developments further facilitate the use of hysteroscopy in an office or procedure room setting.

Diagnostic Hysteroscopy

The goal of evaluation of the uterine cavity is either to obtain a sample of the endometrium, usually for the detection of hyperplasia or neoplasia, or to identify structural abnormalities such as polyps, myomas, or a uterine septum. Blind endometrial sampling has been the diagnostic mainstay for the detection of endometrial hyperplasia, whereas transvaginal ultrasonography, hysterography, and hysteroscopy are options in the detection and characterization of structural anomalies. Hysteroscopic examination is probably superior to hysterography in the evaluation of the endometrial cavity (111,112), but the diagnostic accuracy of transvaginal ultrasonography is similar, especially when intrauterine saline is used as a contrast medium, a procedure called sonohysterography or saline infusion sonography (SIS) (113). Ultrasound-based techniques have the advantage of allowing evaluation of the myometrium, whereas office-based hysteroscopy allows simultaneous removal of small polyps and even some myomas. Diagnostic hysteroscopy provides information not obtained by blind endometrial sampling (114–120), such as detection of endometrial polyps or submucous leiomyomas (117,118,120,121). Malignant or hyperplastic polyps or other localized lesions can be identified with hysteroscopy and removed via directed biopsy (119). However, blind curettage remains an effective approach for the identification of endometrial histopathology (115,118,120,122). Following are potential indications for diagnostic hysteroscopy.

1. Unexplained abnormal uterine bleeding
   - Premenopausal
   - Postmenopausal
2. Selected infertility cases
   • Abnormal hysterography or transvaginal ultrasonography
   • Unexplained infertility

3. Recurrent spontaneous abortion

For most patients, diagnostic hysteroscopy can be performed in an office or clinic with minimal discomfort and at a much lower cost than in an operating room. For some, concerns about patient comfort or a pre-existing medical condition may preclude office hysteroscopy. Although hysteroscopy can, in many patients, provide more information than blind curettage, it should still be used prudently. For most patients, other diagnostic or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For example, in women with perimenopausal and postmenopausal bleeding, office endometrial biopsy or curettage should be the initial method of assessment. If a satisfactory diagnosis cannot be established, or if bleeding continues without explanation, further investigation with ultrasound, SIS, or office hysteroscopy is appropriate. For women in their reproductive years who have abnormal uterine bleeding, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical treatments such as oral contraceptives, transvaginal ultrasonography, SIS, or hysteroscopy with biopsy, if appropriate, can be performed for diagnosis (123).

For women with infertility, hysterosalpingography is the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy can be performed to confirm the diagnosis, to define the abnormality, and perhaps to direct the removal of the lesion. Some experts consider hysteroscopy mandatory for such patients because of the high occurrence of false-negative radiologic images in those with intrauterine anomalies. However, there has been no evidence that identification and treatment of these “missed” anomalies improves pregnancy rates. Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.

Operative Hysteroscopy

A number of intrauterine procedures can be performed under endoscopic direction, including adhesiolysis, sterilization, division of a uterine septum, resection of myomas, and endometrial destruction through Nd:YAG laser vaporization or radiofrequency resection, desiccation, or vaporization. Hysteroscopy may also be used to direct the removal of foreign bodies or to position occluding devices in the fallopian tube for sterilization.

Foreign Body

If the string of an intrauterine device is absent, the device usually can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, the location of the device may be confirmed by hysteroscopy, allowing removal with a grasping forceps.

Septum

When recurrent pregnancy loss is associated with a single corpus containing a uterine septum, hysteroscopic division of the septum improves reproductive outcome at a rate comparable to abdominal metroplasty, with reduced morbidity and cost (see Chapter 31) (124–128). The procedure may be performed mechanically with scissors or with energy-based techniques such as the Nd:YAG laser or an electrosurgical knife or loop. Because most septa have few vessels, scissors can be used easily, and the minimal risk for thermal damage is avoided.
Endometrial Polyps

Although endometrial polyps can be removed with blind curettage, many are missed (117,118,120,121). Therefore, known or suspected endometrial polyps are more successfully treated with hysteroscopic guidance, which can often be performed in a clinic or office using local anesthesia. Hysteroscopy may be used either to evaluate the result of blind curettage or use of grasping forceps, or preferably, with appropriate operating sheaths, to guide directed removal with small-caliber scissors or grasping forceps. Alternatively, for larger polyps, a uterine resectoscope may be used to sever the stalk or morcellate the lesion.

Leiomyomas

Hysteroscopy may be used to remove selected leiomyomas that involve the uterine cavity in women with heavy menstrual bleeding or infertility (113,129–135). However, this approach is limited based on the location, size, and number of the lesions. Preoperative administration of gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal. Perhaps more importantly, they reduce operating time and systemic absorption of distension media (136–138).

To help document and evaluate the results of hysteroscopically directed myoma surgery, a classification system has been developed that is based on the proportion of the myoma that is in the uterine cavity. In patients with myomas that are 5 cm or less in diameter and entirely intracavitary (Type 0), excision is feasible and in many instances relatively easy, whereas in large type 2 lesions an abdominal approach with laparoscopy or laparotomy will be is necessary. Small type 0 leiomyomas may be removed following transection of the stalk with scissors or an electrode attached to a uterine resectoscope. For larger type 0 lesions, or for type 1 myomas, electrosurgical morcellation with a resectoscope is necessary before removal. For a limited number of type 2 myomas, careful myometrial dissection may be attempted provided that ultrasonography or magnetic resonance imaging has demonstrated an adequate margin of myometrium between the deepest aspect of the lesion and the serosa. It may be preferable to undertake such procedures with laparoscopic monitoring to ensure that bowel is not adjacent to the zone of dissection. Patients should be counseled that for some type 1 and 2 myomas, it may take more than one procedure to complete excision (134). Alternatively, the Nd:YAG laser or radiofrequency electrodesiccation can be used to destroy the remaining portion of the leiomyoma, although the efficacy of this approach is unclear (130). The use of intrauterine prostaglandin F₂α has also been described to facilitate extrusion of type 2 myomas (139).

Endometrial Ablation

Heavy Menstrual Bleeding

Heavy menstrual bleeding that does not respond to oral medical therapy may be managed by endometrial ablation or resection, provided the patient is willing to forego future fertility (108-110,132,138,140–147). Alternatively, or if future fertility is desired, a levonorgestrel-releasing intrauterine contraceptive device can provide virtually equal clinical outcomes (148–149). Ablation may be performed with the laser (108,139,140) by radiofrequency electrosurgical desiccation, resection, or vaporization using a uterine resectoscope (110,150) or by any of a number of nonresectoscopic techniques, including those employing thermal balloons, bipolar radiofrequency, cryonics, heated free fluid, or microwaves (151–155).

Endometrial resection is performed with an electrosurgical loop electrode that can shave the endometrium and superficial myometrium (109,142,143). Vaporization utilizes specially designed electrodes that are attached to standard resectoscopes but which are capable of removing large volumes of tissue without morcellation (156). Ablation is achieved using ball or barrel-shaped electrodes that coagulate the endometrial surface.
Complications of these procedures include fluid overload, electrolyte imbalances (if nonelectrolytic media are used), uterine perforation, bleeding, and intestinal and urinary tract injury (140,145). The risk of uterine perforation may be reduced by using a combination of resection or vaporization and electrosurgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu (132). The preoperative use of GnRH analogues or danazol may reduce operating time, and GnRH may reduce bleeding and the amount of fluid absorbed into the systemic circulation (157,158).

For many women, these procedures are successful in reducing or eliminating menses without hysterectomy or long-term medical therapy (129,159,160). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year, and 30% to 90% of patients have amenorrhea. In comparative studies, there is no advantage of laser over electrosurgical techniques (140,145). The nonresectoscopic techniques have similar clinical outcomes, thus reducing the need for resectoscopic ablation. However, the nonresectoscopic approaches all have limitations defined by the size or configuration of the endometrial cavity. Consequently, for those women with heavy menstrual bleeding who are not suitable for nonresectoscopic techniques because of large uteri (>12 cm sounded length), resectoscopic endometrial ablation remains a viable option (161).

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because some endometrium inevitably cannot be ablated, there is the potential for endometrial cancer; therefore, postmenopausal women who have undergone ablation or resection should take progestin as a part of hormonal therapy (159).

**Sterilization**

Sterilization can be performed under hysteroscopic guidance, an approach that eliminates the disadvantages and risks associated with abdominal or laparoscopic techniques (162,163). One such technique is currently available, and others are currently under development. The Essure system comprises a nickel-titanium coil with a Dacron filament that can be inserted relatively quickly in an office or procedure room setting (see Chapter 10). Current protocols require that hysterosalpingography be performed 3 months after the procedure to ensure that bilateral tubal occlusion has taken place.

**Synechiae**

Asherman's syndrome is the presence of adhesions in the endometrial cavity resulting in infertility or recurrent spontaneous abortion with or without amenorrhea. These synechiae may be detected on a hysterogram but are best shown with diagnostic hysteroscopy. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope (164). Thicker lesions may require division by semirigid or rigid scissors or energy-based instruments such as a resectoscope or an operative hysteroscope with an Nd:YAG laser. Reproductive outcome depends on the extent of the preoperative endometrial damage (125,165,166).

**Patient Preparation and Communication**

Most diagnostic hysteroscopy procedures are performed in the office or clinic, whereas operative hysteroscopy is usually performed in an operating room or hospital surgicenter. The patient should understand the rationale for either procedure, as well as the anticipated discomfort, the potential risks, and the expectant, medical, and surgical alternatives. The nature of the procedure and the chance of therapeutic success should be explained to the patient, and she should be given a realistic estimate of success based on the operator's experience.

**Diagnostic Hysteroscopy: Risks**

The risks of diagnostic hysteroscopy are few, and those complications that occur rarely have severe consequences. However, those risks related to anesthesia, perforation, bleed-
Operative Hysteroscopy: Counseling before operative hysteroscopy varies depending on the planned procedure and the type of anesthesia used. The risks of operative hysteroscopy are higher and potentially more dangerous than those of diagnostic hysteroscopy. These risks include those associated with anesthesia, intrinsic to all hysteroscopic procedures, and related to the specific surgical procedure to be performed. With any hysteroscopic procedure, air embolus is a possibility, as are complications associated with the gaseous or fluid distention media used. Hypotonic distension media may not be tolerated in some patients if there is significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must also be aware of the risks associated with uterine perforation, which range from failure to complete the procedure to hemorrhage or damage to the intestines or to the urinary tract. If such complications occur, laparotomy may be necessary to repair the injury.

Equipment and Technique The equipment required for hysteroscopy depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and a decreased probability of complications. A typical hysteroscopy setup for diagnostic and minor operative procedures is shown in Figures 21.24 and 21.25. Core competencies required for hysteroscopy are as follows:

1. Patient positioning and cervical exposure
2. Anesthesia
3. Cervical dilation
4. Uterine distention
5. Imaging
6. Intrauterine manipulation

Patient Positioning and Exposure Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum. Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. “Candy cane” stirrups should be avoided for hysteroscopic surgery on conscious patients.

The smallest speculum possible should be used to expose the cervix. A bivalve speculum hinged on only one side allows its removal without disturbing the position of the tenaculum and hysteroscope. The use of weighted specula should be avoided in conscious patients because of the discomfort involved.

Anesthesia The anesthetic requirements for hysteroscopy vary greatly, depending on the patient’s level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. In some patients, diagnostic hysteroscopy is possible without
anesthesia, especially if the patient is parous or if narrow-caliber (<3 mm in outside diameter) hysteroscopes and sheaths are used. The pain of cervical dilation also is avoided or minimized by inserting a laminaria tent in the cervix 3 to 8 hours before the procedure. However, if laminaria are left in place too long (e.g., longer than 24 hours), the cervix may overdilate, which is counterproductive for CO₂ insufflation.

**Figure 21.24 Office Hysteroscopy Setup.** Hysteroscopic procedures are facilitated with an electric examination table. Distension media may be positioned on an IV pole, but wide, cystoscopy tubing allows maintenance of higher intrauterine pressures suitable for viewing and performing simple procedures such as polypectomy or transcervical sterilization. A light source is necessary and a camera desirable. The camera is attached to the monitor and may be connected to a printer and/or video recorder. The camera head is attached to a flexible hysteroscope.
CHAPTER 21  Gynecologic Endoscopy

For most diagnostic procedures, effective cervical anesthesia is obtained with an intracervical block. A spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix. A tenaculum is used to grasp the cervix. An intracervical block is administered evenly around the circumference of the internal os. A paracervical block may also be injected into the uterosacral ligaments at the 4- and 8-o’clock positions, if necessary (167). Care must be taken to avoid intravascular injection. Additional topical anesthesia may be given by injecting 5 mL of 2% mepivacaine into the endometrial cavity with a syringe. Many operative procedures can be performed with this technique combined with intravenous use of anxiolytics or analgesics, as necessary. Alternatively, regional or general anesthesia may be used.

Cervical Dilation

Dilation of the cervix, although apparently simple, can be incorrectly performed in a way that compromises the whole procedure. If the objective lens of the hysteroscope cannot be placed in the endometrial cavity, the hysteroscopy cannot be done. Although findings have been inconsistent, preoperative administration of prostaglandin E, (misonplast) to ripen the cervix 12 hours before the procedure (400 µg orally or 200 µg vaginally) may facilitate cervical dilation (168,169). Alternatively, there is evidence that intracervical injection of vasopressin (0.05 U/mL, 4 cc at 4 and 8 o’clock) also substantially reduces the force required for cervical dilation (170). The cervix should be dilated asatraumatically as possible. It is best to avoid using a uterine sound because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation.

Figure 21.25 Office Hysteroscopy Instruments. An assembled continuous flow operating hysteroscope with a 5.5-mm diameter external sheath is shown in A. A 5 French semirigid scissors occupies the working channel. An additional biopsy forceps is shown in B. Tubing transporting media to the system is shown in C going into a 3-mm external diameter flexible and steerable hysteroscope (D). A medical video camera is attached to the hysteroscope (F) and the light source is attached at (E). An open speculum (G) facilitates removal with instruments in place. A small dilator (H) or series of dilators will be necessary for a large number of patients. A tenaculum (I) attached to the cervix frequently facilitates both dilation and entry of the hysteroscope into the endometrial cavity.

For most diagnostic procedures, effective cervical anesthesia is obtained with an intracervical block. A spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix. A tenaculum is used to grasp the cervix. An intracervical block is administered evenly around the circumference of the internal os. A paracervical block may also be injected into the uterosacral ligaments at the 4- and 8-o’clock positions, if necessary (167). Care must be taken to avoid intravascular injection. Additional topical anesthesia may be given by injecting 5 mL of 2% mepivacaine into the endometrial cavity with a syringe. Many operative procedures can be performed with this technique combined with intravenous use of anxiolytics or analgesics, as necessary. Alternatively, regional or general anesthesia may be used.
SECTION V  Operative General Gynecology

Uterine Distention

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO₂ gas, high-viscosity 32% dextran 70, and a number of low-viscosity fluids, including glycine, sorbitol, saline, and dextrose in water. A pressure of 45 mm Hg or higher is generally required for adequate distention of the uterine cavity. To minimize extravasation, this pressure should not exceed the mean arterial pressure. For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

Sheaths

A rigid hysteroscope is passed into the endometrial cavity through an external sheath. The design and diameter of the sheath reflect both the dimensions of the endoscope and the purpose of the instrument. Diagnostic hysteroscopes have a sheath slightly wider than the telescope, allowing infusion of the distention media. Sheaths for operative hysteroscopes have one or two additional channels that permit the passage or efflux of distention media or the insertion of semirigid instruments or laser fibers. These sheaths are usually 5 to 8 mm in diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Figs. 21.25, 21.26).

Media

CO₂ provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent CO₂ embolus, the gas must be instilled by an insufflator that is specially designed for the procedure—the intrauterine pressure is kept below 100 mm Hg, and the flow rate is maintained at less than 100 mL/min.

Normal saline is a useful and safe medium for procedures that do not require radiofrequency electricity from standard monopolar resectoscopes. Even if there is absorption of a substantial volume of solution, saline does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office. The development of bipolar radiofrequency instrumentation for hysteroscopic surgery has allowed the application of saline as a distending medium in even more advanced and complex procedures.

Figure 21.26  Hysteroscope optics. Panoramic (0°) and oblique (15° and 30°) viewing angles.
Dextran 70 is useful for patients who are bleeding, because it does not mix with blood. However, it is expensive and tends to “caramelize” on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For standard operative hysteroscopy with monopolar radiofrequency resectoscopes, low-viscosity, nonconductive fluids such as 1.5% glycine, 3% sorbitol, and 5.0% mannitol are used most often. These solutions can be used with standard, monopolar radiofrequency instrumentation because there are no electrolytes to disperse the current and impede the electrosurgical effect. Each of these media is inexpensive and readily available, usually in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is electrolyte-free, extravasation into the systemic circulation can be associated with electrolyte disturbances. Compared with 1.5% glycine or 3.0% sorbitol, 5% mannitol is isosmolar, and it functions as a diuretic, both advantages when performing resectoscopic surgery. Regardless of the electrolyte content of the fluid distending media, systemic “absorption” must be monitored continuously or at least frequently (every 5 minutes) by collecting outflow from the sheath and subtracting it from the total infused volume. There exist a number of machines designed to provide continuous feedback to the surgeon regarding the degree of negative fluid balance. Absorbed volumes greater than 1 L mandate the measurement of electrolyte levels. The administration of an appropriate dose of furosemide should be considered, and the surgeon should plan for the expeditious completion of the procedure. If there is more than a preset limit (1.5–2 L of extravasated fluid), the procedure should be stopped. Excessive circulating sorbitol may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood (171).

Media Delivery Systems

Syringes can be used for office diagnostic procedures and are especially good for infusing dextran solution. The syringe can be operated by the surgeon and is either connected directly to the sheath or attached by connecting tubing. Because this technique is so tedious, it is suited only for simple operations.

Continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient’s uterus. The achieved pressure is the product of the width of the connecting tubing and the elevation—for operative hysteroscopy with 10-mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 to 1.5 m above the uterine cavity.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised, however, because this technique causes increasing extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps are available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the preset level is reached, thereby impeding the efflux of blood and debris and compromising the view.

Imaging

Endoscopes

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes have lower resolution than rigid instruments of a similar diameter and are most useful for cannulation of the fallopian tube. For other uses, rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 3 to 4 mm in
SECTION V Operative General Gynecology

diameter, although those smaller than 2 mm in diameter are available. Small-diameter endoscopes have a somewhat lower resolution but are easier to pass through the cervix.

Endoscopes with angled (foreoblique) lenses are useful for hysteroscopy and are available in 0-degree, 12- to 15-degree, and 25- to 30-degree models (Fig. 21.26). The 0-degree telescope provides a panoramic view and is best for diagnostic procedures. Hysteroscopes with 25- to 30-degree angles are most often used for cannulation of the fallopian tubes or placement of sterilization devices, whereas 12- to 15-degree designs are a suitable compromise useful for diagnosis and ablation or resection.

Light Sources and Cables

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures (172).

Video Imaging

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The camera must be sensitive because of the narrow diameter of the endoscope and the frequently dark background of the endometrial cavity, particularly when it is enlarged (Fig. 21.25).

Image Documentation

A small video camera can be used to teach and to coordinate the procedure with the operating room team. It also allows the acquisition of still or video images for future reference or teaching. When a video recorder is used, the camera should be attached directly to the recorder to preserve the image quality. A number of video recording formats are available, each with inherent advantages and disadvantages. Some video printers provide images suitable for a medical record. Newer digital cameras provide video still images, slides, or prints that are suitable for publication or teaching.

Intrauterine Surgery

The instruments available for use through operative hysteroscopes include grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2-mm diameter operating channel (Fig. 21.25). Their value is limited by their small size and flimsy construction; however, the scissors can be used to divide adhesions, the biopsy forceps can be used to sample targeted lesions, and the grasping forceps can be used to remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser.

The uterine resectoscope is similar to the one used in urology and is designed to apply radiofrequency electrical energy in the endometrial cavity (Fig. 21.27). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the “working element,” one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. An electrode with multiple tips or edges can be used to vaporize tissue, provided high generator outputs are used. A clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications have made the resectoscope more useful in gynecology, extraction of resected fragments is time consuming. The most effective approach is the periodic use of a uterine curette or polyp forceps inserted after
removal of the hysteroscope. Alternatively, much of the myoma or endometrium can be vaporized, thereby minimizing the need for periodic but time-consuming removal of tissue “chips.” If vaporization is used, it is still important to obtain representative samples of the endometrium or myoma for pathological analysis.

Other Instruments

For any hysteroscopic procedure, it is necessary to have available a cervical tenaculum, dilators, uterine curette, and appropriate-sized vaginal specula. When using the resectoscope, it is helpful to have a modern, solid-state, isolated circuit electrosurgical generator capable of delivering both modulated and nonmodulated radiofrequency current. Laparoscopy or laparotomy may be necessary for emergencies secondary to uterine perforation.

Complications

The potential risks of diagnostic hysteroscopy include uterine perforation, infection, excessive bleeding, and complications related to the distention media (145). The latter include CO₂ embolus and pulmonary edema secondary to overinfusion of 32% dextran 70 (Hyskon) or low-viscosity fluids. Diagnostic hysteroscopy performed in the office has a low rate of complications (0%–1%) (114–116). The risks of operative hysteroscopy are related to one of five aspects of the procedure performed: (i) anesthesia, (ii) the distention media, (iii) perforation, (iv) bleeding, and (v) the use of energy.

Anesthesia

Local anesthesia is provided by the intracervical or paracervical injection of 0.5% to 2% lidocaine or mepivacaine solution, with or without a local vasoconstrictor such as adrenaline. Overdosage is prevented by ensuring that intravascular injection is avoided and by not exceeding the maximum recommended doses (lidocaine, 4 mg/kg; mepivacaine, 3 mg/kg). The use of a vasoconstrictor reduces the amount of systemic absorption of the agent, doubling the maximum dose that can be used.

Complications of intravascular injection or anesthetic overdose include allergy, neurologic effects, and impaired myocardial conduction. Allergy is characterized by the typical symptoms of agitation, palpitations, pruritus, coughing, shortness of breath, urticaria, bronchospasm, shock, and convulsions. Treatment measures include administration of oxygen, isotonic intravenous fluids, intramuscular or subcutaneous adrenaline, and intravenous prednisolone and aminophylline. Cardiac effects related to impaired myocardial conduction include bradycardia, cardiac arrest, shock, and convulsions. Emergency treatment measures...
include the administration of oxygen, intravenous atropine (0.5 mg), and intravenous adrenaline, and the initiation of appropriate cardiac resuscitation. The most common central nervous system manifestations are paresthesia of the tongue, drowsiness, tremor, and convulsions. Options for therapy include intravenous diazepam and respiratory support.

**Distention Media**

**Carbon Dioxide**

Carbon dioxide is highly soluble in blood; consequently, even if emboli occur, they are rarely clinically significant. However, rarely, CO$_2$ emboli may result in serious intraoperative morbidity and even death (173–175). These risks can be eliminated by not using CO$_2$ with operative procedures, and by ensuring that the insufflation pressure is always lower than 100 mm Hg and that the flow rate is lower than 100 mL/min. The insufflator used must be especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL/min.

**Dextran 70**

Dextran 70 is a hyperosmolar medium that can induce an allergic response, coagulopathy, and, if sufficient volumes are infused, vascular overload and heart failure (176,177). Because dextran is hydrophilic, it can draw 6 times its own volume into the systemic circulation. Consequently, the volume of this agent should be limited to less than 300 mL, particularly for office use.

**Low-Viscosity Fluids**

The low-viscosity fluids—1.5% glycine, 3% sorbitol, and 5.0% mannitol—are most often used, largely because of their low cost, compatibility with standard electrosurgery, and availability in large-volume bags. However, the use of a continuous-flow system with hypotonic media can create fluid and electrolyte disturbances.

1. **Before undertaking a procedure using the resectoscope, baseline serum electrolyte levels should be measured.** Women with cardiopulmonary disease should be evaluated carefully. The selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption. Intracervical injection of 8 mL dilute intracervical vasopressin (0.01 U/mL) has been shown effective at reducing the amount of systemic absorption of distending media (178).

2. **In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the “absorbed” volume.** The volume should be measured continuously with a device specifically designed for the purpose or calculated every 5 to 10 minutes.

3. **The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, usually at a level that is below the mean arterial pressure.** A good range is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient’s uterus.

4. **Deficits of more than 1 L require measurement of electrolyte levels and may require an appropriate dose of intravenous furosemide.** The procedure should be completed expeditiously. If the deficit is more than a preset limit (1.5–2 L), the procedure should be terminated, and a diuretic such as mannitol or furosemide should be used as needed. In patients with cardiovascular compromise, deficits must be avoided (179).
Perforation

Perforation may occur during dilation of the cervix or during the hysteroscopic procedure. With perforation, the endometrial cavity does not distend, and the visual field is lost. When perforation occurs during dilation of the cervix, the procedure must be terminated, but usually there are no other injuries. If the uterus is perforated by a hysteroscopic instrument, the tip of a laser, or an activated electrode, there is a risk for bleeding or injury to the adjacent viscera. Therefore, the operation must be stopped and the instruments withdrawn under hysteroscopic guidance.

If there is evidence of bleeding or presumed visceral injury, laparoscopy or laparotomy should be performed. Injury to the uterus is relatively easy to detect with a laparoscope. However, mechanical or thermal injury to the bowel, ureter, or bladder is more difficult and may require laparotomy. If the patient’s condition is managed expectantly, she should be advised of the situation and asked to report any symptoms of bleeding or visceral trauma such as fever, increasing pain, nausea, and vomiting.

Bleeding

Bleeding that occurs during or after hysteroscopy results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels can be lacerated during the resectoscopic procedures.

In planning operations that involve deep resection, autologous blood can be obtained before surgery. The risk for bleeding may be reduced by the preoperative injection of diluted vasopressin into the cervical stroma (178). The risk of injury to branches of the uterine artery can be lowered by limiting the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be considered. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desiccate the vessel electrosurgically. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon or similar device in the endometrial cavity (132).

Thermal Trauma

Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be advised of the symptoms that could indicate peritonitis.

SECTION V Operative General Gynecology

SECTION V Operative General Gynecology

Hysterectomy

Thomas G. Stovall

Hysterectomy is one of the most commonly performed surgical procedures in the United States.

Vaginal hysterectomy continues to be the procedure of choice unless this route is contraindicated.

There appears to be no advantage to the routine use of supracervical hysterectomy when compared with total hysterectomy.

Oophorectomy at the time of hysterectomy is associated with an increase in patient mortality, and it is currently recommended that ovarian conservation be considered until at least age 65 years.

A number of concurrent surgical procedures may be performed safely at the time of hysterectomy.

Hysterectomy is one of the most common surgical procedures performed. After cesarean delivery, it is the second most frequently performed major surgical procedure in the United States (1). In 1965, there were 426,000 hysterectomies performed in the United States, with an average length of hospital stay of 12.2 days. This number reached its peak in 1985, when 724,000 procedures were reported, with the length of stay decreasing to 9.4 days. The number of hysterectomies performed in the United States declined to 544,000 in 1991, with an average length of stay of 4.5 days. Of these 544,000 hysterectomies, 408,000 (75%) were performed abdominally, and 136,000 (25%) were performed vaginally (2,3). However, by 1998, the number of hysterectomies performed had increased to more than 600,000 (4). Using 1987 age-specific hysterectomy rates and the population projections supplied by the U.S. Census Bureau, it is projected that there will be 824,000 hysterectomies in the year 2005 (5).

The rate of hysterectomy has varied between 6.1 and 8.6 per 1,000 women of all ages. A woman’s chance of having a hysterectomy is dependent on a variety of factors, including her age, race, and where she lives, and the sex of her physician. Women between the ages of 20 and 49 years constituted the largest segment of women undergoing the procedure. The average age of a woman undergoing hysterectomy is 42.7 years and the median age is 40.9 years, which has remained constant since the
1980s. About 75% of all hysterectomies are performed in women between the ages of 20 and 49 years. The rates of hysterectomy vary by region of the country. The highest overall rate is in the southern states, where the rate tends to be higher for women aged 15 to 44 years. The lowest rates have consistently been in the northeastern portion of the United States. Hysterectomy is more often performed in African American than in white women and is performed more frequently by male gynecologists than by female gynecologists (6–9).

**Indications**

The indications for hysterectomy are listed in Table 22.1. **In virtually all studies, uterine leiomyomas are consistently the leading indication for hysterectomy. As expected, the indications differ with the patient’s age** (10). For instance, whereas pelvic support defects account for 16% of all hysterectomies, this diagnosis is responsible for more than 33% of hysterectomies in women older than 55 years of age. More complete discussions of these indications are presented in the specific chapters indicated.

**Leiomyomas**

Uterine leiomyomas are the most common pelvic tumors in women; therefore, this condition is responsible for a large number of hysterectomies (10). Hysterectomy for uterine leiomyomas should be considered only in patients who do not desire future fertility. Otherwise, fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. **The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms**—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included “rapid” uterine enlargement (although this finding is poorly defined), ureteral compression, or uterine growth after menopause. **The concept of rapid growth has been challenged** (11) **because such patients have not been shown clearly to have malignant conditions.** Furthermore, there is no clearly reproducible definition of rapid growth. The removal of the uterus because it reaches a certain size is widely debated. In the past, surgeons removed the uterus if its size reached that approximating 12 weeks of gestation or greater, even if it was asymptomatic. The reasons given for such an intervention include the inability to palpate the ovaries on bimanual examination and the assumption that, as the uterus enlarges, the morbidity for hysterectomy increases. Malignancy is uncommon in premenopausal patients, however, and adnexal palpation is not possible in many patients whose ovaries are of normal size. If the procedures are performed abdominally, there is no difference in surgical morbidity between patients with a 12-week-sized uterus and those with a 20-week-sized uterus (12). **Therefore, hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility** (12).

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (13–15). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when otherwise an abdominal hysterectomy would have been necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks of gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (15). Treatment with a short course (8 weeks) of leuprolide acetate before surgery enabled the procedures to be converted safely from an abdominal hysterectomy to a vaginal hysterectomy. This preoperative regimen was associated with a rise in hematocrit before surgery and, because patients were more likely to have vaginal than abdominal hysterectomy, a shorter hospital stay and convalescent period.
Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding is the indication for about 20% of hysterectomies. Because dysfunctional uterine bleeding usually is the result of anovulation, the bleeding can be controlled by medical interventions with progestin, estrogen, a combination of progestin and estrogen, oral contraceptives, or nonsteroidal anti-inflammatory agents (see Chapter 14). In most patients, the bleeding requires no therapy unless anemia is present or bleeding is excessive and interferes with the patient’s quality of life. In patients older than 35 years of age, endometrial sampling should be performed before hysterectomy. Dilation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy (16). Therefore, hysterectomy should be reserved for patients...
who do not respond to or who cannot tolerate medical therapy. Alternatives to hysterectomy (eg, endometrial ablation or resection) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate (see Chapter 21).

Intractable Dysmenorrhea

About 10% of adult women are incapacitated for up to 3 days per month as a result of dysmenorrhea (see Chapter 15). Dysmenorrhea can be treated with nonsteroidal anti-inflammatory agents used alone or in combination with oral contraceptives or other hormone agents to reduce or ablate menstrual flow. Hysterectomy is rarely required for the treatment of primary dysmenorrhea. In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily. **Hysterectomy should be considered only if medical therapy fails or if the patient does not want to preserve fertility** (20–22).

Pelvic Pain

In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in symptoms associated with an improvement in the patient’s quality of life (23). In a review of 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin, 78% experienced improvement in their pain after follow-up for a mean of 21.6 months (24). However, 22% of patients had no improvement in or exacerbation of their pain. **Hysterectomy should be performed only in those patients whose pain is of uterine origin and does not respond to nonsurgical treatments** (18) (see Chapter 15).

Cervical Intraepithelial Neoplasia

In the past, hysterectomy was performed as primary treatment of cervical intraepithelial neoplasia. However, the maximum depth of dysplasia at the squamocolumnar junction is 5.2 mm; 99.7% of dysplasias (including carcinoma in situ) are located within 3.8 mm of the epithelial surface (25). Therefore, **more conservative treatments such as cryotherapy, laser, or a loop electrosurgical excision procedure can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions** (see Chapter 17). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy is an appropriate treatment option. Even after hysterectomy, however, patients are at increased risk for vaginal intraepithelial neoplasia.

Genital Prolapse

Hysterectomy for symptomatic genital prolapse accounts for about 15% of hysterectomies performed in the United States (7). **Unless there is an associated condition requiring an abdominal incision, vaginal hysterectomy is the preferred approach for genital prolapse.** Uterine prolapse typically is not an isolated event and most often is associated with a variety of pelvic support defects (see Chapter 24). Each defect must be corrected to optimize the surgical outcome and decrease the risk of future development of pelvic support defects.

Obstetric Emergency

Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.
Pelvic Inflammatory Disease

Pelvic inflammatory disease can generally be treated successfully with antibiotics. The uterus, tubes, and ovaries should not be removed in a patient with pelvic inflammatory disease unless the patient has not responded to intravenous antibiotic therapy (see Chapter 16). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. Surgical intervention also is necessary if the patient has acute abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tubo-ovarian abscess. For the patient who desires future fertility, consideration should be given to unilateral adnexectomy or partial bilateral adnexectomy without hysterectomy. For the patient in whom bilateral adnexectomy is required, the uterus can be left in place for possible ovum donation and in vitro fertilization (see Chapter 30).

Endometriosis

Medical and conservative surgical procedures generally are successful for treatment of endometriosis (see Chapter 29). Therefore, adnexectomy, with or without hysterectomy, should be performed only in patients who do not respond to conservative surgical (resection or ablation of endometriotic implants) or medical therapy. Most patients with endometriosis who require hysterectomy have unrelenting pelvic pain or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon.

Cancer

Metastases from nongynecologic sites may cause symptoms requiring hysterectomy. As a primary procedure, hysterectomy with bilateral salpingo-oophorectomy should be considered for patients with colorectal carcinoma because these patients are at risk for either synchronous pelvic cancers or occult metastases (26,27).

Benign Ovarian Tumor

Benign ovarian tumors that are persistent or symptomatic require surgical treatment. Obviously, if the patient desires fertility, the uterus should be conserved. If fertility is not an issue, however, or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. In a one study, 100 patients who underwent adnexectomy plus hysterectomy for benign adnexal disease were compared with a group of risk-matched women who underwent adnexectomy without hysterectomy for the same indication (28). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.

Vaginal versus Abdominal Hysterectomy

The proportion of abdominal versus vaginal hysterectomies has not changed significantly since the 1980s—about 75% of hysterectomies are abdominal (2,3,7,29–32). There are no specific criteria that can be used to determine the route of hysterectomy. The route chosen should be based on the individual patient. Absolute and relative contraindications have been proposed (27–29). In a large, multicenter retrospective study conducted by the U.S. Centers for Disease Control and Prevention between 1978 and 1981, the risks and outcome of abdominal and vaginal hysterectomy were compared (32). The study included 1,851 patients aged 15 to 44 years in whom hysterectomy was performed for
benign gynecologic disorders (568 vaginal, 1,283 abdominal). Surgical complications were classified into six categories. The overall complication rate was 24.5 per 100 for vaginal hysterectomy compared with 42.8 per 100 women for abdominal hysterectomy. The risk for one or more complications after abdominal hysterectomy was 1.7 times the risk after vaginal hysterectomy. The two major categories of complications were febrile morbidity and hemorrhage requiring transfusion. The risk for febrile morbidity was 2.1 times higher for abdominal hysterectomy than for vaginal hysterectomy, and the risk for transfusion was 1.9 times higher for abdominal surgery. Since the collection of these data, transfusion practices within the United States have changed as a result of increased awareness of the human immunodeficiency virus. Although only one fourth of hysterectomies are performed vaginally, this proportion could probably be increased substantially. In a study of 617 hysterectomies, 548 were performed vaginally; laparoscopic assistance was used in 63 patients, and an abdominal approach was required in only 6 patients (33). If feasible, vaginal hysterectomy is the preferred approach.

Supracervical Hysterectomy

The indications for supracervical hysterectomy are somewhat vague. Potential indications include endometriosis with obliteration of the anterior and posterior cul-de-sac, cesarean hysterectomy when the cervix is fully dilated and difficult to identify, and concern for sexual function. During a technically difficult surgical procedure (e.g., obliteration of the cul-de-sac), there may be concern about the potential morbidity associated with the removal of the cervix. However, the cervix can almost always be removed. Some women desire to conserve the cervix because they believe that it is important for sexual satisfaction, although there are no sound scientific data to prove this perception. Some authors (currently representing the minority view) believe that the cervix should not be removed unless there is a specific reason. They suggest that removal of the cervix leads to a decrease in sexual pleasure, increased operative and postoperative morbidity, vaginal shortening, vault prolapse, abnormal cuff granulations, and the potential for oviductal prolapse (34,35).

There is a debate about the effects of leaving the cervix in situ. In a study of a group of 210 patients who underwent hysterectomy, one half had total abdominal hysterectomies and one half had supracervical hysterectomies (36). Studies of the same population disclosed an increase in psychiatric symptoms in both groups (34–36). Sexual desire and functioning was unchanged, although both groups experienced a decrease in dyspareunia. Patients undergoing supracervical hysterectomy were reported to have increased orgasmic frequency when compared with patients in whom the cervix was left intact (36–39). In a clinical trial, 135 women were randomized to undergo total abdominal hysterectomy or supracervical hysterectomy. After 2-year follow-up, both groups had similar sexual functioning and health-related quality of life (40). Regardless of the reason for leaving the cervix at the time of hysterectomy, preoperative Papanicolaou (Pap) test results must be normal, and appropriate consent must be obtained from the patient.

Laparoscopically Assisted Hysterectomy

Laparoscopy has been used diagnostically before hysterectomy (see Chapter 21). In a study of laparoscopy performed in 46 patients who had been advised to have abdominal hysterectomies, the findings suggested that the referring physicians had overestimated uterine size and underestimated uterine mobility (33). All 14 patients who were referred for assessment of adnexal pathology had none. In 91% (42 of 46) of the patients, vaginal hysterectomy was performed. Another study evaluated seven patients who, aside from their histories suggestive of adhesions, were candidates for vaginal hysterectomy (41). Six
of the patients underwent laparoscopy, which did not reveal any adhesive disease, and were able to undergo vaginal hysterectomy. These findings are consistent with the other data demonstrating that the presence of pelvic adhesions cannot be predicted based on either history or physical examination (42). If laparoscopy is performed on patients with risk factors for adhesions or endometriosis, however, many patients will undergo the procedure needlessly, and about one half of those with adhesions or endometriosis will be overlooked. Thus, the role of diagnostic laparoscopy immediately before hysterectomy seems limited.

The use of operative laparoscopy to complete some or all of the hysterectomy has been widely reported (43–53) (see Chapter 21). However, in most of these studies, the patient population was neither randomized nor defined. Furthermore, the reasons the patient would require an abdominal approach are unclear. The criteria for selection of patients for laparoscopically assisted vaginal hysterectomy (LAVH) versus abdominal hysterectomy have not been clearly established.

In a prospective, controlled trial, patients who were candidates for vaginal hysterectomy were randomized to either LAVH or a standard vaginal approach (47). All procedures were performed on an outpatient basis; included were patients who had uterine leiomyomas up to the size of 16 weeks of gestation. There was no difference between the groups in terms of uterine weight, febrile morbidity, or the need for transfusion. Patients undergoing LAVH had a lower hematocrit value on the first and second postoperative days and required more pain medication on the second postoperative day. Although these findings are not clinically significant, they suggest that, when compared with a vaginal approach, LAVH does not reduce perioperative morbidity. The cost of LAVH is significantly higher than that of vaginal hysterectomy; the largest component of this cost differential resulted from the use of disposable equipment. This study demonstrates that there is no advantage of LAVH over traditional vaginal hysterectomy.

It has been suggested that LAVH may be helpful in treating patients with documented endometriosis, known pelvic adhesive disease, an adnexal mass that requires hysterectomy, and lack of uterine mobility (see Chapter 21). Depending on the circumstances, LAVH may be appropriate in some patients with stage I endometrial cancer or previous episodes of multiple major pelvic surgery. For example, if the patient has had endometriosis that has been treated previously or adhesions that have been lysed previously and now require hysterectomy, a vaginal approach can most likely be taken. In a study of a group of patients with stage III or IV endometriosis, the procedure was successful in 40 of 46 patients (54). Even in the hands of expert laparoscopic surgeons, however, the rate of complications was high.

Mild pelvic adhesions do not preclude vaginal hysterectomy. If the patient has intensive adhesions that involve the adnexa, bowel, and uterus, however, an abdominal approach usually is needed (55). In such patients, laparoscopy may be a better alternative than hysterectomy.

It is uncertain whether LAVH is preferable in patients with limited uterine mobility, and there is no standard method to assess the best approach. The major supporting structures of the uterus are the uterosacral ligaments and lower cardinal complex (56), which are not generally transected with a laparoscopic approach. Transection of the utero-ovarian ligament, round ligament, and broad ligament does not improve mobility.

Both LAVH and pelvic lymphadenectomy may be useful in selected patients with endometrial carcinoma (57). The data suggest that a lymphadenectomy can be performed successfully and that hospital stay and morbidity are decreased when compared with the standard transabdominal approach. Long-term prospective studies are needed to address these questions.
Concurrent Surgical Procedures

Oophorectomy

A laparoscopic approach should not be used in conjunction with hysterectomy solely for the purpose of accomplishing ovarian removal. Although not every ovary can be removed through the vagina, it has been shown clearly that most can be removed in this manner (58).

Prophylactic oophorectomy is the most common surgical procedure performed concurrently with hysterectomy. Oophorectomy is performed prophylactically to prevent ovarian cancer and to eliminate the potential need for further surgery for either benign or malignant disease. However, the optimal age for this prophylactic oophorectomy in women who have increased risk as well as those who do not have increased risk has not been determined. Arguments against prophylactic oophorectomy center on the need for earlier and more prolonged hormone therapy and the potential increase risk of cardiovascular disease (59,60). Although hormone therapy generally is well tolerated and provides good symptomatic relief, it may not be as effective as normal ovarian function, and the implications of long-term hormone therapy are not fully known. Therefore, the decision to proceed with oophorectomy should be considered carefully after the patient has been informed of the risks and benefits.

The risk for developing ovarian cancer after hysterectomy for benign disease is lower than would be expected based on its prevalence. Of those women who have no history of ovarian tumors and normal-appearing ovaries at the time of abdominal hysterectomy, 0.14 to 0.47% subsequently develop ovarian cancer in their conserved ovaries (59,60). Considering that as many as 1.4% of women are expected to get ovarian cancer, this is about one tenth to one third the expected rate. Presumably, this lower rate occurs because the cohort of women with normal-appearing ovaries in whom hysterectomy is performed for benign disease is a “selected” population, and because it excludes patients at high-risk for developing ovarian cancer. In women who do not have ovarian disease at the time of hysterectomy, the risk for developing benign ovarian tumors is less than 5% (61). The risk for ovarian cancer in women with a strong family history is 3% to 50%, depending on the pedigree (62,63) (see Chapter 35).

Long-term compliance with posthysterectomy estrogen therapy is low (64). Only 20% to 40% of women who initiate treatment after hysterectomy and bilateral oophorectomy continue to take estrogen for more than 5 years. Therefore, it should not be assumed that patients will receive adequate estrogen after oophorectomy. Women who subsequently develop breast cancer may be advised not to take estrogen.

A Markov decision analysis model has been used to estimate the best strategy for maximizing a woman’s survival when oophorectomy is considered in low-risk women undergoing hysterectomy for benign disease. Researchers found that women who had oophorectomy before age 55 years had an 8.58% excess mortality by age 80, and those with oophorectomy before age 59 have a 3.92% excess mortality. By age 75 years, this excess mortality is less than 1%. The conclusion was that ovarian conservation until at least age 65 years confers long-term survival benefits for those women at average risk for ovarian cancer undergoing hysterectomy for benign disease (60).

Appendectomy

Appendectomy may be performed concurrently with hysterectomy to prevent appendicitis and to remove disease that may be present. The former use is of limited value, however, because the peak incidence of appendicitis is between 20 and 40 years of age, whereas the peak age for hysterectomy is 10 to 20 years later (65). Appendectomy is effective in removing previously undetected disease, but the likelihood that these
abnormalities would cause any clinical problems is uncertain. In one study, histologic abnormalities were found in 71% (32 of 45) of appendices removed at the time of hysterectomy, and two had asymptomatic carcinoid tumors (66). In another study, 22% of appendices removed at the time of hysterectomy showed evidence of pathologic alterations, and five carcinoid tumors were identified (67).

There is no increase in morbidity associated with appendectomy performed at the time of hysterectomy (67–69), although it does require an average of 10 minutes additional operating time (60). Thus it is felt that incidental appendectomies in all abdominal hysterectomies could reduce the morbidity of appendicitis at a later time (70). Appendectomy has also been performed with vaginal hysterectomy without additional intraoperative or postoperative morbidity (71–74).

**Cholecystectomy**

Gallbladder disease is about four times more common in women than men, and its highest incidence occurs between 50 and 70 years of age, when hysterectomy is most often performed. Thus, women may require both procedures. A combined procedure does not appear to result in increased febrile morbidity or length of hospital stay (75,76).

**Abdominoplasty**

Abdominoplasty performed at the time of hysterectomy is associated with a shorter hospital stay, a shorter operating time, and a lower intraoperative blood loss than when the two operations are performed separately (77,78). Liposuction also can be performed safely at the time of vaginal hysterectomy (79).

**Technique**

Negative results of a Pap test done within the year should be obtained before performing a hysterectomy for benign disease. If the patient is 40 years of age or older and has not recently had a mammography, this examination should be performed. Endometrial sampling is recommended if the patient has reported abnormal uterine bleeding. In patients older than 40 years of age, a stool guaiac test should be performed. Other preoperative testing should be dictated by the patient’s specific medical conditions.

**Abdominal Hysterectomy**

**Preoperative Preparation**

Although not mandatory, a cleansing tap water or soap enema given on the evening before or the morning of the scheduled hysterectomy is preferred by some surgeons. To reduce the colony count of skin bacteria, the patient is asked to shower. Hair surrounding the incision area may be removed at the time of surgery or before surgery using a depilatory agent. Hair clipping is preferable to shaving because it decreases the incidence of incisional infection (80).

**Patient Positioning**

The patient is placed in the dorsal supine position for the procedure. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with an iodine solution. The patient’s legs are then straightened.

**Skin Preparation**

Several methods for skin cleaning can be recommended, including a 5-minute iodine solution scrub followed by application of iodine solution, iodine solution
scrub followed by alcohol with application of an iodine-impregnated occlusive drape, or an iodine-alcohol combination with or without application of an iodine-impregnated occlusive drape.

### Surgical Technique

**Incision**  The choice of incision should be determined by the following considerations:

1. Simplicity of the incision
2. The need for exposure
3. The potential need for enlarging the incision
4. The strength of the healed wound
5. Cosmesis of the healed incision
6. The location of previous surgical scars

The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided. The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy, entering the abdominal cavity.

**Abdominal Exploration**  After entering the peritoneal cavity, the upper abdomen and the pelvis are explored systematically. The liver, gallbladder, stomach, kidneys, para-aortic lymph nodes, and large and small bowel should be examined and palpated. Cytologic sampling of the peritoneal cavity, if needed, should be performed before abdominal exploration.

**Retractor Choice and Placement**  A variety of retractors have been designed for pelvic surgery. The Balfour and the O’Connor-O’Sullivan retractors are used most often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients.

**Elevation of the Uterus**  The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament. The clamp tip may be placed close to the internal os. This placement provides uterine traction and prevents backbleeding (Fig. 22.1).

**Round Ligament Ligation or Transection**  The uterus is deviated to the patient’s left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, the distal portion of the round ligament is ligated with a suture ligature or simply transected with Bovie cautery (Fig. 22.2). The distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrocautery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower uterine segment (Fig. 22.3).

**Ureter Identification**  The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament. Care must be taken to remain lateral to both the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. By following the artery cephalad to the bifurcation of the common iliac artery, the ureter is identified crossing the common iliac
artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply (Fig. 22.4).

**Utero-ovarian or Infundibulopelvic Ligament Ligation** If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral infundibulopelvic ligament, the tube, and the ovary. With the ureter under direct visualization, a window is created in the peritoneum of the posterior leaf of the broad ligament under the utero-ovarian ligament and fallopian tube. The tube and utero-ovarian ligament are clamped on each side with a curved Heaney or Ballentine clamp, cut, and ligated with both a free-tie and a suture ligature. The medial clamp at the uterine cornu should control backbleeding; if it does not, the clamp should be repositioned to do so (Fig. 22.5).

If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the infundibulopelvic ligament and caudal to the uterine artery. This opening allows proper exposure of the uterine artery, the infundibulopelvic ligament, and the ureter. In this manner, the ureter is released from its proximity to the uterine vessels and the infundibulopelvic ligament.

A curved Heaney or Ballentine clamp is placed lateral to the ovary (Fig. 22.6); care is taken to ensure that the entire ovary is included in the surgical specimen. The infundibulopelvic ligament on each side is cut and doubly ligated (Fig. 22.7). Alternatively, free ties
SECTION V Operative General Gynecology

Bladder Mobilization Using Metzenbaum scissors, with the tips pointed toward the uterus, the bladder is sharply dissected from the lower uterine segment and cervix. Alternatively, Bovie electrocautery can be used. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide countertraction and easier dissection (Fig. 22.8).

Uterine Vessel Ligation The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. The uterine vasculature is dissected or “skeletonized” from any remaining areolar tissue, and a curved Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus. Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing. The vessels are cut, and the suture is ligated. The same procedure is repeated on the opposite side (Fig. 22.9).

Incision of Posterior Peritoneum If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix can be passed around the infundibulopelvic ligament, two cephalad and one caudad, before the ligament is cut.

*Figure 22.2  The round ligament is transected and the broad ligament is incised and opened. (From Mann WA, Stovall TG. Gynecologic surgery. New York, NY: Churchill Livingstone, 1996, with permission.)*
and rectum may be incised (Fig. 22.10). A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field. A sponge may be placed to control the venous oozing that often occurs.

**Cardinal Ligament Ligation**  The cardinal ligament is divided by placing a straight Heaney clamp medial to the uterine vessel pedicle for a distance of 2 to 3 cm parallel to the uterus. The ligament is then cut, and the pedicle suture is ligated. This step is repeated on each side until the junction of the cervix and vagina is reached (Fig. 22.11).

**Removal of the Uterus**  The uterus is placed on traction cephalad, and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. Care should be taken to avoid foreshortening the vagina. The uterus is then removed with heavy, curved scissors (Fig. 22.12).

**Vaginal Cuff Closure**  Several techniques of vaginal cuff closure have been described. A figure-of-eight suture of 0-0 braided absorbable material is placed between the tips of the two clamps. The suture is used for both traction and hemostasis. Sutures are also placed at the tip of each clamp, and the pedicles are sutured with a Heaney stitch, thereby incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 22.13). Alternatively, the vaginal cuff can be left open to heal secondarily. If this method is used, a running-locked suture is used for hemostasis along the cuff edge (Fig. 22.14).

**Irrigation and Hemostasis**  The pelvis is thoroughly irrigated with saline or lactated Ringer’s solution. Meticulous care is taken to ensure hemostasis throughout the pelvis, particularly of the vascular pedicles. Ureteral position and integrity are checked again to ensure that they are intact and do not appear dilated.
SECTION V Operative General Gynecology

Peritoneal Closure
The pelvic peritoneum is not reapproximated. Research using animal models suggests that reapproximation may increase tissue trauma and promote adhesion formation (80). If the ovaries have been retained, they may be suspended to the pelvic sidewall to minimize the risk of becoming retroperitoneal or adherent to the vaginal cuff.

Incision Closure
The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or a continuous 0-0 or 1-0 monofilament absorbable suture. A continuous suture may reduce the risk for necrosis, which may occur when interrupted sutures are tied too tightly (80). As with interrupted sutures, bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure
The subcutaneous tissue should be irrigated, with careful attention given to maintaining hemostasis. Subcutaneous sutures are not used because they may increase the incidence of wound infection (80). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A bandage is applied and left in place for about 24 hours.

Peritoneal Closure The pelvic peritoneum is not reapproximated. Research using animal models suggests that reapproximation may increase tissue trauma and promote adhesion formation (80). If the ovaries have been retained, they may be suspended to the pelvic sidewall to minimize the risk of becoming retroperitoneal or adherent to the vaginal cuff.

Incision Closure The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or a continuous 0-0 or 1-0 monofilament absorbable suture. A continuous suture may reduce the risk for necrosis, which may occur when interrupted sutures are tied too tightly (80). As with interrupted sutures, bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure The subcutaneous tissue should be irrigated, with careful attention given to maintaining hemostasis. Subcutaneous sutures are not used because they may increase the incidence of wound infection (80). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A bandage is applied and left in place for about 24 hours.

Intraoperative Complications
Most intraoperative injuries during abdominal hysterectomy can be traced to poor lighting, unsatisfactory assistance, undue haste, anatomic variants, or involvement of the injured organ in the disease process (81). Some of these factors can be eliminated with careful attention to detail and use of proper surgical technique. However, some operative injuries
Figure 22.5  

Figure 22.6  
cannot be avoided by even the most skilled surgeons. The surgeon, therefore, must be prepared to recognize and repair these injuries. Even with a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

Ureteral Injuries

Injury to the pelvic ureter is one of the most formidable complications of hysterectomy (82–84). Because of the risk for subsequent renal impairment, injury to the ureter is far more serious than injury to the bladder or bowel (85,86).

It is essential to be aware of the proximity of the ureter to the other pelvic structures at all times. Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter. The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian cancer. In these instances, a false sense of security may actually increase an already high risk for ureteral injury (87). The use of ureteral catheters can also be associated with hematuria and acute urinary retention. Their complications are usually transitory in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may then be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon has not been trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of 1 ampule of indigo carmine dye.
opening the dome of the bladder, and observing the presence or absence of bilateral spill of tinted urine. Alternatively, ureteral patency may be established by opening the dome of the bladder and positioning retrograde ureteral stents. Cystoscopic evaluation may replace opening the bladder to evaluate the spill of tinted urine (82–87).

Bladder Injury

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury (85,87). Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina (88). Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross
SECTION V  Operative General Gynecology

hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage until the patient is ready for discharge, usually a total of 3 to 4 days. Elective incision into the dome of the bladder is performed similarly (88). If the trigone is involved, a surgeon trained in complicated urologic repair should be consulted.

Bowel Injury

Small bowel injuries are the most common intestinal injuries in gynecologic surgery (89). Small defects of the serosa or muscularis may be repaired using a single layer of continuous or interrupted 3-0 braided absorbable suture. Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3-0 braided absorbable suture. The defect should be closed in a direction perpendicular to the intestinal lumen. If a large area has been injured, resection with reanastomosis may be necessary (88,90). Because the bacterial flora of the ascending colon is similar to that of the small bowel, injuries can be repaired in a similar manner. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the
CHAPTER 22  Hysterectomy

mucosa may be repaired with a single running layer of 2-0 or 3-0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries if the colon has been prepared adequately. Otherwise, diverting colostomy may be necessary in some patients to protect the repair site from fecal contamination, especially if the defect is larger than 5 cm or if there is spillage of the bowel contents (88,90).

Hemorrhage

Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments (91). Blind clamping of these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. It is best to apply a pressure pack to tamponade the bleeding and then slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels. Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding is less dramatic but often is more difficult to manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or Bovie cautery. A variety of laser techniques have been used to control bleeding.

Postoperative Management

**Bladder Drainage**  Overdistention of the bladder resulting from bladder trauma or the patient’s reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy (92). For this reason, an indwelling bladder catheter should be used for the first few postoperative hours until the patient is able to ambulate and urinate.
If retropubic urethropexy has been performed, consideration should be given to using a suprapubic catheter, which allows postvoid residual levels to be checked without repetitive catheterizations. This catheter may be removed when satisfactory postvoid residual levels of less than 100 mL have been obtained.

**Diet** In anticipation of the rare case in which the patient must be returned to the operating room, the patient is allowed only ice chips and liquids on the day of surgery. On the first postoperative day, assuming bowel sounds are present, diet is resumed, advancing to solid foods as tolerated. This dietary regimen assumes minimal intraoperative bowel manipulation and dissection. Early postoperative feeding has been shown not only to be safe but also to speed return of bowel function and recovery. In patients who have undergone pelvic and para-aortic lymphadenectomy, bowel surgery, or other extensive dissections, a slower return to normal bowel function may occur, so care should be taken to advance the diet only as tolerated.

**Activity** Early ambulation decreases the incidence of thrombophlebitis and pneumonia. Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase their time out of bed progressively as their strength improves. On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on fascia to allow full healing. Sexual intercourse is not recommended until 6 weeks after surgery, when the vaginal cuff is fully healed. Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

**Wound Care** The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile bandage for the first 24 hours after surgery, by which time the incision has sealed. After the bandage has been removed, the incision should be cleaned daily with mild soap and water and kept dry.

### Vaginal Hysterectomy

#### Preoperative Evaluation

**Evaluation of Pelvic Support** The most important observation in determining the feasibility of a vaginal hysterectomy is the demonstration of uterine mobility (92,93). A vaginal approach should not be chosen if the uterus is not freely mobile. Pelvic support structures are elevated at the initial pelvic examination. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva maneuvers. Although vaginal hysterectomy is easier to perform when the uterine supporting ligaments are lax, it is not an absolute requirement. Some gynecologists advocate the application of a tenaculum to the anterior cervical lip, with subsequent traction applied as the patient bears down. Although this exercise may give some indication of uterine mobility, it is uncomfortable and not necessarily predictive of the success of vaginal hysterectomy. Therefore, the practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus is not recommended.

**Evaluation of the Pelvis** After assessment of pelvic support, the bony pelvis should be evaluated. Ideally, the angle of the pubic arch should be 90 degrees or greater, the vaginal canal should be ample, and the posterior vaginal fornix should be wide and deep. The surgeon may use a closed fist to approximate the bituberous diameter, which should
CHAPTER 22  Hysterecomy

exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure. The importance of a wide pubic arch was underscored by the result of a study of 25 failed vaginal hysterectomies that were compared with 50 successful vaginal hysterectomies. Risk factors, such as age, parity, body weight, surgical indication, uterine size, presence of leiomyomata in the anterior lower uterine segment, previous pelvic surgeries, adhesions, location and length of the cervix, and narrow pubic arch (less than 90 degrees), were examined. In the study, only the presence of a narrow pubic arch increased the risk of vaginal hysterectomy (94).

Surgical Considerations

**Patient Positioning**  Once the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table’s edge. Several stirrup types are available, including those that support the entire leg and those that suspend the legs in straps. **To avoid nerve injury, adequate padding should be used; marked flexion of the thigh and pressure points should be avoided.** Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.

**Vaginal Preparation**  A povidone-iodine solution is applied to the vagina, the bladder is drained, and the catheter is removed. Several methods for draping have been proposed, including individual or single-piece drapes; the method chosen is at the surgeon’s discretion. There is usually no need to shave or clip the pubic hair. Individual drapes with an adhesive barrier should be used to hold the drapes in place and prevent the pubic hair from compromising the field.

**Instruments**  Instruments specific to and useful in performing a vaginal hysterectomy include right-angled retractors, narrow Deaver retractors, weighted specula, Heaney needle holders, and an assortment of Briesky–Navratil vaginal retractors. Heaney and Heaney–Ballentine hysterectomy clamps are preferable. Several other clamps also are commonly used, including the Masterson clamp.

**Lighting**  Overhead high-intensity lamps should be used and positioned to direct light over the operator’s shoulder. In addition, the surgeon may prefer a headlight, which can be worn to provide direct horizontal lighting. Although not routinely used, a fiberoptic-lighted irrigating suction system can provide additional light and transilluminate tissue planes.

**Suture Material**  Various suture materials have been advocated for gynecologic surgery. The type of suture material chosen should be based on the surgeon’s preference. A synthetic delayed absorbable polyglactin or polyglycolic acid suture and atraumatic needles are generally preferable.

**Procedure**  The patient is examined while anesthetized to confirm prior findings and to assess uterine mobility and descent. The decision is then made whether to proceed vaginally or abdominally.

**Grasping and Circumscribing the Cervix**  The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward traction applied on the cervix, a circumferential incision is made in the vaginal epithelium at the junction of the cervix (Fig. 22.15).

**Dissection of Vaginal Mucosa**  After the initial incision is made, the vaginal epithelium may be dissected sharply from the underlying tissue or pushed bluntly with an open sponge (Fig. 22.16). **If the initial incision is made too close to the external cervical os,**
**Figure 22.15** Circumferential incision in the vagina to infiltrate a vaginal hysterectomy. (From Mann WA, Stovall TG. *Gynecologic surgery.* New York, NY: Churchill Livingstone, 1996, with permission.)

**Figure 22.16** Dissection of the vaginal mucosa. (From Mann WA, Stovall TG. *Gynecologic surgery.* New York, NY: Churchill Livingstone, 1996, with permission.)
there is a greater amount of dissection required and associated bleeding. Therefore, this circumscribing incision should be made just below the bladder reflection. It is important to continue the dissection in the correct cleavage plane because dissection in the wrong plane will increase blood loss.

**Posterior Cul-de-Sac Entry** The peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) can be identified by stretching the vaginal mucosa and underlying connective tissue with forceps (Fig. 22.17). If difficulty is encountered (e.g., if the cervix is elongated and the peritoneum is not evident), the vaginal mucosa may be incised vertically to the point at which the cul-de-sac becomes more apparent.

If the vaginal mucosa has been dissected in the wrong plane, the hysterectomy may be begun extraperitoneally by clamping and cutting the uterosacral and cardinal ligaments close to the cervix. The posterior cul-de-sac will then become readily identifiable. If the peritoneal reflection of the posterior cul-de-sac still cannot be identified, entry into the anterior peritoneum is attempted, and a finger is hooked into the posterior cul-de-sac to place tension on the peritoneum. The peritoneum is opened with Mayo scissors. An interrupted suture is placed to approximate the peritoneum and vaginal cuff and thus provide hemostasis (Fig. 22.18). The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac. The weighted speculum is placed into the posterior cul-de-sac.

**Uterosacral Ligament Ligation** With retraction of the lateral vaginal wall and countertraction on the cervix, the uterosacral ligaments are clamped with the tip of the clamp incorporating the lower portion of the cardinal ligaments (Fig. 22.19). The clamp is placed perpendicular to the uterine axis, and the pedicle is cut close to the clamp and sutured. A small pedicle (0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic and the tissue sloughs, which may become culture medium for micro-organisms.
SECTION V Operative General Gynecology

Figure 22.18 Interrupted suture is placed on posterior vaginal cuff and peritoneum for hemostasis. (From Mann WA, Stovall TG. Gynecologic surgery. New York, NY: Churchill Livingstone, 1996, with permission.)

The pedicle should be incised no more than one half to three fourths of the way around the tip of the clamp. Limiting the incision prevents the next pedicle, which may be vascular, from being cut.

When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator’s wrist. Once

Figure 22.19 Ligation of the uterosacral ligaments. (From Mann WA, Stovall TG. Gynecologic surgery. New York, NY: Churchill Livingstone, 1996, with permission.)
ligated, the uterosacral ligaments may be transfixed to the posterolateral vaginal mucosa (Fig. 22.20). This suture may lend additional support to the vagina and provides hemostasis at this point on the vaginal mucosa. This suture is held with a hemostat to facilitate location of any bleeding at the completion of the procedure and to aid in the closure of vaginal mucosa.

**Entry versus Nonentry into the Vesicovaginal Space (Cul-de-Sac)**

Downward traction is placed on the cervix. Using either Mayo scissors, with the points directed toward the uterus, or an open moistened $4 	imes 4$ gauze sponge, the bladder is advanced. If the vesicovaginal peritoneal reflection is easily identified at this point on the vaginal mucosa, the vesicovaginal space may be entered. Otherwise, it may be preferable to delay entry. There is no danger in delaying entry so long as the operator has ascertained that the bladder has been advanced.

After the bladder has been advanced, a curved Deaver or Heaney retractor is placed in the midline, holding the bladder out of the operative field. This process precedes each step of the vaginal hysterectomy until the vesicovaginal space is entered.

**Cardinal Ligament Ligation**

With traction on the cervix continued, the cardinal ligaments are identified, clamped, and cut. The suture is ligated (Fig. 22.21).

**Advancement of Bladder**

The bladder again is advanced out of the operative field. A blunt dissection technique may be used; however, sharp dissection may be helpful if the patient has had previous surgery, such as cesarean delivery, which may have scarred the bladder reflection.
SECTION V  Operative General Gynecology

Uterine Artery Ligation  Contralateral and downward traction is placed on the cervix. With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the uterine vessels are identified, clamped, and cut, and the suture is ligated (Fig. 22.22). A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury. When the uterus is large or when a fibroid distorts the

CHAPTER 22 Hysterectomy

anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery.

**Entry into the Vescovaginal Space**  The anterior peritoneal fold usually can be identified readily just before or after clamping and suture ligation of the uterine arteries. The anterior peritoneal cavity should not be opened blindly because of the increased risk of bladder injury (Fig. 22.23). The peritoneum is grasped with forceps, tented, and opened with scissors with the tips pointed toward the uterus. A Heaney or Deaver retractor is then placed, and the peritoneal contents are identified. This retractor serves to keep the bladder out of the operative field.

**Delivery of the Uterus**  A tenaculum is placed onto the uterine fundus in a successive fashion to deliver the fundus posteriorly (Fig. 22.24). The operator’s index finger is used to identify the utero-ovarian ligament and aid in clamp placement.

**Utero-ovarian and Round Ligament Ligation**  With the posterior and anterior peritoneum opened, the remainder of the broad ligament and utero-ovarian ligaments are clamped, cut, and ligated (Fig. 22.25). The utero-ovarian and round ligament complexes are double ligated with a suture tie followed by a ligature medial to the first suture. A hemostat is placed on the second suture to aid in the identification of any bleeding and to assist with peritoneal closure. A hemostat should not be placed on the first suture or any other vascular pedicle to avoid the risk for loosening the tie.

**Removal of the Ovaries**  When the adnexa are removed, the round ligaments should be removed separately from the adnexal pedicles. Traction is placed on the utero-ovarian pedicle. The ovary is drawn into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the infundibulopelvic ligament, and the ovary and tube are excised (Fig. 22.26). A transfixion tie and suture ligature are placed on the infundibulopelvic ligament. The surgeon should not be reluctant to remove the fallopian

tube separately from the ovary if taking them together risks loss of the tissue pedicle or injury to the ureter or nearby blood vessels.

**Hemostasis**  A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. If additional sutures are required, they should be placed precisely with care to avoid the ureter or bladder.

**Peritoneal Closure**  Because the pelvic peritoneum does not provide support and re-forms in 24 hours after surgery, the peritoneum need not be reapproximated routinely. If it is believed to be important, the anterior peritoneal edge is identified and grasped with forceps. A continuous absorbable 0-0 suture is begun at the 12-o’clock position. The suture is continued in a purse-string fashion and incorporates the distal portion of the left upper pedicle and the left uterosacral ligament (Fig. 22.27). Tension is applied to the suture placed at the beginning of the procedure that incorporates the posterior peritoneum and vaginal mucosa. This allows for high posterior reperitonealization, which shortens the cul-de-sac and thus helps to prevent future enterocele formation. The right uterosacral ligament and the distal portion of the right upper pedicle are incorporated, and this continuous suture ends at the point on the anterior peritoneum where it was begun.

The intra-abdominal tagged sponge is removed and inspected for the presence of blood at its distal end. The slack of the purse-string peritoneal suture is taken up by pulling the suture tight. Before tying the peritoneal suture, the surgeon should make certain that no prolapse of viscera has occurred.

**Vaginal Mucosa Closure**  The vaginal mucosa can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures (Fig. 22.28). The vaginal mucosa is, in this case, reapproximated horizontally with interrupted absorbable sutures. The sutures are placed through the entire thickness of the vaginal epithelium, with care taken to avoid entering the bladder anteriorly. These sutures will obliterate
the underlying dead space and produce an anatomic approximation of the vaginal epithelium, thereby decreasing the postoperative formation of granulation tissue.

**Bladder Drainage** After completion of the procedure, the bladder is drained. Unless an anterior or posterior colporrhaphy or other reconstructive procedure is performed, neither bladder catheter nor vaginal packing are mandatory.

Surgical Techniques for Selected Patients

Injection of Vaginal Mucosa  The use of paracervical and submucosal injection of 20 to 30 mL of 0.5% lidocaine with 1:200,000 epinephrine before incision of the vaginal mucosa is believed by some to decrease postoperative pain and facilitate identification of surgical planes. There is no need to inject the cervix. Areas to be injected include the bladder pillars, lower portion of the cardinal ligament, uterosacral ligaments, and paracervical tissue. However, it has been shown that the incidence of cuff cellulitis and cuff abscess formation is increased when epinephrine is injected into the cervicovaginal mucosa.

Morcellation of the Large Uterus  Uterine morcellation is a well known but often underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation have been described (95), including hemisection or bivalving, wedge or “V” incisions, and intramyometrial coring. Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered. When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately (96,97). This method seems best suited for fundal, midline leiomyomas.

Wedge morcellation is best suited for anterior or posterior fibroids or for fibroids in the other broad ligaments (i.e., when the fibroids are away from the midline) (97–101). The cervix is amputated, and the myometrium is grasped with clamps. Wedge-shaped portions of myometrium are removed from the anterior or posterior uterine wall. The apex of the wedge is kept in the midline, thereby reducing the bulk of the myometrium. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clip. Traction is then applied, and a “myometectomy” is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the myometrium in a symmetric fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the utero-ovarian pedicle and fallopian tubes.

In a retrospective comparison of 383 patients undergoing abdominal hysterectomy or vaginal hysterectomy with uterine morcellation, length of stay and perioperative complications were significantly increased with abdominal hysterectomy. Therefore, it appears that vaginal hysterectomy with uterine morcellation is safe and allows for an increased number of women to undergo vaginal hysterectomy.

McCall Culdoplasty  Although McCall culdoplasty has been thought by some surgeons to help decrease future enterocele formation (100), whether this is accurate remains open to debate. An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient’s left uterosacral ligament pedicle is grasped and sutured. The suture then incorporates the posterior peritoneum,
between the uterosacral ligaments and the right uterosacral ligament. The suture is completed by passing the needle from the inside to the outside at the same point at which it was begun. The suture is tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

**Schuchardt Incision**

When vaginal exposure is difficult, the Schuchardt incision may be used (100). If the surgeon is right-handed, the incision is made on the patient’s left side. To decrease blood loss, the area can be infiltrated with lidocaine-containing epinephrine. The incision follows a curved line from the 4-o’clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued as high as necessary in the vaginal vault to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

**Intraoperative Complications**

**Bladder Injury**

Injury to the urinary bladder is one of the most common intraoperative complications associated with hysterectomy. **If the bladder is inadvertently entered, repair generally should be performed when the injury is discovered and not delayed until completion of surgery** (87). When bladder injury is recognized, the edges of the wound should be mobilized to assess the full extent of the injury and to allow repair without tension. This assessment should include visualization of the trigone to exclude injury to that area. The bladder may then be repaired with a single- or double-layered closure with a small-caliber absorbable suture. Methylene blue or a dye of sterile milk formula can be instilled into the bladder to ensure that the repair is adequate.

**Bowel Injury**

Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not occur often. Bowel injuries more often are associated with the performance of a posterior colporrhaphy and are usually confined to the rectum (87,100).

**If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation.** Postoperatively, the patient should be given a stool softener and a low-residue diet.

**Hemorrhage**

Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping (100). Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases. Likewise, the use of Heaney-type sutures may minimize ligature slippage and subsequent bleeding from bulky pedicles. When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided. The bleeding vessel should be identified and precisely ligated, with visualization of the ureter if necessary. **If the location of the ureter is in question, it should be visualized before suturing a bleeding vessel.** Although excessive blood loss occasionally occurs despite these precautions, it should be infrequent.
Perioperative Care

Bladder Drainage  Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reparative procedures, surgery for stress incontinence, the use of a vaginal pack, and patient anxiety.

After vaginal hysterectomy without additional repair, most patients can void spontaneously, and therefore, catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If the patient does not tolerate pain well postoperatively or is extremely anxious, the transurethral insertion of a 16-Fr. catheter after completing surgery is warranted. This catheter may also be inserted postoperatively if the patient is unable to void spontaneously on two attempts. Closed-catheter drainage after vaginal hysterectomy usually is not necessary for longer than 24 hours. The catheter is removed without clamping, and there is no need to obtain a urine specimen for culture and sensitivity.

Diet  Although little manipulation of the bowel occurs during vaginal hysterectomy, there is some slowing of gastrointestinal motility. This slowing rarely occurs to a degree that limits some form of oral intake soon after surgery. Most patients experience some degree of nausea after surgery, which, combined with drowsiness from analgesics, usually makes them disinterested in food on the evening after surgery. A clear liquid diet is suitable during the first night after surgery. On the first full postoperative day, a regular diet can usually be consumed. The patient is often the best judge of what she can tolerate.

Perioperative Complications of Hysterectomy

A comprehensive discussion of postoperative complications after gynecologic surgery is presented in Chapter 20.

Wound Infections

Wound infections occur after 4% to 6% of abdominal hysterectomies (29). Measures believed to reduce the incidence of wound infections include a preoperative shower, no removal of hair, or if hair removal is necessary, removal of hair with clippers in the operating room, use of adhesive drapes and prophylactic antibiotics, and delayed primary closure (see Chapter 20).

Hemorrhage

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways (91). First, bleeding from the vagina may be noted by the nursing staff or physician within the first few hours after surgery. Second, and less commonly, the patient may be noted to have little bleeding from the vagina but deteriorating vital signs manifested by low blood pressure and rapid pulse, falling hematocrit level, and flank or abdominal pain. The first presentation usually is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage. Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient’s overall condition.

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any vaginal hysterectomy. However, steady
bleeding 2 to 3 hours after surgery suggests lack of hemostasis. The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting. If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the mucosa.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room. General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. However, bleeding that is coming from above the cuff or is extremely heavy usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding. If it is difficult to localize bleeding to a specific pelvic vessel, or if these maneuvers do not work, ligation of the hypogastric artery may be performed.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intra-abdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas; CT provides better visualization of retroperitoneal spaces, however, and can delineate a hematoma.

If the patient’s condition stabilizes rapidly with intravenous fluids, one of two approaches may be used for continued care. The first is to give the patient a transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma that may eventually be resorbed. The risk with this approach is that the hematoma will later become infected, necessitating surgical drainage. In some instances when the patient’s condition is stable, radiologic embolization may be considered. Another option is to perform abdominal exploratory surgery while the patient’s condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient’s condition deteriorating with continued delay or the formation of a pelvic abscess. Once adequate exposure is obtained, the peritoneum over the hematoma should be opened, and the blood should be evacuated. All bleeding vessels should be identified and ligated. Again, if bleeding is difficult to control, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. Once hemostasis is achieved, the pelvis should be drained using a closed system.

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence (32). If the urethra is unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later. If the patient still has trouble voiding and urethral spasm is suspected, success often can be achieved with a skeletal muscle relaxant such as
diazepam (2 mg twice a day). In most cases, waiting is the best course, and voiding usually occurs spontaneously.

Ureteral Injury

In patients who develop flank pain soon after vaginal hysterectomy, ureteral obstruction should be suspected. The incidence of ureteral injury is lower with vaginal hysterectomy than with abdominal hysterectomy (86). One risk factor for its occurrence is total uterine prolapse, in which the ureters are drawn outside the bony pelvis.

In a patient with flank pain in whom ureteral obstruction is suspected, a CT urogram and a urinalysis should be performed (83). If obstruction is noted on CT scan, it is usually present near the ureterovesical junction. The first immediate step should be attempted passage of a catheter through the ureter under cystoscopic guidance. If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction or kinking to release. If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction (82–87).

Vesicovaginal Fistula

Vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease (86). Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. The development of a postoperative vesicovaginal fistula after hysterectomy is rare; the incidence is as low as 0.2% (85,86).

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery (87). After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of methylene blue or indigo carmine dye through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, however, the presence of a ureterovaginal fistula must be ruled out by the intravenous injection of 5 mL of indigo carmine dye. Within 20 minutes, the tampon should stain blue if a ureterovaginal fistula is present. A CT urogram should also be performed to rule out ureteral obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. Up to 15% of fistulas close spontaneously with 4 to 6 weeks of continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After vaginal hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction generally is undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. When repaired correctly, cystotomy rarely results in the development of a fistula (85).

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and often is confused with granulation tissue at the vaginal apex (32). Predisposing factors for the development of
SECTION V Operative General Gynecology

fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. Approximately one half of patients undergoing vaginal hysterectomy form some granulation tissue at the vaginal vault. In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected. A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present.

If fallopian tube prolapse is diagnosed, it should be repaired with surgery. In general, the surrounding vaginal mucosa should be opened and undermined widely. The tube is then ligated high and removed, followed by closure of the vaginal mucosa.

Discharge Instructions
Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and should include the following information:

1. Avoid strenuous activity for the first 2 weeks, and increase activity level gradually.
2. Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.
3. Bathe as needed using shower or tub baths.
4. Follow a regular diet.
5. Avoid straining for a bowel movement or urination. For constipation, use Milk of Magnesia or Metamucil (1 tsp in juice).
6. Call the physician if excessive vaginal bleeding or fever occurs.
7. Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies both during and after office hours. Typically, the first postoperative visit is scheduled about 4 weeks after discharge from the hospital. At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cuff should be gentle and cursory, but the patient should be assured that the healing process is proceeding normally. Finally, the patient’s questions should be answered, and advice should be given on increasing her activity level, including sexual activity, work, and normal household activity.

Psychosomatic Aspects

The decision to proceed with hysterectomy should be made jointly by the patient and her physician. Factors leading a patient or her physician to choose hysterectomy and reasons that patients with similar conditions choose different treatments are uncertain. For many patients, the decision to undergo hysterectomy may be sudden. They face the potential risks of anesthesia and surgery, and, if premenopausal, they must also cope with the loss of menstruation and the ability to procreate. Many women are concerned that the procedure will result in a loss of femininity, a decrease in sexual satisfaction, or an increase in interpersonal problems with their spouses. The concern over the loss of the reproductive tract is greater than that related to the loss of other intra-abdominal organs (102,103). To minimize the possibility that the patient has a poor outcome, preoperative counseling and preparation are essential.
CHAPTER 22 Hysterectomy

In a study of 23 women who had hysterectomy, most regretted the loss of menstruation, even those who had experienced dysmenorrhea (104). Several of these women viewed the menstrual cycle as a way for the body to “rid itself of waste,” and they felt better after the menstrual phase of their cycle.

Depression

There is wide variation in women’s responses to hysterectomy. Most studies suggest that there is little evidence that hysterectomy increases the risk of depression. Some investigators have reported depression and an increased incidence of psychiatric symptoms after hysterectomy (105,106). One study concluded that almost twice as many women were admitted to a psychiatric hospital after pelvic operations compared with other types of surgery (107). However, others have not found such an association (108), and some report a decrease in symptoms after hysterectomy (109–113). The impact of hysterectomy on the development of depression is unknown because most studies are retrospective and not well controlled for preoperative depression (see Chapter 12).

Patients who had a moderate amount of preoperative anxiety do much better postoperatively than patients with little or no anxiety or patients who had an exaggerated response (114). Both long delays before surgery and a very short time before surgery increase patients’ anxiety. Thus, women should be scheduled for surgery several weeks in advance to avoid this problem (114). Women who planned to have children in the future had more problems during the immediate postoperative period. The patient’s response to previous loss (eg, death of family members) predicted her response after hysterectomy (115).

Sexuality

The incidence of sexual dysfunction after hysterectomy ranges from 10% to 40%. Estimates vary based on study variations, cultural variations, and the definitions used to determine the diagnosis. Some report a decrease in libido after hysterectomy, whereas others suggest that libido is increased because of the reduced fear of unwanted pregnancy (106,116). Humphries found that most patients do not experience a change in their sexual practices after hysterectomy (117), whereas others report a deterioration of sexual relations (118). Preoperative anxiety about sexual functioning often is associated with an overall deterioration of sexual relations (119).

Hysterectomy does not cause psychiatric sequelae or diminished sexual functioning in most patients. The best predictor of satisfaction after hysterectomy is the patient’s preoperative understanding of the procedure. The best predictor of postoperative sexual functioning is the patient’s preoperative sexual satisfaction. Preoperatively, these issues should be discussed with the patient, and her questions and concerns should be addressed to decrease the fear and anxiety associated with surgery.

SECTION VI

UROGYNECOLOGY AND PELVIC RECONSTRUCTIVE SURGERY
Bladder storage and emptying depend on a complex interplay between the brain, spinal cord, bladder, urethra, and pelvic floor.

Urinary incontinence is common in women and is generally treated successfully with a range of nonsurgical and surgical treatments.

Stress urinary incontinence occurs with increases in abdominal pressure (such as coughing, running, lifting) and can be treated with pelvic muscle exercises, vaginal devices, lifestyle changes, and surgery.

Urge urinary incontinence occurs with a sudden sense of urgency (such as on the way to the bathroom or when washing hands) and can be treated with bladder training, medications, lifestyle changes, and neuromodulation.

Bladder pain remains a challenging and poorly understood entity.

Physiology of Micturition

The bladder is a complex organ that has a relatively simple function: to store urine effortlessly, painlessly, and without leakage and to discharge urine voluntarily, effortlessly, completely, and painlessly. To meet these demands, the bladder must have normal anatomic support as well as normal neurophysiologic function.

Normal Urethral Closure

Normal urethral closure is maintained by a combination of intrinsic and extrinsic factors. The extrinsic factors include the levator ani muscles, the endopelvic fascia, and their attachments to the pelvic sidewalls and the urethra. This structure forms a hammock beneath the urethra that responds to increases in intra-abdominal pressure by tensing, allowing the urethra to be closed against the posterior supporting...
shelf (Fig 23.1). When this supportive mechanism becomes faulty for some reason—the endopelvic fascia has detached from its normal points of fixation, muscular support has weakened, or a combination of these two processes—normal support is lost, and anatomic hypermobility of the urethra and bladder neck develops. For many women, this loss of support is severe enough to cause loss of closure during periods of increased intra-abdominal pressure, resulting in stress incontinence. However, many women remain continent in spite of loss of urethral support (1).

The intrinsic factors contributing to urethral closure include the striated muscle of the urethral wall, vascular congestion of the submucosal venous plexus, the smooth muscle of the urethral wall and associated blood vessels, the epithelial coaptation of the folds of the urethral lining, urethral elasticity, and the tone of the urethra as mediated by α-adrenergic receptors of the sympathetic nervous system.

Effective urethral closure is maintained by the interaction of extrinsic urethral support and intrinsic urethral integrity, each of which is influenced by several factors (muscle tone and strength, innervation, fascial integrity, urethral elasticity, coaptation of urothelial folds, urethral vascularity). In the clinical setting, damaged urethral support is manifested clinically by urethral hypermobility, which often results in incompetent urethral closure during physical activity and presents as stress urinary incontinence. Intrinsic urethral functioning is more complicated and is not nearly as well understood as incontinence related to loss of urethral support (2).

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function led to the separation of stress incontinence into two broad types:
1. Incontinence caused by anatomic hypermobility of the urethra

2. Incontinence caused by intrinsic sphincteric weakness or deficiency

Surgical approaches have been based on this arbitrary distinction, with pubovaginal sling recommended for women with intrinsic sphincter deficiency and a colposuspension (also known as retropubic urethropexy) for those with hypermobility. This rationale was based initially on a small study in which women younger than age 50 years with urethral closure pressure less than 20 cm H₂O had a higher failure rate after a Burch colposuspension than did women with a closure pressure greater than 20 cm H₂O (3). No difference in outcome was seen in women older than 50 years. More recently, this dichotomy has been called into question, based on the observation that all women with stress incontinence have some degree of sphincter weakness, regardless of whether they have hypermobility. Currently, it is not known whether women with more severe sphincter weakness have improved success with a specific type of surgery or whether they are more likely to experience treatment failure with any surgery.

The Bladder

The bladder is a bag of smooth muscle that stores urine and contracts to expel urine under voluntary control. It is a low-pressure system that expands to accommodate increasing volumes of urine without an appreciable rise in pressure. This function appears to be mediated primarily by the sympathetic nervous system. During bladder filling, there is an accompanying increase in outlet resistance. The bladder muscle (the detrusor) should remain inactive during bladder filling, without involuntary contractions. When the bladder has filled to a certain volume, fullness is registered by tension-stretch receptors, which signal the brain to initiate a micturition reflex. This reflex is permitted or not permitted by cortical control mechanisms, depending on the social circumstances and the state of the patient’s nervous system. Normal voiding is accomplished by voluntary relaxation of the pelvic floor and urethra, accompanied by sustained contraction of the detrusor muscle, leading to complete bladder emptying.

Innervation

The lower urinary tract receives its innervation from three sources: (i) the sympathetic and (ii) parasympathetic divisions of the autonomic nervous system, and (iii) the neurons of the somatic nervous system (external urethral sphincter). The autonomic nervous system consists of all efferent pathways with ganglionic synapses that lie outside the central nervous system. The sympathetic system primarily controls bladder storage, and the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3 (see Chapter 6). The ganglia of the sympathetic nervous system are located close to the spinal cord and use acetylcholine as the preganglionic neurotransmitter. The postganglionic neurotransmitter in the sympathetic nervous system is norepinephrine, and it acts on two types of receptors: α receptors, located principally in the urethra and bladder neck, and β receptors, located principally in the bladder body. Stimulation of α receptors increases urethral tone and thus promotes closure, whereas α-adrenergic receptor blockers have the opposite effect. Stimulation of β receptors decreases tone in the bladder body.

The parasympathetic nervous system controls bladder motor function—bladder contraction and bladder emptying. The parasympathetic nervous system originates in the sacral spinal cord, primarily in S2 to S4, as does the somatic innervation of the pelvic floor.
floor, urethra, and external anal sphincter. Sensation in the perineum is also controlled by sensory fibers that connect with the spinal cord at this level. For this reason, examination of perineal sensation, pelvic muscle reflexes, and pelvic muscle or anal sphincter tone is relevant to clinical evaluation of the lower urinary tract. The parasympathetic neurons have long preganglionic neurons and short postganglionic neurons, which are located in the end organ. Both the preganglionic and postganglionic synapses use acetylcholine as their neurotransmitter, acting on muscarinic receptors. **Because acetylcholine is the main neurotransmitter used in bladder muscle contraction, virtually all drugs used to control detrusor muscle overactivity have anticholinergic properties.**

**Bladder storage and bladder emptying involve the interplay of the sympathetic and parasympathetic nervous systems.** The modulation of these activities appears to be influenced by a variety of nonadrenergic, noncholinergic neurotransmitters and neuropeptides, which fine-tune the system at various facilitative and inhibitory levels in the spinal cord and higher areas of the central nervous system (4–6). Thus, neuropathology at almost any level of the neurourologic axis can have an adverse effect on lower urinary tract function.

**Micturition**

Micturition is triggered by the peripheral nervous system under the control of the central nervous system. It is useful to consider this event as occurring at a micturition threshold, a bladder volume at which reflex detrusor contractions occur. The threshold volume is not fixed; rather, it is variable and can be altered depending on the contributions made by sensory afferents from the perineum, bladder, colon, and rectum as well as input from the higher centers of the nervous system. The micturition threshold is, therefore, a floating threshold that can be altered or reset by various influences.

The spinal cord and higher centers of the nervous system have complex patterns of inhibition and facilitation. The most important facilitative center above the spinal cord is the pontine-mesencephalic gray matter of the brain stem, often called the pontine micturition center, which serves as the final common pathway for all bladder motor neurons. Transection of the tracts below this level leads to disturbed bladder emptying, whereas destruction of tracts above this level leads to detrusor overactivity. The cerebellum serves as a major center for coordinating pelvic floor relaxation and the rate, force, and range of detrusor contractions, and there are multiple interconnections between the cerebellum and the brain-stem reflex centers. Above this level, the cerebral cortex and related structures exert inhibitory influences on the micturition reflex. Thus, the upper cortex exerts facilitative influences that release inhibition, permitting the anterior pontine micturition center to send efferent impulses down the complex pathways of the spinal cord, where a reflex contraction in the sacral micturition center generates a detrusor contraction that causes bladder emptying.

A normal lower urinary tract is one in which the bladder and urethra store urine without pain until a socially acceptable time and place arises, at which point voiding occurs in a coordinated and complete fashion. Lower urinary tract disorders include disorders of storage (such as urinary incontinence), emptying (such as urinary hesitancy and retention), and sensation (such as urgency or pain). Current definitions for these disorders are depicted in Table 23.1.

**Urinary Incontinence**

**Definitions**

Defining urinary incontinence would seem an easy task: women that leak urine must be “incontinent.” The **International Continence Society, an organization charged with defining the various disorders of pelvic floor dysfunction, recently defined incontinence**
as “the complaint of any involuntary leakage of urine” (7). Unfortunately, this definition does not take into account the wide variation in this symptom and the disruption it causes. For example, half of young nulliparous women report occasional minor urine leakage; for most this is not neither a bother nor a symptom for which they would seek treatment. At the other extreme, 5% to 10% of adult women have severe leakage daily. These women often dramatically alter their lives because of leakage, curtailing activities, social outings, and intimacy. Many suffer marked deterioration in self-esteem. In between these two extremes lies another one-third of adult women who report leakage at least weekly, but without the same degree of life-altering severity as the women previously noted.

Collectively, these women assume a substantial cost burden. The total annual cost to care for patients with incontinence in the United States is estimated at $11.2 billion in the community and $5.2 billion in nursing homes (8). In the United States, much of this cost is borne directly by women in the form of incontinence pads and excess laundry costs. Despite the burden imposed by leakage, many women do not discuss this symptom with a
health care professional. For some women, this is because the leakage does not bother them, whereas others are embarrassed and suffer in silence. Still others do not raise this issue because they mistakenly believe the only treatment option is surgical. Thus, it is incumbent on the provider to ask women about leakage.

Studies have shown that there is little relationship between the volume of urine lost and the distress that it causes a patient. The degree to which women are bothered by leakage is influenced by various factors, including cultural values and expectations regarding urinary continence and incontinence. If the leakage is distressing to the patient, evaluation and treatment should be offered. Incontinence can almost always be improved and frequently can be cured, often using relatively simple, nonsurgical interventions.

Types of Disorders

Stress Urinary Incontinence

Stress urinary incontinence occurs during periods of increased intra-abdominal pressure (e.g., sneezing, coughing, or exercise) when the intravesical pressure rises higher than the pressure that the urethral closure mechanism can withstand. Stress urinary incontinence is the most common form of urinary incontinence in women and is particularly common in younger women. Active women are more likely to notice symptoms of stress urinary incontinence. In a survey of 144 collegiate female varsity athletes, 27% reported stress incontinence while participating in their sport. The activities most likely to produce urinary loss were jumping, high-impact landings, and running.

Stress incontinence is an interesting “disease” as the same symptoms have varying effects on different women. This condition is best thought of by a biobehavioral model that examines the interaction of three variables: (i) the biologic strength of the urethral sphincteric mechanism, (ii) the level of physical stress placed on the closure mechanism, and (iii) the woman’s expectations about urinary control. This model explains the enormous variation that exists among the symptoms, the degree of demonstrable leakage, and a patient’s response to stress incontinence. Modification of any one of these factors may influence the patient’s clinical status; for example, many patients give up certain physical activities (e.g., running, dancing, aerobics) when they experience stress incontinence. Limiting their activities may eliminate the incontinence problem, but it does so at a certain cost to their quality of life. Other women learn to cope with stress incontinence by adopting new body postures during physical activities that prevent them from leaking or by strengthening their pelvic muscles to compensate for increased exertion. Other women may be profoundly relieved to find out that the small amount of leakage they experience from time to time is not abnormal. In any case, the interaction of these three biopsychosocial factors opens up a variety of strategies for the management of stress incontinence. Surgical intervention is only one strategy, and it addresses only the biologic competence of the sphincteric mechanism rather than either of the other factors that interact to produce the clinical problem.

Urge Urinary Incontinence and Overactive Bladder

Although stress incontinence is the most common type of urinary continence in women, urge incontinence is the most common form of incontinence in older women. Urge urinary incontinence is the involuntary leakage of urine accompanied by or immediately preceded by urgency. This is a symptom-based diagnosis and may or may not be caused by detrusor overactivity, which is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase.

Women may also have related problems such as urgency, nocturia, and increased daytime frequency. The definition of nocturia is quantifiable: The woman wakes one or more times a night to void. The other symptoms are more subjective. Increased
daytime frequency occurs when the patient considers that she voids too often. (Note that the term *pollakisuria* is used to describe this condition in many countries.)

**Urgency is the sudden compelling desire to pass urine that is difficult to defer.** Most women have experienced these symptoms during times of voluntary delays in voiding or increased fluid intake. However, urinary urgency implies more than just the feeling that all normal women have if they voluntarily delay voiding beyond a reasonable time (12). When a woman presents for treatment, she generally reports an intrusive, bothersome, persistent need to urinate that takes her attention away from other activities. Increased daytime frequency is often brought up as an issue when a woman experiences a change in her own voiding pattern.

There is very little information about what is “normal” in terms of voiding frequency. Overactive bladder (OAB) is frequently defined in studies of pharmacologic agents as more than eight voids per 24 hours, a definition that was based on the 95th percentile of voids in a small sample of Scandinavian women (13). **More recent data from a broader sample of women in the United States suggests that the median number of voids per day is eight, and 95% of so-called normal women void 12 or fewer times per day** (14).

**Detrusor overactivity is qualified, when possible, by cause and is termed neurogenic detrusor overactivity (formerly called detrusor hyperreflexia) when a neurological condition may account for the finding, and idiopathic detrusor overactivity (formerly called detrusor instability) when there is no defined cause.**

The term *overactive bladder syndrome* also describes women with symptoms of urgency, frequency, and urge incontinence. It is referred to as OAB-dry when women with these symptoms do not leak urine, and OAB-wet when it is accompanied by incontinence. It is important to note that a woman with severe urgency and a sense of impending leakage who remains dry may have the exact same bladder pathology as one with severe urgency and concomitant leakage. A woman with a strong urethral sphincteric mechanism may be able to avoid leakage during uninhibited bladder contractions, whereas one with a strong sphincter may remain dry but be disturbed by the urgency and impending sense of leakage.

**Mixed Incontinence**

As implied by the name, women with mixed incontinence have symptoms of both stress and urge urinary incontinence. Younger women are more likely to have stress incontinence alone, whereas in older women mixed and urge incontinence predominate. In a review of 15 population-based studies of women of all ages with urinary incontinence, a median of 49% (range 24%–75%) had stress urinary incontinence, 21% (range 7%–49%) had urge urinary incontinence, and 29% (range 11%–61%) had mixed urinary incontinence (15).

**Functional and Transient Incontinence**

Functional incontinence is more common in elderly women and refers to incontinence that occurs because of factors unrelated to the physiologic voiding mechanism. A woman who can’t get to the bathroom quickly may often become incontinent. Functional incontinence can be related to such factors as decreased mobility, musculoskeletal pain, or poor vision. Factors leading to transient urinary incontinence are, as the name implies, medically reversible conditions. **A useful mnemonic to help remember these factors is DIAPPERS** (16,17) (Table 23.2). These factors argue strongly for the inclusion of a thorough medical evaluation as part of the workup of any patient with urinary incontinence.

**Extraurethral Incontinence**

While most urinary incontinence represents unwanted urine loss through the urethra (transurethral incontinence), urine loss can also occur through abnormal openings. These
openings can be created by congenital causes or some form of trauma. The congenital causes of urinary incontinence are not common and usually are easy to diagnose. The most extreme cases are caused by bladder exstrophy, in which there is a congenital absence of the lower anterior abdominal wall and anterior portion of the bladder, resulting in the entire bladder opening directly to the outside (18). Such cases are diagnosed at birth. Before the advent of modern reconstructive surgery, these infants usually died very early in life from sepsis.

Ectopic ureter, a subtle congenital anomaly causing extraurethral urine loss, generally is detected early in life, but occasionally one may escape detection until adolescence or early adulthood (19). In infancy, an ectopic ureter should be suspected when a mother seeks care for her baby, whom she says is never dry. Normally, infants have periods of dryness interspersed with periods of wetness. Most commonly, the ectopic ureter drains into the vagina, but occasionally, it may drain into the urethra distal to the point of continence. This condition can be diagnosed by excretory urography.

A traumatic opening between the urinary tract and the outside is called a fistula. Vesicovaginal fistulas, located between the bladder and urethra, are most common, but fistulas may also occur between the vagina, uterus, or bowel, and the urethra, ureter, or bladder.

Worldwide, the most common cause of vesicovaginal fistulas is obstructed labor. This also was true in the Western world 150 years ago, but advances in the provision of basic obstetric services and advanced obstetric intervention have virtually eliminated this problem in developed countries. The rest of the world is not so fortunate.

Obstructed labor often occurs in rural areas where girls are married young (sometimes as early as 9 to 10 years of age) and where transportation is poor and access to medical services is limited. In such circumstances, pregnancy often occurs shortly after menstruation begins and before maternal skeletal growth is complete. When labor begins, cephalopelvic disproportion is common, and little can be done to correct fetal malpresentations. Women may be in labor as long as 5 to 6 days without intervention, and if they survive, they usually give birth to a stillborn infant. In such cases, the soft tissues of the pelvis have been crushed by constant pressure from the fetal head, leading to an ischemic vascular injury and subsequent tissue necrosis. When this tissue sloughs, a genitourinary or rectovaginal fistula develops. Many of these patients have complex or multiple fistulas, involving total destruction of the urethra and sloughing of the entire bladder base (Fig 23.2). Obstetric fistulas are frequently as large as 5 to 6 cm in diameter.

After such fistulas develop, the lives of these young women (most of whom are younger than 20 years of age) are ruined unless they can gain access to curative surgical services.

The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members. They can no longer live with their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy functional young women. The social and economic costs of this problem are enormous, yet it largely has been neglected by the world medical community. The morbidity associated with obstetric fistulas remains, along with the related maternal mortality, one of the single most neglected issues in international women’s health care (20).

Figure 23.2 Moderate-sized obstetric vesicovaginal fistula. A metal probe has been placed through the urethra and is clearly visible through the bladder base. Copyright Worldwide Fistula Fund, used by permission.

The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members. They can no longer live with their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy functional young women. The social and economic costs of this problem are enormous, yet it largely has been neglected by the world medical community. The morbidity associated with obstetric fistulas remains, along with the related maternal mortality, one of the single most neglected issues in international women’s health care (20).

Figure 23.3 Posthysterectomy fistulas. Note three small fistulas in a row.
In the industrialized world, the most common causes of genitourinary fistulas are surgery, malignancy, and radiation therapy, alone or in combination. Most often, a vesicovaginal fistula develops after an otherwise uncomplicated vaginal or abdominal hysterectomy in which a small portion of the bladder was inadvertently trapped in a surgical clamp or was transfixed by a suture. These fistulas most often occur at the vaginal apex and are no larger than 1 to 2 mm. The amount of urine that can leak through a fistula of any size, however, is enormous. Figure 23.3 shows a cystoscopic view of three small vesicovaginal fistulae, lined up where the cuff suture line would have been.

Although rare, vesicouterine fistulas are increasing in incidence as the rate of cesarean deliveries increases. Such fistulas are almost always associated with repeat cesarean deliveries. The classic triad of vaginal urinary leakage, cyclic hematuria, and amenorrhea is known as Yousef's syndrome (21).

Nocturia

Nocturia is the number of voids recorded during a night’s sleep; each void is preceded and followed by sleep. To sort out whether nocturia is due to heightened urine production at night, the nocturnal urinary volume can be assessed from a bladder chart. Nocturnal urinary volume is defined as the total volume of urine passed between the time the woman goes to bed with the intention of sleeping and the time of waking with the intention of rising. Thus, it excludes the last void before going to bed but includes the first void after rising in the morning. Nocturnal polyuria is present when an increased proportion of the 24-hour output occurs at night.

Risk Factors for Urinary Incontinence

Most of the data about risk factors for urinary incontinence come from clinical trials or cross-sectional studies using survey design. Some risk factors have been more rigorously studied than others. Thus, the information available is limited in its general applicability and one cannot infer causality from it. Despite these limitations, there is some evidence that age, pregnancy, childbirth, obesity, functional impairment, and cognitive impairment are associated with increased rates of incontinence or incontinence severity (15,22). Some factors pertain more to certain age groups than others. For example, in studies of older women, childbirth no longer increases the risk of incontinence, possibly because of the presence of comorbidities and other factors that promote incontinence. Medical diagnoses that generally have been associated with urinary incontinence include diabetes, strokes, and spinal cord injuries. Other factors about which less is known or findings are contradictory include hysterectomy, constipation, occupational stressors, smoking, and genetics.

Pregnancy and delivery predispose women to stress urinary incontinence, at least during their younger years. Of women who have not borne children, those who are pregnant leak more often than their nonpregnant counterparts; about half of women report symptoms of stress urinary incontinence during pregnancy, but in most, the symptom resolves after delivery. In a prospective study, 32% of 305 primiparas developed stress urinary incontinence during pregnancy and 7% after delivery. By 1 year, only 3% reported stress urinary incontinence (23). However, 5 years later, 19% of women with no symptoms after the first delivery had stress urinary incontinence. Of women reporting stress urinary incontinence 3 months postpartum (in most of whom it had resolved by 1 year), 92% had such leakage 5 years later. Thus, transient postpartum leakage may be a marker for future incontinence.

Various changes happen after delivery that may predispose women to stress urinary incontinence. Levator ani muscle strength decreases (24). About 20% of women develop a visible defect in the levator ani muscles after vaginal delivery (25). The bladder neck descends (26), and the pelvic muscles undergo partial denervation with
pudendal neuropathy (27). In most studies, parity is strongly associated with urinary incontinence in younger women (28). However, in studies of women 60 years and older, parity is generally no longer an independent risk factor for incontinence (29). The reason for this is not well elucidated, but it may be because the changes in muscle, nerve, connective tissue, and hormonal function that occur with aging make other women “catch up” to those that developed incontinence at a younger age because of delivery trauma. Alternately, it may be that medical problems more common in older women account for a larger proportion of incontinence risk as women age.

Obesity deserves special mention for its role in causing or exacerbating stress incontinence. Many researchers have reported an association (that remains after adjusting for age and parity) between increased weight and body mass index (BMI), and urinary incontinence. For example, a dose-response relationship between BMI and severe urinary incontinence has been described (30). Compared with women with a BMI less than 25 kg/m², odds ratios (OR) for the following BMI groups were: 25–29, OR 2.0 (1.7–2.3); 30–34, OR 3.1 (2.6–3.7); 35–39, OR 4.2 (3.3–5.3); 40+, 5.0 (3.4–7.3).

Initial Evaluation

The initial evaluation of patients with incontinence requires a systematic approach to consider possible causes. The basic evaluation should include the following items: history (including assessment of quality of life and degree of bother from symptoms), physical examination, and simple primary care level tests. Most women can begin nonsurgical treatment after this basic evaluation.

History

A thorough medical history should be obtained from every incontinent patient. The history should include a review of symptoms, general medical history, review of past surgery, and current medications. The woman’s most troubling symptoms must be ascertained—how often she leaks urine, how much urine she leaks, what provokes urine loss, what improves or worsens the problem, and what treatment (if any) she has had in the past. It is essential to keep the patient’s chief symptom at the forefront to avoid inappropriate management. Consider, for example, a woman whose chief concern is that once a month, while leading a business seminar, she has a sudden, overwhelming urge to void following by precipitant emptying of her entire bladder content. She finds this leakage devastating, and is considering quitting her job because of her acute embarrassment. On occasion, she also leaks a few drops of urine during exercise, but this minor leakage does not bother her. During the evaluation, urodynamics reveal minimal stress urinary incontinence at capacity during strong coughing. No detrusor overactivity is seen. The patient is offered, and undergoes, a surgical procedure for her documented urodynamic stress incontinence. Not surprisingly, her chief symptom is not improved and she is devastated.

The general medical history may reveal systemic illnesses that have a direct bearing on urinary incontinence, such as diabetes mellitus (which produces osmotic diuresis if glucose control is poor), vascular insufficiency (which can lead to incontinence at night when peripheral edema is mobilized into the vascular system, resulting in increased diuresis), chronic pulmonary disease (which can lead to stress incontinence from chronic coughing), or a wide variety of neurologic conditions that can affect the neurourologic axis at any point from the cerebral cortex to the peripheral nervous system. Medications that may affect the lower urinary tract are summarized in Table 3.23 (31–34).

Quality-of-life Measures

Physicians caring for incontinent women should ask them about how the incontinence specifically affects their lives and to what degree the incontinence bothers them. There often is discord between the objective symptom severity and subjective bother. Only by understanding each woman’s situation can treatment be appropriately
planned and response evaluated. Some women may be completely satisfied if they are able to sit through a movie without running to the bathroom, even if they leak urine at other times. Others may be satisfied only if they are 100% dry. Given that the latter is likely an unrealistic goal, knowing that the patient feels this way gives the provider the opportunity to educate her about the likely outcome of treatment.

Physicians who have a large number of incontinence patients or who wish to evaluate patients in a more standardized fashion before and after treatment may choose to use one of several well-designed, validated quality-of-life measures available. An expert summary of the literature in this area conducted for the International Consultation on Incontinence recommended the instruments summarized in Table 23.4. These instruments were found to be valid, reliable, and responsive to change following standard psychometric testing.

### Physical Examination

The physical examination of the patient with incontinence should focus on both general medical conditions that may affect the lower urinary tract as well as problems related to urinary incontinence. Such conditions include cardiovascular insufficiency, pulmonary disease, occult neurologic processes (e.g., multiple sclerosis, stroke, Parkinson’s disease, and anomalies of the spine and lower back), abdominal masses, and mobility. Key factors to assess during the physical examination are summarized in Table 23.5. A Q-tip test has poor predictive value for determining either stress urinary incontinence diagnosis or predicting treatment success (35). It is used by some clinicians to determine movement of the anterior vaginal wall with Valsalva. A woman with a fixed nonmobile urethra is a poor candidate for a surgery (such as a Burch colposuspension) designed to elevate the urethra. It is not possible to support an already well-supported urethra.

### Simple (Primary Care Level) Tests

It is important to realize that formal urodynamics tests are neither the only, nor the most important, tests of bladder function. Other simple tests that can easily be performed in the primary care setting provide useful information to guide patient care.
Voiding Diary

A frequency/volume bladder chart (often termed a “bladder diary”) is an invaluable aid in the evaluation of patients with urinary incontinence. A frequency/volume chart is a voiding record kept by the patient for several days. Patients are instructed to write down the time of every void on the chart and measure the amount of urine voided. The time of any incontinent episodes, as well as the specific activities associated with urine loss, should be recorded. If desired, the patient can also be instructed to keep a record of fluid intake. Although the type of intake may guide management suggestions, in most cases volume of intake can be estimated with some accuracy from the amount of urine produced.

A frequency/volume bladder chart provides vital information about bladder function that is not provided by formal urodynamics studies: 24-hour urinary output, the total number of daily voids, number of nighttime voids, the average voided volume, and

---

**Table 23.4 Questionnaires to Assess Urinary Incontinence**

The following questionnaires have been recommended by the International Consultation on Incontinence to assess symptoms of incontinence and impact of incontinence on quality of life in women.

### Symptoms

### Quality of Life

---

the functional bladder capacity (largest volume voided in normal daily life). This information allows the clinician to confirm reports of urinary frequency with objective data and to determine whether part of the patient’s problem is an abnormally high (or low) urinary output. The chart can also be used to calculate the volume of urine generated in nighttime hours versus daytime hours. Nighttime volume is calculated by adding output from voids that occur after the woman has fallen asleep for the night as well as the first morning void on awakening for the day. Older women sometimes have a marked shift in urine production, with more than half of their urine output generated during sleeping hours (Fig. 23.4). Demonstrating this on the voiding diary may lead to further treatment options.

### Urinalysis

Examination of the urine by dipstick testing and microscopy is done to exclude infection, hematuria, and metabolic abnormalities. **Hematuria cannot be diagnosed on the results of a dipstick test alone; confirmation by microscopic evaluation is mandatory.**

If a urinary tract infection is documented by microscopy or culture, it is reasonable to see whether urinary tract symptoms improved with eradication of bacteriuria. Occasionally, a simple urinary tract infection causes the onset or exacerbation of urinary incontinence. However, some women, particularly older ones, have asymptomatic bacteriuria that truly is asymptomatic; thus, if attempted treatment of a woman with bacteriuria but without classic urinary tract infection symptoms (such as dysuria, urgency, frequency) does not improve incontinence, further antibacterial treatment is generally unnecessary.

If hematuria as well as bacteriuria is found, the urine should be rechecked after eradication of the bacteriuria. **Hematuria found in the absence of bacteriuria may need further evaluation to rule out kidney or bladder tumors;** the necessity for and extent of the evaluation depends on concomitant risk factors and the clinical presentation. If
malignancy is suspected, bladder biopsy should be performed by the surgeon who would treat the patient in the event a malignancy is discovered.

Routine urinary cytology is not helpful, but testing may be of value in women older than 50 years with irritative urinary tract symptoms, particularly if those symptoms are of sudden onset.

Postvoid Residual Volume

Incomplete bladder emptying may cause incontinence. Patients with a large postvoid residual urine volume (PVR) have a diminished functional bladder capacity because of the dead space occupied in the bladder by retained urine. This stagnant pool of urine also is a source of urinary tract infections because the major defense of the bladder against infection is frequent, nearly complete emptying.

A large PVR can contribute to urinary incontinence in two ways. If the bladder is overdistended, increases in intra-abdominal pressure can force urine past the urethral sphincter, causing stress incontinence. In some cases, bladder overdistention may provoke an uninhibited contraction of the detrusor muscle, leading to incontinence. These conditions may coexist, further complicating the problem.

The PVR can be assessed by either direct catheterization or ultrasonography. Although sufficiently accurate for clinical purposes, ultrasonography measurements of PVR have a standard error of 15% to 20%. Thus, assessment of the catheterized volume is preferred (36). It is important to perform this test within 10 minutes of a void to avoid an artificially
elevated result because of diuresis. It is generally agreed that a PVR level less than 50 mL is normal and greater than 200 mL is abnormal, but there is much debate about values in the midrange. Because many women are unable to void well during an anxiety-ridden first visit, it is helpful to recheck the PVR at a future visit before embarking on further diagnostic tests. The value of assessing bladder emptying in neurologically normal women who do not have pelvic organ prolapse or symptoms of voiding dysfunction has not been demonstrated.

**Cough Stress Test**

Patients should be examined with a full bladder, particularly if stress incontinence is a consideration. Urine egress from the urethra at the time of a cough documents stress incontinence. If leakage is not observed when the woman is supine, she should stand with her feet separated to shoulder width and cough several times. Many women with urge incontinence caused by detrusor overactivity may experience urine loss during a cough stress test, but this finding may not be relevant to their real symptom. The physical findings must be set within the context of the patient’s history to be relevant.

**Pad Tests**

Pad tests are widely used in patient-oriented research as an objective way of assessing treatment effectiveness, but rarely are they used in clinical practice. Pad tests, usually performed in women with a full bladder, quantify the volume of urine lost by weighing a perineal pad before and after specified activities. Pad tests can be divided into short-term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a symptomatically full bladder or with a certain volume of saline instilled into the bladder before beginning the series of exercises. A pad weight gain of 1 or more grams is considered positive for a 1-hour test, and a pad weight gain greater than 4 grams is positive for a 24-hour test.

**Advanced Testing**

**Urodynamics**

At its most basic level, a urodynamic study is anything that provides objective evidence about lower urinary tract function (37). In this sense, measurement of a patient’s voided urine volume and catheterization to determine her PVR are urodynamic studies. A frequency/volume chart is also a valuable urodynamic study. Obtaining clinically valuable information does not always require the use of expensive, complex technology. After basic testing, further testing is recommended in the following circumstances: the diagnosis is uncertain (for example, because of major discrepancies between the history, the voiding diary, and symptom scales); surgery is being considered; or the patient has hematuria in the absence of an infection, an elevated PVR, a neurologic condition that may complicate treatment (such as multiple sclerosis), marked pelvic organ prolapse, or numerous prior surgical attempts at correction. Current urodynamic definitions are summarized in Table 23.6.

**Uroflowmetry**

To assess voiding function, urodynamic testing usually begins with uroflowmetry, a study in which the volume of urine voided is plotted over time. Flow time, peak flow rate, and time to peak flow usually increase as the voided volume increases.

**Filling Cystometry**

Cystometrography (also termed cystometry) is done to assess bladder and urethral function during bladder filling. Simple (or single-channel) cystometry is performed
### Table 23.6 Urodynamic Definitions

#### I. Bladder sensation

<table>
<thead>
<tr>
<th>First sensation</th>
<th>First becomes aware of bladder filling</th>
</tr>
</thead>
<tbody>
<tr>
<td>B. First desire to void</td>
<td>Feeling that would lead the person to void at next convenient moment, but voiding can be delayed if necessary</td>
</tr>
<tr>
<td>C. Strong desire to void</td>
<td>Persistent desire to void without the fear of leakage</td>
</tr>
</tbody>
</table>

**D. Sensation classified as:**

1. Increased
2. Reduced
3. Absent
4. Nonspecific bladder sensations (other symptoms make person aware of bladder filling, like abdominal fullness)
5. Bladder pain (is abnormal)
6. Urgency (sudden compelling desire to void)

#### II. Detrusor function

<table>
<thead>
<tr>
<th>Normal</th>
<th>Allows bladder filling with little or no change in pressure; no involuntary phasic contractions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Detrusor overactivity</td>
<td>Involuntary detrusor contractions during filling</td>
</tr>
</tbody>
</table>

1. Phasic | Characteristic wave form; may or may not lead to incontinence |
2. Terminal | Single involuntary detrusor contractions occurring at cystometric capacity, which cannot be suppressed, and results in incontinence usually resulting in bladder emptying |
3. Detrusor overactivity incontinence | Incontinence that is due to an involuntary leakage episode |
4. Neurogenic detrusor overactivity | There is a relevant neurologic condition (replaces term detrusor hyperreflexia) |
5. Idiopathic detrusor overactivity | No definite cause (replaces term detrusor instability) |

**C. Bladder compliance**

1. Calculate at start of bladder filling (usually 0)
2. At cystometric capacity (excluding any detrusor contraction)

**D. Bladder capacity**

1. Cystometric capacity | Volume at end of cystometrogram; capacity is volume voided together with any residual urine |
2. Maximum cystometric capacity | Volume at which person feels she can no longer delay voiding |

#### III. Urethral function

<table>
<thead>
<tr>
<th>Normal urethral closure mechanism</th>
<th>Maintains a positive urethral closure pressure during bladder filling</th>
</tr>
</thead>
<tbody>
<tr>
<td>Incompetent urethral closure mechanism</td>
<td>Allows leakage of urine in the absence of a detrusor contraction</td>
</tr>
</tbody>
</table>

**C. Urethral relaxation incontinence**

Leakage that is due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity

**D. Urodynamic stress incontinence**

Involuntary leakage of urine during increased abdominal pressure, in the absence of detrusor contraction (replaces term genuine stress incontinence)

**E. Urethral pressure (P_{ura})**

Fluid pressure needed to open closed urethra

1. Pressure profile | Pressure along length of urethra |
2. Urethral closure pressure | P_{ura} - P_{ves} |
3. Maximum urethral closure pressure (MUCP) | Maximum difference between P_{ura} and P_{ves} |
4. Pressure transmission ratio | Increment in urethral pressure on stress as percentage of simultaneously recorded increment in intravesical pressure |

(Continued)
when bladder pressure only is measured during filling. Because the bladder is an intra-abdominal organ, the pressure recorded in the bladder is a combination of several other pressures, most notably the pressure created by the activity of the detrusor muscle itself and the pressure exerted on the bladder by the weight of the surrounding intra-abdominal contents (e.g., uterus, intestines, straining, or exertion). For this reason, the technique of complex (also called multichannel or subtracted) cystometry is generally used to try to approximate the actual pressure exerted in the bladder by the activity of the detrusor muscle alone. The detrusor pressure ($P_{det}$) is obtained by measuring total intravesical pressure ($P_{ves}$) with a bladder pressure catheter, approximating intra-abdominal pressure ($P_{abd}$) with a rectal or vaginal catheter, and then electronically subtracting the latter from the former:

$$P_{det} = P_{ves} - P_{abd}$$

Measurements can be obtained using electronic microtip transducer pressure catheters, fluid-filled pressure lines, fiberoptic catheters, or air-charged catheters. All are acceptable for clinical use, but it is important to realize that when different types of catheters are used, the correlation between numbers is imperfect. Other technical factors that influence

**IV. Pressure flow studies**

**A. Urine flow is defined as**

1. **Continuous**
2. **Intermittent**
   
   a. **Flow rate**  Volume voided/unit time
   
   b. **Voided volume**  Total volume voided
   
   c. **Maximum flow rate**
   
   d. **Voiding time**  Includes interruptions
   
   e. **Flow time**  Time over which measurable flow actually occurs
   
   f. **Average flow rate**  Voided volume/flow time

   g. **Closing pressure**  Pressure measured at end of measured flow

   h. **Detrusor function during voiding can be classified as:**

   1. **Normal**
   2. **Detrusor underactivity**  Contraction of reduced strength resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying
   3. **Acontractile**  Cannot be demonstrated to contract

   i. **Urethral function during voiding can be classified as:**

   1. **Normal**  Continuously relaxed
   2. **Dysfunctional voiding**  Intermittent and/or fluctuating flow rate that is due to involuntary intermittent contractions of the periurethral striated muscle during voiding in neurologically normal people
   3. **Detrusor sphincter dyssynergia**  Detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle
   4. **Nonrelaxing urethral sphincter obstruction**  Usually occurs in people with a neurologic lesion

---

cystometry results include the choice of distending medium, filling rate, and patient position. The steps involved in a multichannel urodynamic study are outlined in Table 23.7. Normal cystometric values for women are shown in Table 23.8.

An example of detrusor overactivity seen during complex cystometry is shown in Figure 23.5. Surface or needle electromyography may be performed during filling and voiding to assess muscle activity of the urethral sphincter or pelvic floor. Electromyography as generally performed has not been proved useful in neurologically intact women with symptoms of only stress urinary incontinence, and thus is not required in this patient population.

Both false-positive and false-negative results can occur with urodynamic studies. False-positive results occur in patients with asymptomatic detrusor overactivity, detrusor overactivity that is irrelevant to the symptom, or detrusor overactivity that is situational (e.g., caused by test anxiety). False-negative results can occur with 20-minute cystometrography.

### Table 23.7 Steps in Conducting a Multichannel Urodynamic Study

1. **Insert pressure and filling catheter into bladder** (may be two catheters or dual catheter) to measure intravesical pressure and to fill bladder. Insert pressure catheter into upper vagina or rectum to approximate abdominal pressure.

2. **Infuse fluid (usually sterile water or saline, sometimes radiographic contrast dye) at a rate of 50 to 100 mL/min.** Record the volume infused and the pressure measurements continuously. The patient’s bladder may be filled with her lying supine, in a modified lithotomy position, sitting, or standing. When possible, do cystometry in the standing position as most patients with incontinence report this problem more when they are erect.

3. **Note the point at which any leakage occurs.**

4. **During filling, record the first desire to void (that is, the feeling that would lead her to void at the next convenient moment, but voiding can be delayed if necessary) and the strong desire to void (that is, the persistent desire to void without the fear of leakage).** The maximum cystometric capacity, in women with normal sensation, is the volume at which the woman can no longer delay micturition; filling should not be continued to the point of pain or severe discomfort.

5. **If no detrusor overactivity is noted during filling, have the patient do provocative maneuvers at maximum capacity, such as coughing, heel-bouncing, and listening to the sound of running water to provoke uninhibited detrusor contractions, which may be the cause of the patient’s symptoms.**

### Table 23.8 Approximate Normal Values of Female Bladder Function

- Residual urine < 50 mL
- First desire to void occurs between 150 and 250 mL infused
- Strong desire to void does not occur until after 250 mL
- Cystometric capacity between 400 and 600 mL
- Bladder compliance between 20 and 100 mL/cm H$_2$O measured 60 sec after reaching cystometric capacity
- No uninhibited detrusor contractions during filling, despite provocation
- No stress or urge incontinence demonstrated, despite provocation
- Voiding occurs as a result of a voluntarily initiated and sustained detrusor contraction
- Flow rate during voiding is > 15 mL/sec with a detrusor pressure of < 50 cm H$_2$O

because this test is not always an accurate measure of daily bladder activity. Looking for detrusor instability with such a test is like looking for an episodic cardiac arrhythmia using 12-lead electrocardiography, as opposed to looking for the arrhythmia using a 24-hour Holter monitor. The sensitivity of the latter test is far greater than that of the former. Ambulatory urodynamics can be performed and are more likely to detect detrusor overactivity than office-based studies.

Tests of Urethral Function

Several tests of urethral function, including urethral pressure profilometry, Valsalva leak-point pressures, and the fluoroscopic and cystoscopic assessment of the bladder neck, have been used to guide therapy in women with stress urinary incontinence. Women with poor urethral function, evidenced by low Valsalva leak-point pressures, low maximal urethral closure pressures, or a visualized open bladder neck (Fig. 23.6), are thought to be at higher risk of treatment failure using standard retropubic urethropexy. Cutoff values for these tests are poorly defined and remain controversial. Although women with stress urinary incontinence have, on average, significantly lower maximal urethral closure pressures than those without incontinence, there is wide overlap in the values between such women, and no lower limit of urethral closure pressure has been established that predisposes women to stress urinary incontinence.

The urethral pressure profile is a test designed to measure urethral closure. Because continence requires the pressure in the urethra to be higher than the pressure in the bladder, it
was believed that measuring the pressure differential between the two would provide useful clinical information. The urethral pressure profile is determined by slowly pulling a pressure-sensitive catheter through the urethra from the bladder.

The urethral closure pressure ($P_{\text{close}}$) is the difference between the urethral pressure ($P_{\text{ure}}$) and the bladder pressure ($P_{\text{ves}}$): $P_{\text{close}} = P_{\text{ure}} - P_{\text{ves}}$.

Although this pressure can be used to differentiate groups of normal women from groups of those with stress incontinence (women with stress incontinence tend to have higher urethral pressure levels than those who do not), there is considerable overlap between the two groups. It has also been suggested that women with stress incontinence with low urethral closure pressure ($<20 \text{ cm H}_2\text{O}$) have a poorer prognosis for surgical outcome than women who do not have this condition; however, this area has been the subject of considerable debate (3,38,39). Because stress incontinence, by definition, occurs during increases in intra-abdominal pressure that are generated by some kind of physical activity, it is not obvious why measurement of resting urethral pressure should be relevant to stress-related leakage, which is a dynamic event. One review concluded that urethral pressure profilometry is not a useful diagnostic test for stress incontinence in women and that its use in clinical management is unsupported by current evidence (40).

Leak-point pressure (LPP) is a urodynamic measure of the minimum intra-abdominal or intravesical pressure required to cause incontinence during abdominal strain or cough. There is no consensus about whether it should be measured from the resting supine baseline (generally near 0) or from the standing resting baseline (which increases

Figure 23.6. Open and scarred bladder neck in an elderly woman who has undergone three anterior colporrhaphies for stress urinary incontinence in the past.
depending on body mass). Other factors that may affect the results include the catheter’s type, caliber, and placement (vaginal, rectal, or intravesical), the bladder volume at which the measurement is obtained, the mechanism by which intra-abdominal pressure is increased (coughing versus straining), and patient position (41).

Leak point pressure measurements often are performed at a bladder volume of 200 or 300 mL. Patients are asked to cough with gradually increasing force (cough leak-point pressure) and finally to strain slowly (Valsalva) to increase intra-vesical pressure gradually. The lowest pressure at which leakage occurs is recorded as the cough or the Valsalva leak-point pressure (Fig. 23.7). If leakage is not demonstrated, the highest pressure that has been obtained can be recorded with the notation “no leakage” to the specified pressure as measured in cm H2O. Currently, many clinicians use a cutoff point of 60 cm water pressure to separate women who have intrinsic sphincter deficiency from those who do not. This is problematic for two reasons: (i) the marked variability of results that depend on all the aforementioned factors, and (ii) the lack of prospective studies that demonstrate the predictive value of leak point pressure values on surgical outcomes. Results from this and other urodynamics tests must be evaluated as one piece of the patient’s puzzle, along with the history, physical examination, voiding diary and other tests. Current Medicare guidelines require that when bulking agents, such as collagen, are considered to treat stress incontinence, the intra-abdominal leak point pressure when the bladder has been filled with at least 150 mL of fluid must be less than 100 cm H2O.

Fluoroscopy and cystourethroscopy have both been used to visualize the bladder neck because many clinicians and investigators believe that a closed bladder neck is important in maintaining continence. However, studies of continent women reveal that many individuals with normal urethral function show evidence of bladder neck opening with physical stress.
Neither test is recommended in the routine evaluation of women with straightforward incontinence.

**Voiding Cystometrography**

Urodynamic testing usually concludes with an instrumented voiding study (also known as a pressure-flow study or voiding cystometrography), in which the vesical, abdominal, and urethral pressures are measured simultaneously during bladder emptying (Fig. 23.8). Various studies have identified Valsalva voiding, low preoperative flow rate, and high preoperative detrusor pressures during voiding as risk factors for postoperative voiding dysfunction; however, findings often are contradictory.

**Imaging Tests**

The role of imaging techniques in studying female urinary incontinence has not yet been established. Researchers are evaluating the potential roles of ultrasonography, fluoroscopy, functional neuroimaging, and magnetic resonance imaging (MRI). These tests should not be done routinely but are useful in certain conditions. If the patient’s symptoms (easily remembered by the 3 Ds: dysuria, dribbling, and dyspareunia) or examination suggest a urethral diverticulum, MRI is the test of choice (43).

**Neurophysiologic Tests**

The neuromuscular function of the pelvic floor is dependent on the integrity of the nervous system. Injury can theoretically occur anywhere along these nerves, from the cell
body located in Onuf’s nucleus in the ventral part of the spinal cord, along its axon, to the neuromuscular junction. Pelvic floor neurophysiology utilizes techniques applied to nerves and skeletal muscles elsewhere in the body to document neuromuscular integrity or evidence of injury. Currently, these tests are not routinely used in the clinical evaluation of most incontinent women.

**Pudendal Nerve Terminal Motor Latency**

The pudendal nerve terminal motor latency (PNTML) indirectly assesses the integrity and patency of the terminal portion of the pudendal nerve, its neuromuscular junction, and the muscle it serves. Using a specialized electrode affixed over the index finger, the pudendal nerve is electrically stimulated near the ischial spine (either transrectally or transvaginally), and the resulting muscular response is measured. The response, termed a *compound muscle action potential* (CMAP), is detected at the anal sphincter. The interval between the stimulation and the onset of the CMAP is measured. A prolonged latency is noted with injury to large and heavily myelinated axons. The latency time may be within the normal range when only smaller nerve fibers have been affected; thus, neurological dysfunction may exist in the presence of a normal latency time.

**Sacral Reflexes**

Only the distal efferent arm of the pudendal nerve is analyzed in the PNTML. Similar to the clinically obtained anal wink or bulbocavernous reflex, electrically induced sacral reflexes can gather information about both the afferent and efferent arc in the pelvic nerves. A short train of dual impulses delivered next to the clitoris and measured at the anal sphincter is termed the clitoroanal reflex and provides information about the integrity of the afferent and efferent arm of the somatic pudendal nerve. A stimulating electrode placed in the bladder sends these signals along the visceral, autonomic fibers to the spinal cord, and a reflex signal will return along the pudendal nerve to the anal sphincter.

**Somatosensory Evoked Potentials**

Normal pelvic floor and pelvic organ function ultimately is controlled by higher centers in the central nervous system, including the cerebral cortex. Recording electrodes located on the scalp near the motor cortex allow the signal transmission speed between a skeletal muscle and the brain to be measured. Repeated electrical stimuli, called somatosensory evoked potentials, at a muscle of interest are used to assess the integrity of the central afferent limb. In a reverse fashion, electrical or magnetically induced stimuli can be delivered at the motor cortex (or along the spine), and the induced muscle action potentials can be detected. Prolonged latencies not attributable to the peripherally studied nerves (such as with a PNTML or sacral reflex) are evidence of a central nervous system conduction flaw.

**Electromyography**

Electromyography (EMG) assesses the inherent electrical potentials generated during neuronal activation of skeletal muscle. It can be performed using surface electrodes or needle electrodes. Surface EMG measures the summation of muscle activity in the general area of the applied electrode. It is best used for simply describing the pattern and coordination of muscle activity, but is less useful in providing more specific assessments. Needle EMG of the pelvic floor can “map” the anatomic location of muscles but has largely been replaced by ultrasonography. The major value of needle EMG is its ability to assess nerve injury and determine whether the injury is acute and ongoing or chronic. Single-fiber EMG can quantify the ratio of muscle fibers to nerve fibers (the so-called fiber density). An increase in fiber density is evidence of previous nerve injury with successful reinnervation. Concentric needle EMG is more widely available and allows for further neurophysiologic evaluation. Abnormal electrical activity associated with acute injury may be seen, and
motor unit action potentials (MUAPs) can be assessed and quantified. Following nerve injury and reinnervation, MUAP parameters—such as duration, amplitude, number of phases, and turns—are typically larger. Finally, the ability of a muscle to increase the firing frequency of motor neurons and the ability to recruit more motor neurons can also be assessed using this needle.

**Nonsurgical Treatment**

Treatment of urinary incontinence can be either nonsurgical or surgical. The approach to treatment is based on the clinical findings and the degree of discomfort experienced by the patient, who should be fully informed of the risks and expected outcome.

**Lifestyle Changes**

Lifestyle interventions can decrease stress urinary incontinence in many women (44). Weight loss in both morbidly and moderately obese women decreases leakage, and ways to incorporate this intervention in a management plan are being investigated. Postural changes (such as crossing the legs during periods of increased intra-abdominal pressure) often prevent stress urinary incontinence. There is some evidence that decreasing caffeine intake improves continence; however, fluid intake in general seems to play a minor role in the pathogenesis of incontinence. Although smokers are at greater risk for incontinence, no data have been reported on whether smoking cessation resolves incontinence.

**Physical Therapy**

Medical evidence from well-designed randomized clinical trials shows that supervised pelvic floor muscle training (Kegel exercises) is an effective treatment for stress urinary incontinence. The Cochrane Incontinence Group concluded that pelvic floor muscle training is consistently better than no treatment or placebo treatment for stress incontinence and should be offered as first-line conservative management to women. Intensive training sessions that include personal contact with a health care professional to teach and supervise pelvic floor muscle training may be more beneficial than standard care. Biofeedback provides no added benefit over pelvic floor muscle training alone in women with stress urinary incontinence (45).

Several factors improve the likelihood that pelvic muscle training will relieve stress urinary incontinence. The woman must do the exercises correctly, regularly, and for an adequate duration. Based on exercise training of skeletal muscles elsewhere in the body, many physical therapists recommend training sessions three to four times per week, with three repetitions of eight to ten sustained contractions each time.

Electrical stimulation therapy has been used to treat incontinence by delivering low levels of current via a probe placed in the vagina or rectum. When compared with sham devices and pelvic floor exercises, electrostimulation has produced mixed results in the treatment of stress urinary incontinence (46,47) but may be more helpful in women with overactive bladders (48,49). Further research is needed to determine what niche this treatment may fill for women with urinary incontinence.

**Behavioral Therapy and Bladder Training**

Bladder training focuses on modifying bladder function by changing voiding habits. Behavioral therapy focuses on improving voluntary control rather than bladder function (50). The key component to bladder training is a scheduled toileting program. After reviewing the patient’s voiding diary, an initial voiding interval is chosen that represents the longest interval between voiding that is comfortable. She is then instructed to empty her bladder when she awakes, and then every time during the day that the interval is reached (for example, every 30 to 60 minutes). When patients feel the urge to void during that interval, they are instructed to use urge-suppression strategies, such as distraction or
relaxation techniques, until they get to the stated interval. Effective distraction strategies include mental exercises (such as mathematical problems), deep breathing, or “singing” the words to a song silently. The main goal is to avoid running to the bathroom at the moment of severe urgency. Another strategy is to quickly contract the pelvic muscle several times in a row (“freeze and squeeze”), which often lessens urgency. Gradually, the interval is increased (usually weekly), until the patient voids every 2 to 3 hours. Bladder training is most effective when women record every void and check in (by telephone or in person) with a health care provider weekly. Generally this program lasts for about 6 weeks. Bladder training is effective; in a trial in which bladder training was compared with treatment with oxybutynin, 73% of women in the bladder training group were clinically cured (51).

The primary technique of behavioral training is pelvic floor muscle training, as described previously, but with a focus on urge inhibition. Mastering voluntary pelvic floor muscle contractions helps to strengthen the outlet (decreasing leakage) and inhibit detrusor contractions. Other components of therapy may include voiding schedules, urge-inhibitions strategies, and fluid management.

Patients with neurogenic detrusor overactivity, rather than idiopathic detrusor overactivity, do not respond as well to behavioral therapy because the problem is actually one of neural pathway destruction rather than the need to re-establish cortical control mechanisms. Frequently, these patients have a trigger volume of urine that sets off a contraction that they cannot control voluntarily. They may benefit from a timed schedule in which they void at regular intervals (such as every 2 hours) to keep their bladder volume below the trigger point. Attempting to lengthen the interval between voids does not often work well.

Less-intensive treatments also decrease incontinence episodes. In a randomized trial, a simple self-help booklet was only somewhat less effective in reducing leakage (mean reduction in leakage episodes 43%) than behavioral training (mean reduction 69%) or behavioral training plus electrical stimulation (mean reduction 72%) (52).

### Vaginal and Urethral Devices

Vaginal devices (pessaries) and urethral inserts are available for treating stress urinary incontinence. There are no long-term randomized trials comparing devices and other treatments, but devices appear to be an acceptable treatment for some women. In a tertiary care population, approximately two thirds of women with stress urinary incontinence offered a trial of vaginal devices chose to undergo pessary fitting (53). Most (89%) achieved a successful fit. Of those that took a pessary home to manage their stress urinary incontinence, approximately one half used it for more than 6 months. Women who stopped using the pessary generally did so within the first month. Some women are pleased to be able to avoid surgery, or to use a “crutch” while waiting for the effect of pelvic muscle training; others prefer a treatment option (like surgery) that doesn’t require daily intervention. Examples of some vaginal devices are shown in Figure 23.9.

Urethral inserts are sterile inserts placed into the urethra by the patient and removed before a void, after which a new sterile insert is reinserted. Such inserts are appropriate for women with relatively pure stress incontinence, no history of recurrent urinary tract infections, and no serious contraindications to bacteriuria (e.g., artificial heart valves).

Devices that were once marketed in the United States and may be available again include a single-use triangularly shaped foam device with an adhesive hydrogel (54) that adheres to the perineal area to keep urine from exiting the urethral meatus, and a hat-shaped silicone patch (55) that adheres by applying an adhesive gel to the edge of the device, squeezing the central dome, and creating a vacuum. The patch can be reapplied after voids and reused for up to 1 week.
Stress Incontinence

The tone of the urethra and bladder neck is maintained in large part by α-adrenergic activity from the sympathetic nervous system. For this reason, many pharmacologic agents have been used with varying degrees of success to treat stress incontinence. These drugs include imipramine (which has a concomitant relaxing effect on the detrusor), ephedrine, pseudoephedrine, phenylpropanolamine, and norepinephrine. Unfortunately, many of these compounds also increase vascular tone and may, therefore, lead to problems with hypertension, a condition that afflicts many postmenopausal women with stress incontinence. These effects may preclude the use of α-agonists in such patients. A recent U.S. Food and Drug Administration (FDA) statement urged caution in the use of phenylpropanolamine, an α-agonist, in women because of an apparent increased epidemiologic risk for hemorrhagic cerebral vascular accidents. Although the risk remains very low, it is not possible to predict who is at risk for this complication (56). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought (57).

Based on a biologic rationale, it was thought that estrogen could effectively treat urinary incontinence given the presence of estrogen receptors in the bladder, urethra, and levator muscles. In early uncontrolled case series, women using various estrogen preparations experienced less incontinence. However, more recently, in several large randomized trials,
women assigned to receive estrogen and progesterone not only did not have less leakage, but in fact were more likely to experience the onset of incontinence or worsening of baseline symptoms (58). In 23,296 women enrolled in the Women’s Health Initiative double-blind, placebo-controlled, randomized clinical trial, use of menopausal hormone therapy (conjugated estrogen alone in women with a prior hysterectomy, conjugated estrogen and medroxyprogesterone acetate in women with a uterus) increased the incidence of all types of urinary incontinence at 1 year among women who were continent at baseline (59). Among women who reported urinary incontinence at baseline, both frequency and severity of incontinence worsened at 1 year in women taking either hormone preparation compared with those in the placebo group. Thus, conjugated estrogen with or without progestin should not be prescribed for the prevention or relief of urinary incontinence.

Serotonin and norepinephrine reuptake inhibitors (SSRIs) are being investigated for their role in treating stress urinary incontinence but currently are not available for this indication. In a multicenter, double-blind, placebo-controlled randomized trial, there was an 18% to 23% net difference in the percent reduction in incontinence episode frequency comparing duloxetine chloride 40 mg/day (59% reduction) and 80 mg/day (64% reduction) with placebo (40% reduction) after a 12-week treatment period (60). Other investigators have also found a high response rate in women assigned to placebo. This is partly due to the intensity of research protocols (which require paying more attention to one’s bladder than usual) but also speaks to the potential therapeutic role of simply completing the voiding diary.

**Urge Incontinence and Overactive Bladder**

The drugs used for treating detrusor overactivity can be grouped into different categories according to their pharmacologic characteristics; however, for all practical purposes, these drugs are anticholinergic agents that exert their effects on the bladder by blocking the activity of acetylcholine at muscarinic receptor sites. All of these drugs have side effects, the most common of which are dry mouth resulting from decreased saliva production, increased heart rate because of vagal blockade, feelings of constipation resulting from decreased gastrointestinal motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye. Other drugs, such as imipramine, may produce orthostatic hypotension and cardiac arrhythmias.

Current medications commonly used to treat these conditions are listed in Table 23.9. The introduction of several new drugs for overactive bladder has resulted in significant attention being given to urinary incontinence in the media (61–68). The newer drugs have some advantages over oxybutynin, which has been available for decades. These advantages include once- (or sometimes twice-) daily dosing, rather than three to four times per day and, to some degree, a less severe side-effect profile. The latter is due to changes in the delivery system and to more selectivity of muscarinic receptors (so that, for example, the bladder may be targeted more than the salivary glands). In addition, quaternary amines (such as trospium chloride) are not distributed into the central nervous system because of their large molecular size and hydrophilicity. The primary disadvantage of the newer agents is cost. Head-to-head trials of many of these newer drugs (sponsored by the drug manufacturers) have been carried out and generally show favorable results for the newer preparations with respect to the comparison drugs. In general, in these large randomized trials, the drug reduces incontinence episodes by 50% to 70%, whereas placebo reduces incontinence episodes by 40% to 60%. Clinicians must carefully assess whether statistically significant changes in incontinence episodes or frequency translate into clinically significant ones. A review of one newly
A released agent concluded that, “None of these drugs are as effective as advertisements to the public have suggested” (69).

When initiating therapy with generic *oxybutynin*, it is best to start with a lower dose (particularly for elderly patients) and increase it as needed to a higher, more frequent dosage. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs. If this is not effective, the next step is to move to one of the other anticholinergic agents. Some women may respond better to one agent than another. A 2-week trial is sufficient to determine effectiveness. It is helpful to ask patients to record daily episodes of incontinence or urgency before and during therapy so effectiveness can be more accurately determined.

Patients should be warned of the side effects of anticholinergic agents. Patients should be particularly advised about the symptom of a dry mouth and told that this is not due to thirst. Some patients increase their fluid intake to combat this problem, with a subsequent worsening of their incontinence. If dry mouth is a problem, patients should relieve it by chewing gum, sucking on a piece of hard candy, or eating a piece of moist fruit.

Nocturia and Nocturnal Enuresis

Medications that treat nocturia and nocturnal enuresis generally have one of three aims: to reduce urine output, to increase bladder capacity and reduce unstable bladder contractions, and to act centrally on sleep and micturition centers.

An analog of arginine vasopressin, DDAVP, has been used extensively to treat children with nocturnal enuresis. Some studies suggest that it may also be useful in adults (70,71). It is available both as a nasal spray and as an oral preparation. When taken orally, the dose required is approximately 10 times greater because of the increased availability of the nasal preparation. Complications associated with the DDAVP include hyponatremia, particularly in patients with excessive fluid intake; therefore, it is essential in higher-risk patients to measure serum sodium levels periodically.

There are few clinical trials that specifically investigate the use of anticholinergic medications to treat nocturia or nocturnal enuresis. Anecdotal evidence supports a trial of a long-acting or extended-release form of an anticholinergic, taken approximately 1 hour before bedtime.

The most extensively studied medications for the treatment of nocturnal enuresis are tricyclic antidepressants, particularly imipramine. These agents may work by altering sleep mechanism, by providing anticholinergic or antidepressant effects, or by affecting antidiuretic hormone excretion. The typical starting dose of imipramine is 25 mg at bedtime, which may be increased to as high as 75 mg. In the elderly, imipramine should be used cautiously because it increases the risk of hip fracture, presumably related to the potential side effect of orthostatic hypertension (72).

In a randomized, placebo-controlled study comparing nighttime doses of placebo and 1 mg of bumetanide (a loop diuretic), bumetanide decreased nocturia episodes by 25% compared with placebo (73). Patients who produce half of their total urine at night often benefit from the use of a diuretic (e.g., 20 mg furosemide) in the late afternoon to move fluid through the system and decrease their nighttime urine production.

Surgical Treatment for Stress Incontinence

In a systematic review of 943 citations, only 76 (11 randomized trials, 20 prospective cohort studies, and 45 retrospective cohort studies) met minimum criteria that the investigators set for reporting results of surgical trials or series (74). The median follow-up interval was short: 1 year for prospective studies and 2 years for retrospective studies. None of the studies at that time described quality-of-life considerations, and few studies obtained the patient’s perception on outcome in a standardized fashion. Of the 31 prospective studies, 28 were single center, and 29 were limited to teaching hospitals. As a result, the ability to generalize the findings was questionable. Although current studies generally do include instruments for measuring the impact of the surgery on the patient’s quality of life, most published studies continue to represent the short-term experience of surgeons from one site.

In 1997, the American Urological Association convened a clinical guidelines panel to analyze published outcomes data on surgical procedures to treat female stress urinary incontinence and to produce practice recommendations to guide surgical decision-making (56,75). The panel concluded that colposuspensions (e.g., Burch, Marshall-Marchetti-Krantz [MMK]) and slings were more effective than transvaginal needle suspensions or anterior repairs for long-term success (48 month cure/dry rates). The median probability estimates for cure/dry rates at 48 months and longer were 84% (95% CI, 79%–88%) for colposuspensions and 83% (95% CI, 75%–88%) for sling procedures, compared with 67% (95% CI, 53%–79%) for transvaginal needle suspensions and 61% (95% CI, 47%–72%) for anterior repairs.
Historical Perspective

Anterior vaginal repair (also termed anterior colporrhaphy) was described by Howard Kelly in 1914, and this operation remained the standard first approach to stress incontinence until the middle of the twentieth century (76). Many different operations have been lumped together under the term anterior colporrhaphy, including simple plication of the bladder neck, elevation of the bladder neck by plicating the fascia under the urethra, and elevation and fixation of the bladder neck by passing sutures lateral to the urethra and driving the needles anteriorly into the back of the pubic symphysis for fixation. As noted previously, the problem with most techniques of anterior colporrhaphy is that they do not hold up well over time (77–79). In essence, this operation attempts to take weak support from below and to push it back up from below, with hope that these structures will maintain their strength and position over time. Although there have been excellent long-term results shown with anterior colporrhaphy, most of these cases involve specific techniques requiring skillful dissection of the endopelvic fascia, deep bold bites of suture, and fixation of permanent sutures to the pubic bone from below: in essence, a transvaginal retropubic bladder neck suspension (80,81). Most surgical series that have evaluated techniques of anterior colporrhaphy for stress incontinence show long-term success rates of only 35% to 65%, a figure that most would regard as unacceptably low. Anterior colporrhaphy should be reserved primarily for patients requiring cystocele repair who do not have significant stress incontinence.

Needle suspension procedures are so named because they suspend the urethra and bladder neck through a technique that involves passage of sutures between the vagina and anterior abdominal wall using a specially designed long needle carrier. To perform these operations, a vaginal incision is typically made at the level of the bladder neck, the endopelvic fascia is perforated, the space of Retzius is entered from below, and a permanent suture is passed down through a low abdominal incision through the retropubic space, where it is fixed to the endopelvic fascia at the level of the bladder neck. The long needle is then passed back up through the retropubic space to the abdominal incision, where it is tied in place. The first needle suspensions were performed by a gynecologist, Dr. Armand Pereyra, in the 1950s, but many urologic surgeons have since modified the technique (82–87). These procedures are relatively simple and take less time to perform than open procedures, but this advantage is offset by the fact that they are not as effective in curing stress incontinence. Although initial cure rates are between 70% to 90%, rates decrease significantly over time in many series, with 5-year success rates of 50% or less (88–93). Therefore, these operations are also falling out of favor.

Retropubic Urethropexy (Colposuspension)

The modern era of retropubic surgery for stress incontinence began in 1949, when Marshall, Marchetti, and Krantz described their technique for urethral suspension in a man with post prostatectomy incontinence (94). Since that time, a variety of modifications of this operation have been described, all of which share at least two characteristics: They are performed through an open low abdominal incision or with laparoscopically assisted exposure of the space of Retzius, and they all involve attachment of the periurethral or perivesical endopelvic fascia to some other supporting structure in the anterior pelvis (Fig 23.10). In the MMK operation, the periurethral fascia is attached to the back of the pubic symphysis. Another approach, the Burch colposuspension, involves the attachment of the fascia at the level of the bladder neck to the iliopectineal ligament (Cooper’s ligament) (95,96). With the paravaginal repair, the lateral endopelvic fascia along the urethra and bladder is reattached to the arcus tendineus fascia pelvis (97,98). In the Turner-Warwick vagino-obturators procedure, the endopelvic fascia, vagina, or both are attached to the fascia of the obturator internus muscle (99,100). All of these operations aim to correct anatomic hypermobility of the urethra and bladder neck. The long-term success rate for patients undergoing these operations as primary procedures for stress incontinence is in the range of 70% to 90% (88,101–104).
In 1991, Vancaille introduced the laparoscopic colposuspension to meet the growing demand for a minimally invasive surgical approach to stress urinary incontinence. In a summary of randomized comparisons between laparoscopic and open colposuspensions, the Cochrane Incontinence Group concluded that laparoscopic colposuspension may have short-term benefits, such as quicker recovery, but may have more complications and be more costly because it takes longer to perform than other surgical procedures for stress urinary incontinence. The long-term success of laparoscopic colposuspension is unclear, but there is limited evidence to suggest the results are less favorable than with open colposuspension, although this may reflect a learning effect and is unreliable in isolation (105).

Traditional Pubovaginal Sling operations have traditionally been performed using a combined vaginal and abdominal approach (Fig. 23.11). The anterior vagina is opened, the space of Retzius is dissected on each side of the bladder neck, and a sling is passed around the bladder neck and urethra and then attached to the anterior rectus fascia or some other structure to cradle the urethra in a supporting hammock. This both supports the urethra and allows it to be compressed during periods of increased intra-abdominal pressure (106–116). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues harvested from another species and processed for surgical use (e.g., ox dura mater, porcine dermis). Synthetic materials (e.g., Silastic, Gore-Tex, Marlex) are popular because of their consistent strength and availability, but historically these substances have been plagued by problems with erosion and infection when used around the urethra (75,117,118).

Minimally Invasive Sling In the 1990s, various orthopedic bone anchors were marketed to implant into the pubic bone to suspend the urethra with sutures or slings. Despite a lack of medical evidence to support either the bone anchor or the allograft use, bone anchor systems became the quick and minimally invasive method to suspend allograft slings (119). Although bone anchors have not been shown to be superior to standard fixation techniques, their use has led to increased complications in several series.
In 1996, Falconer et al. described the tension-free vaginal tape (TVT) for correcting stress urinary incontinence (120). In this technique, polypropylene mesh is placed under the midurethra with minimal tension (Fig. 23.12, A and B). To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40 x 1-cm mesh tape covered by a plastic sheath and attached to two 5-mm curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is then passed along the back of the pubic bone, through the rectus fascia, into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the remaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (fewer than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

Since its introduction, there have been scores of articles published suggesting that TVT is generally effective and safe and similar in effectiveness to colposuspension. Larger, multi-center trials provide the most realistic look at outcomes of a surgical procedure performed by many surgeons with varying experience on a wide array of patients. A report of the 2-year follow-up of 344 women with urodynamic stress incontinence enrolled from 14 centers in a multicenter randomized clinical trial compared TVT and open Burch colposuspension. The objective cure rates (defined as a negative 1-hour pad test) ranged from 63% to 85% for the TVT procedure and 51% to 87% for open colposuspension, depending on how missing data were handled, leading the authors to conclude that "TVT may be better, worse, or the same as open colposuspension in the
cure of stress incontinence.” Subjectively, only 43% of women in the TVT group and 37% of women in the open colposuspension group reported cure of their stress leakage. Women undergoing the TVT were more likely to have a cystocele after surgery, whereas those undergoing the Burch colposuspension were more likely to have apical prolapse. Two years after the index procedure, seven women (4.8%) in the Burch colposuspension group underwent surgery for pelvic organ prolapse, compared with no women in the TVT group. There was no difference in the number of women that underwent repeat surgery for stress incontinence (1.8% in the TVT group and 3.4% in the Burch group). Women who underwent TVT were less likely to have voiding disorders requiring intermittent self-catheterization than those who underwent colposuspension (0% vs. 2.7%) (121).

Over the past 5 years, numerous modifications of the TVT have been proposed and marketed. Such devices generally circumvent the stringent regulatory control provided by the U.S. FDA by gaining approval through a Premarket Notification 510(k). This mechanism is a submission to the FDA demonstrating that a new device is substantially equivalent either to a legally marketed or “predicate” device introduced before 1976 in the United States or to one approved by the FDA through the 510(k) process itself. Substantial equivalence means the new device has the same intended use as the “predicate” device and has the same technological characteristics or different technological characteristics, but it is as safe and effective as the “predicate” device. **Surgeons should be aware that most new devices for urinary incontinence are not tested in clinical trials before they are marketed.**

One modification gaining favor is the transobturator tape procedure (also known as a TOT, transobturator suburethral tape, subfascial hammock, and TOMUS—
transobturator midurethral sling). This modification was designed to reduce complications associated with retropubic needle passage. Inserting the trocar through the obturator space theoretically lessens the risk of bladder, bowel, or vascular injury because the procedure involves passing the polypropylene midurethral sling through the obturator membrane along its ischiorectal fossa path, bypassing the pelvic cavity altogether.

Currently, data on this technique are limited. One report showed no bladder perforations in the first 71 transobturator tape procedures performed and, in 68 patients examined 6 to 12 weeks postoperatively, 64 were cured and 2 improved (122). Another report indicated a 90.6% cure rate in 32 patients who were followed for a minimum of 1 year. Five patients had voiding disorders suggestive of bladder outflow obstruction, but only one required self-catheterization for 1 month. No problems with urethral erosion, residual pain, or functional impairment were reported (123). In a multicenter trial, 183 women from seven sites underwent a transobturator tape procedure for stress and mixed urinary incontinence. At one year follow up 80.5% patients were cured. (defined as absence of subjective report of stress urine leakage and negative cough stress test). Perioperative complications included one bladder perforation, two urethral perforations, and one lateral vaginal perforation. Tape erosion necessitating removal occurred in five cases (three vaginal and two urethral). Cystoscopy was not routinely performed (124).

Bulking Agents

Injectable (so-called bulking) agents are less invasive than surgery, and although they are less likely to result in cure than surgery, they relieve symptoms in many women. In the United States, gluteraldehyde cross-linked bovine collagen (Contigen) and carbon beads (Durasphere) are approved for use to treat stress urinary incontinence and can be injected either peri- or transurethrally. Injecting a material around the periurethral tissues facilitates coaptation of the urethra under conditions of increased intra-abdominal pressure (125–130). In a 15-article review, the short-term cure or improvement rate was 75% (131). Contigen can be passed easily through small-bore needles under local anesthesia but requires preoperative skin testing to check for possible allergic reactions (3%). Durasphere is nonantigenic (thus no skin testing is required) and does not migrate. As compared with collagen, Durasphere appears to have similar reduction in leakage episodes and is more likely to require only a single injection (132). This bulking agent does require a larger-gauge needle for injection and is somewhat more difficult to inject than collagen. These techniques may require several injections to achieve continence, and the long-term success of these operations remains poorly studied. It is known, however, that success declines with time, and patients often need additional procedures every 1 to 2 years. New, longer-acting agents are in development and potentially will decrease the interval between injections.

Complications

In choosing surgical management, surgeons must weigh the chance of cure against the chance of severe complications. In the aforementioned randomized trial comparing TVT and Burch, women undergoing TVT were more likely to experience a bladder perforation than those undergoing the Burch procedure (9% versus 2%, respectively) but less likely to have a fever (1% versus 5%) or prolonged catheterization more than 29 days (3% versus 13%) (133). Less common complications require a large sample size to detect differences. In the randomized trial, 2% of women in the TVT group had a retropubic hematoma and 1% a vascular injury, compared with no women in the Burch group. Given the small numbers, it is not clear whether the rate of vascular injuries differs. In a report to the FDA in which worldwide safety data from more than 500,000 procedures were summarized, there were seven deaths reported after TVT, six associated with bowel perforation and one from vascular injury. No such data are available for Burch urethropexy.

In a nationwide analysis of 367 complications associated with 1,455 TVT procedures performed in Finland, there was a 1.9% rate (95% CI, 1.2–2.7) of blood loss over 200 mL, a 1.9% rate (95% CI, 1.2–2.7) of retropubic hematoma, a 0.5% rate (95% CI, 0.2–1.0) of
hematoma outside the retropubic area, a 0.1% rate (95% CI, 0.0–0.4) of injury to the epigastric vessel, a 0.1% rate (95% CI, 0.0–0.4) of injury to the obturator nerve, and a 3.8% rate (95% CI, 2.9–5.0) of bladder perforation (134).

Erosion is unique to surgeries in which a graft is placed, and the rate depends largely on the type of graft used. Rates from one type of material cannot be extrapolated to another. Tension-free vaginal tape is associated with a low rate of graft erosion, compared with a much higher rate of erosion with certain synthetics used for pubovaginal slings in the past. In the randomized trial comparing Burch and TVT described previously, of the 170 women who underwent a TVT procedure, one woman had a graft erosion in the first 6 months, and two others had graft erosion or extrusion between 6 and 24 months postoperatively (121).

The most common adverse events (generally 5%–10% rate for each) after all surgeries for stress urinary incontinence include urinary tract infection, failure to cure, new onset detrusor overactivity, voiding dysfunction, genital prolapse, and bladder perforation. When new onset detrusor overactivity occurs after surgery for incontinence, cystoscopy should be considered to rule out a foreign body in the bladder (Fig. 23.13). Less common events (generally 2%–5% for each) include excessive blood loss, wound infection, pain, nerve injury, or incisional hernia. Events such as sinus tracts and fistulae are rare. Erosion rates depend on the material implanted and, as noted previously, are rare for the newer midurethral slings. In addition, medical events, such as thromboembolic, cardiac, or pulmonary events, are rare.

### Surgical Treatment for Detrusor Overactivity

#### Neuromodulation

Even with the development of newer anticholinergic medications with fewer side effects, there continues to be a select group of patients with overactive bladders who remain refractory to standard medical and behavioral treatment. Surgical treatment of this condition has traditionally involved substantial morbidity and major urinary denervation, reconstruction, or both to achieve therapeutic benefits. The development of implantable sacral nerve root stimulators led to FDA approval of sacral root neuromodulation in patients with refractory urinary urgency and frequency, urge incontinence, and voiding dysfunction. This therapy offers patients with severe symptoms an alternative to urinary augmentation or diversion. Sacral nerve stimulation therapy is performed in two phases. In the first phase, a percutaneous nerve evaluation test is performed to determine which patients respond to this type of therapy. Those who respond are then implanted with a permanent electrode lead adjacent to the third sacral nerve root connected to a pulse generator.

A multicenter prospective study demonstrated that 63% of test patients responded to the initial procedure. After implantation, 47% of patients became completely dry, and 77% were successful in eliminating “heavy” leakage episodes. Despite substantial success in nearly 80% of patients who received implants, 30% of patients required further surgical revision because of pain or other complications at the generator or implant site. No permanent injuries or nerve damage was reported in the initial trials (135,136).

In a group of 96 patients with implants (who responded favorably during the test stimulation period), reductions in urge incontinence episodes and severity were still seen at an average of 31 months after implantation. The device was removed in 11 of the 96 patients because of lack of efficacy, pain, or bowel dysfunction. There were no permanent injuries (137). The technique for this procedure has evolved over the last several years to include the location of a generation implant site on the back and the performance of the procedure in two stages with initial percutaneous implantation of a quadpolar instead of a unipolar stimulator. These modifications may improve success rates and decrease the morbidity associated with these procedures.
CHAPTER 23  Lower Urinary Tract Disorders

Botox Injections  
Botulinum toxin A (BtxA), a neurotoxin produced by the anaerobic bacteria *Clostridium botulinum*, acts on peripheral cholinergic nerve endings to inhibit calcium-mediated release of acetylcholine vesicles at the presynaptic neuromuscular junctions. Researchers describing the use of BtxA for detrusor overactivity in spinal cord injury patients reported that 17 of 19 were completely dry 6 weeks after treatment (138). In a report from a multi-center study, a 73% continence rate occurred in 180 patients with neurogenic detrusor overactivity incontinence who underwent cystoscopic Botox injections (139). The procedure is done via cystoscopy and involves injecting 15 to 30 different detrusor muscle sites under direct visualization, sparing the bladder trigone and ureteral orifices. The off-label use of Botox A cystoscopic detrusor injections to treat refractory detrusor overactivity (in women with and without neurologic impairment) is gaining popularity. Clinical trials assessing effectiveness and side effects are ongoing.

Augmentation Cystoplasty and Urinary Diversion  
Surgery to replace the function of a diseased bladder has been done for more than a century and, over the past several decades, gained some popularity in treating people with intractable detrusor overactivity not responsive to any other form of management. These surgical options include (i) conduit diversion (creation of various intestinal conduits to the skin) or continent diversion (which includes a rectal reservoir or continent cutaneous diversion), (ii) bladder reconstruction, or (iii) replacement of the bladder with various intestinal segments. These techniques, both historical and current, are beyond the scope of this chapter; the interested reader is referred to a review by Greenwell et al. (140). In a Cochrane review, the reviewers found only two randomized trials that were of sufficient quality to include and concluded that there were no major differences in outcomes between the techniques and that higher quality research was needed (141). With the advent of sacral neuromodulation, these procedures are done much less often to treat women with detrusor overactivity.

Figure 23.13 Cystoscopic view of encrusted suture penetrating bladder wall following sling urethropexy.
Surgical Treatment of Fistulae

A wide variety of techniques are available for fistula repair (142,143). Traditionally, fistula repair has been performed after a waiting period to allow the resolution of inflammation and formation of scar tissue. This is particularly important in the case of obstetric fistulas, in which the extent of the vascular injury to the soft tissues of the pelvis may not be apparent for many weeks. However, there has been a recent trend toward early closure of small gynecologic fistulas (144). The keys to closure of a vesicovaginal fistula include wide mobilization of tissue planes so that the fistula edges can be approximated without any tension, close approximation of tissue edges, closure of the fistula in several layers, and meticulous attention to postoperative bladder drainage for 10 to 14 days. The closure of large fistulas will be enhanced by the use of tissue grafts (e.g., Martius labial fat-pad grafts, gracilis muscle flaps) that provide an additional blood supply to nourish an area that has sustained vascular injury. The Latzko procedure used to close a vesicovaginal fistula is shown in Figure 23.14.

Cystoscopy

Scientific evidence does not support routine cystoscopy in women with stress urinary incontinence in the absence of other pathologies (145). Cystoscopy cannot be used to predict intrinsic sphincteric deficiency, stress incontinence, or detrusor overactivity. Cystoscopy can be considered in the following circumstances: (i) in women with urge incontinence to rule out other disorders, especially in women with microscopic hematuria, (ii) in the evaluation of vesicovaginal fistulae, and (iii) intraoperatively to evaluate possible ureteral or vesical injury.

Urologists often use flexible cystoscopy in men; however, women tolerate a rigid cystoscope well, given their short urethras and absence of prostate glands. The view afforded by a rigid cystoscope is clearer than that obtained with a flexible scope, and less technical skill is required to view the entire bladder using a rigid scope. **Cystoscopes are available with several viewing angles:** 0° (straight), 30° (forward-oblique), 70° (lateral), and 120° (retroview). The last scope is rarely used in women. Zero-degree lenses are essential for viewing the urethra, whereas a 30° lens provides the best view of the bladder base and posterior wall, and the 70° lens generally provides the best view of the anterior and lateral walls. For diagnostic cystoscopy, sterile water is an ideal medium because it is readily available and inexpensive.

To evaluate the urethra, the cystoscope should be advanced with distention medium flowing, keeping the center of the urethral lumen in the center of the visual field. The mucosa is normally pink and smooth and the urethral folds close.

To examine the bladder, the cystoscope should be inserted into the bladder with both the light cord and the camera cord oriented toward the floor. When using a 70° lens, this will show the bladder dome, which is easily identified by an air bubble anteriorly. The remainder of the bladder is then systematically examined by making a series of sweeps, slowly rotating the cystoscope between the dome and urethrovessical junction. To view the trigone, the light cord should be oriented toward the ceiling (keeping the camera cord toward the floor). The scope is pulled back until it is almost in the urethra, and the base of the bladder is then viewed. Because the trigone is a zone of metaplasia, it generally looks different from the rest of the urothelium (Fig. 23.15).

Vaginal and abdominal hysterectomies are associated with a 0.02% to 0.85% incidence of ureteral injury (146). However, the injury rate increases in reconstructive pelvic surgeries, reaching as high as 11% after uterosacral ligament suspension (147). In a study of 46 women that underwent proximal uterosacral ligament vaginal vault suspension, three of the five women with cystoscopic evidence of obstruction were treated
Figure 23.14 Repair of apical vesicovaginal fistula. A: The fistula at the vaginal apex is exposed with adequate retraction. A pediatric Foley. B: The vaginal epithelium is dissected from the fistula to mobilize the tissue to allow for tension-free closure. In the classic Latzko procedure, the vaginal epithelium 2 cm around the opening of the fistula is removed. C: The fistula tract may either be completely excised, or in the Latzko procedure, the fistula edge may freshened up slightly but is not excised. D: Interrupted absorbable sutures are placed in an extramucosal location in an interrupted fashion. An additional layer of interrupted sutures is often placed to invert the initial suture line. The vaginal epithelium is then closed over the repair. In the classic Latzko procedure, the initial layer involves closure of the vagina over the fistula tract, then two additional layers with the vaginal epithelium result in an apical colpocleisis. Redrawn from original by Jasmine Tan.
by simply removing and replacing the sutures. This finding emphasizes the importance of confirming ureteral integrity at surgery.

Administering indigo carmine dye intravenously 5 minutes before cystoscopy aides in the assessment of ureteral patency. Quick efflux of stained urine should be seen bilaterally. Sluggish efflux should prompt further investigation. However, pre-existing ureteral obstruction may also be responsible for lack of flow. In 157 women who underwent complex urogynecologic procedures, 5 (3.2%) cases of unsuspected ureteral obstruction were identified with intraoperative cystoscopy (148). One was due to ureteral ligation, and the remaining four represented chronic ureteral obstruction resulting from pelvic organ prolapse (two cases), ureteropelvic junction obstruction (one case), and ureterovesical junction stenosis after prior transurethral resection of bladder cancer (one case).

Voiding Dysfunction and Bladder Pain Syndromes

Voiding Dysfunction

Women are afflicted less commonly than men with voiding difficulties, but these disorders do occur in women and can be defined as emptying dysfunction resulting from relaxation of the pelvic floor musculature or failure of the detrusor muscle to contract appropriately. True outflow obstruction (defined as a detrusor pressure of more than 50 cm H2O in association with a urine flow rate of less than 15 mL/sec) is rare in women and, when seen, is usually found in those who have undergone obstructive bladder neck surgery for stress incontinence (149,150). For normal voiding to occur, the pelvic floor and urethral sphincter must relax, which should occur in conjunction with a coordinated contraction of the detrusor muscle that leads to complete bladder emptying. The bladder may also be emptied by other mechanisms, such as by abdominal straining in the absence of a detrusor contraction, or simply by relaxation of the pelvic floor. Complete bladder emptying is not the same as normal voiding. Some women may empty their bladders
completely but only by expending great effort over several minutes. In such cases, voiding is clearly abnormal, even though the bladder is empty when voiding ceases. In the worst cases, voiding is both difficult and incomplete.

**Causes**

Neurologic diseases, such as multiple sclerosis, may cause voiding difficulty as a result of *detrusor-sphincter dyssynergia* (151,152), in which the urethral sphincter contracts at the same time as the detrusor. Great effort is required to overcome urethral resistance; the patient voids with an interrupted stop-and-start stream and usually has a significant amount of residual urine.

Other causes of voiding difficulty include medications (such as antihistamines and anticholinergic agents), infections (in particular, herpes simplex virus and urinary tract infections), obstruction (following bladder neck surgery, or in women with advanced pelvic organ prolapse), overdistension, severe constipation (particularly in elderly), and, rarely, psychogenic factors. Fowler’s syndrome refers to unexplained urinary retention occurring as an isolated phenomenon (153). Generally such women are between 20 and 35 years of age. Commonly the first retention episode will be triggered by an event such as surgery or childbirth. Retention rarely resolves but is not associated with the development of other disorders.

**Evaluation**

Evaluation of a woman with voiding difficulty begins with a careful physical examination. Advanced pelvic organ prolapse may contribute to urinary retention, but it is unlikely that prolapse above the level of the vaginal introitus will be the sole cause of retention. When in doubt, the woman can wear a pessary for a week to see whether elevating the prolapse reduces the voiding difficulty. Occasionally pelvic masses—in particular, low anterior myomas—may cause urinary retention. Abnormal findings detected during neurologic examination of the perineum and lower extremities may suggest the need to focus on the spine. Urodynamics evaluation will help determine whether the woman has an obstruction (manifested by high detrusor pressures during voiding or by no urethral relaxation during voiding) or whether the detrusor muscle is not contracting. The latter is not necessarily indicative of a neurogenic disorder in women, as a large minority of normal healthy women void by urethral and pelvic floor muscle relaxation alone, with no detrusor contraction. Cystourethroscopy may reveal an obstructing lesion, such as a polyp, tumor, ureterocele, or ball-valve stone. Usually, the evaluation reveals no obvious source, and treatment can commence.

**Treatment**

The mainstay in the treatment of voiding difficulty is clean, intermittent self-catheterization (154). The most important protection against urinary tract infection is frequent and complete bladder emptying rather than avoiding the introduction of a foreign body into the bladder. Self-catheterization allows the patient to accomplish this task using a small (14-Fr.) plastic catheter that she inserts through the urethra into the bladder, draining its contents. The catheter is then removed, washed with soap and water, dried, and stored in a clean, dry place. Elaborate sterile procedures are not necessary. Bacteria are introduced into the bladder in this process, and the urine of women after self-catheterization regimens will always be colonized with bacteria; however, this condition should not be treated unless symptomatic infection occurs.

In addition to decreasing urinary urgency and incontinence caused by detrusor overactivity, neuromodulation of the sacral nerve roots also may help women with nonobstructive urinary retention (136). In a trial of 177 patients with idiopathic urinary retention, those who had greater than 50% improvement in baseline voiding symptoms during a test stimulation period qualified for surgical implantation of InterStim. Of these, 37 were randomly assigned to early implantation, whereas 31 in the control group delayed implantation for
6 months. Improved voiding occurred in 83% of the implant group compared with 9% of the control group at 6 months (155). Although this technology requires a major surgical procedure, many women favor this therapy over lifelong self-catheterization.

Mild sedatives are sometimes helpful in this process, as are α-blockers (e.g., prazosin, phenoxybenzamine), which reduce urethral tone. For patients who are unable to generate a detrusor contraction, attempts have been made to enhance detrusor contractility using a cholinergic agonist such as bethanechol chloride. Although cholinergic medications are successful in making strips of bladder muscle contract in a laboratory, there is little evidence that such drugs are helpful clinically (156).

Bladder Pain Syndromes

Most patients with disorders of bladder sensation experience pain rather than lack of bladder sensation. As with the treatment of most chronic pain disorders, the cause of most painful bladder conditions is unknown, and the therapies currently used are only partially successful. As a result, disorders of bladder sensation are among the most frustrating urogynecologic conditions to manage.

Terminology and Prevalence

Painful bladder syndrome, often termed interstitial cystitis, is a poorly defined heterogeneous syndrome, and diagnostic criteria are changing continuously. The latest International Continence Society standardization report recommends adapting the term painful bladder syndrome, rather than interstitial cystitis and defines painful bladder syndrome as the “suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and nighttime frequency, in the absence of proven urinary infection or other obvious pathology” (7). Urgency and pain are the defining characteristics of painful bladder syndrome (157). Several factors have inhibited advances in the understanding of interstitial cystitis, including the lack of specific diagnostic criteria, the lack of specific histopathologic changes, the unpredictable fluctuation in symptoms, and the marked variability among patients in terms of symptoms, objective findings, and treatment responses (158).

The National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK) developed a research definition for interstitial cystitis that requires objective findings of glomerulations or a classic Hunner’s ulcer during hydrodistention of the bladder and subjective symptoms of bladder pain or urinary urgency in the absence of other urogenital pathology (159). Strict application of NIDDK criteria in one study would have misdiagnosed more than 60% of patients thought to definitely or possibly have interstitial cystitis (160). Many clinicians have challenged the clinical utility of the NIDDK research criteria, and most conceptualize interstitial cystitis as the end point on the spectrum of painful bladder disorders (162).

The prevalence of painful bladder syndrome varies widely depending on the diagnostic criteria utilized. When mild and moderately severe cases are considered, the syndrome is not rare (162). Estimates of prevalence in the United States range from 52 per 100,000 women in the population-based Nurses Health Study to as high as 1 in 4.5 women “with accurate diagnostic records” (163,164). The prevalence appears to be 6 to 15 times more common among women than men (163,165). The identification of risk factors for painful bladder syndrome is particularly challenging because of the typically long delay in diagnosis (163). The recently completed Interstitial Cystitis Database study confirms many of the previous epidemiologic observations: Affected individuals are predominately female (92%), white (91%), and report an average age of symptom onset of 32.2 years (158,163).

Diagnosis

A careful history should be obtained, along with a sterile urine specimen for analysis and culture. Many women treated repetitively for chronic cystitis have taken multiple courses
of antibiotics on the basis of symptoms without ever having the presence of an infection confirmed by cultures. Detrusor overactivity may be the cause of frequency, urgency, and urge incontinence but is not usually a factor in dysuria or painful urination. Women older than 50 years (particularly those who smoke or are exposed to chemicals at work) are at risk for bladder cancer, and this possibility must be considered, especially if hematuria is present. Urinary cytologic assessment is sometimes helpful in detecting early tumors of the urinary tract, and cystoscopy and intravenous urography are mandatory in the evaluation of patients with hematuria.

Other possible causes for painful voiding must be considered in the differential diagnosis, including urethral diverticula; vulvar disease; endometriosis; chemical irritation from soaps, bubble bath, or feminine hygiene products; urinary stones; urogenital atrophy from estrogen deprivation; and sexually transmitted disease.

The diagnosis of interstitial cystitis is largely one of exclusion. The ideal diagnostic test for interstitial cystitis has not been determined, and there are myriad proposed tests.

### Treatment

Typically, the evaluation of painful bladder syndrome results in no definitive diagnosis, and management focuses on the treatment of symptoms.

Frequency–urgency syndromes should be managed with a careful voiding regimen (similar to that used in the treatment of detrusor overactivity) and local care.

The use of urinary tract analgesics such as Urised may be helpful in reducing urethral irritation. Urised is a polypharmaceutical agent containing a mixture of methenamine, methylene blue, phenyl salicylate, benzoic acid, atropine sulfate, and hyoscyamine that has a soothing effect on many irritative urethral symptoms.

There is no scientific evidence linking diet to painful bladder syndrome, but many doctors and patients find that alcohol, tomatoes, spices, chocolate, caffeinated and citrus beverages, and high-acid foods may contribute to bladder irritation and inflammation. Some patients also note that their symptoms worsen after eating or drinking products containing artificial sweeteners. Patients may try eliminating various items from their diet and reintroducing them one at a time to determine which, if any, affect their symptoms. Instruction in the basics of vulvar and perineal hygiene is important (thorough drying; avoidance of most body powders, perfumes, or colored irritating soaps; avoidance of tight-fitting undergarments) to avoid other factors that may contribute to painful voiding.

Hydrodistention of the bladder (usually under anesthesia) has been recommended as a treatment option and can result in clinical improvement in some patients. Some patients benefit from the instillation of 50 mL of a 50% solution of dimethylsulfoxide (DMSO) for 20 to 30 minutes every other week for four or five sessions.

Pentosan polysulfate (Elmiron) is an FDA-approved oral agent with heparinlike activity that attempts to replace the glycosaminoglycan sulfate layer that is believed deficient in these patients. In clinical trials, the drug improved symptoms in 38% of patients treated. The FDA-recommended oral dosage of Elmiron is 100 mg, three times a day. Patients may not feel relief from pain for the first 2 to 4 months, and it may take up to 6 months for a decrease in urinary frequency to occur.

Because it has been theorized that bladder pain may result from increased histamine release, some patients benefit from medications that block these inflammatory mediators, such as diphenhydramine hydrochloride, 25 to 50 mg orally three times per day, in combination with 300 mg of cimetidine three times per day. Tricyclic antidepressants help some women by modulating sensory nerve pain.
Transcutaneous electrical nerve stimulation (TENS), through wires placed on the lower back or just above the symphysis, may help some women, though the mechanism of action is unclear. Ongoing preliminary research suggests that some women with severe bladder pain syndrome may find relief following sacral neuromodulation (InterStim) or acupuncture.

In 1998, NIDDK initiated the Interstitial Cystitis Clinical Trials Group, a multicenter group charged with developing and testing new treatment strategies for patients with this disorder. It is hoped that research such as this will ease the great suffering by women with painful bladder syndrome and improve their quality of life.

CHAPTER 23  Lower Urinary Tract Disorders

SECTION VI  Urogynecology and Pelvic Reconstructive Surgery

With the aging of the population, pelvic organ prolapse is an increasingly common condition seen in women.

Causes of pelvic organ prolapse are multifactorial and result in weakening of the pelvic support connective tissue and muscles as well as nerve damage.

Patients may be asymptomatic or have significant symptoms such as those relating to the lower urinary tract, pelvic pain, defecatory problems, fecal incontinence, back pain, and dyspareunia.

Physical examination includes thoughtful attention to all parts of the vagina, including the anterior, apical, and posterior compartments, levator muscle, and anal sphincter complex.

Nonsurgical treatment options include pelvic floor muscle training and the use of intravaginal devices.

Surgical treatment involves an individualized, multicompartmental approach consistent with the patient’s previous treatment attempts, activity level, and health status.

Studies are needed to determine the characteristics of those patients who would benefit long-term from vaginal versus abdominal approaches to the surgical repair of pelvic organ prolapse.

Pelvic organ prolapse (POP) is a bulge or protrusion of pelvic organs and their associated vaginal segments into or through the vagina (1). It is a common and costly affliction of older women (2,3). It has been estimated that over the next 30 years, the demand for treatment of POP will increase 45%, commensurate with an increase in the population of women older than 50 years of age (4,5). As this problem grows in significance, it becomes increasingly important to work toward an understanding of the pathophysiology and risk factors associated with pelvic organ prolapse to try to prevent its occurrence. Furthermore, continued efforts are needed to understand factors that result in long-lasting, robust repair of pelvic organ prolapse for those patients undergoing surgical management.
Despite extensive anecdotal experience, the optimal surgical approach to apical and other compartment prolapse remains elusive (6).

In the United States, 11% of women up to the age of 80 years have surgery for pelvic organ prolapse or urinary incontinence, and nearly one third of procedures are repeat surgery (3). Data from the Women’s Health Initiative revealed anterior pelvic organ prolapse in 34.3%, posterior wall prolapse in 18.6%, and uterine prolapse in 14.3% of women in the study (7). In this study, a significant risk factor associated with prolapse was vaginal delivery. After adjusting for age, ethnicity, and body mass index, women with at least one vaginal delivery were twice as likely as nulliparous women to have pelvic organ prolapse. Causes of pelvic support disorders are most likely multifactorial, however; factors other than vaginal delivery also are associated with the development of these disorders. One study found that the incidence of prolapse doubled with each decade of life between the ages of 20 and 59 years (8). In another study, each year of increasing age was associated with a 12% increase in the risk of developing prolapse (9). Other associated risk factors for the development of POP include history of hysterectomy (8), obesity (7,10,11), history of previous prolapse operations, and race (11).

Pathophysiology

Pelvic organ prolapse results from attenuation of the supportive structures, whether by actual tears or “breaks” or by neuromuscular dysfunction or both. Support of the vaginal canal is provided by the enveloping endopelvic connective tissue and its condensations at the vaginal apex, which form the cardinal uterosacral ligament complex. The endopelvic connective tissue is the first line of support buttressed intimately with the pelvic diaphragm, composed of the levator ani and coccygeus muscles. These muscles provide a supportive diaphragm through which the urethra, vagina, and rectum egress (Fig. 24.1). The muscular support provides basal tonicity and support of the pelvic structures; when contracted as in the setting of increased abdominal pressure, the rectum, vagina and urethra are pulled anteriorly toward the pubis.

Definitions

The more common pelvic support disorders include rectoceles and cystoceles (Fig. 24.2), enteroceles (Fig. 24.3), and uterine prolapse (Fig. 24.4), reflecting displacement of the rectum, small bowel, bladder, and uterus, respectively, resulting from failure of the endopelvic connective tissue, levator ani muscular support, or both.

A rectocele is a protrusion of the rectum into the vaginal lumen resulting from weakness in the muscular wall of the rectum and the paravaginal musculoconnective tissue, which holds the rectum in place posteriorly.

An enterocele is a herniation of the peritoneum and small bowel and is the only true hernia among the pelvic support disorders. Most enteroceles occur downward between the uterosacral ligaments and the rectovaginal space, but they may also occur primarily apically, especially in the setting of a previous hysterectomy.

A cystocele is a herniation of the urinary bladder through the anterior vaginal wall. Cystoceles usually occur when the pubocervical musculoconnective tissue weakens midline or detaches from its lateral or superior connecting points.

Uterine prolapse is generally the result of poor cardinal or uterosacral ligament apical support, which allows downward protrusion of the cervix and uterus toward the introitus.
**CHAPTER 24 Pelvic Organ Prolapse**

**Procidentia**, which involves prolapse of the uterus and vagina, and **total vaginal vault prolapse**, which can occur after hysterectomy, represent eversion of the entire vagina (Fig. 24.5).

These descriptive terms are somewhat inaccurate and misleading, focusing on the bladder, rectum, small bowel, or uterus rather than the specific defects responsible for the alterations in vaginal support. Specific defect support issues will be discussed in the setting of the surgical management section.

**Evaluation**

Although as many as 50% of women older than age 50 have some degree of pelvic organ prolapse (12), fewer than 20% seek treatment (13). This may be due to a number of reasons, including lack of symptoms, embarrassment, or misperceptions.
Figure 24.2  A: Saggital section of the pelvis showing normal anatomy.  B: Cystocele and rectocele.
Figure 24.3  A: Posterior enterocele without eversion.  B: Enterocele with eversion.
SECTION VI  Urogynecology and Pelvic Reconstructive Surgery

Symptoms

Pelvic organ prolapse often is accompanied by symptoms of voiding dysfunction, including urinary incontinence, obstructive voiding symptoms, urinary urgency and frequency, and, at the extreme, urinary retention and upper renal compromise with resultant pain or anuria. Other symptoms often associated with POP include pelvic pain, defecatory problems (e.g., constipation, diarrhea, tenesmus, fecal incontinence), back and flank pain, overall pelvic discomfort, and dyspareunia. Patients seeking care for prolapse may have one or several of these symptoms involving the lower pelvic floor. **Choice of treatment usually depends on severity of the symptoms and the degree of prolapse consistent with the patient’s general health and level of activity.**

Data relating pelvic floor symptoms to the extent and location of prolapse are weak (14–16). Any symptoms associated with physical findings of lower stage prolapse require careful evaluation, especially if surgery is being considered. A recent retrospective study of 330 patients reported that women with more advanced prolapse were less likely to have symptoms of stress incontinence and more likely to use manual reduction of the prolapse to void. Therefore, careful consideration of lower urinary tract symptoms about available treatment options. Although pelvic organ prolapse is not life threatening, it can impose a significant burden of social and physical restrictions of activities, impact on psychological well-being, and overall quality of life.

**Figure 24.4** Uterine prolapse with apical detachment from the uterosacral ligament complex and lateral wall detachment from the endopelvic connective tissue.
CHAPTER 24 Pelvic Organ Prolapse

is important. Prolapse severity was not associated with bowel or sexual problems in this study (17).

Physical Examination

In evaluating patients with pelvic organ prolapse, it is particularly useful to divide the pelvis into compartments, each of which may exhibit specific defects. The use of a Graves speculum or Baden retractor can help to evaluate the apical compartment of the vagina. The anterior and posterior compartments are best examined with the use of a univalve or Sims’ speculum. The speculum is placed posteriorly to retract the posterior wall downward when examining the anterior compartment and placed anteriorly to retract the anterior wall upward when examining the posterior compartment. A rectovaginal examination may be useful in evaluating the posterior compartment to distinguish a posterior vaginal wall defect from a dissecting apical enterocele or a combination of both.

If an anterior lateral detachment defect is suspected, an open ring forceps (or a Baden retractor) may be placed in the vagina at a 45-degree angle posteriorly cephalad to hold the lateral fornices adjacent to the pelvic sidewall.

During the evaluation of each compartment, the patient is encouraged to perform Valsalva so the full extent of the prolapse can be ascertained. If the findings determined with Valsalva are inconsistent with the patient’s description of her symptoms, it may be helpful to perform a standing straining examination with the bladder empty (18).

Pelvic Organ Prolapse Quantitation System

Many systems for staging prolapse have been described. Typically it is graded on a scale of 0 to 3 or 0 to 4, with the grade increasing with the severity of prolapse (19,20). Currently the system approved by the International Continence Society is the Pelvic Organ Prolapse Quantification system, or POP-Q (21). This standardized quantification system facilitates communication between physicians in practice and research and enables progression of these conditions to be followed accurately. In this system, anatomic descriptions of
specific sites in the vagina are used in place of traditional terms. The system identifies nine locations in the vagina and vulva in centimeters relative to the hymen, which are used to assign a stage (from 0 to IV) of prolapse at its most advanced site (Fig. 24.6). Although probably more detailed than necessary for general practice, clinicians should be familiar with the POP-Q system because most published studies use it to describe research results. Its two most important advantages over previous grading systems are (i) it allows the use of a standardized technique with quantitative measurements at straining relative to a constant reference point (i.e., the hymen), and (ii) its ability to assess prolapse at multiple vaginal sites.

The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the POP-Q examination include the genital hiatus, perineal body, and the total vaginal length.

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position. All measurements except the total vaginal length are measured during maximal straining.

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa
CHAPTER 24 Pelvic Organ Prolapse

represents a point on the anterior vagina 3 cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is –3 to +3. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient’s support defect. For example, point Ba is –3 in the absence of any prolapse (it is never less than –3) to a positive value equal to the total vaginal length in a patient with total eversion of the vagina.

The middle compartment consists of points C and D. Point C represents the most dependant edge of the cervix or vaginal cuff after hysterectomy. Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the attachment of the uterosacral ligament to the posterior cervix. It is intended to differentiate suspensory failure from cervical elongation.

The posterior compartment is measured similarly to the anterior compartment: the corresponding terms are Ap and Bp. The nine measurements can be recorded as a simple line of numbers (i.e., –3, –3, –8, –10, –3, –3, 11, 4, 3 for points Aa, Ba, C, D, Ap, Bp, total vagina length, genital hiatus, and perineal body). The six vaginal sites have possible ranges that depend on the total vaginal length (Table 24.1). After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse (Table 24.2). The POP-Q examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist

in instructing those unfamiliar with this staging system. The POP-Q examination provides a standardized measurement system to allow for more accurate assessments of postoperative outcome and to ensure uniform, reliable, and site-specific descriptions of pelvic organ prolapse. A videotape describing the system and showing its use in several patients is available from the American Urogynecology Society.

In a clinical setting, at least three measurements should be obtained: the most advanced extent of the prolapse in centimeters relative to the hymen that affects the anterior vagina, the posterior vagina, and the cervix or vaginal apex.

As noted previously, whether the older staging systems or the POP-Q system is used, it is important to document the most pertinent findings on examination. This will help in documenting the baseline extent of prolapse and the results of treatment.

Pelvic Muscle Function Assessment

Pelvic muscle function should be assessed during the pelvic examination. Following bimanual examination with the patient in lithotomy position, the examiner can palpate the puborectalis muscle inside the hymen along the pelvic sidewalls at approximately the 4 and 8 o’clock positions. One can appreciate basal muscle tone and whether there is increased tone with contraction as well as strength, duration, and symmetry of contraction (22). A rectovaginal examination should also be performed to assess basal and contraction muscle tone of the anal sphincter complex.

As a part of the pelvic organ prolapse examination, urethral mobility often is measured. Many women with prolapse will have urethral hypermobility (defined as a resting urethral angle greater than 30 degrees or a maximal strain angle greater than 30 degrees). The presence of urethral mobility in combination with symptoms of stress incontinence may help determine whether an incontinence procedure should be performed. During pelvic examination, the urethra is typically swabbed with Betadine, and lidocaine jelly is placed in the urethra or on a cotton tip swab. The swab is placed in the urethra at the urethrovesical junction and with the use of a goniometer (Fig. 24.7), and the baseline urethral angle from the horizontal and maximal strain angles are measured.

Figure 24.7 Goniometer, which is used to measure baseline urethral angle and maximal strain angle of the urethra with a Q-tip in place.
Bladder Evaluation

Patients with prolapse exhibit the full range of lower urinary tract symptoms. Despite the fact that some patients may not have significant symptoms, it is important to obtain objective information about bladder and urethral function. With severe POP, the urethral kinking effect of the prolapse may mask a potential urine leakage problem; therefore, basic office bladder testing with prolapse reduction should be performed to mimic bladder and urethral function if the prolapse were treated. At a minimum, the following assessments should be performed: a clean catch or catheterized urine sample to test for infection, a postvoid residual (PVR) volume, and assessment of bladder sensation, which can be performed as a part of office cystometrics. Although there is no consensus on what constitutes an abnormal PVR volume, provided the patient has voided 150 mL or more, a PVR less than or equal to 100 mL is acceptable. Reduction stress testing at the time of simple office cystometrics can be performed with the use of a pessary, large cotton swab, ring forceps, or the posterior blade of a speculum. Care should be taken that the urethra not be overly straightened (with a resultant false-positive test result) or obstructed (with a resultant false-negative test result), or that tension is not placed on the puborectalis muscles by excessive posterior retraction. These risks can be minimized by orienting the vaginal apex toward the sacrum.

Imaging

Diagnostic imaging of the pelvis in women with pelvic organ prolapse is not routinely performed. However, if clinically indicated, tests that may be performed include fluoroscopic evaluation of bladder function, ultrasound of the pelvis, and defecography for patients in whom intussusception or rectal mucosal prolapse are suspected. Magnetic resonance imaging is increasingly being used for the evaluation of pelvic pathology such as mullerian anomalies and pelvic pain, however, generalized use in women with prolapse is not currently clinically indicated and is used primarily for research purposes.

Treatment

Nonsurgical Therapy

Nonsurgical therapy of pelvic organ prolapse includes conservative behavioral management and the use of mechanical devices. A nonsurgical treatment approach usually is considered in women with mild to moderate prolapse, those who desire preservation of future childbearing, those in whom surgery may not be an option, or those who do not desire surgical intervention.

Conservative Management

Conservative management approaches include alteration of lifestyle or physical intervention such as pelvic floor muscle training (PFMT). These approaches are used mainly in cases of mild to moderate prolapse; however, their true role in managing prolapse and associated symptoms is unclear (23,24). The goals of a conservative therapy approach to the treatment of prolapse are as follows (25):

- Prevent worsening prolapse
- Decrease the severity of symptoms
- Increase the strength, endurance, and support of the pelvic floor musculature
- Avoid or delay surgical intervention

Lifestyle intervention includes such activities as weight loss and reduction of those activities that increase intra-abdominal pressure. This interaction is typically anecdotal in practice. No case series, prospective studies, or randomized control trials exist that have examined the effectiveness of this approach to the treatment of prolapse.
Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms (26,27); however, a lower response rate has been noted when prolapse extends beyond the vaginal introitus (28).

The efficacy of biofeedback therapy in the treatment of impaired defecation associated with a rectocele has been determined (29). Thirty-two female patients, median age 52 years (range, 34–77 years), experiencing impaired rectal evacuation with a rectocele greater than 2 cm at proctography underwent a structured behavioral retraining. Immediate and medium-term follow-up results were reported (median 10 months; range 2–30 months). Fifty-six percent of patients (n = 14) felt a little and 16% (n = 4) felt major improvement in symptoms, including 3 (12%) with complete symptom relief. Immediately after biofeedback there was a modest reduction in need to strain (72; 50%), feeling of incomplete evacuation (78; 59%), and need to assist defecation digitally (84; 63%) that was maintained at follow-up. Bowel movement frequency was significantly normalized at follow-up (p = 0.02). These investigators concluded that behavioral retraining, including biofeedback therapy, may be an effective primary therapy for some patients with a rectocele associated with impaired defecation.

Mechanical Devices

The use of mechanical devices such as pessaries is usually considered in women who for medical reasons cannot undergo surgery, desire to avoid surgery, or have a significant degree of prolapse that makes other nonsurgical approaches unfeasible. Some practitioners extend indications to include pregnancy-related prolapse as well as prolapse and incontinence in elderly women. Reports have shown that age older than 65 years, the presence of severe medical comorbidity (30), and sexual activity (31) were associated with successful pessary user. Unsuccessful use or a desire for surgery has been associated with a shortened vaginal length (<6 cm), a wide vaginal introitus (32), sexual activity, stress incontinence, stage III–IV posterior compartment prolapse, and desire for surgery at a first office visit. Few literature-based reviews and reports recommend pessaries as first-line treatment for women with POP, and there is little consensus regarding choice of pessary and management of pessary usage (33). Most of the information on pessary use is derived primarily from descriptive and retrospective studies, relatively small prospective series, manufacturer’s recommendations, and anecdotal experience.

Pessaries provide pelvic organ support within the vaginal vault. Two categories of pessaries—support and space filling—exist for prolapse (33). The ring pessary (with diaphragm) is a commonly used support pessary, and the Gelhorn pessary is a commonly used space-filling pessary. The ring and other support pessaries are recommended for stage I and II prolapse, whereas the space-filling pessaries are used for stage III and IV prolapse (34). It is unclear whether pessaries with regular use can prevent the progression of POP. A prospective cohort study addressed this issue in a series of 56 women who were fit with a pessary, of which 33.9% (n = 19) continued use for at least 1 year (35). Baseline and follow-up pelvic examinations were performed using the POP-Q system (21). The women removed the pessary 48 hours before one visit, but there was no information to ascertain adherence to pessary use. No woman had worsening of the prolapse, and four women (21.1%, 95% CI 0.2, 43.7%) had an improvement. Improvement overall was noted in women with anterior compartment prolapse.

There are no randomized controlled trials of pessary use in women with POP (36). Likewise, there are no consensus guidelines on the care of pessaries (i.e., intervals between changes), the role of local estrogens, or the type of pessary indicated for specific types of POP (36). Manufacturers recommendations and different pessary types can be seen in Figure 24.8. Effective and satisfactory outcomes have been reported for stage II or greater prolapse using the Gelhorn and ring diaphragm pessary (30). After 2 to 6 months, 77% to 92% of women with a successful pessary fitting were satisfied and, using intention-to-treat analysis, 44% to 67% of all women who were treated initially with a pessary for prolapse...
were satisfied. There are few other series describing pessary use for prolapse with greater than 4 weeks follow-up (37–41).

Possible complications associated with pessary use include vaginal discharge and odor. Failure to retain the pessary may occur or, conversely, the pessary may be too large, which could lead to excoriation or irritation. With reduction of vaginal prolapse, de novo or increased stress incontinence may occur (42), and in rare instances, more severe complications, including vesicovaginal fistula, small bowel entrapment, hydronephrosis, and urosepsis, have been described (43,44).

Placement and Management

Pessary placement involves consideration of a number of issues, primarily the patient’s desire and motivation to use this type of device. Typically, if she has had previous surgery or strongly desires to avoid surgery, she may be motivated enough for a primary attempt at pessary placement. Other issues include current sexual function status, type and duration of exercise in which the patient engages, and the status of the vaginal walls and cervix.
In hypoestrogenic women, treatment of the vagina with estrogen and maintenance of intravaginal estrogen treatment is recommended.

**Fitting a Pessary**

The patient should be examined in the lithotomy position after emptying her bladder. The clinician should use a dry glove to better grasp the pessary and water-soluble lubricants as needed. The size of the pessary is estimated after a digital examination and use of ring forceps to reduce the prolapse or bladder neck. Once the approximate size is determined, the appropriate type is selected based on the patient’s needs and activity level. When fitted, the patient is asked to stand, perform Valsalva, and cough to ensure the pessary is retained. The pessary should be assessed to ensure it is providing the desired support and leakage control. The patient should be able to void with the pessary in place before leaving the office. Proper size is assured by the ability to sweep the index finger between the pessary and the vaginal wall. The patient should feel comfortable with the pessary in place.

Insertion of the pessary is eased by using a water-soluble lubricant for insertion, folding or collapsing the pessary to reduce its size, and when it is inside the vagina, pushing it high to an area behind the symphysis pubis and inserting the device more posteriorly to avoid the urethra. Instructing the patient how to insert and remove the pessary may be done with the patient in a standing or supine position, depending on her dexterity.

**Ring pessaries**, with or without support, are the most commonly used type. They are the easiest to fold, insert, and remove. **Gellhorn and cube pessaries** are typically more difficult to insert and remove by the patient. They are held in place by significant space occupation and suction and offer strong support. The suction of the cube pessary needs to be broken, facilitating removal. Cube pessaries should be removed daily; Gelhorns can stay in longer (up to 6–8 weeks). **Donut pessaries**, which are very popular, are considered a space-fitting pessary for large vaginal vault prolapse, complete procidentia with decreased perineal support, and good introital integrity. The patient should be questioned about a latex allergy and instructed to remove and clean the device every 2 to 3 days. Continen ce pessaries, rings, and dishes with support typically also are easy to fold, insert, and remove.

**Follow-Up Recommendations**

After the initial fitting, the patient should return in 1 to 2 weeks and then at 4 to 6 weeks, depending on her independence with the pessary, her proficiency in placement and removal, and her cognitive and motor abilities. After this initial follow-up, continued follow-up should continue at 6- to 12-month intervals at the discretion of the provider and depending on the patient’s ability to insert and remove the pessary effectively. If the patient needs to return to the provider for removal and cleaning of the pessary, 4- 12-week intervals are more appropriate.

On follow-up visits, proper placement of the pessary and support of the prolapse as well as continence efficacy should be assured. Because pessaries are fit by a process of trial and error, it is not uncommon to change the size or type at least once after the initial fitting. The pessary’s integrity should be checked, and the tissue for evaluated for irritation, pressure sores, ulceration, and lubrication.

**Surgical Management**

The primary aims of surgery are to relieve symptoms, which may be caused by prolapse, and, in most cases, to restore vaginal anatomy so that sexual function may be maintained or improved without significant adverse effects or complications. Occasionally, when sexual function is not desired, obliterative or constrictive surgery is more appropriate and also may relieve symptoms. There is no steadfast rule as to when
surgery is indicated. Many patients with more advanced prolapse have few or no symptoms, whereas some with lesser degrees of prolapse have what they term severe symptoms. This is confounded by the observation that many of the “symptoms” may not be specifically related to the anatomic defect or may be worsened by anxiety. In general, surgery should be offered to patients who have tried conservative therapy and were not satisfied with the results or who do not desire conservative therapy. The prolapse should be symptomatic or should be greater than or equal to stage II with apparent progression. All patients should be given the alternative of trying conservative treatments when applicable.

**Approaches to surgery include vaginal, abdominal, and laparoscopic routes, or a combination of approaches.** Depending on the extent and location of prolapse, surgery may involve a combination of repairs directed to the anterior vagina, vaginal apex, posterior vagina, and perineum. Concomitant surgery may be planned for urinary or fecal incontinence. The surgical route is chosen based on the type and severity of prolapse, the surgeon’s training and experience, the patient’s preference, and the expected or desired surgical outcome.

**Procedures for prolapse can be broadly categorized into three groups:** (i) restorative, which use the patient’s endogenous support structures; (ii) compensatory, which attempt to replace deficient support with permanent graft material; and (iii) obliterator, which close or partially close the vagina.

These groupings are somewhat arbitrary and not entirely exclusive. For example, grafts may be used to reinforce repairs such as colporrhaphy, or to replace support that is deficient or lacking. Graft use in sacrocolpopexy substitutes for the connective tissues attachments (cardinal and uterosacral ligaments) that would normally support the vaginal apex. In addition to the primary goal of relieving symptoms related to prolapse, urinary, defecatory, and sexual function must be considered in choosing the appropriate procedures. The following section includes a review of (i) the anatomy of pelvic support structures, (ii) the defects related to these structures, and (iii) some of the most commonly used surgical procedures to correct these defects.

---

**Basic Anatomy of Support Structures**

**Pelvic support structures include:**

1. The muscles and connective tissue of the pelvic floor
2. The fibromuscular tissue of the vaginal wall
3. The endopelvic connective tissue

**The endopelvic connective tissue includes:**

1. The cardinal/uterosacral complex, which attaches the upper vagina and cervix posteriorly
2. Lateral connective tissue attachments of the anterior vaginal wall to the arcus tendineus pelvis and of the posterior vaginal wall to the fascia of the levator ani and to the posterior arcus tendineus near the ischial spine
3. Less dense areolar connective tissue surrounding retroperineal portion of the pelvic organs

The orientation of these structures is noted in Figure 24.1. In general, an intact pelvic floor, including a functional puborectalis muscle and an intact cardinal/uterosacral complex, should prevent pelvic organ prolapse by allowing posterior deflection of the rectum and
SECTION VI  Urogynecology and Pelvic Reconstructive Surgery

The anterior vaginal compartment includes the anterior vaginal wall, its attachments, the urethra, and the bladder. The support structure for the bladder is the rhomboid-shaped anterior vaginal wall (specifically its fibromuscular layer), which is attached laterally to the arcus tendineus fascia (Fig. 24.10). Inferiorly, the fibromuscular layer blends in with the connective tissue, which spans the two bands of puborectalis and pubococcygeus muscles and the pubic rami. The urethra appears to be preferentially supported by these connective tissues as well as by the pubourethral ligaments, which have debatable function. In the apical area, the vaginal fibromuscular layer blends in with the precervical fascia and the connective tissue of the cardinal ligament complex. In the upright position, the rhomboid-shaped anterior vaginal wall is oriented approximately posteriorly, with compression of these structures against the pelvic floor in the upright position (Fig. 24.9). The fibromuscular layer of the vaginal wall and the other endopelvic connective tissue attachments augment the support structure and are particularly important when pelvic floor function is compromised.

Whether to repair all defects is controversial. Restorative repairs may be less successful than compensatory repairs in patients with generally “poor tissue,” and at times one defect repair may exert more tension on the repair of another defect. Management should be based on the patient’s presentation, expectations, the specific anatomical defects noted (preoperatively and, at times, intraoperatively), and on the presence or absence of lower urinary and bowel dysfunction.

The Anterior Compartmen

Figure 24.9  Vaginograms from the same patient at rest (A) and during Valsalva maneuver (B). Illustrates posterior vaginal deflection maintained by apical cardinal/uterosacral posterior suspension and the anterior sling effect of the puborectalis muscle and more distal perineal structures. (From Nichols DH, Randall CL. Vaginal surgery. 4th ed. Baltimore, MD: Williams & Wilkins, 1996:4–5.)
Defects of this support structure may include tears or attenuation of the vaginal fibromuscular wall, or detachment from the pelvic sidewalls, the cervix or cardinal ligament complex, or from the pubis. Specific sites of fibromuscular tears are frequently difficult to recognize.

Physical examination may reveal the following findings:

1. The presence of a central ballooning-type defect
2. Descent of the area of the vaginal wall below the bladder neck
3. Descent of the cervix or apical vaginal area
4. The presence or absence of sulci extending lateroanteriorly, which would indicate that lateral detachment to the arcus is maintained or lost.

Anterior Vaginal Colporrhaphy

Anatomic correction of an anterior defect or cystocele will generally relieve symptoms of protrusion and pressure, and usually will improve micturition function when abnormal micturition is associated temporally with the defect and if there is no associated neuropathy. If a single, well-defined midline defect is recognized, excision of the weak vaginal wall and an imbricating closure of the defect may be performed. Most central
SECTION VI Urogynecology and Pelvic Reconstructive Surgery

Anterior defects require a more extensive dissection of the vesicovaginal space. Following this dissection, many surgeons then separate the vaginal mucosa and submucosal layers from the fibromuscular layer out to a point lateral to the defect, followed by midline plication of this tissue, then excision of excess epithelium, and closure. It appears of great importance to maintain the continuum of repaired fibromuscular tissue to a well-supported vaginal apex. A high central defect may also be corrected via a transabdominal approach by dissecting between the base of the bladder and the upper one third of the anterior vaginal wall. The defective tissue may then be wedged out and the defect closed with running or interrupted sutures. This approach may be of use when performing transabdominal procedures for apical suspension.

If the patient has significant stress incontinence (based on report or the presence of occult or potential incontinence), an appropriate bladder neck suspension may be performed simultaneously with the anterior repair (see Chapter 23). When performing midurethral sling procedures, it may be preferable not to extend the repair procedure below the urethra, but instead to make a separate incision for the sling. Maintaining some degree of the urethrovaginal angle may improve the results of any incontinence procedure. If the patient has voiding dysfunction (reports of incomplete emptying and a high residual urine) and stress incontinence, appropriate urodynamic evaluation should be performed before a procedure is selected, and the patient should be made aware of the potential for continued problems after surgery.

Recurrence rates of traditional “fibromuscular plication” anterior repairs vary from 3% to 92% (47–56); however, studies define recurrence in numerous ways, from minimal prolapse to stage III descent. The clinical significance of recurrent mild cystoceles (stage I) that are asymptomatic is debatable because many of these defects do not progress to larger ones. When traditional anterior repairs are performed in patients with POP-Q stage II or greater cystoceles (frequently concurrently with other procedures), a 20% recurrence rate of stage II or greater prolapse is not uncommon, although overall recurrence rates as low as 3% have been reported (50). Many studies do not define how the subjects were evaluated postoperatively and vary with respect to patient populations, type of and severity of defects, presence of concurrent defects, surgical technique, and follow-up time and length. Some studies have suggested higher recurrence rates when these repairs are performed concurrently with sacrospinous suspensions and hypothesize that this type of apical suspension may predispose the repair anterior wall to greater pressure transmission (51,57,58). These studies may show higher failure rates because patients having such concurrent repairs may be more likely to have more complicated forms of prolapse or more extensive pelvic floor defects than other patients.

The addition of adjunctive graft materials empirically should improve success rates. Two randomized trials (55,56) suggest modest improvement in success, with an additional 12% to 18% to the “cure” rates after 1 year when polyglactin mesh (Vicryl) was placed over the midline plication compared with standard repair. However, most surgeons have abandoned this type of mesh because of subsequent failures. Other graft materials appear to have more promise. Fascial autologous grafts, allografts, xenografts, and newer synthetics are presently used by many surgeons with variable short-term success. Thus far, there are little data on adverse effects and success rates after 3 years. These materials have been used in several ways in the anterior compartment, including placement of smaller grafts to bolster suture lines and larger grafts to provide complete substitution of the entire anterior support plate from the pubis to the arcus to the vaginal apex (59–64).

Paravaginal Repair

The paravaginal or “lateral defect” repair involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, in some cases, muscle at the level of the arcus tendineus pelvis (“white line”) (65,66). It is usually performed as
CHAPTER 24  Pelvic Organ Prolapse

a bilateral procedure via transvaginal or retropubic (abdominal or laparoscopic) access. The procedure essentially restores normal anatomy; however, as it is not practical to rebuild the defective endopelvic–fascial bridge to the pelvic sidewall, it attaches the vaginal wall itself. Observational studies have reported good success with this procedure (80%–95%) (67–72); however, long-term data on durability and function are lacking. Most women with anteriolateral detachments usually have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine (Fig. 24.11) (73). Thus, it is important to resuspend those specific areas.

It is difficult to achieve optimal results when the paravaginal repair is used in combination with traditional central repairs because of the creation of tension on opposing suture lines. A repair that removes a weakened central vaginal wall may decrease the side-to-side dimensions of the anterior vaginal wall, making it difficult to suspend its lateral points more laterally. When large central defects coexist with lateral defects, one option is an extensive central repair accompanied by a good apical support procedure. This changes the shape of the vagina to a more cylindrical structure. Another choice is placement of a graft.

Figure 24.11  Schematics illustrating normal attachments of the anterior fibromuscular vaginal plane (A and C) and bilateral detachments of that plane from the arcus tendineus up to the level of the ischial spines (B and D). Note: For B and D to occur, there will either be concurrent apical descent or a detachment of the upper fibromuscular plane from the apical structures. (From Delancey JO. Fascial and muscular abnormalities in women with urethral hypermobility and anterior vaginal wall prolapse. Am J Obstet Gynecol 2002;187(1):93–98.)
to span the entire anterior rhomboid-shaped plate, thus augmenting anterior paravaginal tissue strength. The graft with tension adjusted may be anchored to the arcus tendineus along with the adjacent vaginal wall from the level of the pubic rami to the ischial spine.

Although most reports indicate that repair of anterior defects with all of these procedures relieves symptoms directly related to prolapse, there are very little data on patient satisfaction and quality-of-life improvement over time.

The support of the rectum and posterior vagina includes the pelvic floor musculature and connective tissue posteriorly and Denonvillier’s (pararectal) fascia, which is the fibromuscular layer of the posterior vaginal wall and its lateral attachments to the lateral pelvic floor (levator) musculature and its fascia (Fig. 24.12). This lateral attachment site, the fascia levator ani, fuses with the arcus tendineus fascia pelvis at the mid- to upper level of the vagina and continues to the level of the ischial spine. Less dense, areolar, connective tissue surrounds the rectum and vagina and may supply some support to these structures as well.

Three levels of vaginal attachment have been described (74):

- **Level 1** includes the upper vagina, which has cardinal/uterosacral attachments.
- **Level 2** is the midvagina and its attachments laterally.
- **Level 3** is the vagina between the puborectalis muscle, bulbocavernous muscle, and perineal membrane.

The fibromuscular layer at the upper vagina fuses with the paracervical fascia and the fan-shaped cardinal ligament structure. The integrity of the attachment of this posterior vaginal layer to the anterior rectal wall just below the rectal sigmoid junction

**Figure 24.12** Sagittal oblique view of the distal midvagina illustrating lateral connection of the posterior musculoconnective tissue wall to the fascia levator ani and anterior wall to the arcus tendineus pelvis. The attachment sites fuse together at a point closer to the ischial spine where the vagina assumes a more oval shape. (Modified by J. Taylor from illustration by Lianne Krueger Sullivan. From Cundiff GW, Fenner D. Evaluation and treatment of women with rectocele: focus on associated defecatory and sexual dysfunction. Obstet Gynecol 2004;104:1403–1421, erratum in Obstet Gynecol 2005;105:222.)
Prevents enterocele formation. In the distal vagina, the fibromuscular layer fuses laterally with the fascia of the puborectalis and then the bulbocavernous muscle and centrally with the perineal connective tissue. Thus, normal posterior support includes a plate of connective tissue that is attached laterally as noted, posteriorly toward sacral segments 2–4, and inferiorly to the perineum. This fibromuscular plane not only holds the rectum in place posteriorly, but also aids in preventing perineal descent by suspending the perineum to the sacrum. The constant resting tone of the pelvic floor muscles, particularly the puborectalis, serve to close the genital hiatus pulling the distal vagina and anorectal junction toward the pubic symphysis, creating an anorectal angle and a posterior deflection of the rectum, vagina, and bladder base.

It has been hypothesized, based on careful cadaveric dissections, that most rectoceles were due to discrete tears in the Denonvillier’s fascia at its lateral, apical, and perineal attachments and centrally within the fascia itself (75). Perineal detachment, along with a defect in the perineal membrane, has been described as a perineal rectocele, which is most commonly associated with reports of difficulty with defeation. Apical attachment defects are generally associated with enteroceles and occasionally sigmoidoceles.

Once a decision is made to perform surgical repair of the posterior compartment based on symptoms, type, and location of defects, an appropriate approach should be determined and the patient should be made aware of the expected outcomes and potential adverse effects such as pain and sexual dysfunction. If the patient has defecatory dysfunction with a rectocele and symptoms of constipation, pain with defeation, fecal or flatal incontinence, or any signs of levator spasm or anal sphincter spasm, appropriate evaluation and conservative management of concurrent problems should be initiated before repair of the rectocele. Specific types of repairs include the traditional posterior colporrhaphy, the defect-directed repair, replacement of fascia with graft materials, transanal repairs, and abdominal approaches by laparotomy or laparoscopy.

**Traditional Posterior Colporrhaphy**

The first description of the posterior colporrhaphy involved plication of the pubococcygeus muscles across the anterior rectum as well as perineal body reconstruction (76). The technique has subsequently been modified in attempts to preserve sexual function. Typically a midline incision is extended from the perineal body to the vaginal apex or to the cephalad border of a small or distal rectocele. The Denonvillier’s fascia is mobilized from the vaginal epithelium, leaving as much of this tissue as possible attached laterally to the levator fascia. After obvious defects in the rectal muscularis are repaired, the fascia is then plicated in the midline with interrupted or continuous sutures. The authors prefer delayed absorbable for this plication. Permanent nonbraided suture material also can be used. Braided permanent suture material is associated with a greater incidence of stitch infection and formation of granulation tissue (77). The vaginal epithelium is trimmed and closed with absorbable sutures.

When a defective perineal body or perineal membrane is present, reconstruction is performed after accompanying posterior colporrhaphy. The superficial muscles of the perineum and bulbocavernoous fascia are plicated in the midline and the skin closed as in an episiotomy repair. Detachments of the inferior portion of the Denonvillier’s fascia from the perineal body are also corrected. The puborectalis muscles are plicated concurrently with these procedures by some surgeons, but this approach is associated with a high incidence of sexual dysfunction and thus is not recommended routinely. It may be worth consideration in patients who have severe prolapse accompanied by a large genital hiatus with palpable levator weakness or who are unable to contract their pelvic floor muscles. Sutures should be placed carefully through the puborectalis muscles at least 3 cm or greater posterior to their insertion on the pubic rami, thereby decreasing the tension of the plication. For those women with an enlarged hiatus and weakened puborectalis muscles
who desire sexual function, an attempt can be made to plicate the muscles far enough posteriorly to allow two fingers to easily pass through the vaginal introitus and to reconstruct the distal posterior vagina and perineum, whereby there will not be a ledge at the site of the puborectalis plication. Outcome data on such procedures are inadequate to make conclusions regarding its efficacy; however, it is reasonable to postulate that pelvic floor defects producing an enlarged genital hiatus are common reasons for failure of support procedures and that puborectalis plication may decrease the incidence of such failures.

A complete review of rectocele, anorectal functional disorders, and various repairs can be found elsewhere (78). Reported anatomic cure rates for traditional posterior colporrhaphy have ranged from 76% to 90% with variable follow-up intervals (79–83). Most studies show a benefit in ease of defecation if patients are using splinting preoperatively; however, overall defecatory dysfunction (defined as constipation) was not relieved in most of the subjects and increased (approximately 30%) after the procedure in one study (81). These repairs appear to have little to no benefit in the treatment of fecal incontinence. It is not surprising that the repairs are not particularly effective for defecatory dysfunction related to disorders of constipation or for fecal incontinence because these problems have multifactorial causes. De novo dyspareunia is reported to occur in 8% to 26% of sexually active patients who have traditional posterior colporrhaphy (79–82,84) and is not always associated with levator plication procedures (85). Potential causes for dyspareunia, other than vaginal strictures or introital tightness, include scarring with immobility of the vaginal wall, levator spasm, and neuralgia associated with sutures or dissection. Dyspareunia also may occur when a Burch procedure or other procedures that displace the vaginal canal anteriorly are combined with a posterior repair (82). Careful surgical technique and appropriate choice of procedure should decrease the incidence of postoperative dyspareunia.

Defect Specific Posterior Repair

Defect or site-specific posterior repairs are restorative procedures by which posterior defects are corrected. These repairs begin with midline posterior vaginal incision through the epithelium, then continue with separation of the epithelium from the fibromuscular wall. After irrigation to provide better exposure, a finger is inserted in the rectum to help define defects of the rectal wall and the fibromuscular layer that has been dissected from the vaginal wall submucosa. The specific defects are closed with either interrupted or running sutures (preferably the delayed absorbable type). Defect closure is accomplished in such a way to minimize tension on the surrounding tissue and may involve vertical, horizontal, or oblique approximation. When fibromuscular tissue has separated from the perineum, the upper anterior rectum, or a well-supported cervix or vaginal cuff, it is important to reapproximate these connections. Repairs of coexistent perineal and apical support defects are important. The object of the surgery is to re-establish an intact plane of connective tissue that positions the rectum against the pelvic floor and obliterates any potential space between a well-supported cervix or vaginal cuff and the cephalad edge of the tissue plane and upper rectum. The technique should minimize tension and potential strictures, which may be more likely to occur with traditional posterior colporrhaphy.

Initial case series reveal anatomical cure rates with mean follow-up times less than 18 months from 82% to 100% (85–89) and de novo dyspareunia rates of 2% to 7% (85), which are much lower than those seen with traditional repairs. Symptom relief appears to be as good or better than that seen with traditional repairs. The greatest concern with these and other procedures has been durability. A recent report (83) indicates that the recurrence rate of rectocele beyond the midvaginal plane was higher with defect-specific posterior repairs than with side-to-side plication procedures using laterally attached fascia pulled to the midline (33% versus 14%) and beyond the hymenal ring (11% versus 4%). The study was not randomized; however, the procedures were performed during the same period with
consistent follow-up evaluations 1 year after surgery. Symptoms (dyspareunia, constipation, and fecal incontinence) after surgery did not differ between the two groups. Long-term follow-up of previously reported case series that had good short-term success or prospective randomized trials looking at modifications of traditional repairs versus defect-specific repairs should clearly delineate durability of these procedures.

As with anterior compartment procedures, graft materials have been used to improve the success of posterior compartment repairs. The use of a dermal allograft to augment defect-directed repairs has been described (90). The graft is sutured to the levator fascia on both sides of the defect to cover the rectovaginal plane. One concern about this technique is that, in patients with relatively thin vaginal walls, removal of the fibromuscular tissue may devascularize the mucosa and make it more subject to erosion over the graft material. The following technique may allow better healing of the vaginal epithelium anterior to the graft: **Vaginal estrogen is administered for 4 to 8 weeks preoperatively to improve the quality of vaginal mucosa in women with vaginal atrophy.** The initial surgical dissection is deep to the fibromuscular layer. Access to the lateral levator fascia is generally easily accomplished with a division of the Denonvillier’s fascia at its incorporation into the posterior vaginal wall or, if the lateral attachment is not present, with combined sharp and blunt dissection to expose the paralevator fascia. This levator fascia on each side, as well as any remaining lateral Denonvillier’s fascia and occasionally muscle, is incorporated into the edge of the graft with sutures. The cephalad edge of the graft is attached posteriorly to the anterior rectum at its sigmoid junction and anteriorly to a well-suspended vaginal cuff. The caudad edge is incorporated in an appropriate repair of the perineal area. With short-term, mean follow-up of 12 to 30 months, overall results reveal good anatomic cure rates of 89% to 100% with cadaveric dermis (90), autologous dermis (91), polyglactin mesh (56), and polypropylene mesh (92–94). Improvement in obstipation has also been reported. Although the numbers of subjects assessed have been relatively low, de novo dyspareunia rates have been between 0 and 7%, which are less than those reported for traditional posterior repairs (78).

**Abdominal Approach to Posterior Repair**

When abdominal sacrocolpopexy is planned for apical vaginal prolapse and concomitant rectocele is present, some have advocated extending the posterior graft down the posterior vaginal wall to correct the defect. The technique of sacral colpoperineopexy is used to replace the normal vaginal suspensory ligaments and to augment or replace the posterior fibromuscular plane with graft material that runs from the sacrum to the perineal body (95). Its purpose is to correct the posterior compartment defects and to suspend the perineal body, thus preventing descent and opening of the genital hiatus. It has been performed transabdominally or as a combined abdominal and vaginal procedure (95,96) with both Mersilene mesh and dermal allografts. Mesh erosion occurred frequently when the vagina was open: 16% for vaginal placed sutures and 40% for transvaginally placed mesh (96). The use of dermal allografts results in an anatomical cure rate of 82% with short-term follow-up and a mean of 12 months following surgery (95,96). Significant improvements also were seen in bowel symptoms. One author (97) reported results on 205 of 236 subjects who underwent an abdominal sacral colpoperineopexy with polypropylene mesh (Marlex) without opening the vagina. This procedure included two straps of mesh attached from the lateral anterior vagina to Cooper’s ligament. Ten-year satisfaction rates were 68%, and erosion rates were 5%.

**Laparoscopic Approach to Posterior Repair**

Laparoscopic rectocele repair involves the dissection of the rectovaginal space to the perineal body with either plication of levator fascia or suturing absorbable or permanent mesh in place (98,99). A few small case series have been reported with variable results.
Transanal Posterior Repair

The aim of transanal rectocele repair, usually performed by colorectal surgeons rather than gynecologists, is to remove or plicate redundant rectal mucosa, to decrease the size of the rectal vault, and to plicate the rectal muscularis. The rectovaginal adventitia and septum are plicated as well, probably along with the posterior vaginal muscularis. The vaginal epithelium is not incised or excised with this procedure, which probably accounts for the reported lack of adverse affects on sexual function in contrast to the vaginal approach to posterior repair. Two randomized trials (100,101) and several case series (102–104) from transanal repairs with mean follow-up intervals of 12 to 52 months report anatomic cure rates of 70% to 98%, improved constipation and fecal incontinence, and less need for vaginal digitation to expel stool. Complications included infections and rectovaginal fistulas, which are surprisingly rare in the reported series. From the gynecologic perspective, transanal posterior repair is an option only when the procedure is performed for defecatory dysfunction and not for prolapse of the posterior vaginal wall. The question remains whether the transanal approach with defect excision and repair improves defecatory dysfunction better than a defect-specific transperineal or transvaginal approach with imbrication of tissues to correct palpable weakness in the rectal wall and its adjacent connective tissues.

The Apical Compartment

Normal apical support includes the integrity of the cardinal/uterosacral ligaments, the upper paravaginal fibromuscular connective tissue, and, when the uterus is present, the paracervical fascia. The fibromuscular tissue of the upper vagina blends in with the paracervical fascia. Both of these are attached laterally and posterior laterally to the cardinal ligaments and uterosacral ligaments (see Fig. 24.1). The vaginal fibromuscular tissue is also attached to the upper anterior rectum at its sigmoid junction and forms the inferior border of the cul-de-sac of Douglas. The cardinal and uterosacral ligaments are condensations of areolar connective tissue. Their origin is at the lateral borders of sacral vertebra 2–4, and they travel retroperitoneally to their insertion at the upper vagina and cervix (Fig. 24.1). They serve as the anterior and lateral borders of the cul-de-sac and cross at or just anterior to the ischial spines. The ureter is closest to the uterosacral ligament at or just posterior to its insertion on the posterior lateral cervix. If anterior cephalad traction is placed on the ureter or cervix, frequently the cardinal uterosacral ligaments will stand out as ridges lateral to the cul-de-sac; however, peritoneal folds may have similar appearance. Therefore, placement of sutures in such structures based on visual appearance alone does not always guarantee inclusion of the ligament.

Defects in apical support include:

1. The loss of cardinal/uterosacral support with resultant cervical/uterine or vaginal cuff descent
2. The detachment of the fibromuscular vagina from the anterior rectum with resultant enterocele or, at times, sigmoidocele into the rectovaginal space
3. Tears or attenuation of the upper fibromuscular tissue, usually after hysterectomy, leading to a central apical descent that frequently presents as a ballooning defect

Often, these defects occur concurrently. Defects in cardinal/uterosacral attachment are at sites close to their insertion where breaks or tears occur; in subjects with apical descent, condensations of cardinal/uterosacral tissue can be found adjacent to the peritoneum just cephalad to the ischial spines (105).

Examination for apical defects is at times difficult. Such defects may easily be missed when large anterior or posterior defects are present. In cases when apical defects are
suspected but not confirmed, surgeons should evaluate the apical support intraoperatively
and plan for management of these defects when they are found. Traction on the cervix with
a tenaculum or on the vaginal cuff both centrally and laterally with Allis clamps may reveal
otherwise unrecognized defects.

Repairs of apical defects may be performed transvaginally or transabdominally, with
laparotomy or laparoscopy. **Transvaginal repairs include extraperitoneal procedures**
**such as sacrospinosus suspensions, iliococcygeal suspensions, and high paravaginal
suspensions** of the apical vaginal fornices to the arcus tendineus at the level of the ischial
spine or to the endopelvic fascia, and intraperitoneal suspensions such as uterosacral
suspensions and McCall culdoplasties (106). It is generally agreed that the vaginal apex
should be resuspended in a posterior cephalad direction to a site or sites posterior and
caudad to the sacral promontory. Anterior apical suspensions change the direction of the
vaginal axis and may be fraught with a greater incidence of posterior compartment defects,
including rectoceles, enteroceles, and sigmoidoceles.

The general principles of the repair should include management of the specific apical
defects:

1. If present, the attenuated part of the upper vaginal wall (fibromuscular defect)
should be repaired or covered by graft material.

2. The vaginal cuff or, in some instances, the cervix should be suspended without
excessive tension.

3. Any defect in the attachment of the upper vagina to the rectum at or below its
sigmoid junction should be corrected.

**Enterocoele repairs may include:**

1. Removal of the peritoneal sac with closure of the peritoneal defect, followed by
closure of the fascial or fibromuscular defect or both below it

2. Dissection and reduction of the peritoneal sac and closure of the defect

3. Obliteration of the peritoneal sac from within with transabdominal Halban or
Moschowitz type procedures or transvaginal McCall or Halban procedures (107).

Historically, the treatment for symptomatic uterine prolapse has been hysterectomy,
which is performed vaginally or abdominally in combination with an apical suspension
procedure, and repair of coexisting defects. Apical support procedures that have been
described for use when the uterus or cervix is to be kept in place include Manchester
and Gilliam procedures and fixation of the cervix to the sacrospinosus ligament (108).
The other procedures described in this section may also be used in women who desire uterine
conservation. Adequate outcome data on such uterine sparing procedures are not yet avail-
able. When the cervix is absent, in addition to repair of fibromuscular defects, both fibro-
muscular planes anterior and posterior to the vaginal cuff should be attached to whatever
suspension is employed.

**Sacrospinosus Ligament Fixation**

The fixation of the vaginal apex to the sacrospinosus ligament, the tendineus component of the
coccygeus muscle, was first described in 1958 (109) and subsequently was modified in
Europe and the United States (110–112). **Access is traditionally extraperitoneal via the**
rectovaginal space with penetration of the pararectal (Denonvillier’s fascia) at the level of
the ischial spine to expose the muscle and ligament. Variations to this approach to the
SECTION VI Urogynecology and Pelvic Reconstructive Surgery

ligament include approaches through an anterior lateral approach, an apical approach posterior to the uterosacral ligament, and a laparoscopic approach (113–115). Bilateral sacrospinous ligament suspensions (116,117) have also been advocated; however, these techniques may impose a greater degree of tension on the sutures and, at times, create a band of apical vagina across the rectum at the level of the suspension. Whether this can cause defecatory dysfunction is debatable. The advantages of the sacrospinous fixation procedure include (i) its transvaginal extraperitoneal approach, (ii) resultant posterior vaginal deflection, and (iii) the fact that it is a relatively durable repair if performed correctly. Reported success for apical support has been good—approximately 97%—with follow-up times ranging from 1 month to 11 years (106). However, there have been subsequent reports of high rates of anterior vaginal prolapse (51,57,58). It is not clear whether this observation is related to the procedure and its exaggerated posterior vaginal deflection or to other inherent factors for anterior prolapse in those women who underwent the procedures. Other disadvantages of the procedure include (i) relative difficulty in adequately exposing the ligament, (ii) an unnatural lateral vaginal deflection toward the fixation site, (iii) an inability to perform without excessive tension when the vaginal length is compromised, as may be the case in repeat procedures, (iv) potential risk for sciatic nerve or pudendal nerve or vessel injury, and (v) occasional need to shorten or narrow the upper vagina when a fibromuscular defect involves much of the apical area. Some of these problems are not unique to this procedure.

Iliococcygeal Vaginal Suspension

Iliococcygeal vaginal suspension involves the attachment, usually bilaterally, of the vaginal apex to the iliococcygeus muscle and fascia (117–119). Extraperitoneal access is achieved via the posterior vagina. Compared with other vaginal suspension procedures, the iliococcygeal suspension has the fewest case series in the literature (118–120); however, cure rates appear comparable to the sacrospinous suspension technique (106). The dissection of the area to the ischial spine is approached from a midline posterior vaginal wall incision using the ischial spine as a landmark for identifying the sacrospinous ligament and the iliococcygeal fascia anteriorly and caudad to it. A no. 1 polydioxanone suture is placed through the fascia and attached to the vaginal apex as a pulley stitch. This procedure is more easily performed bilaterally than the sacrospinous suspension and should be considered particularly in the presence of a shortened vagina. Risk of major vessel, nerve, or ureteral injury should be relatively low compared with other transvaginal suspensions.

Uterosacral Ligament Suspension

Surgical variations of the uterosacral ligament suspension originally described in 1938 (121) have been used prophylactically during hysterectomy or therapeutically for vaginal apical suspension. A therapeutic procedure in which the vaginal apex is suspended to the uterosacral ligaments above the level of the ischial spines had excellent success rates in an observational study of 302 subjects (122). Once access to the posterior cul-de-sac has been attained, the uterosacral ligament remnant can usually be found adjacent to the pelvic sidewall peritoneum just cephalad to the palpable ischial spine. Up to three sutures were placed in each ligament and incorporated into the anterior and posterior fibromuscular layer of the vagina. Some surgeons approximate the ligaments in the midline to close the cul-de-sac with the intention to treat or prevent enterocele formation (123). Other surgeons suspend the right and left vaginal apex to the ipsilateral uterosacral ligament, leaving the cul-de-sac open to avoid impinging on the rectum and adversely affecting bowel function.

Outcome studies have shown that recurrent apical prolapse occurs in 2% to 5% of cases within the first few years following the procedure, which is a rate comparable or superior to other transvaginal apical repairs (122,124), and the incidence of recurrent anterior defects may be less than that reported with sacrospinous suspensions. The most common serious complication has been ureteral obstruction secondary to ureteral kinking or incorporation of an ureter in a suspension stitch. This has been shown to occur
in as many as 11% of cases (124). Intraoperative cystoscopy—with documentation of ureteral patency after administration of indigo carmine dye, whereby such a problem can be corrected—is recommended.

**Multiple sutures may increase the incidence of tissue devascularization and necrosis, thus resulting in failure of the suspension.** Exposure can be accomplished through the vaginal cuff after hysterectomy, a transverse incision at the vaginal cuff in cases of vaginal vault prolapse or descent, and, rarely, through a posterior colpotomy when uterine or cervical conservation is desired. When the apical vaginal wall is attenuated, it is excised. The pelvic side wall, lateral to the sigmoid colon, is exposed using Breisky-Navratil retractors and a pack to hold the small bowel cephalad and to place the sigmoid colon and side wall peritoneum on stretch (Fig. 24.13A). After palpation of the ischial spine, single permanent sutures of 0 or 1 polypropylene are placed through the peritoneum and adjacent ligament approximately 1 cm cephalad to and at the same posterior level as the ischial spines. Traction on the sutures and palpation of the site should reveal good purchase of the ligamentous structures. The sutures are tagged for use after repair of defects of the anterior compartment. The peritoneum is dissected off the vaginal fibromuscular wall posterior to the vaginal cuff. The suspension sutures are then secured with large bites into the posterior vaginal fibromuscular tissue and anterior fibromuscular tissue, then locked in place to

**Figure 24.13** Diagrams illustrating open vaginal apical area with (A) exposure of site for suture placement or lateral pelvic side wall and (B) suture placement through ligament then through the posterior and anterior paravaginal tissue where they are locked to enable pulley action to the ligaments when tied. (Redrawn from an image by J. Taylor.)
approximate anterior to posterior connective tissue and to fix the suture to the vaginal apex so that it may be moved up to the ligament (Fig. 24.13B). If a rectovaginal enterocele is present, it is dissected, reduced, and closed, approximating the prerectal fascia or anterior rectal wall to the posterior fibromuscular vaginal tissue just caudad to the suspension sutures. Absorbable cuff closure sutures are placed at each cuff angle and 1 to 2 bites are taken to approximate anterior to posterior vaginal cuff over the suspension suture sites. When indicated, plication of the central cuff anterior to the posterior fibromuscular tissue with a box stitch is also performed. These sutures are secured after the suspension (pulley) sutures are tied, then cuff closure is completed from each side with the absorbable sutures in a running fashion. Cystoscopy is performed to document ureteral patency. Ureteral compromise has been noted in only 2 of 150 cases performed. The procedure provides adequate support of POP-Q point C and D in all 58 subjects evaluated more than 1 year postoperatively.

Abdominal Procedures

Abdominal Uterosacral Suspension

Abdominal uterosacral colposuspension has been used prophylactically after hysterectomy and therapeutically for apical prolapse with cardinal/uterosacral defects. It can be performed through laparotomy incisions or by laparoscopic techniques. For the therapeutic procedure, a no. 1 polypropylene or delayed absorbable suture is placed cephalad and at the same level posterior as the ischial spines, which may be palpated transabdominally
or with a vaginal finger to push a vaginal fornix to the spine under observation with a laparoscope. One technique is to place one or two permanent sutures through one ligament, then, after reefing across the cul-de-sac peritoneum at the sigmoid border, through the contralateral ligament, then through the fibromuscular tissue just anterior to the vaginal cuff. Tying the suture suspends the vaginal cuff and obliterates any enterocele defect. Another technique employs separate sutures placed at the same level into each uterosacral ligament and anchored anteriorly and posteriorly to the ipsilateral side of the vaginal cuff, similar to procedures performed transvaginally. Cystoscopy is performed after the procedure to document ureteral patency.

Abdominal Sacrocolpopexy

The standard approach to transabdominal apical vaginal suspension procedures is the abdominal sacrocolpopexy. A complete review of published data on these procedures developed by the Pelvic Floor Disorders Network, which is sponsored by the National Institute of Child Health and Human Development (NICHD), has been published (125). These procedures use graft material attached to the prolapsed region of the anterior and posterior vaginal walls at or encompassing the vaginal apex and suspended to the anterior longitudinal ligament of the sacrum. Cervical sacral suspensions may also be performed when uterine or cervical conservation is desired. Surgical variations abound and include configuration of the graft on the vagina, the extent to which the anterior and posterior vagina are attached to the graft, variable graft and suture materials, presence or absence of peritoneal closure over the graft, and obliteration of the cul-de-sac for treatment or prevention of the enterocele or sigmoidocele. A thorough preoperative evaluation to exclude more distal defects or stress incontinence, which should be repaired concurrently, and other lower urinary tract or anorectal problems, is important. In published reports (126–136), cure rates for apical prolapse range from 78% to 100% (most greater than 90%); when cure is defined as no postoperative prolapse, the range widens from 56% to 100%, although subsequent anterior or posterior vaginal prolapse has not been as consistently reported as has apical prolapse. Potential advantages of this procedure over transvaginal procedures are less paravaginal scarring and denervation than may be present with transvaginal approaches, and fixation of the entire vaginal apical area by a permanent piece of material to a stable structure (the anterior sacral ligament), which may be more durable than the transvaginal techniques that use the subject’s own connective tissue.

Complications of these procedures include (i) erosions of graft material or suture material, which may be caused by graft or suture infection usually secondary to vaginal wall penetration, or performing the procedure adjacent to a vaginal incision, or securing the graft to an attenuated avascular wall with inadequate fibromuscular tissue (3.4%); (ii) significant intraoperative hemorrhage (especially in the presacral space) (4.8%); (iii) postoperative ileus, which may be secondary to the need for excessive packing of bowel or to extensive Halban or Moschowitz culdoplasty procedures (3.6%); (iv) small bowel obstruction, requiring reoperation (1.1%); (v) development of intra-abdominal adhesions with resultant pain and bowel dysfunction (unknown incidence); and (vi) wound complications, such as seromas and infections (4.6%) (125).

Several management techniques have been advocated to minimize these problems. Empiric ways to prevent graft erosions include (i) preoperative tissue optimization with vaginal administration of estrogen and treatment of vaginitis and infection of eroded areas; (ii) the use of small-gauge monofilament sutures placed in the fibromuscular tissue, thus avoiding full thickness passage; and (iii) excision of a portion of the vaginal apex when the vaginal wall is thin and depleted of its fibromuscular layer and vascularity. Graft attachment to “healthy” fibromuscular tissue rather than to thin avascular tissue should help prevent erosion. If such excision is necessary, or if the suspension is to be performed concurrently with a hysterectomy, good approximation of the fibromuscular layers above the mucosa, thorough irrigation, prophylactic use of antibiotics, and avoidance
of graft placement across the suture line may decrease the likelihood of graft erosion. **Choice of graft material may also be important.** One would expect synthetic grafts to have greater durability than tissue grafts; however, erosion rates are more serious with the synthetic grafts. Anecdotally, some surgeons are convinced that less porous graft material, such as GORE-TEX, has a greater likelihood of becoming infected and eroding than do porous, filamentous polypropylene meshes. Numerous case series report serious episodes of hemorrhage from the presacral venous plexus (mean incidence 4.8%; range 0.18%–16.9% of sacrocolpopexies requiring, at a minimum, transfusion) (125). This problem is less likely if dissection and graft fixation is limited to the level of S1 and S2 just caudal to the promontory and with the use of good light and meticulous dissection techniques to expose the anterior sacral ligament.

**Careful tissue handling and packing technique may minimize postoperative ileus and adhesions.** Incorporation of the sigmoid into a closure of the cul-de-sac posterior to the graft may also slow bowel function postoperatively. Small bowel obstruction has resulted from direct adhesive processes involving grafts to small bowel. Complete extra peritonealization of the graft using flaps of peritoneum dissected from the prolapsed area and the peritoneum anterior to the sacral promontory and lateral to the right side of the sigmoid colon should prevent this complication. However, loops of bowel have been seen to prolapse through small defects in peritoneal closure with the same effect. Careful technique with adherence to basic surgical principles may help prevent this and other complications related to laparotomy.

**Laparoscopic Techniques**

As with most pelvic operations, sacrocolpopexy has been successfully accomplished by the laparoscopic route and has the potential to offer patients the benefits of less postoperative discomfort and faster recovery as well as potential lower risks for adhesions and ileus. Outcomes depend on the expertise and experience of the surgeon; “cutting corners” to shorten the procedure could affect anatomical success. The applicability of the procedures is limited by the need for a relatively high level of technical skill.

For sacrocolpopexy, whether through laparotomy or laparoscopy, the pelvis should be completely exposed with the lower sigmoid colon stretched cephalad (Fig. 24.14).

1. With a vaginal obturator (an EEA sizer) placed vaginally to visualize the area that is not covered by the bladder or rectum, the peritoneum is dissected from the underlying vaginal fibromuscular layer anteriorly to bladder reflection and posteriorly at least to the level of the sigmoid rectal junction, creating bilateral peritoneal flaps. Laterally, vascular bundles are visible.

2. Two separate loosely woven polypropylene mesh grafts are shaped similar to boat paddles. The “paddle” portions are shaped to cover the areas anterior to the apex and posterior to the apex, respectively, and the “handles,” which are approximately 8 to 10 cm in length and 1 cm wide, are anchored to the anterior sacral ligament. The paddle portions are secured circumferentially to the fibromuscular layers anteriorly and posteriorly with six to eight monofilament 3-0 nylon sutures and one or two sutures placed centrally (Fig. 24.14A).

3. When the fibromuscular tissue in the area is attenuated, a portion of the vaginal wall is excised and closed as noted previously.

4. The peritoneum overlying sacral vertebrae 1 and 2 is incised while retracting the sigmoid colon to the left, and careful dissection is employed down to the anterior ligament. Care is taken to stay well medial to the right ureter and hypogastric vessels.
5. Hemoclips are placed caudad and cephalad on the middle sacral vessels if it is felt that this will allow more optimal suture placement. The peritoneal incision is extended into the right cul-de-sac area adjacent to the sigmoid.

6. Closure of the cul-de-sac lateral to the sigmoid on the left and approximation of the distal presigmoid fat to the distal edge of the posterior graft is accomplished.
with box stitches of 0-delayed absorbable sutures. It is thought that these procedures and the retroperitonealization of the graft through the right side of the cul-de-sac will prevent posterior enterocele and sigmoidocele as well as a Halban or Moschowitz procedure.

7. The two “handle” ends of the graft are then brought to the point of sacral attachment, where their length is adjusted to remove any tension on the vaginal sutures and secured to the anterior sacral ligament with no. 1 permanent braided nylon sutures (Fig. 24.14B).

8. Reperitonealization of the graft is then performed using the right cul-de-sac peritoneum and peritoneal flaps dissected from the vaginal apical area; occasionally presigmoid fat is used.

Following this procedure, adjunctive procedures such as paravaginal repair, Burch procedure, midurethral sling, and any transvaginal procedure that is indicated are performed. When rectocele and pelvic floor defects are present, one option is the sacral colpoperineopexy as discussed in the posterior compartment section (95). A vaginal pack is inserted for approximately 24 hours to ensure that the graft is well applied to the fibromuscular layer at points other than where sutures are placed.
Adjunctive or Graft Materials

Graft materials have been employed in repairing defects or hernias throughout the body. The purpose of grafts is to either completely replace “weak” tissue by spanning across that tissue or to provide a scaffold for fibroblast infiltration. The patient’s own connective tissue may grow into the graft, and, if the graft is degradable, replace the graft as a supportive structure. An ideal graft material should (i) be nonantigenic, (ii) exhibit a low infection rate, (iii) decrease or negate recurrence of anatomic defects, (iv) cause no harm with respect to bowel or renal function, and (v) be relatively inexpensive. Graft materials include autologous tissues, cadaveric allografts and fascia, dermis and other connective tissues, xenografts from animal sources, and various synthetic materials. Allografts and xenografts are treated with processes to remove living cells, thus negating their antigenic potential and allowing them to serve as a temporary connective tissue scaffold. It is assumed that fresh, autologous grafts work similarly; however, there may be some fibroblast survival in fresh harvested tissue. Autologous grafts have limitations in size and shape compared with tissue taken from cadaveric or animal sources. Synthetic grafts are permanent and, as long as the tissues to which they are secured retain their position and strength, they should be durable. Autografts, allografts, and xenografts depend on adequate tissue growth from the subject and potentially may have higher failure rates than synthetic ones. Synthetic grafts are more subject to erosion. Graft erosion may produce bothersome discharge, pain, and sexual dysfunction with vaginal scarring. This may be more likely to occur in women with attenuated, scarred, or less vascular tissue at the time of the repair. More loosely woven polypropylene meshes appear to exhibit fewer problems with erosion and infection than previously used synthetic graft material.

The new midurethral sling procedures that use such mesh have reported erosion rates of 1% or less as compared with rates as high as 6% with more tightly woven polypropylene and polyethylene grafts. A greater incidence of graft infection has been reported when other synthetic grafts are used. One would expect higher rates of erosion and infection when large pieces of graft material are used adjunctively to the vaginal wall; however, there have been favorable reports in which loosely woven polypropylene mesh was used in this manner. Small areas of eroded polypropylene graft may be removed with the surrounding tissue to the point where there is good tissue growth into the graft, and the defect can then be closed. Graft erosion into the bladder, urethra, or rectum is less common than in the vagina. When erosion occurs, however, management is more difficult and long-term adverse effects more common. Numerous surgeons have been reticent to use synthetic graft materials to augment paravaginal musculoconnective tissue support because of complications from erosion. There remains a need for long-term follow-up on subjects who have repairs with graft material, not only to assess anatomical results and complications, but also to assess subsequent sexual function, presence and absence of pain, and patient satisfaction.

Vaginal Obliterative Procedures

Colpocleisis or vaginal narrowing procedures may be appropriate choices for debilitated patients who do not desire vaginal function (137,138), because complete vaginal reconstructive procedures may last several hours and are associated with potentially higher blood loss and increased morbidity. Many variations exist, from partial colpocleisis (where some portion of the vaginal epithelium is left to provide drainage tracts for cervical or upper genital discharge) to total colpectomy (where all of the vaginal epithelium is removed from the hymen posteriorly to within 0.5–2 cm of the external urethral meatus anteriorly). If hysterectomy is performed, blood loss is greater and operative time is longer than procedures without hysterectomy (139). These techniques should include a high perineorrhaphy and often a plication of the puborectalis muscles to reinforce posterior support and to reduce the genital hiatus, with the goal of decreasing the chance of recurrent prolapse. Case series have reported success rates as high as 100%, although the population of patients, by nature of their relatively short life expectancy and limited activity, are probably at lower risk for recurrence. In some instances in which most of the defects are anterior and posterior, a modified anterior and posterior colporrhaphy
may be performed, whereby relatively large portions of the anterior and posterior vaginal wall are removed, and closed creating a narrow (1–2 cm diameter) cylindrical vagina. As with the colpocleisis, the success of the procedure is augmented by an extensive perineorrhaphy and puborectalis plication. Such a procedure may be performed quickly and with relatively low morbidity. The prevention or treatment of stress incontinence, voiding dysfunction, and colorectal dysfunction in the context of these procedures can be problematic. Careful preoperative history and evaluation, if indicated, is important so that additional conservative therapies or operative techniques such as pubourethral plications or less invasive tension-free slings may be employed.

Comparison of Abdominal versus Vaginal Approaches

In recent years there has been controversy as to whether transvaginal or transabdominal procedures for prolapse are best. One cannot discern which is optimal from reports of retrospective and prospective case series because of the considerable differences in numerous factors, including follow-up, characteristics of the subjects, definitions of success and failure, and the expertise or experience of the surgeons performing the procedures. Three prospective randomized trials have compared sacrocolpopexy and sacrospinous suspension procedures (140–142). All three trials showed some increased durability in the sacrocolpopexy group; however, in one of these studies the differences were not statistically significant (142). In the study in which sexual function was examined (141), there was a greater incidence of dyspareunia in the transvaginal group. Most case series reveal that the incidence of serious complications, such as small bowel obstructions, significant hemorrhage, presacral graft infections, pulmonary embolus, and short-term problems (i.e., ileus, hernias, wound seromas or infections, and longer hospitalizations), are more likely to occur in the group undergoing sacrocolpopexy. Vaginal scarring, strictures, and vaginal wall erosions or granulation tissue appear more likely in the group undergoing transvaginal surgery. To date, there is no randomized comparison of vaginal procedures using high uterosacral suspensions and innovative repairs of the fibromuscular tissues, which are less likely to produce strictures than was the case 10 or more years ago.

Most pelvic surgeons would agree that (i) older, less healthy individuals who are more likely to have surgical and medical complications and cannot or will not tolerate a pessary would derive greater benefit from transvaginal approaches and occasionally obliterative approaches, and (ii) relatively healthy, sexually active women with relatively short vaginas and apical prolapse or with isolated apical defects would derive greater benefit from sacrocolpopexy. For the remainder of the patients with apical prolapse, with or without more distal defects, it would ideal if surgeons were equally skilled, knowledgeable, and experienced in both abdominal and vaginal approaches to provide care that is truly individualized, rather than emphasizing one approach to the exclusion of another.

SECTION VI  Urogynecology and Pelvic Reconstructive Surgery

Anorectal Dysfunction

Robert E. Gutman
Geoffrey W. Cundiff

Defecatory dysfunction and fecal incontinence are common conditions that have tremendous psychosocial and economic implications.

The differential diagnosis for anorectal dysfunction is broad and can be classified into systemic factors, anatomic and structural abnormalities, and functional disorders.

A thorough history and physical examination is critical for the evaluation of fecal incontinence and defecatory dysfunction, as well as appropriate ancillary testing.

Treatment of anorectal dysfunction should focus on treatment of the underlying condition with nonsurgical management attempted before surgery.

Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter.

Anorectal dysfunction encompasses a variety of conditions that disrupt normal anorectal function. Such conditions can be subdivided as those that cause defecatory dysfunction and fecal incontinence. Although anorectal dysfunction transcends any individual medical specialty, the pathophysiology, evaluation, and management of conditions relevant to obstetrician–gynecologists are presented in this chapter.

Normal Colorectal Function

Anal continence and defecation are complex physiologic processes that require intact and coordinated neurologic and anatomic function, including colonic absorption and motility, rectal compliance, anorectal sensation, and the multifaceted continence mechanism. An understanding of normal physiology and pathophysiology is essential to the treatment of women with anorectal dysfunction.
Stool Formation and Colonic Transit

The colon plays an important role in absorption and regulation of water and electrolytes. As much as 5 liters of water and associated electrolytes can be absorbed in 1 day. Parasympathetic-mediated peristaltic contraction of colonic smooth muscle transfers fecal material to the rectum. A delay in stool transit at the rectosigmoid region of the colon allows for maximal absorption of water and sodium.

Storage

As stool accumulates in the rectosigmoid, rectal distention triggers a transient decrease in the internal anal sphincter (IAS) tone and an increase in the external anal sphincter (EAS) tone known as the rectoanal inhibitory reflex. Exposure of the anal canal to fecal matter facilitates sampling, whereby the anal canal and its abundant sensory nerves determine stool consistency (i.e., solid, liquid, or gas). Accommodation occurs as the normally compliant rectal vault relaxes in response to increased volume. This cycle, combined with increased rectal distention, stimulates an urge to defecate. This urge can be voluntarily suppressed through cortical control, resulting in further accommodation and activation of the continence mechanism.

Continence Mechanism

Muscles

The key muscles of the continence mechanism are the puborectalis, IAS, and EAS. The puborectalis muscle originates from the pubic rami at the level of the arcus tendineus levator ani and passes laterally to the vagina and rectum in a U-shaped configuration, creating a sling around the genital hiatus. Contraction of the puborectalis muscle narrows the genital hiatus, developing the near 90-degree anorectal angle. The resting tone of the puborectalis muscle serves as the primary continence mechanism for solid stool. The IAS and EAS are essential for continence of flatus and liquid stool. The internal sphincter maintains most of the resting tone for the sphincter complex through autonomic reflex arcs and is essential for passive continence. Although the external sphincter also maintains constant resting tone, it is ultimately responsible for preventing fecal urgency and stress incontinence associated with sudden increases in intra-abdominal pressure. This function is under both voluntary and involuntary control. The anal cushions act as the final anatomic barrier. They fill with blood, causing occlusion of the anal canal.

Nerves

Many pathologic states disrupt normal function through denervation. The IAS receives its sympathetic supply from L5, which passes through the pelvic plexus via the hypogastric plexus. The parasympathetic supply from S2-4 synapses at the pelvic plexus, where it joins the sympathetic nerves. The IAS acts through reflex arcs at the spinal cord without voluntary control. The puborectalis (levator ani) is innervated by branches of the S2-4 sacral roots and does not receive direct innervation from the pudendal nerve (1). The EAS is innervated bilaterally by the pudendal nerve (S2-4) via Alcock’s canal. The pudendal nerve fibers cross over at the level of the spinal cord, allowing preservation of EAS function in the event of unilateral damage. The rich sensory supply from the anal canal travels along the inferior rectal branch of the pudendal nerve.

Evacuation

Initiation of defecation is normally under cortical control. As previously discussed, delivery of stool to the rectum stimulates the rectoanal inhibitory reflex, permitting sampling followed by accommodation. Further rectal distention results in an urge to defecate. Evacuation occurs with voluntary relaxation of the pelvic floor muscles (puborectalis muscle and EAS) in conjunction with increased intra-abdominal and intrarectal pressure.
from Valsalva. This results in widening of the anorectal angle and shortening of the anal canal, which facilitates emptying. Coordinated peristaltic activity of the rectosigmoid assists evacuation. After this process is complete, the closing reflex is initiated, resulting in contraction of the pelvic floor muscles and activation of the continence mechanism.

**Epidemiology**

The epidemiology of anorectal dysfunction has been best defined in terms of the incidence and prevalence of fecal incontinence. Few studies have been done to assess the incidence and prevalence of defecatory dysfunction.

**Defecatory Dysfunction**

The term *defecatory dysfunction* often is used synonymously with the symptom of constipation. *Constipation is an imprecise term used by patients to report a variety of symptoms, including infrequent stools, dyschezia, straining, variation in stool consistency and caliber, incomplete emptying, bloating, and abdominal pain. The most common symptoms associated with constipation are straining and hard stools* (2,3). Defecatory dysfunction is defined by many physicians as infrequent stools, typically fewer than three bowel movements per week. This definition is based on stool frequency studies in which 95% of women have more than three bowel movements per week. Using this definition, the prevalence of constipation should be 5% (4). However, the prevalence of constipation has been estimated to range from 2% to 28%, depending on the definition applied (5–7).

There is an increased prevalence of constipation among women and elderly individuals, nonwhite individuals, and those with low income and low education levels (5–7). Based on an estimated 2.5 million visits to U.S. physicians per year for constipation (8), with an average cost of $2,752 per patient (9), the annual cost for evaluation of constipation would be approximately $6.9 billion. An estimated 85% of physician visits results in a prescription; thus, drug costs would increase this amount substantially (8). Constipation does have a detrimental effect on health-related quality of life (3,10). Constipation contributed to decreased mental and physical scores for quality of life on the SF-36 Health Survey in a Canadian-based population (10).

**Fecal Incontinence**

The reported prevalence of fecal incontinence varies between 2% and 3% for community-dwelling individuals, 3% to 17% for those of increased age, and 46% to 54% for nursing home residents (11). A prevalence of 28% has been reported among patients seeking benign gynecologic care (12). Epidemiological studies of fecal incontinence are compromised by social stigmata and the lack of a uniform definition. Definitions of fecal incontinence vary with respect to the type of material passed (solid, liquid, or gas), the frequency and duration of events (once in a lifetime to twice a week), and the impact on quality of life. Most authors agree that the true prevalence of this condition is underestimated in the current scientific literature. A large health survey in the United States found age, female sex, physical limitations, and poor general health to be independent risk factors associated with fecal incontinence (13).

Fecal incontinence has tremendous psychosocial and economic implications for individuals and society as a whole. The loss of such a basic function can be emotionally devastating, leading to poor self-esteem, depression, social isolation, and decreased quality of life (12,14). Fecal incontinence is the second leading reason for nursing home placement in the United States, even though fewer than one third of individuals with this condition seek medical attention (12,14). The overall annual cost to treat
fecal incontinence is difficult to pinpoint, but accounts for more than $400,000,000 per year in the cost of adult diapers alone (14).

**Symptom-Based Approach to Colorectal Disorders**

Several medical conditions cause defecatory dysfunction, fecal incontinence, or combined symptoms. Following is the differential diagnosis—a proposed classification system based on systemic factors, anatomic and structural abnormalities, and functional disorders.

### Differential Diagnosis

**Disordered Defecation**

Causes of defecatory dysfunction have traditionally been divided into systemic disorders and idiopathic constipation (all nonsystemic causes). Idiopathic constipation can be subdivided into anatomic and structural abnormalities and functional disorders (Table 25.1).

Diabetes, hypothyroidism, and pregnancy are the most common endocrinologic systemic factors that cause constipation, and all have a component of decreased gastrointestinal motility and intestinal transit. In one study, gastrointestinal symptoms were present in 76% of patients with diabetes, including constipation, which occurred in 60% (15). In patients with diabetes, constipation is believed to be secondary to intestinal autonomic neuropathy, resulting in delayed or absent gastrocolic reflex and decreased bowel motility. This enteric neuropathy may also cause gastroparesis and diarrhea. Although diabetes has been classified with the endocrinologic causes, it should also be grouped with the enteric neuropathies. Pregnancy is not considered a disease state; however, there is an 11% to 38% prevalence of constipation that is believed to be due primarily to the effect of progesterone on smooth muscle (16).

The neurologic systemic factors can be divided into central and peripheral processes. Spinal cord lesions, multiple sclerosis, and Parkinson disease affect the autonomic nervous system. Trauma to the sacral nerves often leads to severe constipation from decreased left-sided colonic motility, decreased rectal tone and sensation, and increased distention. These findings are also seen in patients with meningo(myelo)ccele, damage to the lumbosacral spine, and pelvic floor trauma (17,18). Higher spinal cord lesions result in delayed sigmoid transit and decreased rectal compliance. In these upper motor neuron lesions, colonic reflexes are intact, and defecation can be initiated by digital stimulation of the anal canal (19,20). Individuals with multiple sclerosis can have no gastrocolic reflex, decreased colonic motility, decreased rectal compliance, and even rectosphincteric dyssynergia (21,22). Constipation worsens with the duration of illness and may be compounded by the side effects of medical therapy. Similar findings of rectosphincteric dyssynergia and medication side effects are present with Parkinson disease.

Among the peripheral neurogenic disorders, dysfunction occurs at the level of the enteric nerves. The ultimate example of this finding is congenital aganglionosis (Hirschsprung disease). The absence of intramural ganglion cells in the submucosal and myenteric plexuses of the rectum causes loss of the rectosphincteric inhibitory reflex. Patients with this illness usually present with functional obstruction and proximal colonic dilation. In most patients, the condition is diagnosed within 6 months of age, although milder cases can be seen later in life.

Other systemic factors to consider are collagen vascular and muscle disorders. Importantly, some of the most commonly used prescription and over-the-counter medications, including aluminum antacids, beta-blockers, calcium channel blockers, anticholinergics, antidepressants, and opiates, cause defecatory dysfunction (Table 25.2). Lifestyle issues, such as

STRUCTURAL ANOMALIES AND FUNCTIONAL DISORDERS

Inadequate fiber intake and insufficient fluid intake, can exert similar effects independently or in conjunction with other disorders.

Structural abnormalities refer to the obstructive disorders, such as pelvic organ prolapse, perineal descent, intussusception, rectal prolapse, and tumors. Functional disorders are those that do not have an identifiable anatomic or systemic etiology. Most functional disorders are motility disorders, such as slow-transit constipation/colonic inertia, irritable bowel syndrome (constipation predominant), and functional constipation. Patients also may have functional limitations, such as decreased mobility and cognition. It is important to understand that this classification system is somewhat arbitrary, and several of these conditions are interrelated.

Fecal Incontinence

Anal continence depends on a complex interaction of cognitive, anatomic, neurologic, and physiologic mechanisms. The continence mechanism can often compensate for a deficiency in one of these processes, but it can be overwhelmed with increased severity or decreased function over time. Systemic etiologies of fecal incontinence often are due to disease states that cause diarrhea. The rapid transport of large volumes of liquid stool to the rectum can produce urgency and incontinence even in healthy individuals (23). Fecal incontinence frequently results from infectious diarrhea caused by bacteria (e.g., Clostridium, E. coli, Salmonella, Shigella, Yersinia, Campylobacter), viruses (e.g., Rotavirus, Norwalk, human immunodeficiency virus [HIV]), and parasites (e.g., Entamoeba, Giardia, Cryptosporidium, Ascaris). Numerous medications and dietary items cause diarrhea and fecal incontinence (Table 25.3). Endocrine factors that can lead to fecal incontinence include diabetes mellitus and hyperthyroidism. With diabetes, diarrhea can develop from autonomic dysfunction, bacterial overgrowth, osmotic diarrhea with sugar substitutes, and pancreatic insufficiency. Inflammatory bowel disease is considered an idiopathic/autoimmune systemic factor. Ulcerative colitis and Crohn disease cause fecal incontinence during exacerbations with bouts of bloody diarrhea. Inflammatory bowel disease can also result in structural abnormalities, such as anal fissures, fistulas, abscesses, and operative complications that lead to fecal incontinence.

</table>
As with defecatory dysfunction, neurologic causes of fecal incontinence can be divided into central and peripheral disorders. Among the central nervous system disorders, upper motor neuron lesions above the level of the defecation center (located in the sacral cord) cause spastic bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The anal sphincter is under spastic contraction, but digital stimulation can be performed to initiate reflex evacuation. Head trauma, neoplasms, and cerebral vascular accidents that damage portions of the frontal lobe result in loss of control of both micturition and defecation. Greater loss of inhibition is present when the lesion is located more anteriorly in the frontal lobe. Spinal cord trauma and lower motor neuron lesions above the defecation center tend to cause permanent loss of cortical control. For 2 to 4 weeks following spinal cord injury, “spinal shock” occurs, resulting in a temporary loss of reflexes below the level of the lesion, flaccid bowel function, constipation, and fecal impaction. After the initial shock, spastic paralysis ensues with hyperactive bowel function. The gastrocolic reflex, along with digital stimulation, initiates reflex evacuation in the absence of cortical inhibition. Fortunately, IAS tone is maintained despite the loss of EAS control for stress and urge situations. Both constipation and fecal incontinence can occur in these patients.

The demyelination that is seen in multiple sclerosis is randomly distributed and can occur at any level in the central nervous system. In addition to the somatic disruption that is similar to spinal cord injury, autonomic dysfunction frequently is present. People with dementia and other degenerative disorders that cause cognitive impairment frequently have fecal incontinence caused by overflow incontinence. Although sensory nerves are functioning properly, these individuals lack the cognitive awareness necessary to inhibit defecation until a socially acceptable time, and they develop overflow incontinence.

Lower motor neuron lesions occurring at or below the level of the defecation center in the sacral cord cause flaccid bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The bowel reflexes, including the bulbocavernous and anal reflexes, are interrupted. The anal sphincter is flaccid, and fecal retention with overflow incontinence usually occurs. Digital disimpaction and Valsalva often are required for evacuation. Digital stimulation has no effect, and medications tend to work
poorly. Examples of motor neuron lesions include tumor or trauma to the cauda equina, tabes dorsalis, spina bifida, and peripheral neuropathy.

The classic example of peripheral neuropathy is congenital aganglionosis (Hirschsprung disease), which was discussed earlier. The most common peripheral neuropathy occurs with diabetes. **Approximately 20% of individuals with diabetes have fecal incontinence** (24). The cause tends to be multifactorial with the exact mechanism uncertain. Fecal incontinence can occur with diabetic diarrhea or years later from progressive disease. Individuals with diabetes frequently experience intestinal autonomic neuropathy, an abnormal gastrocolic reflex, and chronic constipation. The subsequent pelvic floor denervation causes fecal incontinence by sensory neuropathy, failure of the rectoanal inhibitory reflex, and sphincter dysfunction (25). Consequently, fecal incontinence from peripheral neuropathy can be the result of defective sampling, a disrupted rectoanal inhibitory reflex, or pudendal neuropathy with sphincter dysfunction. Patients may experience stress or urge incontinence as well as overflow incontinence.

**Anatomical and structural causes of fecal incontinence are usually due to obstetric or surgical trauma.** Damage or dysfunction of the IAS, EAS, and puborectalis can result in varying degrees of fecal incontinence. Those with impaired resting tone from a defective IAS will have passive incontinence (incontinence at rest), which is worse during sleep because of decreased EAS activity (26). An inability to respond to sudden distention and to suppress defecation is often seen with external sphincter dysfunction. External and internal sphincter dysfunction often result in incontinence of liquid stool. Incontinence of solid stool is usually seen with widening of the anorectal angle from damage to the puborectalis muscles. Damage to the anal cushions usually causes minor soiling. Other anatomic and structural abnormalities associated with fecal incontinence include obstructive disorders such as pelvic organ prolapse, descending perineum syndrome, anismus, and intussusception; fistulas from diverticulitis, inflammatory bowel disease, cancer, or surgical trauma; and decreased rectal compliance from inflammatory bowel disease, cancer, and radiation. Decreased compliance results in higher intraluminal pressures with smaller volumes of stool, poor storage capacity, urgency, and incontinence (27).

**Functional disorders associated with fecal incontinence include irritable bowel syndrome (diarrhea variant), functional diarrhea, decreased mobility, and decreased cognition.**

**Outlet Obstruction**

*Anismus/Rectosphincteric Dyssynergia*  
Anismus is otherwise known as rectosphincteric dyssynergia, pelvic floor dyssynergia, spastic floor syndrome, and paradoxical puborectalis syndrome. The anorectal angle narrows as a result of paradoxical contraction of the puborectalis and external anal sphincter during defecation. Frequent symptoms
include dyschezia, straining, hard stools, incomplete emptying, and tenesmus. A recent prospective study of 120 consecutive patients with dyssynergic defecation found a higher prevalence in women (77%) (28,29). The need for digital assistance (digital disimpaction or splinting) to evacuate the rectum occurs in up to 58% of patients.

Psychosocial factors, such as a history of sexual abuse, depression, eating disorder, obsessive–compulsive disorder, and stress, may play an important role in this disease. In this study, 22% reported a history of sexual abuse, and 31% reported a history of physical abuse. One third believed the problem began during childhood, and 24% reported a precipitating illness or surgery was related to a particular event. Five percent of women claimed that pregnancy or childbirth was a precipitating factor. This condition also is seen in young children with constipation and dyschezia. The response to biofeedback and pelvic floor physical therapy, as well as the aforementioned patient characteristics, indicate a learned response mechanism is involved (28,29).

Pelvic Organ Prolapse

Pelvic organ prolapse bears special mention because it is often seen by gynecologists but inconsistently associated with defecatory dysfunction. Prolapse is very common, although many women with this condition are asymptomatic. Those with symptoms may report incomplete evacuation and the need to apply digital pressure to the posterior vaginal wall or perineum to aid in evacuation of stool (digitalization or splinting). It is important to rule out other causes of constipation, because these symptoms are nonspecific, and rectocele can result from chronic straining and increased intra-abdominal pressure. Defecatory dysfunction related to pelvic organ prolapse can result from rectocele, enterocele, or perineal descent, either individually or in combination.

Rectocele is a herniation of the rectal mucosa through a defect in the rectovaginal septum. These site-specific defects can be transverse or longitudinal through the inferior, middle, or superior regions of the rectovaginal septum (30). Enterocele is a herniation of a peritoneal sac and bowel through the pelvic floor, typically between the uterus or vaginal cuff and rectum. It is more common following hysterectomy and retropubic urethropexy. There are two theories surrounding the formation of an enterocele. The first theory implicates a defect in the fibromuscular endopelvic fascia of the vagina, allowing peritoneum and bowel to herniate. The second theory attributes its formation to a support defect with full thickness protrusion, including endopelvic fascia (31). Ultimately, the mechanism might be attributed to a combination of the two theories because some support defects are secondary to superior breaks in the rectovaginal and pubocervical fascia. Patients with rectocele and enterocele may have similar symptoms, including pelvic pain, pressure, vaginal protrusion, obstipation, fecal incontinence and sexual dysfunction. Although associations have been made between defecatory dysfunction and advanced stages of pelvic organ prolapse, a causal relationship remains to be established. Controversy remains as to whether anatomic herniation is the cause of these symptoms or the effect of underlying colonic dysfunction, chronic constipation, and straining.

Descending perineum syndrome is defined as descent of the perineum (at the level of the anal verge) beyond the ischial tuberosities during Valsalva. Excessive perineal descent was first described in the colorectal literature by Parks et al. in 1966 (32,33). It occurs as a result of inferior detachment of the rectovaginal septum from the perineal body. As the condition progresses, the patient can develop pudendal neuropathy from stretch injury. Perineal descent has been associated with a variety of defecatory disorders, including constipation, fecal incontinence, rectal pain, solitary rectal ulcer syndrome, rectocele, and enterocele (34).

Rectal Intussusception Rectal intussusception or intrarectal prolapse is the circumferential prolapse of the upper rectal wall into the rectal ampulla but not through the anal verge. It occurs most often in women in the fourth and fifth decade. The most common symptoms are obstructive, including incomplete emptying, manual disimpaction,
splening, pain with defecation, and bleeding. Other symptoms include fecal incontinence, decreased urge to defecate, inability to distinguish between gas and feces, and mucus discharge with pruritus ani. Bleeding often originates from a solitary rectal ulcer or localized proctitis of the involved bowel segment (35). Intussusception is frequently seen in as many as one third of women with defecatory dysfunction and other symptoms, such as constipation, rectal pain, and fecal incontinence (36). It has also been seen in 29% of asymptomatic patients (37). The intussusception rarely develops into total rectal prolapse (38).

Functional Motility Disorders

**Colonic Inertia/Slow-Transit Constipation** Severe constipation, defined as fewer than three stools per week and refractory to therapy, is relatively rare; however, these patients frequently suffer from motility disorders such as global motility disorder and colonic inertia. Women are more likely to be affected than men. Colonic inertia or slow-transit constipation is defined as the delayed passage of radiopaque markers through the proximal colon without retropulsion of markers from the left colon and in the absence of systemic or obstructive disorders. The cause remains unclear. Patients with this disorder have impaired phasic colonic motor activity and diminished gastrocolic reflexes (39,40). Studies on the role of laxatives, absorption, hormones, psychological abnormalities, and endogenous opioids have been inconclusive. Current literature suggests a possible neurologic or smooth muscle disorder (40,41).

Functional Bowel Disorders

Functional bowel disorders, as defined by the Rome II Criteria (42), consist of irritable bowel syndrome, functional abdominal bloating, functional constipation, functional diarrhea, and unspecified functional bowel disorders. In this section we will focus primarily on IBS.

Irritable bowel syndrome (IBS) has been estimated to have a prevalence of 10% to 20% and is more common in women and younger individuals. It accounts for 25% to 50% of all referrals to gastrointestinal clinics. Irritable bowel syndrome has distinct diagnostic criteria, including the exclusion of structural or metabolic abnormalities. These patients often have other gastrointestinal, genitourinary, and psychological illness, including gastroesophageal reflux disease, fibromyalgia, headache, backache, chronic pelvic pain, sexual dysfunction, lower urinary tract dysfunction, depression, and anxiety. Stressful life events seem to correlate with the onset and exacerbation of symptoms. A detailed history frequently reveals past physical or sexual abuse (42). Currently, specific criteria allow for classification of IBS into diarrhea-, constipation-, and pain-predominant categories (Table 25.4). The constipation variant is most commonly associated with defecatory dysfunction, whereas the diarrhea variant causes fecal incontinence. The pain or spastic variant causes predominantly abdominal discomfort but can also be associated with both defecatory dysfunction and fecal incontinence. After excluding organic disease, the criteria listed in Table 25.4 have a sensitivity of 65%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 76% (43).

Functional constipation is a term created by the Rome II criteria as a unifying definition of constipation (Table 25.5). The rationale for the criteria listed in Table 25.5 stems from the variability in patient definitions of constipation (42).

**Fecal Incontinence**

**Sphincter Disruption**

In young women, obstetric injury is the most common cause of fecal incontinence. The mechanism of injury can be from anatomic disruption of the anal sphincter complex, pelvic floor denervation, or a combination of the two conditions. The risk factors for anal
Table 25.4 Diagnostic Criteria of Irritable Bowel Syndrome

At least 12 weeks, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two of three features:

1. Relieved with defecation and/or
2. Onset associated with a change in frequency of stool and/or
3. Onset associated with a change in form (appearance) of stool

Supporting symptoms of IBS

1. Fewer than three bowel movements a week
2. More than three bowel movements a day
3. Hard or lumpy stools
4. Loose (mushy) or watery stools
5. Straining during a bowel movement
6. Urgency (having to rush to have a bowel movement)
7. Feeling of incomplete bowel movement
8. Abdominal fullness, bloating, or swelling

Diarrhea-predominant

1 or more of 2, 4, or 6 and none of 1, 3, or 5; or 2 or more of 2, 4, or 6 and one of 1 or 5.

Constipation-predominant

1 or more of 1, 3, or 5 and none of 2, 4, or 6; or 2 or more of 1, 3, or 5 and one of 2, 4, or 6.

IBS, irritable bowel syndrome.

sphincter laceration are primiparity, high birth weight, forceps delivery, and episiotomy (44–46). Although there are limited long-term prospective studies demonstrating the natural history of anal sphincter injury, pelvic floor neuropathy, and the progression of these conditions to fecal incontinence, current literature supports the relationship of early-onset symptoms to sphincter damage and delayed-onset symptoms to neuropathy (47). This relationship would account for the large discrepancy in the prevalence of fecal incontinence between younger men and women that decreases as the population ages (48).

Table 25.5 Diagnostic Criteria of Functional Constipation

At least 12 weeks, which need not be consecutive, in the preceding 12 months of two or more of:

1. Straining >1/4 of defecations
2. Lumpy or hard stools >1/4 of defecations
3. Sensation of incomplete evacuation >1/4 of defecations
4. Sensation of anorectal obstruction/blockage >1/4 of defecations
5. Manual maneuvers to facilitate >1/4 of defecations (e.g., digital evacuation, support of the pelvic floor)
6. <3 defecations per week

If loose stools are not present, and there are insufficient criteria for IBS.

IBS, irritable bowel syndrome.

Obstetric Trauma. Third- and fourth-degree lacerations at delivery are associated with an increased risk of fecal incontinence (odds ratio [OR] 3.09) (47). Whereas the incidence of clinically documented third- and fourth-degree anal sphincter tears is between 0.5% and 5.9% (44,46,49), occult third- and fourth-degree defects are present in 28% to 35% of primiparous women and 44% of multiparous women, and approximately one third of these patients have symptoms of anal incontinence. Patients with occult anal sphincter tears are 8.8 times more likely to have fecal incontinence (46,50). Forceps-assisted vaginal delivery significantly increases this risk, but the data on vacuum-assisted delivery are less conclusive (45,51,52). Elective cesarean delivery, in contrast with emergency cesarean delivery, was believed to prevent anal incontinence, but recent studies argue against any protective effect with cesarean delivery, irrespective of timing (46,51,53). Midline episiotomy is strongly linked to sphincter damage and fecal incontinence (45,54). One study of a large population found conflicting results, with an overall protective effect seen with episiotomy (OR 0.89). The likelihood of fourth-degree laceration was increased (OR 1.12) and of third-degree laceration was decreased (OR 0.81) (44). A Cochrane review supports the restrictive use of both midline and mediolateral episiotomy (55). In another study, an important finding was that one half of patients who underwent immediate repair of a third-degree laceration had symptoms of anal incontinence, and 85% had persistent sphincter defects on endoanal ultrasonography (56).

Surgical Trauma. Iatrogenic injury follows obstetric trauma as the second most common cause of direct sphincter damage. Surgical procedures that have been associated with fecal incontinence include anal fistula repair, anal sphincterotomy, hemorrhoidectomy, and anal dilation. Fistulotomy is the most common procedure that results in fecal incontinence. Rectovaginal or anovaginal fistulas can develop after obstetric injury, operative complications during pelvic surgery, and inflammatory bowel disease exacerbations. Fistulas cause fecal incontinence, and the degree of postoperative dysfunction depends on the location of the fistula and the amount of sphincter that is disrupted during the surgical repair. It also depends on the preoperative level of sphincter function and pudendal nerve function. Anal sphincterotomy to treat painful anal fissures can lead to incontinence by disruption of rectal sensory innervation and anal cushions and transection of the anal sphincter (57,58). Hemorrhoidectomy often results in minor soiling as a result of resection of the anal cushions, which act as the final mucosal barrier. Similar to sphincterotomy, rectal sensory innervation can be disrupted, and injury to the internal sphincter can occur during sharp dissection (58,59).

Sphincter Denervation

Idiopathic (primary neurogenic) fecal incontinence results from denervation of both the anal sphincter and pelvic floor muscles. Denervation injury related to obstetric trauma accounts for approximately three out of every four cases of idiopathic fecal incontinence and is the most common overall cause of fecal incontinence (60,61).

Obstetric Trauma. The two proposed mechanisms of pudendal neuropathy are stretch injury during the second stage of labor and compression of the nerve as it exits Alcock’s canal (60). Established risk factors for pelvic floor neuropathy include multiparity, high birth weight, forceps delivery, prolonged active second stage, and third-degree laceration (62,63). Several studies have shown increased pudendal nerve terminal motor latencies following vaginal delivery, especially after sphincter laceration (46,61,64). Most women will recover function within a few months postpartum. Others will have evidence of injury several years later, which may represent the cumulative effects of subsequent deliveries (61,65). However, fecal incontinence will develop in only a fraction of patients with neuropathy (63).

Descending Perineum Syndrome. As noted previously, prolonged straining for any reason can cause descending perineum syndrome. This syndrome is defined as descent of the perineum beyond the ischial tuberosities during Valsalva (32,33). Pudendal
neuropathy results from stretching and entrapment of the pudendal nerve. This diagnosis is supported by findings of elongation of the pudendal nerve, prolonged pudendal nerve motor terminal latency, and decreased anal sensation in women with perineal descent (66–68). As pudendal neuropathy progresses, it ultimately leads to fecal incontinence (34,69).

Functional Bowel Disorders

Irritable Bowel Syndrome

The diarrhea variant of irritable bowel syndrome is often associated with fecal incontinence as well as disordered defecation. The criteria for diagnosis are in Table 25.4.

Functional Diarrhea

The Rome II criteria create a unifying definition of diarrhea called functional diarrhea (Table 25.6). The rationale for the criteria listed in Table 25.6 stems from the variability in patients’ descriptions of diarrhea (42).

Pitfalls for the Pelvic Floor Surgeon

It sometimes is easy to overlook or misinterpret signs and symptoms of constipation and defecatory dysfunction. Any acute change in bowel habits must be evaluated thoroughly, and malignancy must be considered in the differential diagnosis. Even in the presence of chronic disease, malignancy must still be excluded. Persistent symptoms after an empiric trial of medical therapy should prompt further evaluation, such as a colonoscopy or flexible sigmoidoscopy. It is also possible to mistakenly attribute symptoms of defecatory dysfunction and constipation to pelvic organ prolapse when prolapse is actually the result of an underlying bowel disorder. In this case, surgical treatment of prolapse will have little lasting benefit if the underlying bowel disorder remains untreated.

History and Physical Examination

History

A thorough history and physical examination are critical to the evaluation of fecal incontinence and defecatory dysfunction. The history of present illness should focus on the bowel habits, including frequency and consistency of bowel movements (hard versus soft, formed versus unformed, diarrhea versus constipation). The duration and severity of symptoms as well as exacerbating factors are important to understanding the impact on quality of life. Patients should be questioned about straining with bowel movements, symptoms of incomplete emptying, and splitting of the perianal region, perineal body, or posterior vaginal wall to assist with evacuation. They should also be asked about the need to perform digital disimpaction because they are unlikely to volunteer this information. With respect to fecal incontinence, information should be obtained about leakage with solids, liquid, and flatus and the ability to discriminate between these different types of stool (sampling). Similar to urinary incontinence, fecal incontinence can
be stress related, urge related, or unconscious. Questions about alternating diarrhea and constipation, mucus or blood in the stools, constitutional symptoms, and changes in stool caliber can help the investigator uncover systemic and functional etiologies. Finally, it is important to ask about adaptive behaviors, pad or diaper use, and past and present treatments including surgery, physical therapy, and medications.

A large amount of information can be obtained efficiently through questionnaires. Validated questionnaires quantify symptoms, which are subjective in nature, to objectively measure response to treatment. A valuable survey to assess defecatory dysfunction is the Colorectal-Anal Distress Inventory (CRADI), which has been incorporated into the Pelvic Floor Distress Inventory (PFDI) (70). The latter is a useful tool for evaluating symptoms of prolapse, urinary incontinence, fecal incontinence, voiding dysfunction, and defecatory dysfunction. Other useful symptom scales and bother scores for fecal incontinence include the Wexner Score (71), Fecal Incontinence Severity Index (72), and Fecal Incontinence Quality of Life Scale (73).

A large amount of information can be obtained efficiently through questionnaires. Validated questionnaires quantify symptoms, which are subjective in nature, to objectively measure response to treatment. A valuable survey to assess defecatory dysfunction is the Colorectal-Anal Distress Inventory (CRADI), which has been incorporated into the Pelvic Floor Distress Inventory (PFDI) (70). The latter is a useful tool for evaluating symptoms of prolapse, urinary incontinence, fecal incontinence, voiding dysfunction, and defecatory dysfunction. Other useful symptom scales and bother scores for fecal incontinence include the Wexner Score (71), Fecal Incontinence Severity Index (72), and Fecal Incontinence Quality of Life Scale (73).

The medical history, surgical history, family history, and review of systems should focus on uncovering potential systemic and obstructive disorders shown in Table 25.1. A complete obstetric history should include the number of vaginal deliveries, operative vaginal deliveries, or presence of a third- or fourth-degree laceration, which is critical for patients with fecal incontinence. Length of the second stage of labor, birth weight, and the use of episiotomy should be ascertained because they may pose risk factors for sphincter damage and denervation. The sexual history should include questions about prior rape, anal intercourse, and dyspareunia. Use of over-the-counter, prescription, and illegal drugs should be recorded as well as food allergies.

### Physical Examination

The evaluation of anorectal dysfunction requires a basic general examination as well as a focused abdominal and pelvic examination. The general physical survey should include a global assessment of mobility and cognitive function. Routine examination of the abdomen involves inspection, palpation, and auscultation to rule out the presence of masses, organomegaly, and areas of peritoneal irritation. This examination should be followed by a detailed evaluation of the vagina, perineum, and anorectum. The goals of the pelvic examination are to define objectively the degree of prolapse and determine the integrity of the connective tissue, neurologic function, and muscular support of the pelvic organs.

### Neurologic Examination

Important elements of the neurologic examination are assessment of cranial nerve function, sensation and strength of the lower extremities, and reflexes for the lower extremities, bulbocavernosus, and anal wink. These examinations evaluate the function of the lower lumbar and sacral nerve roots, recognizing the importance of the second through fourth sacral nerve roots in pelvic floor dysfunction. The perineal reflexes can be elicited by stroking the labia majora and perianal skin or tapping the clitoris with a cotton-tipped swab. The anal wink, bulbocavernosus, and cough reflexes all test the integrity of motor innervation to the external anal sphincter (S2-4). Sensation over the inner thigh, vulva, and perirectal areas should be tested for symmetry to light touch and pinprick.

### Muscle Strength

The integrity of the pelvic floor muscles should be assessed at rest and with voluntary contraction to determine strength, duration, and anterior lift. The ability to relax these muscles and tenderness on palpation should also be evaluated. Several standardized systems have been described to objectively measure muscle strength, but none has been accepted as a standard. The puborectalis muscle should be readily palpable posteriorly as it creates a 90-degree angle between the anal and rectal canals. Voluntary contraction of this muscle “lifts” the examining finger anteriorly toward the pubic rami. An intact
external anal sphincter muscle that has decreased tone and contractility often indicates pudendal neuropathy. Similarly, neuropathy affecting the puborectalis can be recognized by an obtuse anorectal angle and weak voluntary contraction. Similar to the urethral axis, the anorectal angle can also be tested using a cotton-tipped swab, although this test is rarely performed. Deflection is measured in the supine position at rest, with strain, and with squeeze.

Vaginal Support

The salient points of pelvic organ prolapse (see Chapter 24) for patients with defecatory dysfunction are the support of the vaginal apex, posterior wall, and perineal body, although some experts believe anterior wall defects can also affect defecatory dysfunction. The posterior wall is assessed while supporting the vaginal apex and anterior wall with a Sims’ speculum. This permits the examiner to focus on identifying specific locations of rectovaginal fascial defects. A rectovaginal examination aids in identification of defects in the rectovaginal fascia or perineal body. Loss of vaginal rugation has also been reported overlying the site of a rectovaginal fascial tear (74). This technique is especially useful for enteroceles, which have a smooth, thin epithelium over the enterocele sac or peritoneum.

Normally, the perineum should be located at the level of the ischial tuberosities, or within 2 cm of this landmark. A perineum below this level, either at rest or with straining, represents perineal descent. Subjective findings of perineal descent include widening of the genital hiatus and perineal body, as well as flattening of the intergluteal sulcus. Women with perineal descent also tend to have less severe stages of pelvic organ prolapse based on the Pelvic Organ Prolapse Quantification (POP-Q) staging system (75) because it measures descent from the hymenal ring. Consequently, an increase in the length of the perineal body and genital hiatus with straining suggests perineal descent. The degree of perineal descent can also be measured objectively with a St. Mark’s perineometer, although a thin ruler placed in the posterior introitus at the level of the ischial tuberosities also can be used. Descent is measured as the distance the perineal body moves when the patient strains. Although pelvic floor fluoroscopy is the standard technique for measuring perineal descent, this technique is most useful in patients with symptoms of severe defecatory dysfunction and evidence of perineal descent on pelvic examination.

Anorectal Examination

Visual and digital inspection of the vagina and anus will help to identify structural abnormalities such as prolapse, fistulas, fissures, hemorrhoids, or prior trauma. As previously mentioned, a rectovaginal examination provides useful information regarding the integrity of the rectovaginal septum and can demonstrate laxity in the support of the perineal body. The rectovaginal examination also is helpful in the diagnosis of enteroceles, which can be felt as protrusion of bowel between the vaginal and rectal fingers with straining. Digital rectal examination should be performed at rest, with squeeze, and while straining. The presence of fecal material in the anal canal may suggest fecal impaction or neuromuscular weakness of the anal continence mechanism. Circumferential protrusion of the upper rectum around the examining finger during straining suggests intussusception, which often occurs in combination with laxity of the posterior rectal support along the sacrum.

The integrity of the external anal sphincter and puborectalis muscle can be evaluated by observation and palpation of these structures during voluntary contraction. Evidence of dovetailing of the perianal skin folds and the presence of a perineal scar with an asymmetric contraction often indicates a sphincter defect. When a patient is asked to contract her pelvic floor muscles, two motions should be present: The external anal sphincter should contract concentrically, and the anal verge should be pulled inward. These actions should also be apparent on digital rectal examination. As mentioned previously, the 90-degree angle created by the puborectalis should be readily palpable posteriorly and, with voluntary contraction, the examining finger should be lifted anteriorly toward the pubic rami.
Both the puborectalis and external anal sphincter should relax during Valsalva effort. Patients with anismus may experience a paradoxical contraction of these muscles during straining. Finally, defects in the anterior aspects of the external anal sphincter may be detected by digital examination.

### Testing

Sophisticated diagnostic testing is currently being used in clinical research and in anorectal physiology laboratories to quantify the function of the colon and anorectum. Following is a description of these techniques as they relate to the management of fecal incontinence and disordered defecation.

#### Fecal Incontinence

**Endoanal Ultrasonography**

Endoanal ultrasonography permits accurate imaging of both the internal and external anal sphincters. It can assess the continuity and thickness of the muscle and currently is considered the single best method for detecting anal sphincter defects. Endoanal ultrasonography is performed using a Bruel-Kjaer (Copenhagen, Denmark) ultrasound scanner with a 360-degree rectal endoprobe (type 1850) with a 7.0 MHz transducer (focal length, 2–5 cm) housed within a plastic cone (Fig. 25.1). The normal IAS is a continuous hypoechoic band of smooth muscle surrounded by the thick echogenic layer of the striated EAS. A sphincter defect occurs when there is disruption in these muscle bands. Location and severity of the defect can be described by circumferential distance in degrees, percent thickness, and distance from the anal verge (Fig. 25.2). Measurements are usually taken in the proximal, middle, and distal anal canal. It is important to recognize the physiologic split in the proximal EAS as it merges with the puborectalis muscle of the levator ani. Misinterpretation of this finding as a sphincter defect can result in an increased prevalence of reported defects. The puborectalis muscle appears as a U-shaped or V-shaped thick echogenic layer outside the IAS in the proximal anal canal. Magnetic resonance imaging (MRI) may be equally as effective or better at diagnosing sphincter defects, especially with the use of a vaginal or rectal coil. For this purpose, MRI is more expensive, and currently its use is largely investigational. It may be beneficial in cases in which endoanal ultrasonography results are inconclusive or the quality of the study is poor.

**Electromyography**

Electromyography (EMG) is used to evaluate neuromuscular integrity of the EAS following a traumatic injury such as childbirth, as well as to document the presence

![Figure 25.1](image-url) Bruel-Kjaer (Copenhagen, Denmark) ultrasound probe (type 1850) with a 7.0 MHz transducer (focal length, 2 to 5 cm) housed with a plastic cone.
Figure 25.2  
**A:** Endoanal ultrasound image from the distal anal canal demonstrating defects in the internal sphincter from 10 to 3 o’clock and the external sphincter from 10 to 2 o’clock. 
**B:** Endoanal ultrasound image from the middle anal canal demonstrating defects in the internal sphincter from 12 to 2 o’clock and the external sphincter from 10 to 1 o’clock. 
**C:** Endoanal ultrasound image from the proximal anal canal demonstrating an intact IAS and a normal physiologic split in the external sphincter.
of pelvic floor neuropathy (76). This technique measures the electrical activity arising in muscle fibers during contraction and at rest. Different types of electrodes may be employed, including surface electrodes, concentric needle electrodes, and single-fiber electrodes. Surface electrodes are less invasive because they are applied near or within the anal canal, but they are capable only of recording basic anal sphincter activity. This technique often is used in conjunction with biofeedback therapy. Concentric needle electrodes are most commonly used in anorectal physiology laboratories to selectively survey an individual muscle’s activity. Insertion of the thin needlelike cannulas containing steel wire electrodes can be painful. Even smaller single-fiber EMG electrodes are used to record the activity of single muscle fibers, which can be quantified to calculate fiber density. Following denervation injury, increased muscle fiber density occurs during reinnervation. Thus, single-fiber EMG can provide indirect evidence of neurologic injury by mapping the EAS and identifying injured areas. This technique rarely is used in clinical practice. Endoanal ultrasonography offers increased patient comfort and more reliable results than EMG and has replaced this technique for the detection of EAS disruption because of increased patient comfort and more reliable results.

Motor nerve conduction studies provide another means of measuring pelvic floor neuropathy. The axon of a nerve is stimulated, and the time it takes the action potential to reach the muscle supplied by the nerve is recorded. The delay between stimulation and the muscle response is called the nerve latency. Pudendal nerve terminal motor latency (PNTML) can be determined by transrectal stimulation of the pudendal nerve using a St. Mark’s electrode (77). A nerve stimulator is mounted on an examination glove at the fingertip (Fig. 25.3) and positioned transrectally over each ischial spine. A stimulus of up to 50 mV over a duration of 0.1 milliseconds is applied, and the latency of the EAS muscle contraction is measured. A value of 2.2 milliseconds or less is considered normal. A recent study evaluating normative values for pudendal and perineal nerve latencies observed increased latencies with increased age (78). Prolongation of the PNTML is indicative of damage to that nerve or the presence of a demyelinating condition. Pudendal nerve function has prognostic value in the surgical repair of traumatic sphincter injuries (79) and is useful in preoperative counseling.

Figure 25.3  St. Mark’s electrode used for measuring pudendal nerve motor terminal latency. The stimulating electrode is on the fingertip, and the receiving electrode is on the proximal finger near the knuckle.
CHAPTER 25 Anorectal Dysfunction

Anal Manometry

Anal manometry is used to quantify function of the anal sphincter mechanism. Water-perfused manometry catheters or water-filled balloons are most often used to measure anal canal pressures. Resting anal canal pressures reflect IAS function, and pressures in the lower anal canal during maximal voluntary contraction reflect EAS function. Vector analysis can be used to detect asymmetry within the anal sphincter. Anal manometry provides indirect evidence of sphincter injury; low resting tone indicates IAS injury, and decreased maximum squeeze pressures indicates EAS injury. Anal pressures are influenced by a variety of factors, including tissue compliance and muscular tone. Consequently, anal manometry results are difficult to interpret and correlate poorly with the specific anatomic defect. Interpretation is further complicated by the wide variation of normal pressure values that change with age and parity. Significant overlaps occur between manometric values for incontinent patients and those without incontinence. Thus, anal manometry may be of limited value in the evaluation and treatment of anal sphincter defects and fecal incontinence.

Proctoscopy and Flat Tire Test

Proctoscopy has an important role in the evaluation of fecal incontinence. It can be performed independently or during colonoscopy, flexible sigmoidoscopy, and flat tire test. Proctoscopy can detect anorectal pathology, such as prolapsing hemorrhoids, intussusception, ulcerative or radiation proctitis, or a solitary rectal ulcer. The flat tire test is added when a rectovaginal or colovaginal fistula is suspected but cannot be visualized on routine office evaluation. This test usually is performed under anesthesia but can also be done in the office setting. Saline or water is placed in the vagina with the patient in Trendelenberg’s position. Using a proctoscope or rigid sigmoidoscope, air is instilled into the rectum. Vaginal retractors provide visualization of the posterior vaginal epithelium and vaginal apex. Observation of bubbling into the vaginal fluid confirms the diagnosis of a rectovaginal or colovaginal fistula. The rectal site of the fistula usually is identifiable, depending on the size and location of the fistula as well as the quality of the bowel preparation.

Disordered Defecation

Sitzmark Study

Colonic transit studies are performed using ingested radiopaque markers followed by serial abdominal radiography. Patients are asked to follow a high-fiber diet over the test period and avoid the use of laxatives, suppositories, or enemas. A capsule containing 20 to 24 markers is ingested initially, and abdominal radiography is performed either daily or on the fourth day, the seventh day, and every 3 days thereafter until all the markers are gone. Segmental transit times are then calculated using a mathematical formula. Colonic transit study results are used to classify patients with constipation into delayed transit, normal transit, and outlet obstruction. After day 6, there should be fewer than five markers remaining in the colon. With slow transit, more than five markers are scattered throughout the colon. With outlet obstruction, more than five markers are in the rectosigmoid region, and transit is normal throughout the rest of the colon.

Pelvic Floor Fluoroscopy and Magnetic Resonance Imaging

Pelvic fluoroscopy permits radiological evaluation of pelvic floor and anorectal anatomy and physiology. It is particularly useful in obstructive defecation disorders, such as intussusception, rectocele, enterocele, anismus, and perineal descent. The patient is placed on a radiolucent commode, and contrast material is instilled into the rectum. The addition of vaginal, bladder, and oral contrast material is helpful diagnostically when multicompartmental prolapse is suspected. A series of lateral still images or continuous imaging using videography are made with fluoroscopy while the patient is at rest, during defecation, and with contraction of the anal sphincter. Similar films can be obtained for evacuation of the bladder. Pelvic fluoroscopy has many names, including defecography,
defecating proctography, defecating cystoproctography, and colpocystoproctography, depending on the technique used. The measurements obtained include size of the rectal ampulla, length of the anal canal, anorectal angle, puborectalis motion, and pelvic floor descent. Severity of prolapse and pelvic floor descent is quantified in relation to the pubococygeal line. Pelvic fluoroscopy is superior to physical examination for diagnosing enterocele (80), and this technique has the advantage of being able to distinguish enteroceles from sigmoidoceles. Rectosphincteric dyssynergia may be present when the patient experiences incomplete relaxation of the puborectalis muscle during rectal evacuation, the anorectal angle is preserved, and there is incomplete emptying. Pelvic fluoroscopy is considered the definitive test for diagnosing intussusception (81), and it is the preferred technique for quantifying perineal descent.

**Dynamic MRI with luminal contrast is an imaging modality similar to pelvic fluoroscopy.** Its ability to detect prolapse is similar to that of fluoroscopy, but MRI can visualize pelvic floor musculature and soft tissue, thus giving it the advantage of detecting ballooning of the levator muscles and levator ani hernias. The supine position of the testing is a drawback; however, there are isolated reports of upright dynamic MRI using open scanners that show results comparable to fluoroscopy for detection of anorectal pathology (82). Fluoroscopy and dynamic MRI can be used in situations involving severe multicompartmental prolapse or in which the severity of the symptoms is disproportionate to examination findings.

**Anal Manometry**

Anal manometry is used to determine maximum resting pressure, maximum squeeze pressure, rectal sensation and compliance, as well as the presence of an intact rectoanal inhibitory reflex. With disordered defecation, it can be used to diagnose Hirschsprung disease and anismus. The addition of surface EMG to document relaxation helps exclude anismus as a cause of obstructed defecation. Failure of the anal sphincter to relax with defecation and increased electrical activity of the EAS and puborectalis are seen in patients with anismus. In contrast, there should be no increase in the electrical activity measured by surface electrodes for patients with Hirschprung disease.

**Colonoscopy and Proctoscopy**

Standard gastrointestinal evaluation for patients with symptoms of disordered defecation should include a barium enema or colonoscopy to eliminate the possibility of colorectal malignancy. Proctoscopy should be included as part of the routine examination because it may reveal anorectal pathology.

**Therapeutic Approach to Fecal Incontinence**

Treatment of fecal incontinence should first focus on nonsurgical options, including dietary modification, medical therapy, and biofeedback. Any underlying systemic conditions or gastrointestinal disorders should be treated before initiating an extensive evaluation for other causes of fecal incontinence. If symptoms persist, further investigation should be undertaken. If the evaluation discloses an underlying EAS defect and conservative therapy has been unsuccessful, it is reasonable to proceed with surgical treatment.

Following is an overview of treatment options and the efficacy of each approach. The lack of a consistent outcome measures makes it difficult to compare efficacy among treatments. Some studies base success on strict conformity with criteria for continence, but the results vary for continence of flatus, liquid, or solid stool. Other studies base success on more subjective criteria, such as improvement following treatment. Daily diaries can be maintained, but the results may be unreliable. Even if a validated symptom survey and quality-of-life scale are employed, few studies use the same outcome measure.
Nonsurgical Treatment

Nonsurgical management focuses on maximizing the continence mechanism through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one to two well-formed stools per day. The rationale for this approach is that formed stool is easier to control than liquid stool. Additionally, behavior modification can be employed using bowel regimens that focus on the predictable elimination of feces. Physical therapy and biofeedback can also be useful for strengthening the continence mechanism.

Pharmacologic Approaches

Dietary Modification and Fiber

Dietary modification for treatment of fecal incontinence frequently involves avoidance of foods that precipitate loose stools and diarrhea. Common dietary irritants include spicy foods, coffee and other caffeinated beverages, beer and alcohol, and citrus fruits. Avoidance of dairy products or the addition of lactase dietary supplements is essential for those with lactose intolerance. The addition of fiber may improve fecal incontinence by functioning as a stool bulking agent to increase volume and density. The average individual in the United States consumes less than one half of the recommended daily fiber intake (25–35 g). Various fiber sources are listed in Table 25.7, with the highest content found in fiber cereals. It is difficult to consume the recommended daily amount from diet alone, and fiber supplements often are required. Although the increased stool volume and density helps many individuals maintain continence, excessive fiber with inadequate fluid intake may predispose elderly patients to fecal impaction.

Constipating Agents

Constipating agents have the most value in patients with chronic loose stools or diarrhea. They can also help improve symptoms in patients with fecal frequency and urgency. Loperamide (Imodium) and diphenoxylate hydrochloride with atropine (Lomotil) are the most commonly used agents. Loperamide has been shown to prolong transit time and stimulate anal sphincter function. With either of these agents, careful titration is recommended to prevent the primary side effect of constipation. It is generally preferable

to begin using 2 to 4 mg of *loperamide* daily and then titrate up to 4 mg three to four times per day. A 4-mg dose before meals has been shown to increase anal tone and improve continence (83). *Lomotil* is started at a dose of 1 to 2 tablets every day or every other day and titrated up to 1 to 2 tablets three to four times a day as needed. Caution should be exercised for patients taking other anticholinergic medications. Anticholinergic side effects include dry mouth, drowsiness, lightheadedness, and tachycardia. *Codeine* can also be used as a constipating agent. It should be used judiciously in those with chronic disorders and in elderly patients because of side effects common to narcotics, including addiction with prolonged usage and central nervous system and respiratory depression. A study of 82 geriatric patients documented the efficacy of pharmacologic treatment for fecal incontinence (84). Patients were treated based on the underlying cause. Those with fecal impaction received lactulose and enemas, whereas those with neurogenic fecal incontinence received codeine phosphate as a constipating agent and enemas. The rate of cure for fecal incontinence was 60% in the treatment group versus 32% for controls (P < 0.001).

**Medications for Irritable Bowel Syndrome**

**Dietary treatment of IBS consists of avoiding foods that are associated with symptoms, including alcohol, caffeine, sorbitol, and foods that increase gas production.** Although increased dietary fiber or fiber supplementation has been shown to improve the constipation-predominant form of this illness, fiber supplementation has little effect on the diarrhea variant associated with fecal incontinence. Pharmacologic therapy is directed toward the predominant symptom. *Loperamide* and *Lomotil* tend to be useful first-line agents for treating diarrhea. Tricyclic antidepressants improve abdominal discomfort and are also valuable in diarrhea-predominant patients because of their constipating effect. The serotonin type 3 (5HT3) antagonist *alosetron* (*Lotronex*) has been approved by the U.S. Food and Drug Administration for the treatment of severe diarrhea-predominant IBS refractory to treatment. It has shown improvement in global assessment measures, but its use is limited because of multiple isolated case reports of ischemic colitis. The recommended dose is 1 mg once or twice daily. It does not appear to be effective for the spastic-pain variant of IBS. Anticholinergics (*dicyclomine*, *hyoscyamine*) and antispasmodics (*mebeverine*, *pinaverine*) are targeted at the pain and bloating symptoms but may also be useful for the diarrhea variant because of their constipating side effects. Studies comparing anticholinergic medications to placebo show inconclusive results with only modest benefits. Antispasmodic agents may also be of value and are available in many countries but are not approved for use in the United States. Currently, additional 5HT3 antagonists and 5HT4 antagonists are under development. Most studies are poorly designed and difficult to interpret because of a high placebo response rate that often exceeds 30% (85,86).

**Behavioral Approaches**

**Biofeedback**

Biofeedback can be an effective therapeutic modality provided patients are motivated and comprehend instructions. The two proposed mechanisms through which biofeedback improves fecal continence are afferent and efferent training. Afferent training focuses on improving sensation in the anorectal canal through recruitment of adjacent neurons to decrease the sensory threshold of volume stimulation. The goal of this training is to enhance and restore anal sensation and the rectoanal inhibitory reflex. Efferent training enhances and restores voluntary contraction of the EAS, which permits additional recruitment of motor units and stimulates muscle hypertrophy. These two methods of training can be performed independently, but are often combined for additional therapeutic benefit. The most common training method uses an intrarectal balloon. The balloon acts to stimulate rectal distention and provide pressure feedback from coordinated or synchronized contraction of the...
pelvic floor muscles. Other techniques focus on strength training of the EAS alone using anal pressure feedback or EMG or afferent training alone using an intrarectal balloon without pelvic floor muscle contraction in response to the stimulus.

More than 35 studies have been done to evaluate the efficacy of biofeedback for treatment of fecal incontinence, and several excellent review articles and meta-analyses have determined the effects of individual treatments and predictors of patient response to treatment (87–89). The results of all of these studies uniformly agree that biofeedback and pelvic floor exercises improve fecal incontinence and have a role in clinical practice. They also agree that the existing literature is fraught with methodologic problems and lacks validated outcomes and controls. Thus it is difficult to compare directly the study results.

Biofeedback is an ideal first-line therapy because it offers an effective, minimally invasive treatment without any reported adverse events. Biofeedback also appears to provide a higher probability of successful outcome than standard medical care for treating functional fecal incontinence (67% versus 36%, respectively, \( P < 0.001 \)) (87).

A Cochrane review of biofeedback and exercises for treatment of fecal incontinence found only five randomized or quasirandomized control trials that qualified for inclusion (90). The authors concluded that there is insufficient evidence to evaluate the efficacy of exercises and biofeedback for treatment of fecal incontinence. Specifically, they were not able to determine which patients are suitable for treatment, nor which method of treatment is optimal. A meta-analysis of biofeedback techniques included a review of 13 studies using strength training alone, 4 studies with sensory training alone, and 18 with coordinated sensory and strength training (89). The authors found no advantages between coordinated training (67% improved) and strength training (70% improved). However, strength training using EMG appeared to be better than strength training with anal canal pressure biofeedback (74% versus 64% improved, respectively, \( P < 0.04 \)). The limitations of this study and the literature were acknowledged.

A large randomized control trial of biofeedback for fecal incontinence in 171 patients, divided into four treatment groups, showed no significant benefit when comparing standard care to similar care with the addition of biofeedback (54% versus 53% improvement, respectively) (91). In all groups, there was a high median rating of change of symptoms and median satisfaction with benefits relatively maintained at 1-year follow-up. All groups also displayed improvement in the validated symptom surveys and quality-of-life measures as well as in anal sphincter function. The authors concluded that interactions with the therapist, patient education, and development of better coping strategies seem to be the most important factors for improvement rather than pelvic muscle exercises or biofeedback. Additional benefit may be derived with augmented biofeedback using electrical stimulation (92).

There are no clear indicators to predict which patients will benefit from biofeedback. Potential factors include age, duration and severity of incontinence, prior treatments or surgery, and severity of neurologic or physical damage. Controversy exists as to whether response to biofeedback is dependent on the presence of a structurally intact anal sphincter or normal pudendal nerve function (93–96). There is an obvious need for well-designed control trials using validated symptom surveys and quality-of-life instruments. More objective measures are desirable, and studies should carefully document duration of treatment and length of follow-up.

**Bowel Regimens**

The goal of bowel regimens is to achieve predictable elimination of feces. This can be accomplished by using the gastrocolic reflex as well as by dietary and pharmacologic means. Defecation immediately following meals involves the physiologic response of the
SECTION VI  Urogynecology and Pelvic Reconstructive Surgery

gastrocolic reflex to facilitate predictable emptying. The strength of the gastrocolic reflex varies among individuals and may be hypoactive or hyperactive with certain systemic disorders, such as diabetes and multiple sclerosis. This technique can be especially useful in the morning to give the individual freedom from fecal incontinence throughout the day. The use of suppositories or enemas in the morning or at night in conjunction with the gastrocolic reflex may provide further relief of daytime symptoms. The goal is to leave the rectum empty between evacuations. Enema use, typically once or twice daily, should be titrated to the patient’s baseline colonic activity. Regular toileting in elderly patients in nursing homes can improve fecal incontinence caused by overflow incontinence from fecal impaction. The use of cone-tip colostomy-irrigation catheters is reserved for patients in whom other therapeutic modalities have failed. These catheters avoid the risk of rectal perforation and provide a dam to prevent efflux of the irrigating solutions (97).

Surgical Treatment

In general, surgical treatment should be employed after conservative measures have failed. Although there may be exceptions to this principle, most surgeons follow this recommendation because of the poor long-term outcomes and high complication rates with surgery for fecal incontinence.

Overlapping Sphincteroplasty

Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter. Most authorities believe that an overlapping technique is superior to an end-to-end repair, although there are few direct comparisons in the literature. The rationale for the overlapping technique is that a more secure repair can be accomplished by placing sutures through the scarred connective tissue rather than the sphincter muscle. Sutures should be less likely to tear through or pull out of connective tissue than muscle. Therefore, the key component of the overlapping technique is preservation of the scarred ends of the ruptured EAS for suture placement.

Technique

The initial step involves wide mobilization of the ruptured EAS without excision of the scarred ends of the sphincter. This is accomplished through an inverted semilunar perineal incision or a transverse incision near the posterior vaginal fourchette with inferolateral extension. The latter incision facilitates repair in patients with damage to the recto-vaginal septum attachment to the perineal body. Patients with EAS defects have either a band of intervening fibrous scar tissue between the viable muscular ends of sphincter or a complete separation with scar tissue present only on the ruptured ends of the sphincter. In the presence of complete separation of scar tissue, perineal body reconstruction usually is indicated at the time of repair to restore normal anatomy. A Peña muscle stimulator aids in identification of the distal ends of the EAS and differentiates viable muscle tissue from scar tissue. The stimulator can be used to outline the sphincter before incision as well as during the dissection. It is important to apprise the anesthesiologist of the stimulator usage so that paralytic agents are avoided.

Excessive lateral dissection of the EAS past the 3 and 9 o’clock positions should be avoided as this is where the inferior rectal branches of the pudendal nerve innervate the EAS. Moderate bleeding often is encountered during this dissection, and the use of needlepoint electrocautery can maximize hemostasis. Controversy exists regarding the need to separate the EAS and IAS before repair. Identification of the intersphincteric groove facilitates dissection of the EAS. Dissection in this plane is relatively simple and avoids damage to either sphincter. Defects in the IAS can be more difficult to visualize because this muscle is intimately associated with the rectal mucosa. Examination with a finger in the anal canal is often helpful.
CHAPTER 25 Anorectal Dysfunction

The reconstruction begins with repair of an existing IAS defect using a 3-0 delayed absorbable monofilament suture. Next, the EAS defect is repaired with the primary goal of overlapping at least 2 to 3 cm to ensure adequate bulk of sphincter muscle encircling the anal canal. The EAS is overlapped using three to four mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. Once the sutures are tied, there should be resistance palpable with placement of a finger in the anal canal. Copious irrigation is performed throughout the procedure. Following sphincter repair, a perineal body reconstruction and rectocele repair should be undertaken, if indicated, to maximize the normal continence mechanism. Finally, the perineal skin is closed with interrupted absorbable monofilament sutures. Closure frequently requires modification of the initial incision because of changes in the perineal architecture that result from the repair. The most common approach is an inverted Y-shaped closure of the incision (Fig. 25.4).

Some surgeons recommend the overlapping repair regardless of whether it is performed immediately postpartum, delayed postpartum, or several years after obstetric injury. Performance of the overlapping technique is difficult immediately postpartum and requires

![Figure 25.4 Overlapping sphincteroplasty procedure. A: Inverted semilunar perineal incision with the distal ends of the external sphincter outlined using the Peña muscle stimulator. B: The external sphincter has been dissected, the scar divided in the midline, and the internal sphincter repaired. C: The external sphincter is overlapped using three mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. D: The sutures are tied. E: The skin is closed.](image-url)
adequate anesthesia, exposure, and equipment. Many surgeons believe that this can only be accomplished in the operating room. This repair lacks the theoretical advantage of using scar tissue to improve suture holding; however, it maximizes surface area for scarification of the sphincter ends. For a delayed postpartum repair, it is recommended to wait 3 to 6 months to permit complete resolution of inflammation and reinnervation. Two randomized control trials compared end-to-end approximation to overlapping sphincteroplasty
Figure 25.4  (continued)
One study randomized 112 primiparous women undergoing immediate repair of a third- or fourth-degree sphincter tear. The authors did not detect any significant differences in objective or subjective outcomes between either of the two repairs at 3 months follow-up. Approximately one half of the women had minor alteration in fecal continence, whereas 7 (6\%) had daily soiling. Despite good symptomatic results, 74 (66\%) had full-thickness EAS defects on endoanal ultrasonography. The other randomized trial involved a delayed repair in 23 patients more than 1 year following delivery. The scar was preserved for each repair, and a puborectalis plication was performed. At a median follow-up of 18 months, there were no detectable differences in continence scores; however, the study was clearly underpowered.

**Efficacy**

Despite the many large series reporting the outcomes of overlapping sphincteroplasty, almost all are retrospective in nature and lack validated measures of symptom severity and quality-of-life considerations. Several overlapping sphincteroplasty series with a total of 891 patients were evaluated from 1984 to 2001. Although the length of follow-up was variable, the results showed excellent and good outcomes in approximately two thirds of patients (median 67\%, range 52\%–83\%) (100). None of these studies had long-term outcomes.

More recent studies suggest poor long-term outcomes for the overlapping sphincteroplasty. In a series of 55 women who underwent overlapping sphincteroplasty for fecal incontinence secondary to obstetric trauma (101), researchers contacted 47 (86\%) patients by postal questionnaire and telephone interview with a median time since surgery of 77 months (range 60–96 months). The investigators observed less symptomatic improvement when compared with the results at 15 months postoperative evaluation. After excluding one patient because of Crohn disease, eight (17\%) failed because they required additional surgery, such as colostomy, postanal repair, and artificial bowel sphincter. Among the remaining 38 patients, 27 (71\%) reported improved bowel control, 5 (13\%) were unimproved, and 6 (16\%) were worse. No patient was fully continent to solid and liquid stool and flatus. Only 23 (50\%) patients had “good” outcomes defined as not requiring further continence surgery and fecal incontinence less than once per month.

In another study, investigators contacted 49 (69\%) of 71 patients by telephone interview (102). All underwent overlapping sphincteroplasty with a median follow-up of 62.5 months (range 47–141 months). Only 6 (12\%) patients were totally continent, and another 18 (37\%) were continent to liquid and solid stool. In other words, more than half of the patients had incontinence to liquid or solid stool. The largest series with long-term follow-up involved contact of 130 (71\%) of 191 patients using a postal or telephone questionnaire (103). The median time from surgery for respondents was 10 years (range 7–16 years). Of those who responded, 6\% had no incontinence, 16\% were incontinent of flatus only, 19\% had soiling only, and 57\% were incontinent of solid stool. These outcomes were significantly worse than the previously reported 3-year assessment (104). Despite the fact that 61\% had a poor outcome defined as having fecal incontinence or requiring additional surgery for incontinence, 62\% still considered their bowel control to be better than before surgery, and 74\% were satisfied with the results of their surgery. Thus, although control may be improved when compared with preoperative status, continence outcomes do not seem to be maintained at long-term follow-up.

The cause of this deterioration in long-term outcomes is unknown. Possible explanations include weakening of the muscles with normal aging, repair breakdown, and underlying nerve damage from either obstetric injury or the repair itself. A problem with most studies is the lack of a follow-up ultrasonography to determine if the repair is intact. The effect of
pudendal nerve function on overlapping sphincteroplasty is somewhat controversial. Significantly lower success rates have been shown in a comparison of those with normal pudendal nerve terminal motor latencies to those with abnormal latencies (63% versus 17%, \( P < 0.01 \)) (105). Other studies have confirmed this finding (79,106,107), but the more recent studies fail to show a difference based on preoperative neurophysiologic testing (101,103). Other controversial factors that may affect outcome include age, duration of fecal incontinence, size of the defect, and anal manometry results.

Although there are many controversial aspects to overlapping sphincteroplasty, the literature is in agreement that diverting colostomy is not necessary (99,108,109); bowel confinement does not improve outcomes (99,108,110); clinical improvement correlates with postoperative endoanal ultrasonography results (101,111,112); and prior sphincteroplasty does not affect outcomes (105,111,113).

Subsequent Deliveries

Multiple studies confirm the impact of anal sphincter laceration during the first delivery on the risk of a sphincter laceration in a second delivery (114–116). These studies have calculated odds ratios ranging between 2.5 and 5.3 for a second sphincter disruption. Two recent population-based studies revealed adjusted odds ratios of 4.2 (95% CI, 3.9–4.6) and 4.3 (95% CI, 3.8–4.8) (115,116). These odds ratios probably represent underestimates because they do not take into account higher cesarean delivery rates in subsequent births for women with a history of sphincter laceration. Both of these studies observed significantly increased risk of recurrent sphincter laceration associated with increased birth weight. The studies estimated that approximately 25 cesarean deliveries have to be performed to prevent one recurrent sphincter laceration. In fact, only 10% of women with anal sphincter lacerations at second delivery had a history of prior sphincter laceration. Therefore, although a history of prior sphincter laceration increases the risk of recurrent sphincter laceration, the risk remains relatively small. Nevertheless, it is important to accurately counsel expectant mothers about their risk of sphincter laceration. Using this information, they can decide whether the risk of recurrent laceration outweighs the risk of elective cesarean birth. The risk of subsequent vaginal delivery on symptoms of fecal incontinence is unknown for women with a repaired anal sphincter. The presence or absence of pre-existing fecal incontinence, as well as the estimated fetal weight, should be considered in counseling for a subsequent pregnancy.

Graciloplasty

Surgical reconstruction with a muscle flap should be considered in cases in which there is insufficient muscle to repair the EAS and all conservative measures have failed. Insufficient muscle can be caused by trauma or severe atrophy that results from denervation injury and congenital disease. Most patients considering this procedure have already undergone an overlapping sphincteroplasty that failed. Graciloplasty, first described by Pickrell et al. in 1952 (117), is a skeletal muscle transposition procedure that uses the gracilis to create a new anal sphincter. There are three suitable muscles for this type of procedure: the gracilis, sartorius, and gluteus maximus. Ideally, the muscle should be easily mobilized and transposed but not essential for locomotion or posture. The sartorius and gluteus maximus are suboptimal because the sartorius receives segmental vascularization, which restricts rotation, and the gluteus maximus is important in daily activities such as running, climbing stairs, and rising from a sitting position. The gracilis is a better choice because it can easily be mobilized without damage. As the most superficial adductor, it receives neurovascular supply proximally and has no important independent function.
Technique

Either one long incision or three small incisions are made in the medial thigh. The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. Anterior and posterior perianal incisions are made approximately 1.5 cm from the anal verge. Tunnels are developed in the extrasphincteric space and from the proximal thigh to the anterior perianal incision. The gracilis muscle is then gently delivered to the anterior perianal incision, guided around the anus to the posterior perianal incision, and returned to the anterior incision encircling the anal canal. The distal tendon of the gracilis is passed behind the muscle and anchored to the contralateral periosteum of the ischium. In cases where there is inadequate length, it can be sutured to the ipsilateral ischium. This procedure can also be performed bilaterally.

In patients with a large rectovaginal fistula or cloaca, a myocutaneous flap can be mobilized and used to help close the defect. Improvement of fecal incontinence is caused by passive increase of the resistance of the anal canal by the bulk of the encircling muscle (Fig. 25.5).

Experimental efforts to improve the efficacy of this procedure have focused on developing resting tone in the transposed muscle through the use of an implanted neurostimulator. The intent of the stimulated graciloplasty is to convert the fast-twitch muscle fibers into slow-twitch muscle fibers, which are more fatigue resistant. Initially, implantation of the pacemaker was performed at 6 weeks after the graciloplasty, but now most are performed concomitantly. Stimulation can be applied directly to the obturator nerve or intramuscularly to the nerve branches inside the muscle. The muscle is stimulated at a cyclic frequency, with gradual increases every 2 weeks. After 2 months, continuous stimulation is performed. Stimulation is adjusted to maintain tonic contraction around the anus, and it is interrupted or turned off to defecate.

Efficacy

An exhaustive review of the published literature identified 37 articles of patients undergoing dynamic graciloplasty (118). Most of these articles were case series, and there were no randomized trials or cohort studies evaluating safety and efficacy. Mortality rate was 1% (range 0%–13%, 95% CI, 1%–3%) after excluding cancer deaths. There was a high rate of morbidity (1.12 events per patient). Thus, most patients will have at least one adverse event, and several will have multiple complications. There is also a very high reoperation rate. The most common complications were infections (28%), stimulator and lead faults (15%), and leg pain (13%). Satisfactory continence was achieved 42% to 85% of the time, although satisfaction was not defined consistently across studies. The authors concluded that dynamic graciloplasty appeared to have equal or better efficacy than colostomy but carried a higher morbidity rate. Another review of the three largest case series (119–121) found success rates ranging from 55% to 78%. Major infections were found in 13% to 29%, pain in 27% to 28%, and device or lead problems in 12% to 18%. More recent series containing large numbers of patients found similar results for efficacy, morbidity, and reoperation rate (122,123). High rates of disturbed evacuation also were reported.

Artificial Sphincter

The artificial anal sphincter is an alternative to a graciloplasty. This is a modification of the device originally designed to treat urinary incontinence. The current device is the Acticon® Neosphincter (American Medical Systems, Minnetonka, Minnesota, USA) (Fig. 25.6). The indications for its use are similar to those for the graciloplasty.

Technique

Implantation of the artificial anal sphincter is performed, similar to the graciloplasty, through perianal tunnels. A Silastic inflatable cuff is placed around the native sphincter.
Figure 25.5 Graciloplasty. A: The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. B: Anterior and posterior perianal incision are made approximately 1.5 cm from the anal verge. The muscle is then tunneled around the extrasphincteric space circumferentially. The distal tendon is passed behind the muscle and anchored to the contralateral periosteum of the ischium.

to occlude the anal canal. A pressure-regulating balloon containing radio-opaque solution is situated in the retropubic space, and a control pump is positioned in the labia majora. Activation of the control pump deflates the cuff, permitting defecation (see Fig. 25.6).
Efficacy

A recent extensive review of the literature summarized 13 case series and one case report from 1996 to 2003. There were no randomized trials or cohort studies (124). The largest series consisted of 112 patients (125). There was one series with 53 patients, and all others had fewer than 28 patients apiece (126). Explantation was required in 17% to 41% of patients. Reasons for explantation included infection, erosion, device malfunction, pain, incontinence, and dissatisfaction, with infection being the most common. Surgical revision was necessary in 13% to 50% of the reports. Almost everyone had at least one adverse event, and more than one third of these events required surgical intervention. Reasons for surgical revision were similar to those for explantation. Rates of fecal impaction ranged from 6% to 83%. All studies recorded statistically and clinically significant improvement in continence scores for patients with a functional artificial sphincter; however, most did not report the continence status for those in whom the device was explanted. The proportion of patients with a functional device ranged from 49% to 85%. The authors concluded that there is insufficient evidence on the safety and effectiveness of the artificial sphincter for fecal incontinence.

One randomized control trial of 14 patients compared artificial sphincter with a program of supportive care (127). Supportive care included all aspects of conservative management.

Figure 25.6  Acticon® Neosphincter. This device includes an inflatable cuff placed around the anal canal, a balloon reservoir stored behind the pubic bone, and a pump located in the labia. (Courtesy of American Medical Systems, Inc. Minnetonka, Minnesota, www.AmericanMedicalSystems.com.)
such as physiotherapy, dietary advice, pharmacotherapy, and advice regarding skin care, odor management, anxiety reduction, and use of incontinence aids or appliances. Significant improvements in continence scores and quality-of-life measures were seen in the artificial sphincter group but not in the control group at 6 months follow-up. Explantation rate was 14% (1 of 7 patients). Two other patients had complications, including severe fecal impaction and perineal wound erosion requiring reoperation. The authors conclude that the artificial sphincter is safe and effective compared with supportive care alone. They anticipate perioperative and late complications, which may require explantation in up to one third of patients. It is also remarkable that only one patient (14%) whose condition was managed conservatively had significant improvement based on continence scores, whereas the status of all others was relatively unchanged.

Another study compared the effectiveness of artificial sphincter with dynamic graciloplasty (128). Two surgeons each performed four consecutive operations with each technique to minimize the learning curve of a new operation. Each started with a different procedure to avoid discrepancies in the time of follow-up. This prospective cohort study involved eight patients in each group who had similar demographic variables. Length of follow-up was 44 months in the artificial sphincter group and 39 months in the dynamic graciloplasty group. Early postoperative complications were similar in each group at 50%, as were late complications, with both groups reporting a high reoperation rate of 63%. There were six (75%) late complications in the artificial sphincter group, of which three (38%) were nonreversible and required explantation. Postoperative continence scores were significantly lower with the artificial sphincter than with graciloplasty. The authors conclude that artificial sphincter has better efficacy and similar morbidity compared with dynamic graciloplasty. The rate of late complications for the artificial sphincter exceeded that reported in the literature, which may indicate poor long-term durability. Postoperative continence scores reflect those reported for artificial sphincter but are far worse than those for dynamic graciloplasty. The authors feel that the learning curve with the artificial sphincter is less important than that with graciloplasty.

Sacral Nerve Root Stimulation

**Sacral neuromodulation** (InterStim®, Medtronic, Minneapolis, Minnesota, USA) was approved by the U.S. Food and Drug Administration for treatment of urinary urge incontinence in 1997 and for nonobstructive urinary retention and urgency in 1999. It has been employed experimentally for the treatment of fecal incontinence. The exact mechanism of action has not been fully elucidated. The goal of sacral nerve stimulation is to recruit residual function of the continence mechanism through electrical stimulation of its peripheral nerve supply. Initially, indications were confined to patients with deficient EAS and levator ani function without gross morphologic defects and intact neuromuscular connections. More recently, the acceptable indications have expanded to include deficiency of the IAS, limited structural defects, and functional deficits of the internal and external anal sphincter.

**Technique**

The device is instilled exactly the same way as for treatment of urinary incontinence. Current application is performed as a two-stage outpatient surgical procedure. The first stage involves instillation of the electrodes. The electrode is placed through the S2-4 foramen using minimally invasive surgical technique. During the test phase, multiple electrodes can be employed either bilaterally or at different levels to determine the site with the best response. Proper location is confirmed intraoperatively using fluoroscopy as well as visualization of an appropriate pelvic floor muscle response (bellows) with minimal plantar flexion of the first and second toes, which usually corresponds to S3 stimulation. An interval testing phase utilizes an external pulse generator that typically lasts 1 to 2 weeks. Those with a good response (decrease in fecal incontinence episodes
SECTION VI Urogynecology and Pelvic Reconstructive Surgery

of at least 50% documented by bowel-habit diary) will proceed to the second stage, implantation of the permanent pulse generator (IPG). Typically only one electrode is left in place at the end of the second stage. Once the permanent pulse generator is implanted, all adjustments are made using telemetry. The patient has a basic remote control that enables her to turn the device on or off and adjust the amplitude of the stimulation.

Efficacy

By the end of 2003, sacral nerve stimulation had been used to treat more than 1,300 patients with fecal incontinence (129). Despite this large number, the analysis of the results is limited to several small case series. In all studies, significant improvements in continence scores lasting up to 99 months occurred. Most patients experienced at least a 75% improvement in continence scores, and improvement also occurred in the frequency of incontinence episodes, the ability to postpone defecation, and bowel emptying. Intent-to-treat analysis revealed 80% to 100% therapeutic success. There also were significant improvements in quality-of-life measures using validated measurement scales. Complications occurred in 0% to 50% of patients, with the most common complications consisting of pain at the electrode or IPG site, electrode migration, infection, or worsening of bowel symptoms. No permanent sequelae occurred, however. Effects of anorectal physiology varied among the published studies, highlighting the fact that the precise mechanism of action remains unclear.

A review of both fecal incontinence and constipation found that 149 (56%) of the 266 patients went on to permanent implantation (130). The rate of permanent implantation was higher for most studies, approximating 80%. Among implanted patients, 41% to 75% were completely continent to solid and liquid stool, and 75% to 100% had at least a 50% improvement in the number of incontinent episodes. One double-blind crossover trial with two patients had the stimulators set below the sensory threshold and turned on or off for 2-week intervals (131). The number of fecal incontinence episodes per week improved from two to zero for one patient and from ten to one for the other patient. In another review, 19 (13%) adverse events occurred in 149 patients, findings that were similar to those mentioned previously (130). Thus, sacral nerve stimulation appears to be a promising new treatment for fecal incontinence with relatively limited complications.

Therapeutic Approach to Constipation

As with fecal incontinence, it is imperative to attempt conservative management of constipation and defecatory dysfunction before performing surgery. Initial evaluation should focus on identifying any underlying systemic conditions (see Table 25.1) associated with disordered defecation and optimizing treatment for these conditions. In the absence of systemic etiologies, it is reasonable to proceed with empiric, nonsurgical management, such as diet, fiber supplementation, and toileting behavior. Biofeedback and laxatives can be used in more severe cases. Initially, disimpaction with regular enemas or laxatives is essential if the patient has fecal impaction. Symptoms that persist despite a trial of conservative management indicate the need for further evaluation of colonic and anorectal function. A diagnostic algorithm for idiopathic (nonsystemic) constipation is given in Figure 25.7. Treatment should then be tailored to the underlying cause. Some conditions associated with disordered defecation are best treated using nonsurgical techniques, whereas others may benefit from surgery once conservative management has failed. As with fecal incontinence, the lack of consistent outcome measures in the published literature makes it difficult to compare efficacy among treatments.
Nonsurgical Treatment

Nonsurgical management focuses on maximizing anorectal function through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one stool every day or every other day. Additionally, behavior modification can be employed using regular toileting to prevent fecal impaction. Physical therapy and biofeedback can also be useful for coordinating pelvic floor and anal sphincter relaxation with defecation.

Pharmacologic Approaches

Dietary Modification and Fiber

The role of increased fluid and fiber intake for the treatment of constipation is controversial. For years, it has been a commonly accepted belief that constipation is caused by low fluid intake and can be improved by increasing consumption. Several studies showed no association between fluid intake and constipation (132–134). However, one large study of 21,012 nursing home residents found a weak association between decreased fluid intake and constipation with an odds ratio of 1.49 (135). In one interventional study, increased fluid intake failed to improve stool frequency, consistency, or defecatory dysfunction in children (136). Another interventional study using fiber and mineral water displayed an increase in stool frequency and a decrease in laxative use in adults with constipation (137). This study lacked baseline data collection resulting in recall bias, and the use of mineral water containing magnesium may confound the results because of its mild laxative effect. Overall, the existing data do not support increased fluid intake to treat constipation unless there is evidence of dehydration (132).
The addition of fiber may improve constipation through several mechanisms. Fiber acts as a stool bulking agent and improves stool consistency through water absorption. It can also act as a substrate for bacterial proliferation and gas production. These mechanisms of action are believed to result in increased colonic motility, decreased transit time, and increased stool frequency.

**Fiber therapy appears to have a beneficial effect in the treatment of diverticular disease** (138), **constipation of pregnancy** (139), and possibly **IBS** (140). Its efficacy for idiopathic (nonsystemic) constipation remains uncertain. Dietary fiber intake for patients with constipation was similar to that of controls in several studies (133,134). A meta-analysis of 36 randomized trials using laxatives or fiber therapy for the treatment of constipation showed that the use of fiber or laxatives resulted in increased stool frequency and improved symptoms without the presence of severe side effects (141). Conversely, another meta-analysis showed an inability to restore transit time and stool weight in constipated patients using dietary fiber (140). Approximately one half of the patients in another study responded to fiber treatment, but a much better response occurred in patients without an identifiable structural or motility disorder (142). Consequently, a low-fiber diet may be a contributing factor in chronic constipation, and an empiric trial of fiber therapy can be expected to help some patients. Side effects of increased gas production may limit compliance with treatment, so doses should be slowly titrated. Fiber therapy should be avoided in patients with impaction, megacolon or megarectum, or obstructive gastrointestinal lesions. Fiber therapy should also be used with caution in patients with cognitive dysfunction (dementia), difficulty with ambulation, and underlying neurogenic disease for fear of worsening the condition. There is no evidence to substantiate the recommendation for extra water intake with fiber supplements (143).

**Laxatives**

Laxatives are commonly used to treat constipation and disordered defecation. Many classes of laxatives are available over the counter.

**Bulk-forming Laxatives** These come in natural forms (*psyllium*) as well as synthetic form, (*Metamucil, Konsyl, Citrucel*), and are felt to be the safest laxatives. They have mechanisms of action and side effects similar to that of fiber (144).

**Hyperosmolar Laxatives** These consist of poorly absorbed substances that increase intraluminal osmolarity and water absorption. This action results in greater stool volume with decreased consistency. Examples include nonabsorbable sugars (*lactulose and sorbitol*), *glycerin*, and *polyethylene glycol* (*GoLytely*). Polyethylene glycol is a common preoperative bowel preparation. Side effects are diarrhea, increased flatus, and abdominal cramping (144).

**Emollient Laxatives** These agents are divided into two subsets: *docusate salts* and mineral oil. The *docusate salts* have hydrophilic and hydrophobic properties similar to detergents. They soften stool and decrease surface tension by increasing stool water and lipid content. Examples include *docusate calcium* (*Surfak*), *docusate potassium* (*Dialose, Kasof*), and *docusate sodium* (*Colace, Comfolax*). They also improve the absorption of other laxatives and are combined in preparations with stimulant laxatives such as *Correctol, Peri-Colace, and Feen-a-Mint*. The limited absorption of mineral oil allows it to penetrate and soften the stool. It can be used orally or rectally. Prolonged daily use can lead to decreased absorption of the fat-soluble vitamins A, D, E, and K. Use of mineral oil should be avoided in elderly and debilitated patients, as well as in those with esophageal motility disorders because of the potential for aspiration pneumonia. Side effects include diarrhea, anal leakage, and pruritis ani (144–146).
Saline Laxatives These usually contain magnesium cations and phosphate anions that are relatively nonabsorbable and produce an osmotic gradient with increased water absorption. They also stimulate intestinal motility by increasing cholecystokinin release. Fast-acting effects can be seen with both oral (2–6 hours) and rectal (15 minutes) preparations. Examples include magnesium citrate, magnesium hydroxide (Milk of Magnesia), magnesium sulfate, sodium phosphate, and biphosphate (Phospho-soda, Fleet enema). Although generally well tolerated, electrolyte abnormalities can occur. These side effects should be avoided in patients with renal insufficiency because of the potential for magnesium toxicity (144–146).

Stimulant Laxatives These are found in three basic types: castor oil, anthraquinones, and diphenylmethanes. A metabolite of castor oil, ricinoleic acid, increases intestinal motility and secretion. Anthraquinones (cascara sagrada, senna [Senekot], casanthranol [aloe], and danthron) are absorbed by the small intestine and stimulate motility by increasing intraluminal fluid and electrolyte content. Diphenylmethanes (phenolphthaleins [Feen-a-Mint, Correctol] and bisacodyl [Dulcolax]) have a mechanism of action similar to anthraquinones. These agents are potent and are intended for short-term use in cases refractory to bulk or osmotic laxatives. It has been a long-standing belief that prolonged use can lead to a dilated atonic colon known as cathartic colon syndrome, melanosis coli, or neuronal degeneration. A recent article refutes the theory that stimulant laxatives damage the autonomic nervous system when used at recommended doses (132). Other side effects include cramping, nausea, and abdominal pain (144–146).

Prokinetic Agents Medications that stimulate gastrointestinal motility primarily through neuromodulation of acetocholine levels include metoclopramide, cisapride, cholinergic agonists (bethanechol), cholinesterase inhibitors (neostigmine), and serotonin agonists. Their efficacy in the treatment of chronic idiopathic constipation is uncertain. Metoclopramide is better for upper gastrointestinal motility disorders, whereas cisapride appears to exert its effect at the level of the colon (144–146).

Behavioral Approaches Behavioral techniques such as biofeedback and bowel regimens may have a role in certain conditions associated with constipation and defecatory dysfunction. Overall, these approaches have far less application to disordered defecation than to fecal incontinence. Biofeedback is important in the treatment of anismus. Relaxation techniques and behavioral modification may be helpful for IBS. Bowel regimens in conjunction with laxatives, suppositories, and enemas can facilitate emptying by optimizing the gastrocolic reflex and increased peristaltic activity.

Efficacy of Nonsurgical Treatment Irritable Bowel Syndrome The most commonly used first-line treatment for the constipation variant of IBS is fiber supplementation and osmotic laxatives. The efficacy of bulking agents for this condition is controversial, and many studies, including meta-analyses, exhibit an effect similar to placebo. There may be benefit to the use of fiber because of the high placebo effect with IBS treatment and lack of serious adverse events associated with its use. However, patients may experience exacerbation of bloating and abdominal discomfort with fiber therapy. There are limited data (no randomized control trials) to determine the efficacy of osmotic laxatives. They can be useful as adjunctive treatment options, but can also exacerbate abdominal pain and discomfort. A newer class of drugs., serotonin 5HT4 agonist
Tegaserod (Zelnorm), stimulates peristalsis, increases colonic motility, decreases intestinal transit times, and reduces visceral hypersensitivity. The recommended dose is 6 mg twice daily. Randomized trials have consistently shown an approximately 10% greater improvement in global IBS symptoms when compared with placebo. Improvement in the bloating and pain symptoms also occurred. No episodes of ischemic colitis or cardiac toxicity have been reported with the use of this medication, and the most common side effects are diarrhea and headache. Cisapride, a 5HT4 agonist with partial 5HT3 antagonist actions, has been withdrawn from use secondary to rare cardiac toxicity. Additional 5HT4 agonists, 5HT3 agonists, and cholecystokinin antagonists are in development (85,86).

Colonic Inertia and Slow-Transit Constipation

Patients with slow-transit constipation tend to respond poorly to fiber supplementation, although most have already tried an empiric trial of fiber before testing to confirm the diagnosis (142). Some patients may benefit from regular toileting, either in the morning or after meals when there is increased colonic motor activity. Biofeedback may have modest short-term benefits, but the long-term effect is questionable (147). Enemas and suppositories can be used in conjunction with bowel regimens. It is also reasonable to attempt a trial of any of the laxatives listed in Table 25.8. Stimulant laxatives commonly are used, but questions remain about the development of neuronal degeneration with prolonged usage. It is imperative that patients adhere to and not exceed the recommended dosages. Data regarding laxative use for this condition have failed to show a significantly better response than placebo. Prokinetic agents are intuitively the ideal choice to stimulate colonic motility. Currently there is only one available prokinetic agent, tegaserod, approved for the treatment of constipation that improves colonic transit. Its data are almost entirely based on treatment of IBS, and there is a lack of information for its use in slow-transit constipation. Other prokinetic agents in various stages of testing include bethanechol, neostigmine, cholecystokinin antagonists, misoprostol, colchicine, neurotrophin-3, and other 5HT4 agonists such as prucalopride and mosapride (40).

Anismus

As with slow-transit constipation, initial management using bowel regimens, laxatives, enemas, suppositories, and fiber supplementation is appropriate for patients with anismus, yet many will have already tried conservative management before undergoing testing to confirm the diagnosis. These treatments are relatively well tolerated with few serious side effects. They have not been shown to have greater efficacy when compared with placebo, and their role in the treatment of anismus remains uncertain. Specific treatment for this condition tends to focus on biofeedback because of studies indicating that this is an acquired behavioral disorder of defecation. Modalities such as diaphragmatic muscle training, simulated defecation, and manometric or electromyography-guided anal sphincter and pelvic muscle relaxation have been employed independently or combined with other techniques. These techniques have yielded symptomatic improvement in approximately 60% to 80% of patients. Many patients with dyssynergic defecation also have abnormal rectal sensation, so rectal sensory conditioning may provide additional benefit (28,40,148,149). Others have tried botulinum toxin injections to paralyze the puborectalis and anal sphincter muscle. Small case series have shown modest early improvement but the results do not appear to be long lasting (150,151).

Pessary for Treatment of Pelvic Organ Prolapse

Pessaries of various shapes and sizes have been used for centuries to treat pelvic organ prolapse (152). They are a safe alternative to surgery, with the most common complications being increased vaginal discharge and erosion or ulceration of the vaginal wall. Although pessaries represent a common therapeutic modality, there are limited data regarding fitting and management (153). Even less is known about which type
of pessary is better for enteroceles and rectoceles, although the site of prolapse does not appear to affect the ability to retain a pessary (154). Pessaries can be divided into subtypes of supportive and space occupying (155). Some of the space-occupying pessaries, such as the Gellhorn and cube, use a suction mechanism to maintain vaginal retention, whereas others, like the donut, do not. In theory, space-occupying pessaries and those that exert forces against the posterior wall and vaginal apex (donut, inverted Gehrung) should aid in treatment of rectoceles and enteroceles. However, there is a lack of data regarding the efficacy of pessaries for relieving symptoms of disordered defecation. One prospective study

found that stage III–IV posterior vaginal wall prolapse was an independent predictor for discontinuation of pessary use in favor of surgical repair (156). More research is needed to determine the role of pessaries for treatment of rectoceles and enteroceles as well as symptoms that are likely to be improved using a pessary.

**Surgical Treatment**

Following is a review of the efficacy of various surgical treatments for specific conditions associated with constipation and disordered defecation.

**Slow Transit/Colonic Inertia**

**Subtotal colectomy with ileosigmoid or ileorectal anastomosis is considered by many to be the surgical treatment of choice for slow-transit constipation refractory to medical management.** Most surgeons restrict the use of this surgical procedure to the most extreme cases and typically operate on fewer than 10% of patients. Strict criteria for surgery include the following: chronic, severe, disabling symptoms unresponsive to medical therapy; slow transit in the proximal colon; no evidence of pseudo-obstruction; and normal anorectal function (144). Success rates are variable and depend on several factors. An extensive review of colectomy for slow-transit constipation analyzed 32 studies from 1981 to 1988 and found satisfaction rates ranged from 39% to 100% (157). Higher success rates occurred in studies in the United States (n = 11, median 94%, range 75%–100%) and prospective studies (n = 16, median 90%, range 50%–100%). Superior outcomes occurred in those who had a complete physiologic evaluation and proven slow-transit constipation. Patients with anismus had higher rates of recurrent symptoms and lower satisfaction levels (158). Poorer outcomes occurred with ileosigmoid and cecorectal anastomosis than with ileorectal anastomosis. Those with segmental resection (hemicolectomy) had the worst outcome. None of the studies had a comparison group, and outcomes were variable and lacking validated measures. Morbidity associated with the operation included small bowel obstruction (median 18%, range 2%–71%), need for reoperation (median 14%, range 0%–50%), diarrhea (median 14%, range 0%–46%), fecal incontinence (median 14%, range 0%–52%), recurrent constipation (median 9%, range 0%–33%), persistent abdominal pain (median 41%, range 0%–90%), and permanent ileostomy (median 5%, range 0%–28%). Mortality ranged from 0%–6% (159). A quality-of-life study revealed that the score correlated poorly with frequency of bowel movements. However, a lower score was seen in those patients who had persistent abdominal pain, diarrhea, fecal incontinence, and permanent ileostomies. Overall satisfaction with the procedure was very high and correlated with the quality-of-life score (160).

**Surgical alternatives to subtotal colectomy include ileostomy, cecostomy with antegrade continence enemas, and sacral nerve stimulation.** Subtotal colectomy has never been directly compared with ileostomy, but those who had a permanent diversion after subtotal colectomy had lower quality-of-life scores. Patients undergoing cecostomy with antegrade continence enemas can expect to have satisfactory function approximately one half of the time, with most requiring additional revision procedures secondary to stomal complications (161). Although sacral nerve stimulation has primarily been used for fecal incontinence, the results of a few small studies evoke optimism for its use in chronic constipation and slow-transit constipation (130,162,163).

**Pelvic Organ Prolapse**

The variety of surgical treatment techniques for the repair of rectocele include posterior colporrhaphy, defect-directed repair, posterior fascial replacement, transanal repair, and abdominal repair with sacral colpopexy. When an enterocele is present, a culdoplasty usually is performed. In cases of perineal descent, abdominal sacral colpoperineopexy is the procedure of choice. Suture rectopexy can be performed in
conjunction with sacral colpoperineopexy if rectal prolapse is present. Despite the routine use of these procedures, data are limited regarding symptomatic improvement of disordered defecation. Greater detail regarding the specific techniques for many of these procedures will be provided in Chapter 24. This section will focus on surgical outcomes, including anatomic cure of prolapse, improvement of defecatory dysfunction symptoms, and morbidity associated with the procedure.

**Posterior Colporrhaphy**

Posterior colporrhaphy has been the surgical procedure for rectocele repair preferred by gynecologic surgeons for more than 100 years. Traditional posterior colporrhaphy narrows the vaginal caliber through plication of the rectovaginal septum and usually includes a perineorrhaphy, which narrows the introitus. Despite its broad use, there is a paucity of data regarding long-term anatomic success, symptomatic improvement, and sexual function following the procedure. The outcomes of several studies are summarized in Table 25.9 (164–182). Anatomic cure and relief of vaginal bulge occurred in 76% to 96% of patients. In these studies, the procedure was ineffective at treating constipation, vaginal digitations (splinting), and fecal incontinence. Dyspareunia developed in 8% to 26% of patients with and without levator plication (164–168,183). As early as 1961, high rates of dyspareunia have been reported with this procedure in as many as 50% of patients (184).

Many feel that the successful anatomic support obtained with this procedure is offset by the modest relief of functional symptoms and high rate of *de novo* dyspareunia. However, a recent prospective case series of 38 women undergoing posterior colporrhaphy along with concomitant procedures for rectocele and obstructed defecation revealed markedly different results (185). Fascial plication was performed without levator plication, and perineal body reconstruction rather than routine perineorrhaphy was employed when indicated. Anatomic cure rate was 87% at 12 months and 79% at 24 months. Subjective cure rate was 97% at 12 months and 89% at 24 months. There was significant improvement in preoperative and postoperative symptoms for constipation (76% versus 24%), digitations (100% versus 16%), awareness of prolapse (100% versus 5%), obstructed defecation (100% versus 13%), and dyspareunia (37% versus 5%). There was no difference in fecal incontinence and only 1 case of *de novo* dyspareunia. The authors attribute their improved anatomic and functional outcomes and combined improvement in dyspareunia to exclusion of levator plication, perineorrhaphy, and excision of vaginal epithelium. An additional benefit may be derived during mobilization of the vaginal epithelium, when scar tissue from prior episiotomy or surgery is divided. They also found that preoperative defecating proctography was of limited value and have stopped its routine use as part of the preoperative evaluation for women with symptomatic rectoceles and obstructive defecation.

**Defect-Directed Repair**

The goal of a defect-directed repair or site-specific repair is to restore normal anatomy (30). This procedure can be combined with a perineal body reconstruction, if necessary, but usually does not routinely involve perineorrhaphy. Table 25.9 lists the anatomic and functional outcomes for this type of repair. Anatomic cure rates range from 82% to 100%, which are similar to those for posterior colporrhaphy. This procedure also resulted in modest improvement for symptoms of difficult evacuation, vaginal bulge, and vaginal digitations, which appear to be slightly better than for posterior colporrhaphy (169–173,183). Constipation symptoms significantly decreased in only one study (169). All studies reported low rates of *de novo* dyspareunia with good functional and anatomic outcomes, but the long-term durability of the procedure is unknown. All but one of these studies included concomitant prolapse and urinary incontinence procedures.

There are no randomized trials comparing posterior colporrhaphy with defect-directed repair. A retrospective (historical) cohort study of 307 patients with at least 1 year

(Continued)
Anorectal Dysfunction

of postoperative follow-up evaluated 124 women who underwent site-specific repair and 183 who underwent posterior colporrhaphy (186). The decision regarding the type of surgical repair was made intraoperatively by the surgeon. If a discrete defect was identified, a site-specific repair was performed. Otherwise, posterior colporrhaphy was performed for cases with diffuse attenuation of the rectovaginal septum. Approximately 75% of patients in each group underwent perineorrhaphy for separation of the perineal muscles.

The recurrence rates for defect-directed repairs were more than double those for posterior colporrhaphy (33% versus 14% for second degree, 11% versus 4% for third degree or greater based on the Baden-Walker halfway system). Mean postoperative point Bp was 2.2 ± 0.3 vs. −2.7 ± 0.4, respectively, based on the POP-Q system. There were no detectable differences in postoperative constipation and fecal incontinence between the two procedures. When comparing preoperative and postoperative outcomes, neither procedure improved symptoms of constipation (31% versus 35%), abdominal pain (11% versus 10%), or fecal incontinence (17% versus 19%). Dyspareunia was higher postoperatively (17% versus 8%, \( p = 0.001 \)) with no difference between surgical techniques (16% versus 17%). The high rate of dyspareunia in the absence of levator plication is most likely attributed to the perineorrhaphy, which was commonly used in both groups. Their outcomes must be interpreted with caution because of the large selection bias and lack of validated measures. Differences in postoperative blood pressure measurements may be statistically significant but not necessarily clinically significant. The results are intriguing, but future randomized control trials are necessary to ultimately determine which procedure is optimal.

### Transanal Repair

Transanal repair involves repair of the rectocele through a transanal incision with excision of redundant rectal mucosa and plication of the rectovaginal septum and rectal wall. The procedure was developed and is primarily used by colorectal surgeons to treat constipation or obstructed defecation associated with “low” or distal rectoceles. The advantages of this approach include excision of redundant rectal mucosa and the ability to treat other anorectal pathology, such as hemorrhoids or anterior rectal wall prolapse (187). Disadvantages include the inability to repair higher rectoceles, enteroceles, cystoceles, uterine prolapse, and defects in the perineal

Combined Transanal and Transvaginal Repair
body or anal sphincter (188). Major complications of infection (6%) and rectovaginal fistula (3%) are relatively rare (179). Most studies did not require vaginal bulging or protrusion symptoms as a prerequisite for surgery. The results of several studies are summarized in Table 25.8. The anatomic cure rate was 70% to 98%, and symptoms of constipation, difficult evacuation, and vaginal digitations appear to improve (178–183).

Recent reviews have compared transanal with transvaginal rectocele repair using the results of two small, randomized control trials (189–192). Women with compromised sphincter function and other symptomatic prolapse were excluded. The results for transvaginal repair were superior to those for transanal repair with respect to subjective failure rate (relative risk [RR] 0.36, 95% CI 0.13–1) and objective failure rate (RR 0.24, 95% CI 0.09–0.64) (189). In one study, a significant decrease occurred in the depth of rectocele on postoperative defecography for the transvaginal group compared with the transanal group (2.73 cm versus 4.13 cm, respectively) (192). The transvaginal group had fewer problems with bowel evacuation, but this finding was not statistically significant. In one study, researchers discovered that 38% of patients developed fecal incontinence following transanal repair (164). In the two randomized trials, no significant differences were seen in the rate of fecal incontinence or dyspareunia, but the studies were underpowered to detect a difference (191,192). Although a vaginal approach has been considered superior to a transanal approach for rectocele repair, studies are retrospective and impossible to compare because the indications for transanal repairs are generally different from those for transvaginal repairs. A prospective, randomized trial with adequate power to evaluate symptomatic outcomes of bowel and sexual function along with anatomic cure is warranted.

Posterior Fascial Replacement

Rectocele repair with graft augmentation is becoming more common despite a paucity of supporting evidence indicating its benefits over standard procedures. The reason for its emergence is the theory that vaginal hernia repairs behave similar to abdominal hernia repairs, which have a documented decrease in recurrence when augmented with grafts. A variety of graft materials have been employed with posterior colporrhaphy and defect-directed repairs including autograft, allograft, xenograft, and synthetic mesh. There are no comparison data to aid in selecting the optimal graft. The purpose of the graft is debatable. It can either be intended to replace existing fascia as a permanent barrier or to provide an absorbable scaffold for collagen deposition, scar formation, and remodeling. The ideal material should have a low erosion rate, be relatively inexpensive, and decrease recurrence rates without causing bowel or sexual dysfunction. The outcomes for rectocele repair using graft materials placed either vaginally or abdominally appear in Table 25.9 (34,168,174–177,183,193,194), High anatomic cure rates of 89% to 100% occurred, and symptoms of constipation, difficult evacuation, and vaginal bulge also appeared to improve.

The largest prospective study and only randomized trial used absorbable vaginal mesh for rectocele repair (168). Patients were randomly assigned to fascial replacement with polyglactin 910 mesh at the time of anterior and posterior colporrhaphy. There were no differences in recurrence rates when comparing 70 women with a traditional colpoperineorrhaphy with 73 women having a traditional repair plus mesh: 10% versus 8% respectively. This study did not describe changes in bowel or sexual function, and there were no mesh-related adverse events. The risks of vaginal mesh erosion and severe complications may be relatively low but carry significant morbidity, including rectovaginal fistula, persistent vaginal bleeding and discharge, dyspareunia, and the need for additional surgery (175,183). Nonsynthetic grafts appear to be safer, with fewer erosions compared with synthetic grafts. Future prospective, randomized trials are under way to assess the effect of fascial replacement on symptoms of bowel and sexual function as well as long-term anatomic cure.
Abdominal Rectocele Repair

The abdominal approach to rectocele repair may be of value when a superior defect in the rectovaginal fascia occurs in a patient with accompanying enterocele, uterine prolapse, or vault prolapse. If a patient is undergoing an abdominal or laparoscopic procedure such as a sacral colpopexy, the graft can be extended along the posterior vaginal wall to correct proximal defects in the rectovaginal septum (195). There are limited data regarding the efficacy of abdominal rectocele repair. The indication for this procedure, as well as the need for additional vaginal repair of distal defects, often is determined intraoperatively.

Sacral Colpoperineopexy for Perineal Descent

Sacral colpoperineopexy is a modification of sacral colpopexy aimed at correction of apical prolapse combined with rectocele and perineal descent (34). A continuous graft is placed from the anterior longitudinal ligament of the sacrum down to the perineal body. This procedure can be accomplished either through a total abdominal approach or a combined abdominal and vaginal procedure. If performing a total abdominal approach, the rectovaginal space is opened, and the rectum is dissected off the posterior vaginal wall and rectovaginal septum toward the perineal body. The graft is then sutured to the perineal body or as close to it as possible. A rectovaginal examination with the surgeon’s nondominant hand facilitates this attachment by supporting the perineal body. The graft is secured to additional points along the posterior vaginal wall and apex, and sacral colpopexy is completed in the usual fashion.

If performing a combined abdominal and vaginal approach, the graft is secured to the perineal body vaginally. The posterior vaginal wall is opened, and a defect-directed rectocele repair is performed. Sacral colpopexy is accomplished in the usual fashion except that the vaginal dissection is opened superiority, creating a window to the abdominal dissection. The graft can then be passed down from the abdominal field to the vaginal field and anchored inferiorly to the perineal body and laterally to the arcus tendineus fascia rectovaginalis. Alternatively, perineal body stitches can be placed vaginally and then retrieved abdominally once the rectovaginal space is entered from above. The sutures are then incorporated into the caudal portion of the graft. The idea behind the latter technique is to minimize graft exposure to the vagina, which theoretically will decrease vaginal erosion rates (Fig 25.8).

Short-term outcomes for 19 patients who underwent sacral colpoperineopexy indicated good anatomic results for apical and posterior support as well as for perineal descent (34). Complete cessation of defecatory dysfunction symptoms was accomplished in 66% of patients. In a report of outcomes for a slightly different variation of the sacral colpoperineopexy, the authors’ technique involved attachment of Marlex mesh to the perineal body using a needle carrier (194). The failure rate was 25% and mesh erosion rate was 5% for 205 patients with up to 10-year follow-up. A study of Mersilene mesh erosion rates related to sacral colpopexy and sacral colpoperineopexy (196). They noted similar erosion rates between sacral colpopexy and colpoperineopexy when the vagina was not opened, 3.2% versus 4.5%, respectively. However, the erosion rate was 16% with vaginal suture placement and 40% when the mesh was placed vaginally. The use of nonsynthetic grafts such as dermal allograft and xenograft may help prevent high erosion rates. In a case series of 11 patients, researchers performed sigmoid resection (if indicated) and suture rectopexy in conjunction with sacral colpoperineopexy using Alloderm for women with coexistent rectal prolapse, perineal descent, and defecatory dysfunction. Early follow-up (12.5 ± 7.7 months) revealed excellent improvement of defecatory dysfunction symptoms and quality-of-life considerations, with an 82% cure of perineal descent (197). Sacral colpoperineopexy appears to have value for a select group of patients, but larger prospective series with long-term anatomic and symptomatic outcomes are necessary to evaluate the durability of this procedure.
Numerous surgical procedures have been described for the treatment of rectal prolapse and are broadly categorized into perineal or abdominal approaches. Most surgeons prefer an abdominal procedure because of lower recurrence rates, reserving perineal procedures for more debilitated patients.

**Abdominal Procedures**

Abdominal procedures vary with respect to the extent of rectal mobilization, method of rectal fixation, and inclusion or exclusion of bowel resection. During abdominal rectopexy, the mesorectal plane is developed and the rectum mobilized down to the pelvic floor posteriorly, with care taken to identify and preserve the hypogastric nerves. Division of the lateral ligaments may or may not be performed. The concern is that division of the lateral ligaments will lead to rectal denervation and increased postoperative constipation. If performing a suture rectopexy, the fascia propria of the rectum is secured to the sacral peristemeum from S-1 to S-3 (198). If performing a sigmoid resection with the rectopexy (Frykman-Goldberg resection rectopexy), the bowel resection is performed after mobilization and before suturing (199). The theoretical advantages of a rectosigmoid resection are creation of...
a dense area of fibrosis between the anastomotic suture line and the sacrum; removal of abundant rectosigmoid, avoiding torsion or volvulus; additional fixation through straightening of the left colon and decreased mobility from the phrenocolic ligament; and relief of constipation in select patients. It is typically reserved for patients with a long redundant sigmoid colon, although specific criteria have not been proposed. Mesh rectopexies are usually avoided because of concern for increased complications and infections associated with placement of a foreign body at the time of bowel resection. There are two basic types of mesh rectopexy: **posterior mesh rectopexy** and **anterior sling rectopexy (Ripstein procedure)** (200,201). A variety of materials have been used for this procedure, including absorbable and permanent mesh. The assumption is that placement of this material will provide increased support through increased fibrous tissue formation. During the Ripstein procedure, an anterior sling of fascia lata or synthetic mesh is placed in front of the rectum and sutured to the sacrum. Most surgeons avoid this procedure because of fear of obstructed defecation. Modifications using a posterolateral wrap have been developed to resolve this problem.

In a series of greater than 10 patients, there were five open series and five laparoscopic reports for suture rectopexy (202). The recurrence rates ranged between 0% and 9%. Most reports showed an improvement in fecal incontinence symptoms, but the results for constipation were variable. There were no mortalities noted and no difference between laparoscopic and open results. For posterior mesh rectopexy, there were 14 open series and five laparoscopic reports. The recurrence rates ranged between 0% and 6%. As with suture rectopexy, there was general improvement in fecal incontinence, mixed results for constipation, and no differences between laparoscopic and open outcomes. The mortality rate was between 0% and 3%, with increased rates of infection if resection rectopexy was performed. For anterior sling rectopexy (Ripstein procedure), there were eight studies with a recurrence rate between 0% and 12%. Again, there was a trend toward improvement of fecal incontinence and mixed response for constipation. Mortality ranged from 0% to 3%. For resection rectopexy (Frykman-Goldberg procedure), there were nine open series and three laparoscopic reports. Recurrence ranged between 0% and 5%. There was general improvement in continence as well as an overall reduction in constipation observed in most studies. Mortality rate was 0% for all studies but one, in which it was 6.7% (203). The authors concluded that sigmoid resection did not seem to increase operative morbidity but tended to diminish postoperative constipation, possibly by causing less outlet obstruction. The study was underpowered to detect a difference in morbidity or mortality.

The laparoscopic series demonstrated similar safety and efficacy to the open techniques, and the effect on continence and constipation tended to mirror the type of rectopexy performed. In a small, randomized trial, there were significant short-term benefits with laparoscopic rectopexy compared with open rectopexy, including earlier ambulation, more rapid return to normal diet, shorter hospital stay, and lower morbidity (204). Most surgeons believe that there are no differences in recurrence rates between suture and mesh rectopexy. Consequently, the role of mesh in these procedures is suspect. The role of division of the lateral ligaments is somewhat controversial. A Cochrane Review performed in 2000 concluded that division of the lateral ligaments was associated with less recurrent prolapse but more postoperative constipation (205). The authors acknowledged the limitations of their review, which consisted of very few trials with small sample sizes and methodological weakness. A review of seven open and four laparoscopic series involving division of the lateral ligaments revealed a general improvement in fecal incontinence and either no change or worsening of constipation (202). Conversely, there were 15 open and four laparoscopic series with preservation of the ligaments that displayed improved continence and a trend toward reduced constipation. This study suggests that preservation of the lateral ligaments is associated with an improvement in fecal incontinence and constipation symptoms.
Perineal Procedures

Perineal procedures are more easily tolerated because they avoid laparotomy. Thus, they are ideal for patients at high-risk for perioperative and postoperative morbidity and mortality. There are basically two perineal procedures: the Delorme procedure and perineal rectosigmoidectomy (Altemeier operation). Perianal encirclement procedures such as the Thiersch procedure are not recommended because of poor success rates, high recurrence rates, and fecal impaction.

The Delorme procedure was first described in 1900 and involves separation of the rectal mucosa from the sphincter and muscularis propria, followed by resection of the rectal mucosa, and plication of the distal rectal wall (muscularis propria) (206) (Fig. 25.9). A review of 10 series found a recurrence rate ranging between 4% and 38% and mortality rates of 0% to 4% (202). The low mortality rates are impressive considering a higher-risk population; however, the recurrence rates make it a less desirable procedure among healthy patients. There was a general improvement in fecal incontinence and constipation. Fecal incontinence (presumably indicating anal sphincter disruption or denervation), chronic diarrhea, and severe perineal descent are associated with failure of this procedure (207). The Delorme operation may be preferred in cases when the prolapsing segment is shorter than 3 to 4 cm or there is no circumferential full-thickness prolapse, making perineal rectosigmoidectomy difficult to perform (202,208).

Perineal rectosigmoidectomy (Altemeier operation) has become the perineal procedure of choice (209). Among 12 studies, performance of full thickness excision of the rectosigmoid was associated with recurrence rates from 0% to 16% and mortality rates of 0% to 5%. Patients generally have minimal pain and a relatively uneventful postoperative course. Recurrent prolapse probably reflects inadequate resection. Incontinence results are modest at best but seem to improve substantially with the addition of levatorplasty. The addition of levatorplasty also appears to decrease the short-term recurrence rate (210), but there is no significant change in constipation with this procedure. Most agree that perineal rectosigmoidectomy with levatorplasty is the best procedure for very elderly patients and those with profound comorbidity. This is the preferred approach for patients with incarcerated, strangulated, or even gangrenous prolapsed rectal segment who are not candidates for abdominal rectopexy. Although there is a general consensus that abdominal rectopexy is better than perineal rectosigmoidectomy, there is

Puberty

Robert W. Rebar

- Normal pubertal development occurs in a predictable orderly sequence over a definite time frame.
- The major causes of delayed puberty include anatomic genital tract abnormalities and hypo- and hypergonadotropic amenorrhea.
- When pubertal development occurs asynchronously, with development of breasts in the absence of significant pubic and axillary hair, the diagnosis is usually androgen insensitivity.
- The most common cause of precocious puberty is constitutional (idiopathic), but more serious causes must be ruled out and therapy geared toward optimizing adult height.
- The most common cause of heterosexual development at the expected age of puberty is polycystic ovary syndrome (PCOS).

Puberty is the period during which secondary sexual characteristics develop and the capability of sexual reproduction is attained. The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls the monthly rhythm as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development requires an understanding of the normal hormonal and physical changes that occur at puberty. An understanding of these changes is also important in evaluating young women with amenorrhea.
Normal Pubertal Development

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is no doubt genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state. The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors. Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light.

In Western Europe, the age of menarche declined 4 months each decade between 1850 and 1960. Recent data suggest that the trend toward earlier pubertal development may be continuing among girls (but not boys) who live in the United States. It has been presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses has centered on the role of total body weight and body composition on the age of menarche. It has been argued that a girl must reach a critical body weight (47.8 kg) before menarche can occur. More importantly, body fat must increase to 23.5% from the typical 16% of the prepubertal state, which presumably is influenced by nutritional status. This hypothesis is supported by observations that menarche occurs earliest in obese girls, followed by normal-weight girls, then underweight girls, and lastly anorectic girls (Fig. 26.1). The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Moreover, girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% (6). The hypothesis linking menarche to body weight and composition does not always seem valid because menarche is a late event in pubertal development.

Physical Changes during Puberty

The changes associated with puberty occur in an orderly sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. Moreover, the pubertal changes, their relationships to each other, and the ages at which they occur are distinctly different in girls and in boys. Although this chapter focuses on girls, changes in boys are considered briefly as well.

Tanner Stage

In girls, pubertal development typically takes place over 4.5 years (Fig. 26.2). Although generally the first sign of puberty is accelerated growth, breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development.

With regard to breast development (Fig. 26.3), Tanner stage 1 refers to the prepubertal state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In Tanner stage 2, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge,
Figure 26.1 Normal twins at 12 years of age. The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menstruation are linked. (From Wilkins L. The diagnosis and treatment of endocrine disorders in childhood and adolescence. 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission).

The skin of the areolae thins, and the nipple develops to varying degrees. **Tanner stage 3** is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, **Tanner stage 4** is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until **Tanner stage 5**, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in development, and Montgomery’s glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years, but it may occur in as little as 2
years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

Pubic hair staging is related both to quantity and distribution (Fig. 26.4). In **Tanner stage 1**, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. **Tanner stage 2** is characterized by the first appearance of coarse, long, crinkly pubic hair along the labia majora. In **Tanner stage 3**, coarse, curly hair extends onto the mons pubis. **Tanner stage 4** is characterized by adult hair in thickness and texture, but the hair is not distributed as widely as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in **Tanner stage 5**.

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. **Tanner stage 1** is prepubertal. **Tanner stage 2** of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases as well. Pigmented, curly pubic hair is first
visible around the base of the penis. In Tanner stage 3, there is further growth of the penis in both length and diameter, the scrotum develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. Tanner stage 4 involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In Tanner stage 5, the genitalia are within the adult range in size. Stretched penile length measured along the dorsum averages 15.7 cm in adult men. Pubic hair spreads laterally onto the medial thighs. Hair may or may not extend from the pubic area toward the umbilicus and anus.

Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty often is accompanied by symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.
Height and Growth Rate

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (see Fig. 26.2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 13 cm taller than adult women largely because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone (GH), insulinlike growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important. Mutations limiting conversion of androgens to estrogens in males have confirmed that estrogen is the major stimulus to the pubertal growth spurt in both boys and girls (8).

During the growth spurt associated with puberty, the long bones in the body lengthen, and the epiphyses ultimately close. The bone or skeletal age of any individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas is used most often for this purpose (9). Skeletal age is more closely correlated with pubertal stage than with chronologic age during puberty. With height and chronologic age, an individual’s bone age can be used to predict final adult height using the Bayley-Pinneau tables (10).
Another practical clinical approach to predicting adult height uses midparental height. The adjusted midparental height is calculated by adding 13 cm to the mother’s height (for boys) or subtracting 13 cm from the father’s height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 8.5 cm to the calculated predicted height approximates the target range of the third to the ninety-seventh percentile for the anticipated adult height of the child. This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition also occur during pubertal development. Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men (1). The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. In this regard, testosterone is a potent anabolic steroid and is responsible for the major changes in boys, whereas estrogen increases total body fat in a characteristic distribution at the thighs, buttocks, and abdomen in girls.

Other physical changes show sexual dimorphism at puberty. In boys both the membranous and cartilaginous portions of the vocal cords lengthen much more than they do in girls, accounting for deepening of the voice. Comedones, acne, and seborrhea of the scalp begin because of increased secretion of adrenal and gonadal steroids at puberty. In general, early-onset acne correlates with the development of severe acne later in puberty. The appearance of comedones in the nasal creases and behind the pinna may be the first indications of impending pubertal development.

### Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (11). Gonadotropin levels are elevated in both female and male fetuses before birth; the levels of FSH are higher in females. At birth, gonadotropin and sex steroid concentrations are still high, but the levels decline during the first several weeks of life and remain low during the prepubertal years. The hypothalamic–pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood. Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (12).

Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (13). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (14). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day (15) (Fig. 26.5). This delay in estradiol secretion is believed to be due to the additional synthetic steps required in the aromatization of estrogens from androgens. Basal levels of both FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels (16) (Fig. 26.6). Although it now appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (17).
Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in both boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (18–20). The accelerated increases in adrenal androgens begin about 2 years before the increases in gonadotropin and gonadal sex steroid secretion when the hypothalamic–pituitary–gonadal unit is still functioning at a low prepubertal level.

In girls, estradiol, secreted predominantly by the ovaries, increases steadily during puberty (16). Although, as noted, increases in estradiol first appear during the daytime hours, basal levels eventually increase during both the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, also increases early in puberty but plateaus by midpuberty. Thus, the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes increasingly important and peripheral conversion of androgens to estrone becomes less important during maturation.

**Figure 26.5** Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol in a stage 3 pubertal girl over a 24-hour period with the encephalographic stage of sleep indicated. (From Boyar RM, Wu RHK, Roffwarg H, et al. Human puberty: 24-hour estradiol patterns in pubertal girls. J Clin Endocrinol Metab 1976;43:1418–1421, with permission.)
Figure 26.6  Increases (+ standard error) in circulating levels of gonadotropins and adrenal and gonadal steroids through puberty in girls. DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate. (From Emans SJH, Goldstein DP. The physiology of puberty. In: Emans SJH, Goldstein DP, eds. Pediatric and adolescent gynecology. 3rd ed. Boston, MA: Little, Brown, 1990:95, with permission.)
In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5α reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2 (21).

Growth hormone secretion increases along with increased gonadotropin secretion at the onset of puberty. It is believed that the increase in GH is mediated by estrogen, which in boys is dependent on aromatization of testosterone to estradiol and reflects increasing sex steroid production at puberty. Nonetheless, there are profound sex differences in GH secretion during puberty. Girls have higher basal levels of GH throughout puberty, reaching maximal levels around the time of menarche and decreasing thereafter. In contrast, basal concentrations of GH remain constant throughout puberty in boys. Growth hormone secretion is highly pulsatile, with most pulses occurring during sleep and with sex steroids increasing pulse amplitude rather than altering pulse frequency.

Growth hormone stimulates production of insulin-like growth factor 1 (IGF-1) in all tissues, with concentrations found in the circulation spilling over from the liver. During puberty the negative feedback effect of IGF-1 on GH secretion must be reduced because both IGF-1 and GH levels are high. Growth hormone and IGF-1 no doubt play significant roles in the changes in body composition that occur at puberty because both hormones are potent anabolic agents.

In the final stages of puberty in both boys and girls, GH secretion begins to diminish, returning to prepubertal levels in adult life, despite continued exposure to high levels of gonadal steroids.

**Mechanisms Underlying Puberty**

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a “central nervous system program” must be responsible for initiating puberty. It appears that the hypothalamic–pituitary–gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Current evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time (22). Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which together act as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. In turn, the increased GnRH secretion results in increased gonadotropin and then gonadal steroid secretion. What causes this “disinhibition” of GnRH release is unknown.

The relationship between body mass and the onset of puberty has focused attention on leptin, produced by adipocytes, as a candidate for the factor initiating puberty. In the infertile leptin-deficient mouse, leptin therapy can induce sexual maturation and maintain fertility. Observations of two patients with leptin receptor mutations who failed to enter puberty suggest that leptin may have a similar role in humans.

Longitudinal studies of leptin secretion have noted that there is increased leptin secretion around the time of pubertal onset. Leptin levels are increased throughout puberty in girls but not in boys. Thus, it is not clear how important leptin is to pubertal development.
Aberrations of Pubertal Development

Classification

Several aberrations of pubertal development, as detailed in Table 26.1, can occur in girls. Pubertal aberrations can be classified in four broad categories:

1. **Delayed or interrupted puberty** exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 16, or have not attained menarche 5 or more years since the onset of pubertal development.

2. **Asynchronous pubertal development** is characterized by pubertal development that deviates from the normal pattern of puberty.

3. **Precocious puberty** has been defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls (3). This new definition is controversial and has been challenged because some feel that evaluation for breast or pubic hair development before 9 or 8 years of age in white or African American girls, respectively, may be warranted (23). It is clear that, in most cases, development nearer to the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In *isosexual* precocious puberty, the early changes are common to the phenotypic sex of the individual. In *heterosexual* precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes termed “true” when it is of central origin with activation of the hypothalamic–pituitary unit. In precocious pseudopuberty, also known as *precocious puberty of peripheral origin*, secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.

4. **Heterosexual puberty** is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty.

Disorders of sexual development and amenorrhea may be considered in relation to this classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual’s height and weight on one of several commonly available growth charts (Fig. 26.7).

**Delayed or Interrupted Puberty**

The history and physical examination, with particular attention to growth, are most important in the evaluation of individuals with delayed puberty. **Pubertal delay is much more common in boys than in girls.** It is important to remember that puberty may be delayed in any child suffering from any severe chronic disease, including celiac disease, Crohn disease, sickle cell anemia, and cystic fibrosis. Thus, chronic illness should be excluded during the history and physical examination. One possible approach to evaluation is depicted in Figure 26.8.

Section VII Reproductive Endocrinology

Anatomic Abnormalities of the Genital Outflow Tract

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination (Fig. 26.9). One of the most logical classification schemes that has been proposed is shown in Table 26.2 (24). The incidence of these anomalies was estimated to be 0.02% of the female population several years ago (25), but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) (26). Of the disorders unrelated to drug use, the septate uterus (class V) is most common.

Disorders of the outflow tract and uterus often occur as part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (Rokitansky-Küster-Hauser syndrome). Familial aggregates of the most common disorders of müllerian differentiation in girls—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance (27). It is clear that the HOX genes, a family of regulatory genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period (28), and HOXA 13 has been found to be altered in hand–foot–genital syndrome.
The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (hydrocolpos) or uterus (hydrometrocolpos) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with approximately monthly exacerbations. It is sometimes difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.
Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) are compatible with normal pregnancy. However, increased fetal wastage has been reported in the presence of these anomalies (29). Uterine malformations have been associated with spontaneous abortion, preterm labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography (see Fig. 26.9). Hysterosalpingography, laparoscopy, and hysteroscopy have been used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). It is now clear that magnetic resonance imaging (MRI) and endovaginal ultrasonography (sometimes with sonohysterography) are as accurate as these invasive techniques in identifying the abnormality (30).

Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity. Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.

Hypergonadotropic and Hypogonadotropic Hypogonadism Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity (see Fig. 26.8). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty.
as well. If thyroid function is normal, a hypothalamic or pituitary neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian "failure," (i.e., primary hypogonadism).

### Forms of Gonadal Failure

**Turner Syndrome** Most affected individuals have a 45,X karyotype and Turner syndrome; still others have mosaic karyotypes (i.e., 45,X/46,XX; 45,X/46,XY) and may present with the Turner phenotype as well. Intrauterine growth restriction is common in infants with a 45,X karyotype. After birth, these patients generally grow slowly, beginning in the second or third year of life. They typically have many of the associated stigmata, including lymphedema and sometimes large cystic hygromas of the neck at birth; a webbed neck; multiple pigmented nevi; disorders of the heart, kidneys (most commonly horseshoe), and great vessels (most commonly coarctation of the aorta); and small hyperconvex fingernails (31) (Fig. 26.10). Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals.
with 45,X karyotypes. Most 45,X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development). Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females). In fact, the 45,X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy. However, trisomy is the most common chromosomal type or category of abnormality in first-trimester losses.

The short stature commonly associated with the Turner phenotype appears largely to be due to the loss of a homeobox-containing gene (which encodes for an osteogenic gene).
located on the pseudoautosomal region (PAR 1) of the short arms of the X (Xp22) and Y (Yp11.3) chromosomes (32). This gene, which is called either *SHOX* (short stature homeobox-containing gene) or *PHOG* (pseudoautosomal homeobox osteogenic gene), escapes X inactivation because of its pseudoautosomal location. The gene appears to account for about two thirds of the height deficit commonly associated with Turner syndrome.

Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of the presence of any portion of a Y chromosome. If a Y chromosome is identified, surgical extirpation of the gonads is warranted to eliminate any possibility of a germ cell neoplasm (estimated 20%–30% prevalence) (33,34). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left in situ for donor *in vitro* fertilization and embryo transfer. **Individuals with Turner syndrome are at increased risk of sudden death from aortic rupture or dissection resulting from cystic medial necrosis during pregnancy, and the risk may be as great as 2% or more** (35). Echocardiography and counseling about this risk is warranted before pregnancy is contemplated. The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous pyelography or a renal ultrasonography.

**Treatment of Turner Syndrome** To increase final adult height, commonly accepted treatment strategies include use of *exogenous GH* (36–38). With recombinant human GH use, the average height gain has varied from 4 to 16 cm. It appears that early initiation of therapy (between 2–8 years of age), gradually increasing the dose, and continuing treatment for a mean of 7 years can lead to achievement of a final height greater than 150 cm in most patients (37). Weekly doses of GH of 0.375 mg/kg divided into seven daily doses are typical. It is not clear if an anabolic steroid such as oxandrolone will provide additional growth.

The gonadal steroid treatment of patients with Turner syndrome is as follows:

1. To promote sexual maturation, therapy with *exogenous estrogen* should be initiated when the patient is psychologically ready, at about 12 to 13 years of age, and after GH therapy has been administered for several years. Low-dose estrogen can be introduced at this time without compromising final adult height (39).

2. Because the intent is to mimic normal pubertal development, therapy with low-dose estrogen alone (such as 0.025 mg/day transdermal estradiol or 0.3–0.625 mg conjugated estrogens orally each day) should be initiated.

3. Progestins (5–10 mg medroxyprogesterone acetate or 200 mg micronized progesterone orally for 12–14 days every 1–2 months) can be added to prevent endometrial hyperplasia after the patient first experiences vaginal bleeding or after 6 months of unopposed estrogen use if the patient has not yet had any bleeding.

4. The dose of estrogen is increased slowly over 1 to 2 years until the patient is taking about twice as much estrogen as the amount administered to postmenopausal women.

5. Girls with gonadal dysgenesis must be monitored carefully for the development of hypertension with estrogen therapy.

6. The patients and their parents should be counseled regarding the emotional and physical changes that will occur with therapy.
Mosaic Forms of Gonadal Dysgenesis  Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty. The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels. Levels in the normal range for the patient’s age imply the presence of functional gonads.

These individuals can become pregnant, with success rates of more than 50% using donor oocytes (40). The increased risk of sudden death during pregnancy resulting from aortic rupture should be assumed to be similar to that of other women with the Turner phenotype (35).

Pure Gonadal Dysgenesis  The term pure gonadal dysgenesis refers to 46,XX or 46,XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal dysgenesis (Fig. 26.11). Affected girls typically are of average height and have none of the stigmata of Turner syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibin. When gonadal dysgenesis occurs in 46,XY individuals, it is sometimes termed Swyer syndrome. Surgical extirpation is warranted in individuals with a 46,XY karyotype to prevent development of germ cell neoplasms. Both 46,XX and 46,XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.

In early gonadal failure, the ovaries apparently develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see Chapter 27).

Hypogonadotropic Hypogonadism  Hypothalamic–pituitary disturbances are usually associated with low levels of circulating gonadotropins (with both LH and FSH levels less than or equal to 10 mIU/mL) (41). There are both sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. Mutations in several genes have been shown to cause hypogonadotropic hypogonadism in humans (42). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both. At least six separate genes have been identified as causes of hypogonadotropic hypogonadism: (i) KAL1, (ii) FGFR1/KAL2, (iii) DAX1 (the gene for X-linked congenital adrenal hypoplasia), (iv) GNRHR (the gene for the GnRH receptor), (v) PCD1 (the gene for prohormone convertase 1), and (vi) GPR54 (encoding a G-protein coupled receptor) (43–45). Because defects in these genes account for less than 20% of all cases of isolated hypogonadotropic hypogonadism, additional mutations probably exist but have yet to be identified. It is important to remember, however, that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. In fact, constitutional delay is the most common cause of delayed puberty. In a normal population, 2% to 3% of normal children will be classified as having pubertal delay, and this finding may be considered a normal variant. Constitutional delayed growth and adolescence can be diagnosed only after careful evaluation excludes other causes of delayed puberty and normal sexual development is documented by longitudinal follow-up. The farther below the third percentile for height that the young girl is, the less likely it is that the cause is constitutional. Because some children are severely handicapped socially by constitutional pubertal delay, some physicians occasionally provide exogenous estrogen in low doses for 3 to 4 months to stimulate some pubertal development. However, the benefits of treatment are not well documented, and there is little evidence to support the idea that treatment improves psychosocial function.

Kallmann Syndrome  As originally described in 1944 (46), Kallmann syndrome consisted of the triad of anosmia, hypogonadism, and color blindness in men. Women may be affected as well, and other associated defects may include cleft lip and palate,
Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients.

Cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release. The frequency approximates 1 in 10,000 men and 1 in 50,000 women. Because autopsy studies have shown partial or complete agenesis of the olfactory bulb, the term olfacto-genital dysplasia has also been used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus (47). In some affected individuals, gene defects have been found in one protein, anosmin, that facilitates this neuronal migration, thus leading to an absence of GnRH neurons in the hypothalamus and olfactory bulbs and consequent hypogonadotropic hypogonadism and anosmia (Kallmann syndrome) (48). The gene defect resulting in loss of this facilitory
Figure 26.11 (Continued) B: A 16-year-old individual with 46,XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels. Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. (From Rebar RW. Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al, eds. *Gynecology and obstetrics: a longitudinal approach*. New York, NY: Churchill Livingstone, 1993:97–133, with permission.) C: Clitoromegaly noted in the girl with 46,XY gonadal dysgenesis depicted in Figure 26.11B. D: The same individual as depicted in Figure 26.11B and D with 46,XY gonadal dysgenesis 1 year after gonadectomy and replacement with exogenous estrogen.
adhesion protein has been localized to the Xp22.3 locus in an X-linked form of the syndrome, and this locus has been designated KAL1. Because confirmed mutations in the coding sequence of the KAL gene occur only in a minority of individuals with Kallmann syndrome (49), other mutations no doubt will be identified in the future. Moreover, the disorder is so heterogeneous that it appears likely that it forms a structural continuum with other midline defects. Septo-optic dysplasia represents the most severe form of the disorder.

Clinically, affected individuals typically present with sexual infantilism and an eunuchoid habitus, but some degree of breast development may occur (Fig. 26.12). Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but almost invariably measurable. Affected individuals respond readily to pulsatile administration of exogenous GnRH, and clearly this is the most physiologic approach to ovulation induction (40). For women not seeking pregnancy, therapy with exogenous estrogen and progesterin is indicated.

Isolated gonadotropin deficiency can also occur in association with the Prader-Labhart-Willi syndrome, which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia. When the syndrome occurs in association with the Laurence-Moon-Bardet-Biedl syndrome, retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism also may be present. Prader-Labhart-Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome (50). Laurence-Moon-Bardet-Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped to date (51).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If GH or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypopituitarism have a high mortality rate, predominantly caused by vascular and respiratory disease (52), it is important to identify affected individuals. Later age at diagnosis, female sex, and above all cranioopharyngioma have been identified as significant independent risk factors. Untreated gonadotropin deficiency also is an important risk factor for early mortality.

_Tumors of the Hypothalamus and Pituitary_ Several different tumors of the hypothalamic and pituitary regions also may lead to hypogonadotropic hypogonadism (53) (Fig. 26.13A). Except for cranioopharyngiomas, these tumors are relatively uncommon in children. Cranioopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life. Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should document hypogonadotropism and may also reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and is best managed by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.

_Other Central Nervous System Disorders_ Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans cell-type
histiocytosis, particularly the form known previously as *Hand-Schüller-Christian disease* (Figs. 26.13B and 26.13C). Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder (54).
Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency is the most frequent finding, partial or complete gonadotropin deficiency may develop in some patients. Severe chronic illnesses, often accompanied by malnutrition, also may lead to slowed growth in childhood and delayed adolescence. Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

Anorexia Nervosa and Bulimia

Significant weight loss and psychological dysfunction occur simultaneously with anorexia nervosa (55,56). Although many anorectic girls experience amenorrhea after pubertal development has begun, if the disorder begins sufficiently early, pubertal development may be delayed or interrupted (Fig. 26.14). The following constellation of associated findings confirms anorexia nervosa in most individuals:

1. Relentless pursuit of thinness
2. Amenorrhea, sometimes preceding the weight loss
3. Extreme inanition
4. Obsessive-compulsive personality often characterized by overachievement
5. Distorted and bizarre attitude toward eating, food, or weight

6. Distorted body image

Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotropic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, chemical hypothyroidism with low serum triiodothyronine (T₃) and high reverse T₃ levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism (57).

Fear of obesity, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, also may slow growth and delay pubertal development (58). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. An additive role for endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. It is clear, however, that delayed puberty will occur inevitably unless adequate caloric intake is provided.
Hyperprolactinemia  Low levels of LH and FSH may be associated with hyperprolactinemia. As noted, galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. Many individuals with prolactinomas have a history of delayed menarche. The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothyroidism also is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The empty sella syndrome, in which the sella turcica is enlarged but has been replaced by cerebrospinal fluid, may also be associated with hyperprolactinemia.

Use of Chemotherapeutic Agents  As survival rates following treatment for childhood malignancy improve, the effects of cancer therapy become ever more important. Both radiation therapy to the abdomen and systemic chemotherapeutic agents, particularly alkylating agents, have toxic effects on germ cells. Although prepubertal gonads appear less vulnerable than those of adults, ovarian failure is common. An argument can be made for endocrine assessment as early as 1 year following completion of therapy to identify children who will suffer from hypogonadism. Spontaneous ovarian activity can resume even years after therapy.

Asynchronous Puberty  Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair present (Fig. 26.15). In this disorder, 46,XY individuals have bilateral testes, female external genitalia, a blindly ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (59). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as incomplete androgen insensitivity.

Asynchronous puberty is heterogeneous but is always related to some abnormality of the androgen receptor or of androgen action (60). In perhaps 60% to 70% of cases, androgen receptors cannot be detected (i.e., the patient is receptor negative). In the remaining cases, androgen receptors are present (i.e., receptor positive), but mutations in the androgen receptor gene have been detected or there is a defect at a more distal step in androgen action (i.e., a postreceptor defect). Receptor-positive individuals are indistinguishable clinically from receptor-negative individuals. Several different mutations in the androgen receptor gene, most of which occur within the androgen-binding domain of the receptor, have been identified in affected individuals who are receptor positive. Severe X-linked androgen receptor gene mutations cause complete androgen insensitivity, whereas mild mutations impair virilization with or without infertility, and moderate mutations result in a wide phenotypic spectrum of expression among siblings (61).

Because the Sertoli cells of the testes make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes are often normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. Recognizing that most such girls will be 46,XX, it is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus cannot be detected with certainty by ultrasound.

The frequency of gonadal neoplasia is increased with this condition, but the extent is uncertain (33). Most clinicians believe the risk for neoplasia is low before 25 years of age;
Figure 26.15  A: This 17-year-old individual presented with primary amenorrhea and was found to have a blind-ending vagina and bilateral inguinal masses. Circulating levels of testosterone were at the upper limits of the normal range for men, and the karyotype was 46,XY, confirming androgen insensitivity. B: Two inguinal testes were found at surgery. (From Simpson JL, Rebar RW. Normal and abnormal sexual differentiation and development. In: Becker KL, ed. Principles and practice of endocrinology and metabolism. 2nd ed. Philadelphia, PA: JB Lippincott, 1995:788–822, with permission.)
thus, the testes should be left in place until after pubertal feminization, especially because the risk of neoplasia appears to increase with age. Exogenous estrogen should be provided after gonadectomy.

The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46,XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient has been reared as a girl. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

**Precocious Puberty**

Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). Precocious puberty is 20 times more common in girls than in boys. In fully 90% of girls, the precocious development is idiopathic, whereas this appears to be true for only 10% of boys. Family history, the rapidity with which secondary sexual characteristics are developing, the rate of growth, and the presence or absence of central nervous system disease should all be considered in deciding whether to pursue evaluation of a girl for precocious puberty. The evaluation of precocious puberty is as follows:

1. **Measurement of basal gonadotropin levels** is the first step in the evaluation of a child with sexual precocity (Fig. 26.16).

2. **Thyroid function should also be evaluated** to rule out primary hypothyroidism as the cause of precocious development.

3. **High levels of LH** (which really may be human chorionic gonadotropin detected because of cross-reactivity with LH in immunoassays) suggest a gonadotropin-producing neoplasm, most often a pinealoma (ectopic germi-noma) or choriocarcinoma or, less often, a hepatoblastoma. (Gonadotropin-producing neoplasms are the only causes of precocious puberty in which the gonadotropin dependence does not equate with central precocious puberty.)

4. **Low or pubertal levels of gonadotropins indicate the need to determine circulating estradiol concentrations in girls with isosexual development and to assess androgen levels, specifically testosterone, DHEAS, and 17α-hydroxyprogesterone in girls with heterosexual development.**

5. **Increased estradiol levels suggest an estrogen-secreting neoplasm, probably of ovarian origin.**

6. **Increased testosterone levels suggest an androgen-producing neoplasm of the ovary or the adrenal gland.** Such neoplasms may be palpable on abdominal or rectal examination. Increased 17α-hydroxyprogesterone levels are diagnostic.
of 21-hydroxylase deficiency (i.e., congenital adrenal hyperplasia [CAH]). Levels of DHEAS are elevated in various forms of CAH as well.

7. If the estradiol levels are compatible with the degree of pubertal development observed, evaluation of the central nervous system by MRI or CT scanning is warranted.

8. Bone age should always be assessed in evaluating an individual with sexual precocity.

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (precocious thelarche) or the appearance of pubic or axillary hair alone (precocious pubarche or adrenarche) (Fig. 26.17). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and to proceed with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents. Premature thelarche may be caused by
increased sensitivity of the breasts to low levels of estrogen or to increased estradiol secretion by follicular cysts. Premature adrenarche or pubarche may be due to increased sensitivity to low levels of androgens and must be distinguished from late-onset (nonclassic) CAH. If there is no evidence of breast development and the appearance of sexually stimulated hair (i.e., precocious puberty) or of progression, these conditions are virtually always benign.

Some girls with premature adrenarche are at risk of developing polycystic ovarian syndrome (PCOS) (62). Although mean androgen levels are within the normal range, a significant minority have an exaggerated response to corticotropin stimulation. Moreover, the magnitude of this response is inversely related to insulin sensitivity. Thus, premature adrenarche may be the first sign of insulin resistance or PCOS in some individuals. Treatment of coexisting obesity and long-term follow-up are indicated to address potential complications of PCOS and insulin resistance.

Constitutional (idiopathic) sexual precocity is the most common cause of precocious puberty. It is often familial and represents the so-called “tail” of the gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty). In many of these girls, puberty is slowly progressive, but in a few, development progresses rapidly. The major complication of sexual precocity is limitation of height. Thus, therapy, may be warranted to prevent this consequence.

### Central (True) Precocious Puberty

In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed constitutional or idiopathic. Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. Tumors of the hypothalamus include hamartomas and, less frequently, neurogliomas and pinealomas. It appears that hamartomas produce GnRH in a pulsatile manner and thus stimulate gonadotropin secretion (63) (Fig. 26.18). A number of congenital malformations, including hydrocephalus, craniostenosis, arachnoid cysts, and septo-optic dysplasia, also can be associated with precocious puberty (as well as with sexual infantilism).

### Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (64). Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time. Of the various ovarian neoplasms that can secrete estrogens, granulosa-theca cell tumors occur most frequently but are still rare (65). Although such tumors may grow rapidly, more than two thirds are benign.

The McCune-Albright syndrome is characterized by polyostotic fibrous dysplasia of bone, irregular café-au-lait spots on the skin, and hyperfunctioning endocrinopathies. Girls develop sexual precocity as a result of functioning ovarian cysts. Other endocrinopathies may include hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly. It is now known that mutations of the Gs \(_{\alpha}\) subunit of the G protein, which couples extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and, presumably, for the other defects present in this disorder (66). Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods, as well as the topical use of estrogens, have been implicated in cases of precocious development in infants and children. Severe primary
Figure 26.17 Five-year-old girl with development of pubic hair (A) as shown more closely in (B) (precocious adrenarche). Gonadotropin levels were prepubertal, and bone age was appropriate for age. No further development occurred until breast budding at approximately age 9.
hypothyroidism has also been associated with sexual precocity; associated hyperprolactinemia may result in galactorrhea in affected individuals.

**Congenital Adrenal Hyperplasia**

*Heterosexual precocious puberty* is always of peripheral origin and is most often caused by CAH. Three adrenal enzyme defects—21-hydroxylase deficiency, 11β-hydroxylase deficiency, and 3β-hydroxysteroid dehydrogenase deficiency—can lead not only to heterosexual precocity but also to virilization of the external genitalia because of increased androgen production beginning *in utero* (67). The clinical presentation of the various forms of CAH depends on the following factors: (i) the affected enzyme, (ii) the extent of residual enzymatic activity, and (iii) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

**21-Hydroxylase Deficiency** Most patients with classic CAH have 21-hydroxylase deficiency (Fig. 26.19). All forms of 21-hydroxylase deficiency are caused by homozygous or compound heterozygous mutations in the human *CYP21A2* gene, which encodes the 21-hydroxylase enzyme; in the carrier, heterozygote state, only one allele is mutated (68). Two *CYP21A2* genes, a 3' *CYP21A2B* gene encoding the functional enzyme and a pseudogene termed *CYP21A2A*, are situated very close to each other within the major histocompatibility locus on the short arm of chromosome 6. At least one fourth of cases of 21-hydroxylase deficiency are due to unequal crossover and genetic recombination between the two genes during meiosis. However, severe mutations do not correlate with severe phenotype, and phenotypic variability likely depends on the activity of other interacting genes.

Neonatal screening suggests an incidence of about 1 in 15,000 births. Because of the location of the gene within the major histocompatibility locus, siblings with 21-hydroxylase deficiency usually have identical human leukocyte antigen (HLA) types. There are various forms of 21-hydroxylase deficiency, including simple virilizing or classic (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid as well as glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). The nonclassic form is discussed in the following section on heterosexual pubertal development.

**Deficiency of 21-hydroxylase results in the impairment of the conversion of 17α-hydroxyprogesterone to 11-deoxycortisol and of progesterone to deoxycorticosterone** (Fig. 26.20). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris and fusion of the labioscrotal folds and the urogenital sinus. The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. Almost two thirds of affected newborns rapidly develop salt-wasting 21-hydroxylase deficiency, hyponatremia, hyperkalemia, and hypotension. During childhood, untreated girls with either the classic or salt-wasting form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual differentiation in which normal pregnancy and childbearing are possible. The classic and salt-wasting forms of 21-hydroxylase deficiency are easily diagnosed based on the presence of genital ambiguity and markedly elevated levels of 17α-hydroxyprogesterone. Some states have initiated neonatal screening programs to detect 21-hydroxylase deficiency at birth.

**3β-Hydroxysteroid Dehydrogenase** Deficiency of 3β-hydroxysteroid dehydrogenase (3β-HSD), caused by mutations in the *HSD3B2* gene encoding the 3β-HSDII enzyme,
affects the synthesis of glucocorticoids, mineralocorticoids, and sex steroids. Typically, levels of 17-hydroxypregnenolone and DHEA are elevated (see Fig. 26.20). The classic form of the disorder, detectable at birth, is quite rare, and affected girls may be masculinized only slightly. In severe cases, salt wasting may also be present.

A nonclassic form of this disorder may be associated with heterosexual precocious pubertal development (as is the classic form if untreated), but postpubertal hyperandrogenism occurs more often. The androgen excess in individuals with nonclassic 3β-HSD deficiency appears to result from androgens derived from the peripheral conversion of increased serum concentrations of DHEA. This disorder is inherited in autosomal recessive fashion, with allelism at the 3β-HSD gene on chromosome 1 believed to be responsible for the varying degrees of enzyme deficiency.
11-Hydroxylase Deficiency  The classic form of 11-hydroxylase deficiency is believed to constitute 5% to 8% of all cases of CAH. Deficiency in 11-hydroxylase, caused by mutations in the CYP11B1 gene, results in the inability to convert 11-deoxycortisol to cortisol and the consequent accumulation of androgen precursors (see Fig. 26.20). Markedly elevated levels of 11-deoxycortisol and deoxycorticosterone are present in the disorder. Because deoxycorticosterone acts as a mineralocorticoid, many individuals with this disorder become hypertensive. A mild nonclassic form of 11-hydroxylase deficiency has been reported but apparently is very uncommon.

Treatment of Congenital Adrenal Hyperplasia  The treatment of CAH involves providing replacement doses of the deficient steroid hormones. Hydrocortisone (10–20 mg/m² body surface area) or its equivalent is given daily in divided doses to suppress the elevated levels of pituitary corticotropin present and thus suppress the elevated androgen levels. With such treatment, signs of androgen excess should regress. In children, growth velocity and bone age should be monitored carefully because both overreplacement and underreplacement can result in premature closure of the epiphyses and short stature. Data now indicate that early diagnosis and compliance with therapy lead to adult height within 1 standard deviation of the anticipated target height in girls with 21-hydroxylase deficiency (69).

Mineralocorticoid replacement is generally required in individuals with 21-hydroxylase deficiency whether or not they are salt losing. The intent of glucocorticoid therapy should be to suppress morning 17α-hydroxyprogesterone levels to between 300 and 900 ng/dL. Sufficient fluorocortisone should be given daily to suppress plasma renin activity to less than 5 mg/mL per hour.

Girls with ambiguous genitalia may require reconstructive surgery, including clitoral recession and vaginoplasty. Timing of such surgery is debated, but the girl must be of appropriate size to permit the surgery to be as simple as possible.

Heterosexual Pubertal Development  The most common cause of heterosexual development at the expected age of puberty is PCOS (Fig. 26.21). Because the syndrome is heterogeneous and poorly defined, clinical difficulties result in diagnosis and management (70). For the sake of simplicity, PCOS may be defined as LH-dependent hyperandrogenism (71). Most clinical manifestations arise as a consequence of the hyperandrogenism and often include hirsutism beginning at or near puberty and irregular menses from the age of menarche because of oligo-ovulation or anovulation. Clinical manifestations are as follows:

1. Affected girls may be but are not necessarily somewhat overweight.

2. In rare instances, menarche may be delayed, and primary amenorrhea also may occur.

3. Basal levels of LH tend to be elevated in most affected individuals, and androgen production is invariably increased, even though circulating levels of androgens may be near the upper limits of the normal range in many affected women.

4. In anovulatory women, estrone levels are typically greater than estradiol levels.

5. Because circulating levels of estrogens are not diminished in PCOS and androgen levels are only mildly elevated, affected girls become both feminized and masculinized at puberty. This is an important feature because girls with classic forms of CAH who do not experience precocious puberty (and even those who do) only become masculinized at puberty (i.e., they do not develop breasts).
6. Some degree of insulin resistance may be present, even in the absence of overt glucose intolerance (72).

7. Polycystic ovaries are frequently, but not always present in ultrasound examination.

**Differential Diagnosis and Evaluation**

Distinguishing PCOS from the nonclassic forms of CAH is problematic and controversial (73,74). The evaluation is as follows:

1. Some clinicians advocate measurement of 17α-hydroxyprogesterone in all women who develop hirsutism. Although values of 17α-hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxylase deficiency, they may or may not be elevated in nonclassic late-onset forms of the disorder.

2. Measurement of 17α-hydroxyprogesterone also can identify women with various forms of 11-hydroxylase deficiency.

3. Basal levels of DHEAS as well as 17α-hydroxyprogesterone may be moderately elevated in patients with PCOS, making the diagnosis even more difficult.
4. To screen for CAH, 17α-hydroxyprogesterone should be measured in early morning.

5. In women with regular cyclic menses, it is important to measure 17α-hydroxyprogesterone only in the follicular phase because basal levels increase at midcycle and in the luteal phase.

Measurements of 17α-hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 50 Yugoslavs, and 1 in 300 Italians (67). The incidence is also increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more “typical” features of nonclassic 21-hydroxylase deficiency, including severe hirsutism beginning at puberty, “flattening” of
the breasts (i.e., defeminization), shorter stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypertension might be screened as well (41) (Fig. 26.22).

**Basal Levels of 17α-Hydroxyprogesterone** Basal levels of 17α-hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCOS and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17α-hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases as well.

**Cosyntropin Stimulation Test** The most commonly used stimulatory test involves measurement of 17α-hydroxyprogesterone 30 minutes after administration of a bolus of 250 mg of synthetic cosyntropin (Cortrosyn) (75). In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17α-hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3β-HSD deficiency.

The elevated levels of 17α-hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single dose of a glucocorticoid such as dexamethasone will suppress 17α-hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

**Hirsutism** It has been suggested that androgen-receptor blockade may be preferable to glucocorticoids as primary treatment of nonclassic 21-hydroxylase deficiency (76). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder has proved to be remarkably refractory to glucocorticoids.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism also may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCOS from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17α-hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to adrenocorticotropic hormone stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (77).

**Mixed Gonadal Dysgenesis**

The term **mixed gonadal dysgenesis** is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side. Most individuals with this rare disorder have a mosaic karyotype of 45,X/46,XY and are raised as girls who then experience virilization at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

**Rare Forms of Male Pseudohermaphroditism**

Individuals who have rare forms of male pseudohermaphroditism, especially 5α-reductase deficiency (the so-called *penis at 12 syndrome*) and the Reifenstein syndrome, generally have ambiguous female genitalia with variable virilization at puberty. *Cushing syndrome*, too, may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.
Genital Ambiguity at Birth

Because of the concerns of the parents and the need to prevent life-threatening complications, the infant with genital ambiguity should be evaluated promptly. Evaluation and treatment is best conducted by a team of physicians. The initial evaluation is as follows:

1. Cytogenetic and endocrine studies should be initiated promptly. Use of specific probes for the Y chromosome and fluorescent in situ hybridization can assist in obtaining a karyotype within 48 hours. Probes for many specific inherited disorders are now available.

2. To exclude CAH, the most common cause of genital ambiguity, serum levels of sodium, potassium, and 17α-hydroxyprogesterone and urinary excretion of 17-ketosteroids, pregnanetriol, and tetrahydrodeoxycorticisol should be measured. Infants should be monitored closely to prevent development of dehydration, hyponatremia, and hyperkalemia.

3. It has been suggested that antimüllerian hormone be measured in infants with genital ambiguity because it is elevated in boys and undetectable in girls in the first several years of life (78).
Physical Signs

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach any unusual significance to the genital ambiguity and to treat the abnormality as just another “birth defect.” Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. Either a name compatible with either sex should be chosen, or the naming of the infant should be delayed until the studies have been completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features (Fig. 26.23). In normal boys, there is only a single midline frenulum on the ventral side of the phallus; in normal girls, there are two frenula lateral to the midline. A girl with clitoral enlargement still has two frenula, and a boy with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee). It is important to determine whether any müllerian derivatives are present. Recent studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (79).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a testis or a streak gonad that has undergone neoplastic transformation. If a well-differentiated fallopian tube is absent on only one side, the side without the tube probably contains a testis or ovotestis.

Diagnosis and Management

Although genital ambiguity is usually identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. It has been believed that sex-of-rearing may be changed before 2 years of age without psychologically damaging the child, but experience with individuals with 5α-reductase deficiency suggests that gender changes may be made after 2 years of age in certain instances (80). In any case, surgery for genital ambiguity to make the external genitalia (and development) as compatible with the sex-of-rearing of the child is warranted but has not always been successful. Clitoral recession and clitorectomy are the most frequently performed surgical procedures.

*Those agents proved to cause genital ambiguity do so only when administered in relatively high doses. Insufficient data exist regarding effects of dimethisterone and norgestrel. In low doses (e.g., as in oral contraceptives), progestins, even including norethindrone, seem unlikely to virilize a female fetus.
It is possible to diagnose 21-hydroxylase deficiency prenatally in patients known to be at risk (67). The diagnosis is established by documenting elevated levels of 17α-hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis also is possible. Prenatal treatment of the fetus by administering dexamethasone to the mother is usually but not always successful in preventing genital ambiguity (81). Moreover, maternal complications, including hypertension, massive weight gain, and overt Cushing syndrome, have been noted in about 1% of pregnancies in which the mothers are given low doses of dexamethasone. Despite the risks and the nonuniformity of beneficial outcome to affected female fetuses, many parents may choose prenatal medical treatment because of the psychological impact of ambiguous genitalia.

Teratogens

It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids (Table 26.3). Exposure to the teratogen must occur early in pregnancy, during genital organogenesis. Moreover, not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. However, the doses required to produce genital ambiguity are generally so great that the concern is only theoretical. The one agent that clearly can lead to genital ambiguity when ingested in clinically used quantities is danazol. There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of either mestranol or ethinyl estradiol and a 19-nor-steroid, results in virilization (82,83).

SECTION VII Reproductive Endocrinology

Amenorrhea

Wendy J. Schillings
Howard D. McClamrock

- Girls have experienced menarche at increasingly younger ages during the past century. To continue to represent two standard deviations above the mean age for development of secondary sexual characteristics and menses, respectively, the age limitations defining primary amenorrhea have been lowered. Primary amenorrhea is now defined as absence of menses at age 13 years when there is no visible secondary sexual characteristic development or age 15 years in the presence of normal secondary sexual characteristics.

- When premature gonadal failure occurs in conjunction with primary amenorrhea, it is associated with a relatively high incidence of genetic abnormalities (30%).

- The anatomic causes of amenorrhea are relatively few, and the majority may be diagnosed by history and physical examination.

- The most important elements in the diagnosis of amenorrhea include physical examination for secondary sexual characteristics and anatomic abnormalities measurement of human chorionic gonadotropin (hCG) to rule out pregnancy, and assessment of follicle-stimulating hormone (FSH) levels to differentiate between hypergonadotropic and hypogonadotropic forms of hypogonadism.

- Therapeutic measures may include specific therapies (medical or surgical) aimed at correcting the primary cause of amenorrhea, hormone replacement to initiate and maintain secondary sexual characteristics and provide symptomatic relief, treatments aimed at maintenance of bone mass (bisphosphonates), and ovulation induction for patients desiring pregnancy.

A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen; after ovulation, the follicle is
converted to a corpus luteum, and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development. If pregnancy does not occur, estrogen and progesterone secretion decrease, and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, outflow tract, and feedback mechanism) are nonfunctional, bleeding cannot occur. Amenorrhea occurs in 3% to 4% of reproductive age women who are not pregnant.

The mean age of menarche has become younger during this century. Therefore, the definition has changed: Primary amenorrhea is defined as the absence of menses by 13 years of age when there is no visible secondary sexual characteristic development or by 15 years of age in the presence of normal secondary sexual characteristics. It has been adjusted by 1 year to continue to represent two standard deviations above the mean age of developing secondary sexual characteristics and menses, respectively (1). A woman who has previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three normal menstrual cycles or 6 months (2).

Patients may develop slight alterations in the hypothalamic–pituitary–ovarian axis that are not severe enough to cause amenorrhea but instead cause anovulation. Anovulatory patients usually have irregular menses and may bleed excessively during menstruation because estrogen is unopposed. This often occurs at the beginning and end of the reproductive years. Luteal phase defect is caused by minimal alterations in the hypothalamic–pituitary–ovarian axis, and patients have regular menses along with infertility or recurrent pregnancy loss. Except for anatomic and chromosomal etiologies, luteal phase defects and anovulation have causes similar to those of amenorrhea, but the hypothalamic, pituitary, or ovarian hormonal dysfunction is less severe or of shorter duration than with amenorrhea.

To detect the cause of amenorrhea, it is useful to determine whether secondary sexual characteristics are present (Fig. 27.1). The absence of secondary sexual characteristics indicates that a woman has never been exposed to estrogen stimulation.

### Amenorrhea without Secondary Sexual Characteristics

Although the diagnosis and treatment of disorders associated with hypogonadism have been discussed in another chapter, they also will be mentioned here because these conditions may present as primary amenorrhea. Because breast development is the first sign of estrogen exposure in puberty, patients without secondary sexual characteristics have primary not secondary amenorrhea. The absence of a uterus suggests certain enzyme deficiencies (see Fig 27.1) and indicates the presence of antimüllerian hormone (AMH) in an XY individual. Because these conditions are very rare, it is easier to categorize the causes of amenorrhea in the absence breast development on the basis of gonadotropin status.

### Causes of Primary Amenorrhea

**Hypergonadotropic Hypogonadism**

Primary gonadal failure and the resulting impaired secretion of gonadal steroids are manifested by elevated levels of LH and FSH that arise from decreased negative feedback. Gonadal failure as well as primary amenorrhea are most often associated with genetic abnormalities (Table 27.1). Approximately 30% of patients with primary amenorrhea...
CHAPTER 27 Amenorrhea

have an associated genetic abnormality (3). The syndrome of gonadal dysgenesis, or Turner syndrome, and its variants represent the most common form of hypogonadism in women (see Chapter 26). Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism, pure gonadal dysgenesis (46,XX and 46,XY with gonadal streaks), enzyme deficiencies that prevent normal estrogen production, and gonadotropin-receptor inactivating mutations. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Therefore, gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis. Most patients with these conditions have primary amenorrhea and lack secondary sexual characteristics. However, occasionally patients with a partial deletion of the X chromosome, mosaicism, or pure gonadal dysgenesis (46,XX) may synthesize enough estrogen in early puberty to induce breast development and a few episodes of uterine bleeding. Ovulation and, occasionally, pregnancy are possible.
Genetic Disorders

Turner syndrome (45,X) is the most common chromosomal abnormality causing gonadal failure and primary amenorrhea (3,4). Turner syndrome is discussed in detail in Chapter 26. In addition to gonadal failure, there are associated stigmata that include short stature, webbed neck, shield chest, cubitus valgus (increased carrying angle of the arms, short metacarpals, low hair line, high arched palate, multiple pigmented nevi, and short fourth metacarpals) that are easily seen on physical examination (4).

Once the diagnosis of Turner syndrome is confirmed, studies should be performed to assure that cardiac (30% have coarctation of the aorta), renal (especially horseshoe kidney), and autoimmune (thyroiditis) abnormalities are diagnosed and treated.

X inactivation is a process that inactivates most of the genes on one X chromosome. Of the genes on the X chromosome, 20% escape X inactivation, and it is believed that loss of the second copy of these genes in a 45,X patient cause the stigmata associated with Turner syndrome (5).

It appears that patients with Turner syndrome initially have normal ovarian development. Amenorrhea is the result of accelerated atresia of the follicles. The fibrotic ovaries are called streak ovaries.

Abnormal X Chromosome 46,XX individuals with partial deletions of the X chromosome have variable phenotypes depending on the amount and location of the missing genetic material. Patients with a deletion of the long arm of the X chromosome (Xq-) from Xq13 to Xq26 have sexual infantilism, normal stature, no somatic abnormalities, and streak gonads (6,7). Some patients may be eunuchoid in appearance and have delayed epiphyseal closure. Patients with a deletion of the short arm of the X chromosome (Xp) usually are phenotypically similar to individuals with Turner syndrome (8). Many genes on the Xp chromosome escape X inactivation and act similarly to genes on autosomes. The effective monosomy created by the deletion results in the phenotypic

Genetic Disorders

**Gonadal Dysgenesis** Turner syndrome (45,X) is the most common chromosomal abnormality causing gonadal failure and primary amenorrhea (3,4). Turner syndrome is discussed in detail in Chapter 26. In addition to gonadal failure, there are associated stigmata that include short stature, webbed neck, shield chest, cubitus valgus (increased carrying angle of the arms, short metacarpals, low hair line, high arched palate, multiple pigmented nevi, and short fourth metacarpals) that are easily seen on physical examination (4). Once the diagnosis of Turner syndrome is confirmed, studies should be performed to assure that cardiac (30% have coarctation of the aorta), renal (especially horseshoe kidney), and autoimmune (thyroiditis) abnormalities are diagnosed and treated. X inactivation is a process that inactivates most of the genes on one X chromosome. Of the genes on the X chromosome, 20% escape X inactivation, and it is believed that loss of the second copy of these genes in a 45,X patient cause the stigmata associated with Turner syndrome (5).

It appears that patients with Turner syndrome initially have normal ovarian development. Amenorrhea is the result of accelerated atresia of the follicles. The fibrotic ovaries are called streak ovaries.
features of Turner syndrome (5). Most patients with a ring X have ovarian failure and
phenotypes similar to Turner syndrome, although some have been able to reproduce
successfully. These patients differ from those with Turner syndrome in that they are more
likely to be mentally retarded and have syndactyly. Patients with isochromosome of the long
arm of the X chromosome (i[Xq]) are also similar to XO patients, with the exception that
autoimmune disorders are more common. Half of the women with balanced translocations
of the X chromosome to an autosome have gonadal failure. Typically, the normal X
is inactivated to preserve the balance of autosomal genes. The gonadal failure can be
caused by the chromosomal break occurring in a gene that is required for ovarian func-
tion, abnormal meiosis, or X inactivation of the translocated X and adjacent autosomal
genes (5,9).

Mosaicism  Primary amenorrhea is associated with various mosaic states, the most
common of which is 45,X/46,XX (10). As discussed in Chapter 26, the clinical findings
in 45,X/47,XXX and 45,X/46,XX/47,XXX are similar to those in 45,X/46,XX and vary in
estrogen and gonadotropin production, depending on the number of follicles in the gonads.
When compared with the pure 45,X cell line, individuals with 45,X/46,XX and 45,X/46,XX/47,XXX are taller and
have fewer abnormalities, although 80% of those with 45,X/46,XX mosaics are shorter
than their peers, and 66% have some somatic abnormalities. Spontaneous menstruation
occurs in approximately 20% of these patients (10).

Pure Gonadal Dysgenesis  Individuals who are phenotypically female with sexual
infantilism, primary amenorrhea, normal stature, and no chromosomal abnor-
malities (46,XX or 46,XY) have pure gonadal dysgenesis
The gonads are usually streaks, but
there may be some development of secondary sexual characteristics, as well as a few
episodes of uterine bleeding.

Swyer syndrome occurs when mutations in the SRY (sex-determining region gene on
the Y chromosome) located at Yp11 result in XY females with gonadal dysgenesis
(11,12). This explains 15% to 20% of women who are 46,XY. Most of the mutations in
SRY cause abnormalities in the DNA-binding domain (the human menopausal
gonadotropin box) of the protein (13).

Mutations in other genes such as SOX9, DAX1, WT-1, and SF 1, which affect testicular
differentiation and inhibit antimüllerian hormone production, also result in XY pure
gonadal dysgenesis. The SOX9 gene located at 17q24 has a role in testis differentiation
and promotes antimüllerian hormone secretion. Some but not all mutations in the SOX9
gene are known to cause XY sex reversal, along with camptometic dysplasia (severe
skeletal abnormalities) (14,15). Duplications of the DAX 1 gene at Xp21 cause dose-
sensitive XY sex reversal (16). DAX 1 is hypothesized to antagonize the SRY gene,
preventing testis development. Transgenic XY mice with overexpression of the DAX 1
gene develop as phenotypic females, supporting this hypothesis (13). Mutation in the WT
1 gene (Wilms’ tumor suppressor gene 1) located at 11p13 causes several different
syndromes, depending on where the mutation in the gene occurs. In Frasier syndrome,
there is alternative splicing, which causes the protein product to lack a highly conserved
KTS triplet repeat. The normal +KTS isoform of the protein is believed to synergize with
SF 1 (steroidogenic factor 1) to promote the expression of antimüllerian hormone. Lack of the +KTS isoform in an XY patient results in normal female internal and external
genitalia, streak gonads, and progressive glomerulopathy. These women frequently
develop gonadoblastomas but rarely develop Wilms’ tumor, which is associated with
mutations in other locations in the WT 1 gene. XX patients with the mutation that
prevents the +KTS isoform have similar kidney abnormalities but develop normal
ovaries and genitalia (13,17,18). One XY patient with a heterozygous mutation of the
SF 1 gene had adrenal failure and sex reversal (19). SF 1 is an orphan nuclear receptor
that not only regulates AMH expression but also regulates all the cytochrome P450
steroid hydroxylase enzymes (18).
Duplication of 1p, which encodes the WNT 4 gene, has caused XY sex reversal. WNT 4 may upregulate DAX 1 transcripts. A TRX mutation has also caused XY sex reversal. Other genes that cause XY gonadal dysgenesis are likely to be identified in the future. Mutations at 9p24 and 10q cause XY sex reversal, but the exact genes causing the defects have not yet been elucidated (13,18,20).

XX pure gonadal dysgenesis can be caused by the presence of small Y chromosome fragments in their genome. It is estimated that 5% to 40% of patients with Ullrich-Turner syndrome were found to have Y sequences by polymerase chain reaction (PCR), depending on the DNA sequences targeted for testing (21,22). If Y sequences are present, gonadectomy is advised because of the risk of gonadoblastoma (21). In other patients with XX gonadal dysgenesis, the condition is likely to be caused by genes that lead to ovarian failure before pubertal development, resulting in streak gonads. Genes that cause ovarian failure are discussed later in this chapter.

**Mixed Gonadal Dysgenesis**  Most patients are XY and have ambiguous genitalia with a streak gonad on one side and a malformed testis on the opposite. A small proportion of these patients have mutations in the SRY gene (13).

**Enzyme Deficiencies**

**Congenital Lipoid Adrenal Hyperplasia**  Patients with this autosomal recessive disorder are unable to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis. A defect has not been found in the P450scc gene, which is the conversion enzyme responsible for this step in the pathway. Instead, 15 different mutations have been identified in the steroidogenic acute regulatory protein (StAR), which facilitates the transport of cholesterol from the outer to the inner mitochondrial membrane. This protein appears to be the rate-limiting step for steroid hormone biosynthesis stimulated by tropic hormones. These patients present in infancy with hyponatremia, hyperkalemia, and acidosis. Both XX and XY individuals are phenotypically female. Genetic clusters of the disorder are found in the Japanese/Korean and Palestinian Arab populations. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood. Most patients are XY and do not have a uterus. Without hormone replacement, they remain sexually infantile. XX patients may acquire secondary sexual characteristics at puberty but develop large ovarian cysts and early ovarian failure as a result of accumulation of cholesterol in the ovaries (23,24).

**17α-Hydroxylase and 17,20-Desmolase Deficiency**  Mutations in the CYP17 gene cause abnormalities in both the 17α-hydroxylase and 17,20-desmolase functions of the protein that is active in the adrenal and gonadal steroidogenic pathways. More than 20 mutations that alter the reading frame of the gene have been identified, even though fewer than 200 people have the disorder (25). Patients have either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with 46,XX karyotype. Individuals with CYP17 mutations have primary amenorrhea, no secondary sexual characteristics, female phenotype, hypertension, and hypokalemia (26). The diminished levels of 17α-hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotropic hormone (ACTH). 17α-hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. Patients with 17α-hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency prevents synthesis of sex steroids.

**Aromatase Deficiency**  This rare autosomal recessive abnormality, which has only been reported in six cases, prevents the affected individual from aromatizing androgens to estrogen. This syndrome may be suspected even before birth because most mothers of
affected children also become virilized during pregnancy. This occurs because the placenta cannot convert the fetal androgens to estrogen, and they are diffused into the maternal circulation. At birth, a female child has clitoromegaly and posterior labioscrotal fusion. At puberty, there is no breast development, primary amenorrhea, worsening virilization, absent growth spurt, delayed bone age, and multicystic ovaries. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels, and undetectable levels of estradiol. Estrogen therapy has been shown to improve the ovarian and skeletal abnormalities but must be titrated to mimic normal estrogen levels. Therefore, amounts given should be minimal during childhood and then increased at puberty (27,28).

**Gonadotropin Receptor Mutations**

**Luteinizing Hormone Receptor Mutation** Inactivation of LH receptors has been identified in XY pseudohermaphrodites with primary amenorrhea in the absence of secondary sexual characteristics caused by homozygous premature stop codon, deletions, and missense mutations in the LHR gene located on chromosome 2. The Leydig cells in these individuals are unable to respond to LH, causing Leydig cell hypoplasia. This leads to early testicular failure and prevents masculinization. XX siblings with the same mutations develop normal secondary sexual characteristics but are amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries (29,30).

**Follicle-Stimulating Hormone Receptor Mutation** An autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor, which prevents FSH binding, has been identified in six families in Finland. This condition leads to primary or early secondary amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH (31).

**Other Causes of Primary Ovarian Failure**

Amenorrhea and premature ovarian failure can occur in association with irradiation of the ovaries (32), chemotherapy with alkylating agents (e.g., cyclophosphamide) (33), or combinations of radiation and other chemotherapeutic agents. In girls, galactosemia often is associated with premature ovarian failure, but it usually is detected by newborn screening programs. Gonadotropin resistance, autoimmune ovarian failure, and ovarian failure resulting from infectious and infiltrative processes have also been described.

**Hypogonadotropic Hypogonadism**

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

**Physiologic Delay** Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the lack of physical development caused by delayed reactivation of the GnRH pulse generator. Levels of GnRH are functionally deficient in relation to chronologic age but normal in terms of physiologic development.

**Kallmann Syndrome** The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann syndrome), which has varied modes of genetic transmission, as discussed in Chapter 26. Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH. Deficiencies in GnRH may also be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. Patients with isolated deficiencies of LH and FSH usually are a normal height for their age, whereas
patients with physiologic delay of puberty are usually short for their chronologic age but normal for their bone age (34).

**Central Nervous System Tumors** Central nervous system tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracellular masses that interfere with the synthesis and secretion of GnRH or stimulation of pituitary gonadotropins. Virtually all of these patients have disorders in the production of other pituitary hormones as well as LH and FSH (35,36). Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

**Genetic Disorders**

**5α-Reductase Deficiency** 5α-Reductase deficiency should also be considered as a cause of amenorrhea (37). Patients with this disorder are genotypically XY, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures as a result of functioning AMH. 5α-Reductase converts testosterone to its more potent form, dihydrotestosterone. **Patients with 5α-reductase deficiency** differ from patients with androgen insensitivity because they do not develop breasts at puberty. These patients have low gonadotropin levels as a result of testosterone levels that are sufficient to suppress breast development and allow normal feedback mechanisms to remain intact. Normal male differentiation of the urogenital sinus and external genitalia do not occur because dihydrotestosterone is required for this development. However, normal internal male genitalia derived from the wolffian ducts are present because this development requires only testosterone. Male pattern hair growth, muscle mass, and voice deepening are also testosterone dependent.

**Gonadotropin-releasing Hormone Receptor Mutations** Several mutations have been identified in the GnRH receptor gene that cause abnormal GnRH function. Most affected patients are compound heterozygotes, but homozygous autosomal recessive mutations have also been identified. The GnRH receptor is a G-protein–coupled receptor. Functional studies show that the mutations either cause marked decrease in binding of GnRH to its receptor or prevent second-messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth (38). All patients are normosomic. **Receptor mutations in GnRH cause 17% of sporadic cases of idiopathic hypogonadotropic hypogonadism with normal olfaction** (39).

**Follicle-stimulating Hormone Deficiency** Patients with FSH deficiency usually seek treatment for delayed puberty and primary amenorrhea caused hypoestrogenism. They are distinguished from other hypoestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients, autosomal recessive mutations in the FSHβ subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, have been identified (40). Pregnancy was achieved in one patient after induction of ovulation with injectable gonadotropins (41).

**Other Hypothalamic/Pituitary Dysfunctions** Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, excessive exercise, chronic disease, neoplasias, and marijuana use (42–46). Hypothyroidism, polycystic ovarian syndrome (PCOS), Cushing syndrome, hyperprolactinemia, and infiltrative disorders of the central nervous system are rare causes of primary amenorrhea (47,48). Constitutional delay without
underlying causes is less common in girls than in boys, and the reason for lack of development should be vigorously pursued (49).

Diagnosis

A careful history and physical examination are necessary to appropriately diagnose and treat primary amenorrhea associated with hypogonadism. The physical examination may be particularly helpful in patients with Turner syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optic disks, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest central nervous system lesions (36). Galactorrhea may be seen with prolactinomas. The history of galactorrhea may provide helpful information in the diagnosis of postinfectious, inflammatory, or vascular lesions of the central nervous system; trauma; anorexia nervosa; stress-related amenorrhea; or other systemic disease process.

The diagnostic workup is summarized as follows:

1. The initial laboratory test should be assessment of serum FSH levels unless the history and physical examination suggest otherwise. The FSH level differentiates hypergonadotropic and hypogonadotropic forms of hypogonadism. If the FSH level is elevated, a karyotype should be obtained. An elevated FSH level in combination with a 45,X karyotype confirms the diagnosis of Turner syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype.

2. Because of the association with coarctation of the aorta (up to 30%) and thyroid dysfunction, patients with Turner syndrome should undergo echocardiography every 3 to 5 years and thyroid function studies yearly. They should also be evaluated for hearing loss and hypertension.

3. If the karyotype is abnormal and contains the Y chromosome, as in gonadal dysgenesis, the gonads should be removed to prevent tumors. Patients should also be screened for nephrotic syndrome, which can occur in Frasier syndrome.

4. If the karyotype is normal and the FSH level is elevated, it is important to consider the diagnosis of 17α-hydroxylase deficiency because it may be a life-threatening disease if untreated. This diagnosis should be considered when testing indicates elevated serum progesterone (>3.0 ng/mL) levels, a low 17α-hydroxyprogesterone (0.2 ng/mL) level, and an elevated serum deoxycorticosterone level (DOS) (50). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone compared with baseline levels and no change in serum 17α-hydroxyprogesterone levels.

5. If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established.

6. Central nervous system lesions should be ruled out by imaging using computed tomography (CT) or magnetic resonance imaging (MRI), especially if galactorrhea, headaches, or visual field defects are identified. Suprasellar or intrasellar calcification in an abnormal sella is found in approximately 70% of patients with craniopharyngioma (36).
7. Physiologic delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion. The diagnosis can be supported by a history suggesting physiologic delay, an x-ray showing delayed bone age, and the absence of a central nervous system lesion on computed tomography (CT) or MRI scanning.

8. Gonadotropin-deficient patients can usually be distinguished from patients with physiologic delay by their response to GnRH stimulation. Patients with physiologic delay have a normal LH response to GnRH stimulation for their bone age, in contrast with gonadotropin-deficient patients, in whom the LH and FSH responses are low (51).

<thead>
<tr>
<th>Treatment of Amenorrhea</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestin therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:</td>
</tr>
<tr>
<td>1. Therapy is usually initiated with 0.625 mg/day of conjugated estrogens or 1 mg/day of estradiol.</td>
</tr>
<tr>
<td>2. If the patient is short in stature, higher doses should not be used in an attempt to prevent premature closure of the epiphyses. Most of these patients are of normal height, however, and higher estrogen doses may be used initially and then reduced to the maintenance doses after several months.</td>
</tr>
<tr>
<td>3. Estrogen can be given daily in combination with progestin (medroxyprogesterone acetate) or progesterone to prevent unopposed estrogen stimulation of the endometrium in patients with a uterus. Medroxyprogesterone acetate may be administered at a dose of 2.5 mg daily or 5 to 10 mg for 12 to 14 days every 1 to 2 months. Oral micronized progesterone may be administered at a dose of 100 mg daily or 200 mg for 12 to 14 days every 1 to 2 months. Likewise, progesterone suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days every 1 to 2 months.</td>
</tr>
<tr>
<td>4. Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of estrogen replacement therapy (52).</td>
</tr>
<tr>
<td>5. If 17α-hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement as well as estrogen. Progestin is added if the patient has a uterus.</td>
</tr>
</tbody>
</table>

If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

1. Craniopharyngiomas may be resected with a transsphenoidal approach or during craniotomy, depending on the size of the tumor. Some studies have shown improved prognosis with radiation therapy used in combination with limited tumor removal (36,53).

2. Germinomas are highly radiosensitive, and surgery is rarely indicated (54).

3. Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (bromocriptine or cabergoline) (55).
4. Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases.

5. Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile GnRH. This form of therapy is often impractical, however, because of the necessity to use an indwelling catheter and a portable pump for prolonged periods. Therefore, these patients should be treated with cyclic estrogen and progestin therapy at least until sexual maturity is achieved. Once sexual maturation is achieved, hormone replacement therapy can be continued to treat hypoestrogenic symptoms. Alternatively, consideration may be given to nonestrogenic regimens, such as bisphosphonates for maintenance of bone mass and prevention of osteoporosis.

6. Patients with Kallmann syndrome, as well as patients with exercise or stress amenorrhea and anorexia and weight loss, are treated with hormone replacement in a similar fashion as described for hypogonadotropic hypogonadism.

7. If the patient has physiologic delay of puberty, the only management required is reassurance that the anticipated development will occur eventually (56). Individuals whose karyotypes contain a Y cell line (45,X/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors, such as gonadoblastomas, dysgerminomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation (34,50). There is some evidence that hirsute individuals without Y chromosomes should also undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad; the contralateral gonad was dysgenic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be HY antigen–positive (57). Clomiphene citrate is ineffective in inducing ovulation in patients with hypogonadism who desire pregnancy because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful, and pulsatile treatment with GnRH may be used in patients who have normal pituitary function. In patients without ovarian function, oocyte donation may be appropriate. There have been recent reports of deaths in pregnant patients with Turner syndrome resulting from aortic dissection and rupture (58). Careful counseling and investigation should be undertaken in patients with Turner syndrome before treating them with donated oocytes. Because most patients with hypogonadism and lack of sexual development are young, pregnancy is not desired.

---

**Amenorrhea with Secondary Sexual Characteristics and Anatomic Abnormalities**

**Causes**

**Anatomic Abnormalities**

Amenorrhea occurs if there is blockage of the outflow tract or if the outflow tract is missing (Table 27.2). An intact outflow tract includes a patent vagina as well as a functioning cervix and uterus. Any transverse blockage of the müllerian system (Buttram and Gibbons classification I) will cause amenorrhea (59). Such outflow obstructions include imperforate hymen, transverse vaginal septum, and hypoplasia or absence of
the uterus, cervix, and vagina (Mayer-Rokitansky-Küster-Hauser syndrome). Mayer-Rokitansky-Küster-Hauser syndrome has been associated with abnormal galactose metabolism (60). Of the patients with this syndrome, 15% have an absent, pelvic, or horseshoe kidney; 40% have a double urinary collecting system (61,62); and 5% to 12% have skeletal abnormalities (63). Transverse blockage of the outflow tract with an intact endometrium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or hemoperitoneum. Endometriosis may develop.

When the findings of the physical examination are normal, anatomic abnormalities may still be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea. Asherman syndrome, which is more common with secondary amenorrhea or hypomenorrhea, may occur in patients with risk factors for endometrial or cervical scarring. Such risk factors include a history of uterine or cervical surgery, infections related to use of an intrauterine device, and severe pelvic inflammatory disease. Asherman syndrome is found in 39% of patients undergoing hysterosalpingography who have previously undergone postpartum curettage (64). Infections such as tuberculosis and schistosomiasis may cause Asherman syndrome but are rare in the United States. Cervical stenosis resulting from surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may also lead to amenorrhea.

### Androgen Insensitivity

Phenotypic females with complete congenital androgen insensitivity (previously called testicular feminization) develop secondary sexual characteristics but do not have menses. These patients are male pseudohermaphrodites. Genotypically, they are male (XY) but have a defect that prevents normal androgen receptor function, leading to the development of the female phenotype. Defects in the androgen receptor

gene located on the X chromosome include absence of the gene that encodes for the androgen receptor and abnormalities in the binding domains of the receptor. Androgen receptor deficits are diverse and may result from diminished receptor function or concentration. The diversity of androgen receptor mutations may be related to diversity in phenotype. More than 250 extremely diverse mutations have been described, with amino acid substitution being the far most common (65,66). Postreceptor defects also exist (67). Total serum testosterone concentration is in the range of normal males. Because antimüllerian hormone is present and functions normally in these patients, internal female (müllerian) structures such as a uterus, vagina, and fallopian tubes are absent. Testes rather than ovaries are present in the abdomen or in inguinal hernias because of the presence of normally functioning genes on the Y chromosome. Patients have a blind vaginal pouch and scant or absent axillary and pubic hair. These patients experience abundant breast development at puberty; however, the nipples are immature and the areolae are pale. Testosterone is not present during development to suppress the formation of breast tissues; at puberty, the conversion of testosterone to estrogen stimulates breast growth.

Figure 27.2  A: A well-developed patient with complete androgen insensitivity. Note the characteristic paucity of pubic hair and well-developed breasts. (From Yen SSC, Jaffe RB. Reproductive endocrinology. 3rd ed. Philadelphia, PA: WB Saunders, 1991:497, with permission.) B: Another patient with androgen insensitivity syndrome with a contrasting thin body hiatus. This is a 17-year-old twin 46,XY. (From Jones HW Jr, Scott WW. Hermaphroditism, genital anomalies, and related endocrine disorders. 2nd ed. Baltimore, MD: Williams & Wilkins, 1971, with permission.)
Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet) (Fig. 27.2).

**True Hermaphroditism**

True hermaphroditism is a rare condition that should be considered as a possible cause of amenorrhea. Both male and female gonadal tissue are present in these patients, in whom XX, XY, and mosaic genotypes have been found. Two thirds of the patients menstruate, but menstruation has never been reported in XY genotypes. The external genitalia usually is ambiguous, and breast development frequently occurs in these individuals. **Fifteen percent of XX true hermaphrodites have SRY translocations, and another 10% have Y chromosomal mosaicism within the gonad** (13).

**Diagnosis**

Most congenital abnormalities can be diagnosed by physical examination:

1. **An imperforate hymen** is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver. Ultrasonography or MRI is useful to identify the müllerian anomaly when the abnormality cannot be found by physical examination. The patient should also be examined for skeletal malformations and assessed with intravenous pyelography to detect concomitant renal abnormalities. These abnormalities occur less frequently than in müllerian agenesis (62).

2. **It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male pseudohermaphrodite. Androgen insensitivity is diagnosed when pubic and axillary hair is absent.** To confirm the diagnosis, a karyotype determination should be performed to see whether a Y chromosome is present. In some patients, the defect in the androgen receptor is not complete, and virilization occurs.

3. **An absent endometrium** is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea. This abnormality is so rare that in a patient with normal physical findings, it may be advisable to proceed with evaluation of endocrine abnormalities. Absence of the endometrium should be suspected in patients with primary amenorrhea and normal secondary sexual characteristics when the results of hormonal studies are normal and the patients do not bleed after withdrawal of combined estrogen and progesterone replacement.

4. **Asherman syndrome also cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalphingography, saline infusion, ultrasonography, or hysteroscopy.** These tests will show either complete obliteration or multiple filling defects caused by synechiae (Fig. 27.3). If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.

**Treatment**

The treatment of congenital anomalies can be summarized as follows:

1. **Treatment of an imperforate hymen involves making a cruciate incision to open the vaginal orifice.** Most imperforate hymens are not diagnosed until a hematocolpos forms. It is unwise to place a needle into a hematocolpos without completely removing the obstruction because a pyocolpos may occur.

2. **If a transverse septum is present, surgical removal is required.** Forty-six percent of transverse septa occur in the upper third of the vagina, and 40% occur
in the middle third of the vagina (68). Frank dilators should be used to distend
the vagina until it is healed to prevent vaginal adhesions (69). Patients have a
fully functional reproductive system after surgery; however, patients with
repaired high transverse septa have lower pregnancy rates (70).

3. Hypoplasia or absence of the cervix in the presence of a functioning uterus is
more difficult to treat than other outflow obstructions. Surgery to repair the
cervix has not been successful, and hysterectomy is required (71). Endometriosis
is a common finding, and it is questionable whether this condition should be
treated initially with surgery or if it will resolve spontaneously after surgical
repair of the obstruction. The ovaries should be retained to provide the benefits of
estrogen and to allow for the possibility of future childbearing by removing
mature oocytes for in vitro fertilization using a gestational carrier mother.

4. If the vagina is absent or short, progressive dilation is usually successful in
making it functional (69,72). If dilation fails or the patient is unable to perform
dilation, the McIndoe split thickness graft technique may be performed (62,73,74).
The initial use of vaginal dilators is required to maintain a functional vagina.

**Figure 27.3** A: Intrauterine adhesion seen on hysterosalpingogram in a patient
with Asherman syndrome. B: Hysteroscopic view of intrauterine adhesion in a patient
with Asherman syndrome (From Donnez J, Nisolle M. The encyclopedia of visual
medicine series—an atlas of laser operative laparoscopy and hysteroscopy. New York,
NY: Parthenon Publishing Group, 1994:306, with permission.)
5. In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration (75). In patients with testes, 52% develop a neoplasia, most often a gonadoblastoma. Almost one half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually does not occur until after puberty (76). In patients who develop virilization and have an XY karyotype, the testes should be removed immediately to preserve the female phenotype and to promote female gender identity. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intra-abdominal testes.

6. Adhesions in the cervix and uterus (Asherman syndrome) can be removed using hysteroscopic resection with scissors or electrosurgery. A pediatric Foley catheter should be placed in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy), and a 2-month course of high-dose estrogen therapy with monthly progesterone withdrawal is used to prevent reformation of adhesions. Eighty percent of patients thus treated achieve pregnancy, but complications including miscarriage, preterm labor, placenta previa, and placenta accreta are common (77). Cervical stenosis can be treated by cervical dilation.
Amenorrhea with Secondary Sexual Characteristics and Nonanatomic Causes

Pregnancy must be considered in all women of reproductive age with amenorrhea. Thyroid dysfunction and hyperprolactinemia also are frequent causes of amenorrhea and are discussed further in Chapter 28. Amenorrhea with secondary sexual characteristics and normal anatomy can be caused by ovarian failure, pituitary/hypothalamic lesions, and abnormal hypothalamic GnRH secretion.

Causes

Ovarian Failure

Ovarian failure is a normal occurrence during menopause. The age of menopause is determined by genetic inheritance. Once a patient is exposed to estrogen, estrogen withdrawal causes hot flashes and vaginal dryness. This occurs in approximately 50% of patients, whether ovarian failure is premature or occurs at the normal age (78). Physical examination reveals vaginal mucosal atrophy and no cervical mucus. Ovarian failure occurs before 40 years of age in 1% to 5% of women and is considered pathologic (premature ovarian failure). Early failure may be caused by decreased follicular endowment or accelerated follicular atresia. If ovarian failure occurs before puberty, the patient’s breasts will not develop (i.e., Turner syndrome), and gonadal agenesis results (Tables 27.1 and 27.3).

Despite the array of causes of ovarian failure, in most cases the etiology cannot be determined. In some patients, ovarian failure resolves spontaneously. Pregnancies have been reported to occur after the diagnosis of ovarian failure in less than 0.09% to 8.2% of patients (78,79).

Cigarette smoking has been shown to have a clear inverse dose-response relationship with age of menopause (80). Other studies have confirmed this association, some eliminating potential confounding factors such as body weight, which could affect the age of menopause (81). Cigarette smoking alters both gametogenesis and hormonogenesis, suggesting an effect on the follicle. Smoking has also been shown to increase the risk of diminished ovarian reserve (82).

Sex Chromosome Disorders  Deletion of the X chromosome (Turner syndrome) is associated with premature ovarian failure despite normal development of the ovaries because of accelerated atresia of the follicles (83). Mosaicism of an XO or XY cell line may cause ovarian failure in patients younger than 30 years of age. A deletion of a portion of the X chromosome may be present in patients with premature ovarian failure. The Xq21-28 region is critical (7,84). Several genes in this region have been identified as the cause of ovarian failure in humans. Examples include the POF1B gene located at Xq21 (85), the DIAPH2 gene located at distal Xq21 (85), and the XPNPEP2 gene located at Xq25 (86). The specific functions of these genes require further investigation. Undoubtedly, more genes that cause ovarian failure will be identified (87). In addition, a mutation of the BMP15 gene located at Xp11.2 has been identified in two patients with premature ovarian failure (88). Mutations in the autosomal genes FOXL2 and ATM have been shown to cause premature ovarian failure (13,89).

Individuals with a 47,XXX karyotype also may develop ovarian failure. Familial ovarian failure is inherited by dominant Mendelian inheritance in some cases (90).

Fragile X Carriers  Fragile X syndrome is the most common cause of inherited (X-linked) mental retardation. It is caused by inactivation of the FMR1 gene located on Xq27.3 as a result of expansion of a CGG triplet repeat of more than 200 copies. The normal population has an average size repeat of 30. Female carriers of the disorder have between 60 to 200 repeats (premutations) and are not mentally retarded. These premutations are unstable and can expand in the next generation to transmit fragile X syndrome to male offspring, especially with individuals who have more than 100 repeats. Women who have premutations have a 15% to 25% chance of premature ovarian failure (91,92). Interestingly, women with full mutations are not at higher risk for premature ovarian failure. It is hypothesized that expression of abnormal FMR1 mRNA produced by patients with the premutation causes dysfunction in the ovary, which does not occur when the FMR1 gene is inactivated and not transcribed (91,92). Patients with premature ovarian failure have a 4% to 5% chance of having the premutation for fragile X. If premature ovarian failure is present in another family member, the chance of finding a premutation increases to 15% (91,93).

Iatrogenic Causes  Radiation, chemotherapy (especially alkylating agents such as cyclophosphamide) (94), surgical interference with ovarian blood supply, and infections can cause ovarian failure from early loss of follicles. A radiation dose of 800 cGy causes sterility in most individuals. Ovarian failure can be caused by as little as 150 cGy in some patients, especially if they are older than 40 years of age with limited follicle reserves. In an evaluation of ovarian function in 100 childhood cancer survivors, 17 had premature ovarian failure. Those with spontaneous menses had smaller ovarian volume, fewer antral follicles, and lower inhibin B levels when compared with controls (95). Ovarian suppression with GnRH agonists and oral contraceptives to reduce the risk of ovarian failure have not been promising (96,97). Improvements in techniques of oocyte and ovarian tissue cryopreservation may allow future pregnancies in patients requiring treatments that cause follicular destruction (98,99).

Infections  In rare cases, mumps has been associated with premature ovarian failure (100). Tubo-ovarian abscess, even in the absence of surgical treatment, has also been associated with follicular destruction and premature ovarian failure (49). Cytomegalovirus has been shown postmortem to cause oophoritis, but premature ovarian failure had not developed yet clinically in the patient, so the relationship of cytomegalovirus to ovarian failure is unclear (101).

Autoimmune Disorders  Premature ovarian failure may be part of a polyglandular autoimmune syndrome. Antibodies are present in a variable number of patients with premature ovarian failure, depending on the autoimmune studies performed. One study showed that 92% of patients with premature ovarian failure had autoantibodies (102).
However, only 20% of these patients exhibited signs of immunologic dysfunction, most frequently in the form of a thyroid disorder (79). Before treatment for thyroid deficiency, adrenal insufficiency characterized by hyperpigmentation, weakness, nausea, vomiting, diarrhea, and weight loss should be ruled out; otherwise, adrenal crisis may occur (12). Rarely, premature ovarian failure is associated with myasthenia gravis, idiopathic thrombocytopenia purpura, rheumatoid arthritis, vitiligo, autoimmune hemolytic anemia, diabetes mellitus, and other autoimmune disorders (103–105).

**Galactosemia**

Galactosemia is caused by a lack of functional galactose-1-phosphate uridyl transferase. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction (106). Cataracts and mental retardation are also associated with galactosemia. There is also evidence that heterozygote carriers of this disorder may have suboptimal ovarian function (107). Early dietary modification may delay but not prevent the ovarian failure (25).

**Savage Syndrome**

Gonadotropin resistance, also referred to as Savage syndrome, is likely due to FSH receptor dysfunction (104). Compound heterozygote mutations in the FSH receptor have been identified in women who have secondary amenorrhea with high levels of FSH and LH levels (24). The FSH receptors are partially functional in these patients, as opposed to the more severe FSH resistance present in Finnish families. These women usually present with primary amenorrhea without secondary sexual characteristics; however, some affected individuals have normal breast development (31).

Patients who experience ovarian resistance (Savage syndrome) have ovarian follicles, as opposed to those who have ovarian failure and no follicles. Except in the rare cases when a genetic defect has been identified, ovarian biopsy is the only way to distinguish these disorders. Biopsy is not advised, however, because diagnosing resistant ovarian failure will not affect management. Although the use of GnRH agonists, estrogen therapy, and ovarian stimulation have been attempted in patients desiring pregnancy, studies have shown little success (108).

**Autosomal Gene Mutations**

An autosomal recessive form of premature ovarian failure is associated with hearing loss in Perrault syndrome (109). Mutations in FOXL2 causes ovarian failure and ptosis (89). Undoubtedly, more autosomal mutations that cause primary ovarian failure will be recognized as the genes involved in ovarian and follicular development are identified.

**Pituitary/Hypothalamic Lesions**

**Hypothalamic Tumors**

For normal menstruation to occur, the hypothalamus must be able to secrete GnRH, and the pituitary must be able to respond with production and release of FSH and LH. Tumors of the hypothalamus or pituitary, such as craniopharyngiomas, germinomas, tubercular or sarcoid granulomas, or dermoid cysts, may prevent appropriate hormonal secretion. Patients with these disorders may have neurologic abnormalities, and secretion of other hypothalamic and pituitary hormones may be abnormal. Craniopharyngiomas are the most common tumors. They are located in the suprasellar region and frequently cause headaches and visual changes. The surgical and radiologic treatment of tumors may in itself cause further abnormalities in hormone secretion (Table 27.4).

**Pituitary Lesions**

Hypopituitarism is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically. The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, infiltrating lesions such as lymphocytic hypophysitis, granulomatous lesions, and surgical or radiologic ablations.
Sheehan syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), presents with the patient in shock. The patient may develop a localized, severe, retro-orbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis cannot lactate, lose pubic and axillary hair, and do not menstruate after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) as well as gonadotropins; therefore, thyroid and adrenal function also must be evaluated. If hypopituitarism occurs before puberty, menses and secondary sexual characteristics will not develop.

Growth hormone (GH), TSH, ACTH, and prolactin also are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. Excess prolactin secretion is one of the more common causes of amenorrhea. The menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by direct effects on the ovary. Prolactinomas are the most common hormone-secreting tumors in the pituitary (see Chapter 28).

Abnormal secretion of GnRH accounts for one third of patients with amenorrhea. Chronic disease, malnutrition, stress, psychiatric disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle (Table 27.5). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and adversely affect GnRH secretion. In hyperprolactinemia, Cushing disease (excess ACTH), and acromegaly (excess GH), excess pituitary hormones are secreted that inhibit GnRH secretion. It is uncommon to find a hypopituitary syndrome caused by these hormones.
to have functional hypothalamic amenorrhea without a secondary cause. Prognosis for recovery is better if the precipitating cause of the amenorrhea can be reversed (111).

When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation can occur. Even slight defects in the pulsatility may result in luteal phase defect.

The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Endogenous opioids, corticotropin-releasing hormones (CRH), melatonin, and $\gamma$-aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamines, acetylcholine, and vasoactive intestinal peptide stimulate GnRH pulses. Dopamine and serotonin have variable affects (112).

Decreased leptin levels have been associated with hypothalamic amenorrhea (113,114) regardless of whether it is caused by exercise, eating disorders, or idiopathic

*Severity of the condition determines estrogen status—the more severe, the more likely to manifest as hypoestrogenism.
factors. Leptin is a hormone secreted by adipocytes that is involved in energy homeostasis. Receptors are found in the hypothalamus and bone, making it an excellent candidate for a modulator of menstrual function and bone mass. Levels correlate with nutritional changes and body mass index. Administration of leptin to women with hypothalamic amenorrhea increases levels of LH, estradiol, insulin-like growth factor-1 (IGF-1), and thyroid hormone. Ovulation and increased bone mass also occurred in these patients (114).

Weight Loss and Dieting

Weight loss can cause amenorrhea even if weight doesn’t decrease below normal. Loss of 10% body mass in 1 year is associated with amenorrhea. Some but not all of these women have an underlying eating disorder. Prognosis is good for the return of menses if the patients recover from the weight loss. Dieting without weight loss and changes in diet can also lead to amenorrhea (111).

Anorexia Nervosa

Anorexia nervosa is an eating disorder that affects 5% to 10% of adolescent women in the United States. The criteria for diagnosis of anorexia nervosa as stated in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) are refusal to maintain body weight above 15% below normal, an intense fear of becoming fat, altered perception of one’s body image (ie, patients see themselves as fat despite being underweight), and amenorrhea. Patients attempt to maintain their low body weight by food restriction, induced vomiting, laxative abuse, and intense exercise. This is a life-threatening disorder with a mortality rate as high as 9%. Amenorrhea may precede, coincide, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T3) is low, yet circulating inactive reverse T3 concentrations are high (115).

Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.

Patients with anorexia nervosa have combinations of restrictive and binge eating. Binge eating is associated with bulimia consisting of vomiting, laxative abuse, and diuretics to control weight. Signs of bulimia include tooth decay, parotid gland hypertrophy (chipmunk jowls), hypokalemia, and metabolic alkalosis (116).

Exercise

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in LH pulsatility can be caused by hormonal alterations, such as elevations in endogenous opioids, ACTH, prolactin, adrenal androgens, cortisol, and melatonin (117). Differences in body-fat content have been used to explain the different rates of amenorrhea by sport. Runners and ballet dancers are at higher risk for amenorrhea than swimmers (118). It has been suggested that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses (119). However, newer studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat (120). Higher-intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete’s risk for menstrual dysfunction (121). The “female athlete triad” consists of amenorrhea, osteoporosis, and eating disorders.
SECTION VII Reproductive Endocrinology

Osteoporosis may result in stress fractures during training and lifelong increased fracture risk. Stress fractures most commonly occur in the weight-bearing cortical bone such as the tibia, metatarsal, fibula, and femur. These athletes fail to reach peak bone mass and have abnormal bone mineralization. Scoliosis is also common (117).

Stress-induced Disorders Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH (112). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition.

Obesity Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases from 2.6% in normal-weight patients to more than 8.4% in women above 75% ideal body weight. The menstrual disorder is more often irregular uterine bleeding with anovulation rather than amenorrhea. Obese women have an excess number of fat cells in which extraglandular aromatization of androgen to estrogen occurs. They also have lower circulating levels of sex hormone–binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a higher risk for endometrial cancer for these women. The decrease in sex hormone–binding globulin also allows an increase in free androgen levels, which initially are eliminated by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having PCOS. Alterations in the secretion of endorphins, cortisol, insulin, growth hormone, and IGF-1 may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

Other Hormonal Factors The secretion of hypothalamic neuromodulators can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, glucocorticoids, androgens, and estrogens can cause menstrual dysfunction. Even though PCOS usually causes irregular bleeding rather than amenorrhea, it remains one of the most common causes of amenorrhea (2). It is likely that PCOS is the result of peripheral alteration in IGF-1, androgen, and estrogen levels, which leads to hypothalamic dysfunction (see Chapter 28). Elevations in androgens (e.g., Sertoli-Leydig, hilus, and lipid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. In patients who are hirsute and amenorrheic, androgen-secreting adrenal tumors and congenital adrenal hyperplasia should be considered.

Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea. Growth hormone excess causes acromegaly, which may be associated with anovulation, hirsutism, and polycystic ovaries as a result of stimulation of the ovary by IGF-1. More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is recognized by enlargement of facial features, hands, and feet; hyperhidrosis; visceral organ enlargement; and multiple skin tags. Cushing disease is caused by an ACTH-secreting pituitary tumor, which is manifested by truncal obesity, moon facies, hirsutism, proximal weakness, depression, and menstrual dysfunction.

Diagnosis A pregnancy test (urine or serum hCG) should be performed in a reproductive-age woman who has amenorrhea with normal secondary sexual characteristics and a normal pelvic examination. If the results of the pregnancy test are negative, the evaluation of amenorrhea is as follows:
1. Serum TSH
2. Serum prolactin
3. FSH levels
4. Estrogen status
5. Imaging of the pituitary and hypothalamic assessment as necessary

**Thyroid-stimulating Hormone and Prolactin Levels**

<table>

**Follicle-stimulating Hormone Levels**

Assessment of serum FSH levels is required to determine whether the patient has hypergonadotrophic, hypogonadotrophic, or eugonadotrophic amenorrhea. A circulating FSH level of greater than 25 to 40 mIU/mL indicated on at least two blood samples is indicative of hypergonadotrophic amenorrhea. Hypergonadotropism signifies that the cause of amenorrhea is at the level of the ovary. The history should establish whether the cause of ovarian failure is chemotherapy or radiation therapy. A galactose-1 phosphate uridyl transferase level should be measured to assess the patient for galactosemia or carrier status. Fragile X carrier status should be evaluated in patients with first-degree relatives with premature ovarian failure.

In patients younger than 30 years of age with hypergonadotrophic amenorrhea, a karyotype is required to rule out the presence of a Y cell line. In situ hybridization studies may prove the existence of Y chromosomal material with a Y-specific probe when the karyotype is normal (122). It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration.

There is much debate regarding the extent of an autoimmune workup required for a patient with ovarian failure:

1. It is reasonable to screen patients with nonspecific tests such as those to detect antinuclear antibodies, rheumatoid factor, and erythrocytic sedimentation rate.
2. A normal partial thromboplastin time is sufficient to exclude lupus anticoagulant.
3. Assessments of serum electrolytes, calcium, and phosphorus concentrations can be used to evaluate the possibility that parathyroid autoantibodies are active.
4. Other assessments that should be performed include TSH, antithyroglobulin antibodies, antimicrosomal antibodies to evaluate thyroid status, and 24-hour urinary free cortisol to detect the presence of antiadrenal antibodies.

5. A more extensive workup may include parietal cell antibodies, islets of Langerhans antibodies, and antiadrenal antibodies; it is unclear, however, if the results of these tests will alter clinical management.

Tests should be repeated yearly because of the transient nature of autoimmune disorders.

In a patient with hypergonadotropic amenorrhea, ovarian biopsy to determine whether follicles are present is not advised. Even if oocytes are found, there is no good method of stimulating those oocytes to ovulate. Some patients with negative biopsy results later ovulate spontaneously. This can be explained by considering that the biopsies sample only a small portion of the ovary (79).

Assessment of Estrogen Status

Traditionally, estrogen status has been determined by giving medroxyprogesterone acetate, either 5 mg or 10 mg, for 10 days. Withdrawal bleeding usually occurs within 2 to 10 days after the last dose. There is a debate as to how much bleeding constitutes withdrawal bleeding. There is a 20% false-positive rate in women who do not bleed despite having estrogen, and a 40% false-negative rate in women who bleed despite low estrogen states caused by hypothalamic dysfunction. A 50% false-negative rate occurs with ovarian failure (2). If vaginal bleeding does not occur after oral administration of progesterone, frequently 100 to 200 mg progesterone in oil is given intramuscularly. Other ways of testing for estrogen status may be quicker and easier. The development of vaginal dryness and hot flashes increase the likelihood of a diagnosis of hypoestrogenism. A sample of vaginal secretions can be obtained during the physical examination, and mucosal estrogen response can be demonstrated by the presence of superficial cells. A serum estradiol level higher than 40 pg/mL is considered adequate, but interassay discrepancies often exist. A DEXA (dual-energy x-ray absorptiometry) scan to determine bone mineral density should be performed in any patient in whom hypoestrogenism is suspected. The finding of vaginal bleeding after progesterone challenge is important when Asherman syndrome is suspected. In a patient with primary amenorrhea and an apparently normal estrogen status, a progesterone challenge will diagnose the rare finding of congenitally absent endometrium. If estrogen status is questioned, 2.5 mg conjugated estrogen or 2 mg micronized estradiol can be given for 25 days with 5 to 10 mg of medroxyprogesterone acetate added for the last 10 days. Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. Transvaginal ultrasound to assess endometrial thickness may also be helpful. If similar findings occur in patients with secondary amenorrhea, Asherman syndrome is diagnosed. Asherman syndrome must be confirmed by showing filling defects on hysterosalpingography or by visualizing adhesions with hysteroscopy.

Assessment of the Pituitary and Hypothalamus

If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded.

1. A complete neurologic examination, including electroencephalography, may help localize a lesion.

2. Either CT or MRI scanning should be performed to confirm the presence of a tumor. MRI will identify smaller lesions than CT; if a lesion is too small for identification by CT, it may be clinically insignificant.
3. After anatomic lesions have been excluded, the patient’s history of weight changes, exercise, eating habits, body image, and career or school achievements are important factors in differentiating anorexia nervosa, malnutrition, obesity, or exercise-induced or stress-induced menstrual disorders.

Amenorrheic patients who have hypothalamic dysfunction and are hypoestrogenic may have disorders similar to those who have normal estrogen levels. The hypothalamic dysfunction caused by chronic disease, anorexia nervosa, stress, and malnutrition may be more severe or may exist for a more prolonged time in hypoestrogenic patients than in euestrogenic patients.

Patients with appropriate clinical findings should undergo screening for other hormonal alterations:

1. Androgen levels should be assessed in any hirsute patient to ensure that adrenal and ovarian tumors are not present as well as to diagnose PCOS (see Chapter 28).

2. Acromegaly is suggested by coarse facial features, large doughy hands, and hyperhidrosis and may be confirmed by measuring IGF-1 levels.

3. In patients with truncal obesity, hirsutism, hypertension, and erythematous striae, Cushing syndrome should be ruled out by assessing 24-hour urinary cortisol levels or performing a 1-mg overnight dexamethasone suppression test.

### Treatment

The treatment of nonanatomic causes of amenorrhea associated with secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. When thyroid abnormalities are detected, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. When hyperprolactinemia is present, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as bromocriptine or cabergoline, and, rarely, surgery for particularly large pituitary tumors. When ovarian failure causes amenorrhea, hormone replacement may be considered to diminish menopausal symptoms as well as to prevent osteoporosis. Counseling regarding the risks and benefits of hormone replacement therapy is indicated (123). Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is generally advocated for treatment of central nervous system tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens once all the deficits have been elucidated. These regimens include estrogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH, thyroid hormone for lack of TSH, and desmopressin acetate (1-deamino-8-D-APV [DDAVP]) to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction also depends on the underlying cause:

1. Hormonally active ovarian tumors are surgically removed.

2. Obesity, malnutrition or chronic disease, Cushing syndrome, and acromegaly should be specifically treated.
3. Pseudocyesis and stress-induced amenorrhea may respond to psychotherapy.

4. Exercise-induced amenorrhea may improve with moderation of activity and weight gain, when appropriate. If hypoestrogenism persists, higher doses of estrogen may be needed in these women than in older menopausal women to maintain bone density. In addition, 1,200 to 1,500 mg of calcium and 400 IU of vitamin D daily is advised. Bisphosphonates do not improve bone density in amenorrheic athletes because it is lack of bone formation rather than increased resorption that causes the osteopenia. In addition, the use of bisphosphonates is not advised because they can be deposited into the bone, and long-term effects, especially during pregnancy, are unknown (117).

5. Treatment of anorexia nervosa generally demands a multidisciplinary approach, with severe cases requiring hospitalization.

6. Chronic anovulation or PCOS may be treated after identifying the desires of the patient. Patients often are concerned about their lack of menstruation but not about hirsutism or infertility. The endometrium of these individuals should be protected from the environment of unopposed estrogen that accompanies the anovulatory state. Oral contraceptives are a good alternative for those patients who also require contraception. For those patients who are not candidates for oral contraceptive use, cyclic administration of progestin is advised. This treatment option presumes an adequate estrogenic environment to induce proliferation of the endometrium and is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (i.e., those who have anorexia nervosa). In these individuals, estrogen replacement must be added to the progestin regimen for successful menstrual regulation and prevention of osteoporosis. The most common progestin used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is medroxyprogesterone acetate (10 mg for 10 days per month). Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible and appropriate contraceptive measures should be used. There is concern that medroxyprogesterone acetate used in early pregnancy may increase the incidence of pseudohermaphroditism (124). Alternatively, progesterone suppositories (50–100 mg) or micronized progesterone (200 mg) could be given for 10 days to induce withdrawal bleeding. No increased incidence of birth defects has been associated with the use of these natural progesterones (125).

7. When chronic anovulation is caused by attenuated congenital adrenal hyperplasia, glucocorticoid administration (i.e., dexamethasone 0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms, thereby permitting regular menstruation and ovulation.

**Hirsutism**

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism (Chapter 28). After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.

**Oral Contraceptives** Oral contraceptives may be effective by decreasing ovarian androgen production as well as increasing circulating levels of sex hormone–binding globulin, leading to decreased free androgen circulation.

**Antiandrogens** Spironolactone decreases androgen production and competes with androgens at the androgen receptor level. Side effects include limited diuresis and dysfunctional uterine bleeding.
**Flutamide** is approved by the U.S. Food and Drug Administration (FDA) for adjuvant therapy in prostatic cancer and for treatment of hirsutism. Its effects are similar to those of *spironolactone* with fewer side effects (126). Liver function should be monitored because of the rare complication of hepatotoxicity.

*Cyproterone acetate,* a strong progestin and antiandrogen, is used widely abroad but is not currently available in the United States. It is usually administered in combination with *ethinyl estradiol* in an oral contraceptive. By decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level, *cyproterone acetate* is effective in treating hirsutism (127).

**GnRH Agonist**  
GnRH agonist administration with add-back therapy is increasingly being used in the United States. Administration of GnRH agonist agents virtually eliminates ovarian steroid production, and estrogen-progestin add-back therapy allows long-term administration and protection against osteoporosis.

**5α-Reductase Inhibitors**  
*Finasteride,* a 5α-reductase inhibitor, is approved by the FDA for the treatment of benign prostatic hypertrophy (*Proscar*) and male pattern baldness (*Propecia*). It is effective in treating hirsutism, although perhaps no more effective than other available agents (128,129). *Finasteride* has significant teratogenic potential, which precludes its use in any woman who may become pregnant. Its major advantage is that it is exceptionally well tolerated and may be used when side effects preclude the use of other therapeutic options for hirsutism.

*Eflornithine hydrochloride,* a topical cream, has been approved by the FDA for use on the face and chin. Improvements in facial hirsutism may be seen in 4 to 8 weeks of twice-daily applications.

---

**Ovulation Induction**

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive (Chapter 30). Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy (130). **Patients may be advised that there is no increase in congenital anomalies in children born following ovulation induction** (131).

Earlier studies have raised the possibility of a relationship between ovulation induction and the risk of ovarian cancer (132,133). Ongoing studies are attempting to address this issue conclusively, but **data support an increase of approximately 2.5-fold in ovarian cancer in patients with infertility,** which appears unrelated to the use of ovulation-inducing drugs (134,135). **There is no conclusive evidence to date to link fertility drug use and ovarian cancer** (136); thus, no change in current ovulation induction practices seems warranted at present. **Pregnancy and treatment with oral contraceptives before or after childbearing may protect against ovarian cancer.**

*Clomiphene citrate* is the usual first choice for ovulation induction in most patients because of its relative safety, efficacy, route of administration (oral), and relatively low cost (137). *Clomiphene citrate* is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (138). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCOS, are also candidates for therapy with *clomiphene citrate.* **As many as 80% of**
certain patients can be expected to ovulate after clomiphene citrate therapy, and pregnancy rates approach 40% (130). Contraindications to the use of clomiphene citrate include pregnancy, liver disease, and pre-existing ovarian cysts. Side effects include hot flashes (>11% of patients) and poorly understood visual symptoms, which generally have been viewed as an indication to discontinue subsequent clomiphene citrate use. The incidence of multiple gestation ranges from 6.25% to 12.3% (130). The most commonly recommended treatment regimen is 50 mg daily for 5 days, beginning on the third to fifth day of menstrual or withdrawal bleeding. Cycles are easily monitored by measuring midluteal progesterone levels to assess ovulation. Measurement of midcycle estradiol levels and ultrasonographic monitoring to assess folliculogenesis may also be helpful, especially when hCG is used to induce ovulation. Endometrial thinning caused by the antiestrogenic effects of clomiphene citrate may also be detected with midcycle ultrasound. With these data, it is possible to immediately adjust the dose in the subsequent cycle if a given regimen is ineffective. Dosage increases of 50 mg/day are usually used, and more than 70% of conceptions occur at doses no higher than 100 mg/day for 5 days (139). Dosages higher than 150 mg/day for 5 days are usually ineffective, and patients who remain anovulatory with this dosage should undergo further evaluation accompanied by changes in the therapeutic plan. Longer courses of clomiphene citrate therapy, as well as adjunctive therapy with glucocorticoids and hCG, have been recommended (138). Patients with PCOS, especially those with insulin resistance, may benefit from the use of insulin-sensitizing agents, used either as primary or adjunctive therapy (140). These agents include the biguanide metformin and thiazolidinediones (rosiglitazone and pioglitazone). Thinning of the endometrium at midcycle in the face of adequate midcycle estradiol and midluteal progesterone levels is generally an indication to change therapy to injectable gonadotropins.

Women who do not ovulate or become pregnant with clomiphene citrate, as well as women with hypogonadotropic hypoestrogenic anovulation, may be candidates for therapy with injectable gonadotropins. Much higher pregnancy rates (up to 90%) occur in the latter category. Available preparations include recombinant FSH or products purified from the urine of menopausal women (FSH or FSH-LH combinations). Oral gonadotropin therapy is undergoing research and development. Administration protocols and dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and serial estradiol measurements. In general, gonadotropins are administered at a dose of 50 to 150 IU/day by subcutaneous or intramuscular injection for 3 to 5 days, after which time estradiol and follicular monitoring commence. In most cycles, gonadotropin is administered 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU hCG or subcutaneous injection of 250 μg of recombinant hCG once the lead follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 36 hours after hCG administration. Luteal phase support is sometimes provided with the administration of progesterone supplementation or with additional injections of hCG.

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10%–30%) and ovarian hyperstimulation syndrome. The incidence of both of these complications can be lowered by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by estradiol levels approaching or exceeding 2,000 pg/mL may be canceled by withholding the ovulatory dose of hCG. Selected patients may be converted safely to in vitro fertilization. Because severe ovarian hyperstimulation syndrome is life-threatening and may lead to prolonged hospitalization, ovulation induction with gonadotropins generally is performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with GnRH may be effective in patients who have chronic anovulation associated with low levels of estrogen and gonadotropins. For therapy to
be successful, a functional ovary and pituitary gland must be present. Therefore, patients with ovarian or pituitary failure do not respond to GnRH therapy. To be effective, GnRH must be administered in a pulsatile fashion, either intravenously or subcutaneously by a programmable pump. Ovulation induction with GnRH, as compared with gonadotropins, is associated with a relatively low incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of hCG is avoided because patients treated with pulsatile GnRH have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site. After ovulation, luteal phase support is necessary and may be provided with hCG, progesterone, or continuation of the GnRH therapy.

Patients who lack oocytes (ovarian failure) and desire pregnancy may be candidates for oocyte donation. Oocytes may be harvested after ovulation induction from appropriate donors, fertilized with sperm from the recipient’s husband, and transferred into the recipient’s uterus after the endometrium has been appropriately prepared with hormonal regimens. Estrogen and progesterone are used to prepare the endometrium for implantation of the transferred embryo(s).

SECTION VII  Reproductive Endocrinology

CHAPTER 27 Amenorrhea

Hyperandrogenism most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands. By contrast, virilization is rare and indicates marked elevations in androgen levels.

The most common cause of hyperandrogenism and hirsutism is polycystic ovarian syndrome (PCOS). There are only two major criteria for the diagnosis of PCOS: anovulation and the presence of hyperandrogenism as established by clinical or laboratory means. Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia.

Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two thirds of hirsute patients.

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Excluding cases that are of iatrogenic or factitious etiology, adrenocorticotropic hormone (ACTH)-independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest.

Congenital adrenal hyperplasia is transmitted as an autosomal recessive disorder. Deficiency of 21-hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from adrenal synthetic enzyme deficiency.

Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. Ovarian neoplasms are the most frequent androgen-producing tumors.
Elevations in prolactin may cause amenorrhea or galactorrhea. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women. In patients with both galactorrhea and amenorrhea, approximately two thirds will have hyperprolactinemia; of those, approximately one third will have a pituitary adenoma. In more than one third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (>1 cm) is found.

Because levels of thyroid-stimulating hormone (TSH) are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced. Severe primary hypothyroidism is associated with amenorrhea or anovulation. The classic triad of exophthalmos, goiter, and hyperthyroidism in Graves disease is associated with symptoms of hyperthyroidism.

The endocrine disorders encountered most frequently in gynecologic patients are those related to disturbances in the regular occurrence of ovulation and accompanying menstruation. The most prevalent problems are those characterized by androgen excess, often with insulin resistance, including what is arguably the most common endocrinopathy in women—polycystic ovary syndrome (PCOS). Other conditions leading to ovulatory dysfunction, hirsutism, or virilization, as well as common disorders of the pituitary and thyroid glands associated with reproductive abnormalities, are reviewed in this chapter.

Hyperandrogenism

Hyperandrogenism most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands, constitutive increase in expression of androgen effects at the level of the pilosebaceous unit, or a combination of the two. By contrast, virilization is rare and indicates marked elevations in androgen levels. Virilization usually is caused by an ovarian or adrenal neoplasm, which may be benign or malignant.

Hirsutism

The most frequent manifestation of androgen excess in women, hirsutism is defined as excessive growth of terminal hair in a male distribution. This condition refers particularly to midline hair, sideburns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens in these androgen-responsive areas transforms vellus hair (fine, nonpigmented, short) that is normally present into terminal hair (coarse, stiff, pigmented, and long).

Androgen effects on hair vary in relation to specific regions of the body surface. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. The hair of the limbs and portions of the trunk exhibits minimal sensitivity to androgens. Pilosebaceous units of the axilla and pubic region are sensitive to low levels of androgens. Even the modest androgenic effects of adult levels of androgens of adrenal origin are sufficient for substantial expression of terminal hair in these areas. Follicles in the distribution associated with male patterns of facial and body hair (midline, facial, infra-mammary) require higher levels of androgens, such as those seen with normal testicular function or abnormal
ovarian or adrenal androgen production. Scalp hair is inhibited by gonadal androgens in varying degrees, as determined by age and genetic determination of follicular responsiveness, resulting in the common frontal-parietal balding seen in some men and in virilized women. **Hirsutism results from both increased androgen production and skin sensitivity to androgens.** Skin sensitivity depends on the genetically determined local activity of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the bioactive androgen in hair follicles.

**Hair demonstrates cyclic activity between growth (anagen), involution (catagen), and resting (telogen) phases.** The durations of both the growth and resting phases vary according to region of the body, genetic factors, age, and hormonal effects. The cycles of growth, rest, and shedding are normally dysynchronous, but when synchronous entry into telogen phase is triggered by major metabolic or endocrine events such as pregnancy and delivery or severe illness, dramatic (although transient) hair loss may occur in the following months (telogen effluvium).

**Hirsutism is a relative, rather than absolute, designation.** What is normal in one setting may be considered abnormal in others; social and clinical reactions to hirsutism may vary significantly, reflecting ethnic variation in skin sensitivity to androgens and cultural ideals. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal Caucasian women and is considered abnormal by white women of North America, whereas considerable facial and male pattern hair in other parts of the body may be more common and acceptable among groups such as Inuit women and women of Mediterranean background.

---

**Hypertrichosis and Virilization**

Two conditions should be distinguished from hirsutism. **Hypertrichosis** is the term reserved for the presence of androgen-independent terminal hair in nonsexual areas, such as the trunk and extremities. This condition may result from an autosomal-dominant congenital disorder, a metabolic disorder (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda), or medication use (e.g., acetazolamide, corticosteroids, cyclosporine, diazoxide, interferon, minoxidil, phenytoin, streptomycin). **Virilization** is a marked and global masculine transformation that includes coarsening of the voice, increase in muscle mass, clitoromegaly (normal clitoral dimensions plus or minus standard deviation are 3.4 + 1 mm width by 5.1 + 1.4 mm length), and features of defeminization (loss of breast volume and body fat contributing to feminine body contour) (1). Although hirsutism accompanies virilization, the presence of virilization indicates a high likelihood of a more serious condition than those that occur with hirsutism alone. The history should focus on the age at onset and rate of progression of hirsutism or virilization. A rapid rate of progression of androgen effects or the presence of virilization, regardless whether it occurs before, during, or after puberty, is associated with a more severe degree of hyperandrogenism and should raise suspicion of ovarian and adrenal neoplasms or Cushing syndrome. Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability of underlying hyperandrogenism. Hirsutism occurring with regular cycles is more often associated with normal androgen levels; it is attributed to increased genetic sensitivity of the pilosebaceous unit and is termed **idiopathic hirsutism.** Anovulation virtually always occurs in the presence of virilization.

**Determining the extent of hirsutism requires a sensitive and tactful approach by the physician and should include questions about shaving and the use of chemical or mechanical depilatories.** Typically, clinical evaluation of the degree of hirsutism is subjectively classified as mild, moderate, or severe. Objective assessment is helpful, however, especially in establishing a baseline from which therapy can be evaluated. A hirsutism scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 has been used (2). Hirsutism is defined as a score higher than 8.
A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital or adult onset adrenal hyperplasia (CAH or AOAH), diabetes mellitus, and cardiovascular disease. A history of drug use should also be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause hirsutism and even virilization. During the physical examination, attention should be directed to obesity, hypertension, galactorrhea, male-pattern baldness, acne (face and back), and hyperpigmentation. Hirsutism often is the presenting symptom of Cushing syndrome, which may mimic AOAH and PCOS. Physical signs of the syndrome include “moon face,” plethora, purple striae, dorsocervical and supraclavicular fat pads, and proximal muscle weakness. The preservation or enhancement of the radial musculature, which is present in other hyperandrogenic disorders, may be a useful finding in determining the differential diagnosis.

**Role of Androgens**

Androgens and their precursors are produced by both the adrenal glands and the ovaries in response to adrenocorticotropic hormone (ACTH) and luteinizing hormone (LH), respectively (Fig. 28.1). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid dehydroepiandrosterone (DHEA) along the Δ-5 steroid pathway. This conversion is accomplished by
CYP17, an enzyme with both 17α-hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the Δ-4 steroid pathway. The metabolism of Δ-5 to Δ-4 intermediates is accomplished via a Δ-5-isomerase, 3β-hydroxysteroid dehydrogenase (3β-HSD).

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids increases prepubertally, independent of pubertal maturation of the hypothalamic–pituitary–ovarian axis. This alteration in adrenal steroid secretion is termed adrenarche and is characterized by a dramatic change in the response of the adrenal cortex to ACTH and preferential secretion of Δ-5 steroids, including 17-hydroxyprognenolone, DHEA, and 17-hydroxy pregnenolone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17-hydroxylase and the 17,20-lyase enzymes. The increase in adrenal androgens that occurs with adrenarche causes significant increases in the growth of pubic and axillary hair and production of sweat by the axillary pilosebaceous units.

Testosterone

Approximately one half of a woman’s serum testosterone is derived from peripheral conversion of secreted androstenedione, and the other half is derived from direct glandular (ovarian and adrenal) secretion. The ovaries and adrenal glands contribute about equally to testosterone production in women. The contribution of the adrenal glands is achieved primarily through secretion of androstenedione.

Approximately 66% to 78% of circulatory testosterone is bound to sex hormone–binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is weakly associated with albumin (20%–32%). A small percentage (1%–2%) of testosterone is entirely unbound or free.

The fraction of circulating testosterone that is unbound by SHBG has an inverse relationship with the SHBG concentration. Increased SHBG levels occur in situations associated with high estrogen levels such as pregnancy, the luteal phase, and use of estrogen (including oral contraceptives). Conditions causing elevated thyroid hormone levels and cirrhosis of the liver are associated with reduced fractions of free testosterone, which result from elevated SHBG levels. Conversely, as levels of SHBG decrease, free testosterone fractions increase in response to androgens, which can derive from androgenic disorders (i.e., PCOS, adrenal hyperplasia, Cushing syndrome), medications (i.e., progestational agents with androgenic biologic activities, danazol, glucocorticoids), growth hormone, hyperinsulinemia, obesity, and prolactin.

Assessment of Hyperandrogenemia

In hyperandrogenic states, increases in testosterone production are not proportionately reflected in increased total testosterone levels because of the depression of SHBG levels that occurs concomitant with increasing androgen effects on the liver. Therefore, when moderate hyperandrogenism occurs, which is characteristic of many functional hyperandrogenic states, elevations in total testosterone levels may remain within the normal range, and only free testosterone levels will reveal the hyperandrogenism. Severe hyperandrogenism, as occurs with virilization and neoplastic production of testosterone, can be detected by measures of total testosterone, however. Therefore, determination of the total testosterone level in concert with clinical assessment of a patient with hyperandrogenism is frequently sufficient for diagnosis and management. When more precise delineation of the degree of hyperandrogenism is desired, free testosterone levels can be measured to assess increases in testosterone production. Although such measurements are not necessary in evaluating most patients, they are often performed in research and may be useful in some clinical settings.
Because many practitioners measure some form of testosterone level, they should understand the methods used and their accuracy. Although equilibrium dialysis is the standard technique used for measuring free testosterone, it is expensive, complex, and usually limited to research settings. In a clinical setting, free testosterone levels can be estimated by assessment of testosterone binding to albumin and SHBG.

Testosterone that is nonspecifically bound to albumin (AT) is linearly related to free testosterone (FT) by the following equation:

\[ AT = K_a [A] \times FT \]

In this equation, AT is the albumin-bound testosterone, \( K_a \) is the association constant of albumin for testosterone, and \([A]\) is the albumin concentration.

In many cases of hirsutism, albumin levels are within a narrow physiologic range and thus do not significantly affect the concentration of free testosterone. When physiologic albumin levels are present, the free testosterone level can be estimated by measuring total testosterone as well as SHBG. In individuals with normal albumin levels, this method has reliable results compared with those of equilibrium dialysis. It provides a rapid, simple, and accurate determination of the total and calculated free testosterone level as well as the concentration of SHBG.

The level of bioavailable testosterone is based on the relationship of albumin and free testosterone in addition to the levels of actual albumin, total testosterone, and SHBG. This combination of total testosterone, SHBG, and albumin measurements can be used to obtain a more accurate estimate of available bioactive testosterone and thus the androgen effect derived from testosterone (3).

Pregnancy can alter the accuracy of measurements of bioavailable testosterone. During pregnancy, estradiol, which shares with testosterone a high affinity for SHBG, occupies a large proportion of SHBG binding sites. Thus, measurement of SHBG levels can result in overestimating the binding capacity of SHBG for testosterone. Derived estimates of free testosterone, as opposed to direct measure by equilibrium dialysis, are therefore inaccurate during pregnancy. Testosterone measurements in pregnancy are useful when autonomous secretion of testosterone by tumor or luteoma is suspected. In these instances, total testosterone determinations provide sufficient information for diagnosis.

For testosterone to exert its biologic effects on target tissues, it must be converted into its active metabolite, DHT, by 5α-reductase (a cytosolic enzyme that reduces testosterone and androstenedione). Two isoforms of 5α-reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5α-reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in men result in ambiguous genitalia, and both isoforms may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. Although DHT is the key intracellular mediator of most androgen effects, measurements of circulating levels are not clinically useful. The relative androgenicity of androgens is as follows:

- DHT = 300
- Testosterone = 100
- Androstenedione = 10
- DHEAS = 5

Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is
extremely short (about 30 minutes) but extends to several hours if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress, and levels decline steadily throughout adult life. After menopause, ovarian estrogen secretion ceases, and DHEAS levels continue to decline, whereas testosterone levels are maintained or may even increase. Although postmenopausal ovarian steroidogenesis contributes to testosterone production, testosterone levels retain diurnal variation, reflecting an ongoing and important adrenal contribution. Peripheral aromatization of androgens to estrogens increases with age, but because small fractions (2%–10%) of androgens are metabolized in this fashion, such conversion is rarely of clinical significance.

**Laboratory Evaluation**

When laboratory testing for the assessment of hirsutism is indicated, a bioavailable testosterone level (total testosterone, SHBG, and albumin level) or a calculated free testosterone level (if albumin levels are assumed to be normal) provides the most accurate assessment of the androgen effect derived from testosterone. In most clinical situations, however, total testosterone (less than or equal to 200 ng/mL), DHEAS, and 17-hydroxyprogesterone (17-OHP) measurements can be used to help detect conditions requiring further workup (Table 28.1). When hirsutism is accompanied by absent or abnormal menstrual periods, assessment of LH, follicle-stimulating hormone (FSH), prolactin, and thyroid-stimulating hormone (TSH) values are required to diagnose an ovulatory disorder. Hypothyroidism and hyperprolactinemia may be associated with reduced levels of SHBG and may increase the fraction of unbound testosterone levels, occasionally resulting in hirsutism. Elevated LH:FSH ratios are noted in some women with PCOS, but cannot be used to confirm the diagnosis. In cases of suspected Cushing syndrome, patients should undergo screening with a 24-hour urinary cortisol (most sensitive and specific) assessment or an overnight dexamethasone suppression test. For this test, the patient takes 1 mg of dexamethasone at 11:00 PM, and a blood cortisol assessment is performed at 8:00 AM the next day. Cortisol levels of 2 μg/dL or higher after overnight dexamethasone suppression require a further workup for evaluation of Cushing syndrome. Elevated 17-OHP levels identify patients with AOAH and are found in 1% to 5% of hirsute women. Levels of 17-OHP vary significantly within the menstrual cycle, increasing in the periovulatory and luteal phases, and may be modestly elevated in PCOS. Standardized testing requires evaluation in the morning during the follicular phase.

SHBG, sex hormone–binding globulin.

*Normal values may vary among different laboratories. Free testosterone is calculated using measurements for total testosterone and sex hormone–binding globulin, whereas bioavailable testosterone is calculated using measured total testosterone, sex hormone–binding globulin, and albumin. Calculated values for free and bioavailable testosterone compare well with equilibrium dialysis methods of measuring unbound testosterone when albumin levels are normal. Bioavailable testosterone includes free plus very weakly bound (non-SHBG, nonalbumin) testosterone. Bioavailable testosterone is the most accurate assessment of bioactive testosterone in the serum without performing equilibrium dialysis.*
Normal morning baseline follicular phase 17-OHP levels are less than 200 ng/dL (6 nmol/L). When levels are greater than 200 ng/dL but less than 800 ng/dL (24 nmol/L), ACTH testing should be performed to distinguish PCOS from AOAH. Levels greater than 800 ng/dL (24 nmol/L) also warrant ACTH testing but are virtually diagnostic of AOAH because of 21-hydroxylase deficiency.

Some hirsute women manifest total testosterone levels above normal (20–80 ng/dL [0.723 nmol/L]). Because increased testosterone production is not reliably reflected by total testosterone levels, the diagnosis can be based on the presence of typical male pattern hirsutism or measurement of free or unbound testosterone (bioavailable or calculated free testosterone levels). Total testosterone does, however, serve reliably as a marker for testosterone-producing neoplasms. Total testosterone levels greater than 200 ng/dL should prompt a workup for ovarian or adrenal tumors, and DHEAS levels greater than twice the upper limit of normal should prompt evaluation for adrenal neoplasm. Both total testosterone and DHEAS should be measured in the presence of virilization.

In the past, testing for androgen conjugates (e.g., 3α-androstenediol G [3α-diol G] and androsterone G [AOG]) as markers for 5α-reductase activity in the skin) has been advocated. However, routine determination of androgen conjugates to assess hirsute patients is not recommended. Hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle, and androgen conjugates arise from adrenal precursors and are likely markers of adrenal and not ovarian steroid production (4).

In most laboratories, the upper limit of a DHEAS level is 350 μg/dL (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life characteristic of sulfated steroids. A normal level essentially rules out adrenal disease, and moderate elevations are a common finding in the presence of PCOS. A DHEAS level of more than twice the upper limit of normal, 700 μg/dL (20 nmol/L), usually indicates the need to rule out an adrenal tumor or Cushing syndrome. Absolute ceilings for this threshold vary significantly with age, with levels declining steadily after a peak at around age 20 years; laboratories commonly provide reference levels for age. Rarely, ovarian tumors are associated with high DHEAS levels.

**Polycystic Ovary Syndrome**

The most common cause of hyperandrogenism and hirsutism is PCOS. The association of amenorrhea with bilateral polycystic ovaries and obesity was first described in 1935 by Stein and Leventhal (5) and was known for decades as the Stein-Leventhal syndrome. Subsequently, it is now recognized that PCOS is a disorder that is characterized principally by oligomenorrhea or amenorrhea with clinical or laboratory evidence of hyperandrogenemia. Furthermore, it is now recognized that a significant proportion of overweight women with PCOS have hyperinsulinemia. Its origins are likely polygenic or multifactorial or both (6). Following are diagnostic criteria based on the modified consensus of the National Institutes of Health and Child Health and Human Development.

- **Major**
  - Chronic anovulation
  - Hyperandrogenemia
  - Clinical signs of hyperandrogenism
  - Other etiologies excluded
- **Minor**
  - Insulin resistance
  - Perimenarchal onset of hirsutism and obesity
  - Elevated LH-to-FSH ratio
Intermittent anovulation associated with hyperandrogenemia (free testosterone, DHEAS)

In this schema, there are only two major criteria for the diagnosis of PCOS: anovulation and the presence of hyperandrogenism as established by clinical or laboratory means. These features alone are sufficient for the diagnosis in the absence of other pathologies accounting for hyperandrogenism (i.e., AOAH, adrenal or ovarian neoplasm, Cushing syndrome) or anovulation (i.e., hypogonadotropic or hypergonadotropic disorders, hyperprolactinemia, thyroid disease).

Other frequently encountered manifestations are less consistent findings and, therefore, qualify only as minor criteria. They include elevated LH:FSH ratio, insulin resistance, oligo-ovulation, perimenarchal onset of hirsutism and obesity, and ultrasonographic evidence of PCOS.

Hirsutism occurs in approximately 70% of patients with PCOS in the United States (7) and in only 10% to 20% of patients with PCOS in Japan (8). A likely explanation for this discrepancy is the genetically determined differences in skin 5α-reductase activity (9,10).

The menstrual dysfunction that occurs with PCOS arises from anovulation or oligo-ovulation and ranges from amenorrhea to oligomenorrhea. When anovulation is present, it is uncommon for women with PCOS to have regular menses, although one report found that among hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (11). Classically, the disorder may be lifelong, characterized by abnormal menses from puberty with acne and hirsutism arising in the teens. It may arise in adulthood, concomitant with the emergence of obesity, presumably because obesity is accompanied by increasing hyperinsulinemia (12).

Obesity occurs in more than 50% of patients with PCOS. The body fat is usually deposited centrally (android obesity). A higher waist-to-hip ratio is associated with insulin resistance, which indicates an increased risk of diabetes mellitus and cardiovascular disease (13).

Insulin resistance, resulting in hyperinsulinemia, is commonly exhibited in PCOS. Insulin resistance may eventually lead to the development of hyperglycemia and type 2 diabetes mellitus (14). About one third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (15). These rates are mildly increased even in nonobese women who have PCOS (10% IGT; 1.5% diabetes) (16), compared with the general population of the United States (7.8% IGT; 1% diabetes) (17).

Abnormal lipoproteins are a common finding in PCOS and include elevated total cholesterol, triglycerides, and low-density lipoproteins (LDL); and low levels of high-density lipoproteins (HDL) and apoprotein A-I (13,18). According to one report, the most characteristic lipid alteration is decreased levels of HDL (19).

Other findings that occur in women with PCOS include impaired fibrinolysis as shown by elevated circulating levels of plasminogen activator inhibitor (20), an increased incidence of hypertension over time that approaches 40% by perimenopause (18), a greater prevalence of atherosclerosis and cardiovascular disease (21,22), and an estimated sevenfold increased risk for myocardial infarction (23).

Pathology

Macrosopically, ovaries in women with PCOS are 2 to 5 times the normal size. A cross-section of the surface of the ovary discloses a white, thickened cortex with multiple cysts that are typically less than a centimeter in diameter. Microscopically, the superficial...
cortex is fibrotic and hypocellular and may contain prominent blood vessels. In addition to smaller atretic follicles, there is an increase in the number of follicles with luteinized theca interna. The stroma may contain luteinized stromal cells (24).

**Pathophysiology and Laboratory Findings**

The hyperandrogenism and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments: (i) the ovaries, (ii) the adrenal glands, (iii) the periphery (fat), and (iv) the hypothalamus–pituitary compartment.

In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the central pathogenetic mechanisms underlying hyperandrogenism in PCOS (25). The ovarian stroma, theca, and granulosa contribute to ovarian hyperandrogenism and are stimulated by LH (26). This hormone relates to ovarian androgenic activity in PCOS in a number of ways:

1. Total and free testosterone levels correlate directly with LH levels (27).
2. The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (25).
3. Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (28).
4. Larger doses of a GnRH agonist are required for androgen suppression than for endogenous gonadotropin-induced estrogen suppression (29).

The increased testosterone levels that occur in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice the upper normal range (20–80 ng/dL). However, in ovarian hyperthecosis, values may reach 200 ng/dL or more (30). The adrenal compartment also plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in both the ovaries and the adrenal glands, DHEAS is increased in only about 50% of patients with PCOS (31,32). The hyperresponsiveness of DHEAS to stimulation with ACTH (30), the onset of symptoms around puberty, and the observation that 17,20-lyase activation (one of the two CYP17 enzymes) is a key event in adrenarche have led to the hypothesis that PCOS arises as an exaggeration of adrenarche.

The peripheral compartment, defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways:

1. The presence and activity of 5α-reductase in the skin largely determines the presence or absence of hirsutism (9,10).
2. Aromatase and 17β-HSD activities are increased in fat cells (33), and peripheral aromatization is increased with body weight (34).
3. With obesity, the metabolism of estrogens, by way of reduced 2-hydroxylation and 17α-oxidation, is decreased (35), and metabolism via estrogen active 16-hydroxyestrogens (estriol) is increased.
4. Whereas E2 is at a follicular phase level in patients with PCOS, E1 levels are increased as a result of peripheral aromatization of androstenedione (36).
5. A chronic hyperestrogenic state, with reversal of the E1:E2 ratio, results and is unopposed by progesterone.
The hypothalamic–pituitary compartment also participates in aspects critical to the development of PCOS:

1. An increase in LH pulse frequency relative to those in the normal follicular phase is the result of increased GnRH pulse frequency (37).

2. This increase in LH pulse frequency explains the frequent observation of elevated LH and LH:FSH ratios.

3. FSH is not increased with LH, which may result from the combination of increased gonadotropin pulse frequency and the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibin.

4. About 25% of patients with PCOS exhibit mildly elevated prolactin levels, which may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS, administration of bromocriptine has reduced LH levels and restored ovulatory function (38).

At present, genetic studies of PCOS have reported allele sharing in large PCOS patient populations, and linkage studies have focused on candidate genes most likely to be involved in the pathogenesis of PCOS. Recent linkage reports have identified the follistatin (39), CYP11A (40), Calpain 10 (41), IRS-1 and IRS-2 regions and loci near the insulin receptor (19p13.3) (39,42), SHBG (43), and the insulin gene (44) as candidate genes associated with PCOS. Using theca cells derived from women with PCOS, elevated mRNA levels were noted for CYP11A, 3BHSD2, and CYP 17 genes with corresponding overproduction of testosterone, 17 alpha-hydroxyprogesterone, and progesterone. Despite the characteristically heightened steroidogenesis in PCOS, the STARB gene was not found to be overexpressed (39). Recent data derived from theca cells from PCOS women did not identify any genes near the 19p13.3 locus that were differentially expressed; however, the mRNAs of several genes that map to 19p13.3, including the insulin receptor, p114-Rho-GEF, and several expressed sequence tags, were detected in both PCOS and normal theca cells. Those studies further identified new factors that might affect theca cell steroidogenesis and function, including cAMP-GEFII, genes involved in all-transretinoic acid (atRA) synthesis signaling, genes that participate in the signal transduction pathway, and transcription factor GATA6. These findings suggest that a 19p13.3 locus or some other candidate gene may be a signal transduction gene that results in overexpression of a suite of genes downstream that may affect steroidogenic activity (45).

### Insulin Resistance

Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia. Insulin resistance and hyperinsulinemia participate in the ovarian steroidogenic dysfunction of PCOS. Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulinlike growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor–mediated signaling (diminished autophosphorylation) has been identified in 50% of women with PCOS (46).

The most common cause of insulin resistance and compensatory hyperinsulinemia is obesity, but despite its frequent occurrence in PCOS, obesity alone does not alone explain this important association (38). The following observations provide evidence that the insulin resistance associated with PCOS is not the result of hyperandrogenism:

1. Hyperinsulinemia is not a characteristic of hyperandrogenism in general but is uniquely associated with PCOS (47).
2. In obese women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (47). The associations between PCOS and obesity on the action of insulin appear to be synergistic.

3. Suppression of ovarian steroidogenesis with long-acting GnRH analogs in women with PCOS does not change insulin levels or insulin resistance (48).

4. Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change insulin resistance, despite a decrease in androgen levels (49).

Acanthosis nigricans is a reliable marker of insulin resistance in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, beneath the breast, and on the inner thigh (50). The HAIR-AN syndrome (46,51) consists of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN). These patients often have high testosterone levels (>150 ng/dL), fasting insulin levels of greater than 25 μIU/mL (normal <20 to 24 μIU/mL), and maximal serum insulin responses to glucose load (75 g) exceeding 300 μIU/mL (normal <160 μIU/mL at 2 hours postglucose load).

Screening Strategies for Diabetes and Insulin Resistance

Multiple testing and screening approaches have been proposed to assess the presence of hyperinsulinemia and insulin resistance. In one approach, the fasting glucose:insulin ratio is determined, and values less than 4.5 indicate insulin resistance. Using the 2-hour glucose tolerance test (GTT) with insulin levels, 10% of nonobese and 40% to 50% of obese women with PCOS have impaired glucose tolerance (IGT = 2 hr glucose level ≥140 or ≥199 mg/dL) or overt type II diabetes mellitus (any glucose level >200 mg/dL). Some research studies have utilized a peak insulin level of more than 150 μIU/mL or a mean level of more than 84 μIU/mL over the three blood draws of a 2-hour GTT as criteria for the diagnosis of hyperinsulinemia (Table 28.2).

The documentation of hyperinsulinemia using either the glucose:insulin ratio or the 2-hour GTT with insulin is problematic. When compared with the standard measure for insulin resistance, the hyperinsulinemic-euglycemic clamp, the glucose:insulin ratio does not always accurately portray insulin resistance. Furthermore, a relative insulin secretion deficit exists in the presence of hyperglycemia. This deficit in appropriate insulin secretion exacerbates the effects of insulin resistance and renders inaccurate the use of hyperinsulinemia as an index of insulin resistance. Thus, routine measurements of insulin levels may not be particularly useful.

*WHO Criteria, after 75-g glucose load.*
Although detection of insulin resistance per se is not of practical importance to the diagnosis or management of PCOS, testing women with PCOS for glucose intolerance is of value because their risk of cardiovascular disease correlates with this finding. An appropriate frequency for such screening depends on age, body mass index, and waist circumference, all of which increase risk.

**Interventions**

Abnormal glucose metabolism may be significantly improved with weight reduction, which also may reduce hyperandrogenism and restore ovulatory function (52). In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the severity of insulin resistance (a 40% decrease in insulin level with a 10-kg weight loss) (53). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (54). Exercise also reduces insulin resistance, independent from any associated weight loss, but data on the impact of exercise on the principal manifestations of PCOS are lacking.

Insulin resistance/hyperinsulinemia has been recognized as a cluster syndrome now called the *metabolic syndrome* or *dysmetabolic syndrome X*. Its importance as a risk factor for cardiovascular disease has led to the establishment of diagnostic criteria. Three criteria confirm the diagnosis, and the greater the number of dysmetabolic syndrome X diagnostic criteria present, the higher the level of insulin resistance and its consequences. Patients who may be candidates for treatment with an insulin-lowering agent may be identified by the following diagnostic criteria:

- Female waist >35 inches
- Triglycerides >150 mg/dL
- HDL cholesterol <50 mg/dL
- Blood pressure >130/85 mm Hg
- Fasting glucose: 110–125 mg/dL
- 2-hour GTT (75 g): 140–199 mg/dL

Risk factors include non-Caucasian race, sedentary lifestyle, body mass index (BMI) >25, age older than 40 years, cardiovascular disease, hypertension, PCOS, hyperandrogenemia, insulin resistance, HAIR-AN syndrome, nonalcoholic steatohepatosis, and a family history of type II diabetes mellitus or gestational diabetes or impaired glucose tolerance.

**Ultrasonographic Studies**

Ultrasonographic examination often shows characteristic abnormalities in women with PCOS (55,56). Ovarian size often is increased. The most important ultrasonographic finding is a bilateral increase in the number of microcysts measuring 0.5 to 0.8 cm, with generally more than five microcysts in any given imaging plane in each ovary. These findings are neither sufficiently sensitive nor specific to be considered an important part of the evaluation of women in whom PCOS is suspected.

**Long-term Risks**

In patients with PCOS who have chronic anovulation, persistently elevated estrogen levels, unopposed by progesterone, increase the risk of endometrial carcinoma (57). These endometrial cancers are usually well-differentiated, stage I lesions with cure rates approaching 100% (see Chapter 33). Endometrial biopsy should be considered in PCOS patients, as they may occasionally have these cancers as early as the third decade of life. Abnormal bleeding, increasing weight, and age are factors that should influence the
decision to perform endometrial sampling. Prevention of endometrial cancer is a goal of management in patients with PCOS. If other dimensions of management do not induce regular ovulation (e.g., clomiphene) or impose continuous progesterational influence (e.g., oral contraceptives), regular secretory transformation and menstruation should be induced with periodic administration of a progesterational agent. Likewise, the hyperestrogenic state is associated with an increased risk of breast cancer (58) and ovarian cancer (two- to three-fold increase) (59). The risk is greater in nonobese women and those who have not been taking oral contraceptives (OCs).

**Treatment of Hyperandrogenism and PCOS**

Treatment depends on a patient’s goals. Some patients require hormonal contraception, whereas others desire ovulation induction. In all cases in which there is significant ovulatory dysfunction, progesterational interruption of unopposed estrogen effects on the endometrium is required. This may be accomplished by periodic luteal function resulting from ovulation induction, progesterational control via contraceptive formulations, or intermittent administration of progesterational agents for endometrial or menstrual regulation. Interruption of the steady state of hyperandrogenism and control of hirsutism usually can be accomplished simultaneously. An exception is those patients desiring pregnancy, in whom effective control of hirsutism may not be possible. Treatment regimens for hirsutism are listed in Table 28.3. The induction of ovulation and treatment of infertility are discussed in Chapter 30.

**Weight Reduction**

Weight reduction is the initial recommendation for patients with accompanying obesity because it promotes health; reduces insulin, SHBG, and androgen levels; and may restore ovulation either used alone or in combination with ovulation-induction agents (53). Weight loss of as little as 5% to 7% over a 6-month period can reduce the bioavailable or calculated free testosterone level significantly and restore ovulation and fertility in more than 75% of women (60). Exercise involving large muscle groups

**Table 28.3 Medical Treatment of Hirsutism**
reduces insulin resistance and can be an important component of nonpharmacologic, lifestyle-modifying management.

### Oral Contraceptives

**Combination OCs decrease adrenal and ovarian androgen production** (61–64) and reduce hair growth in nearly two thirds of hirsute patients. Treatment with OCs offers the following benefits:

1. **The progestin component suppresses LH**, resulting in diminished ovarian androgen production.

2. **The estrogen increases hepatic production of SHBG**, resulting in decreased free testosterone concentration (65,66).

3. **Circulating androgen levels are reduced**, including those of DHEAS, which to some extent is independent of the effects of both LH and SHBG (13,67).

4. **Estrogens decrease conversion of testosterone to DHT** in the skin by inhibition of 5α-reductase.

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (norgestrel, norethindrone, and norethindrone acetate) are believed to be androgen dominant. The androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids (68). Oral contraceptives containing the so-called new progestins (desogestrel, gestodene, norgestimate, and drospirenone) have minimized androgenic activity. There is limited evidence that there is a difference in clinical outcome determined by these differences in in vitro estimates of androgenic potency, however.

**Medroxyprogesterone Acetate**

Oral or intramuscular administration of medroxyprogesterone acetate has been used successfully for treatment of hirsutism (71). It directly affects the hypothalamic–pituitary axis by decreasing GnRH production and the release of gonadotropins, thereby reducing testosterone and estrogen production by the ovary. Despite a decrease in SHBG, total and free androgen levels are decreased significantly (72). The recommended oral dosage is 20 to 40 mg daily in divided doses or 150 mg given intramuscularly every 6 weeks to 3 months in the depot form. Hair growth is reduced in as many as 95% of patients (73). Side effects of the treatment include amenorrhea, bone mineral density loss, depression, fluid retention, headaches, hepatic dysfunction, and weight gain.

**Gonadotropin-releasing Hormone Agonists**

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources (29). It has been shown to suppress ovarian steroids to castrate levels in patients with PCOS (74). Treatment with leuprolide acetate given intramuscularly every 28 days decreases hirsutism and hair diameter in both idiopathic hirsutism and hirsutism secondary to PCOS (75). Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add-back therapy) prevents bone loss and other side effects of menopause, such as hot flushes and genital atrophy. The hirsutism-reducing
effect is retained (72,76). Suppression of hirsutism is not potentiated by the addition of estrogen therapy to GnRH agonist treatment (77).

**Glucocorticoids**

*Dexamethasone* may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of *dexamethasone* as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 μg/dL. *Because dexamethasone has 40 times the glucocorticoid effect of cortisol*, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing syndrome. To avoid oversuppression of the pituitary–adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 μg/dL). Reduction in hair growth rate has been reported (78), as well as significant improvement in acne associated with adrenal hyperandrogenism.

**Ketoconazole**

*Ketoconazole*, an antifungal agent approved by the U.S. Food and Drug Administration, inhibits the key steroidogenic cytochromes. Administered at a low dose (200 mg/day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (79).

**Spironolactone**

*Spironolactone* is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is an effective potassium-sparing diuretic that was originally used for treatment of hypertension. The effectiveness of *spironolactone* in the treatment of hirsutism is based on the following mechanisms:

1. Competitive inhibition of DHT at the intracellular receptor level (9)
2. Suppression of testosterone biosynthesis by a decrease in the CYP enzymes (80)
3. Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone)
4. Inhibition of skin 5α-reductase activity (9)

Although total and free testosterone levels are significantly reduced in patients with both PCOS and idiopathic hirsutism (hyperandrogenism with regular menses) after treatment with *spironolactone*, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (hyperandrogenism with regular menses) (81). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of *spironolactone* treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of *spironolactone* daily for 6 months (82). Spironolactone reduces the daily linear growth rate of sexual hair, hair-shaft diameters, and daily hair volume production (83). The most common dosage is 50 to 100 mg twice daily. Women treated with 200 mg/day show a greater reduction in hair-shaft diameter than women receiving 100 mg/day (84). Maximal effect on hair growth is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of *spironolactone* for permanent hair removal.

The most common side effect of *spironolactone* is menstrual irregularity (usually metrorrhagia), which may occur in more than 50% of patients with a dosage of
200 mg/day (84). Normal menses may resume with reduction of the dosage. Infrequently, other side effects—such as mastodynia, urticaria, or scalp hair loss—occur. Nausea and fatigue can occur with high doses (82). Because spironolactone can increase serum potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in as many as 60% of cases (81). Patients must be counseled to use contraception while taking spironolactone because it theoretically can feminize a male fetus.

Cyproterone Acetate

Cyproterone acetate is a synthetic progestin derived from 17-OHP that has potent antiandrogenic properties. The primary mechanism of cyproterone acetate is competitive inhibition of testosterone and DHT at the level of androgen receptors (80). This agent also induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (85). A European formulation of ethinyl estradiol with cyproterone acetate significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG levels (86). Cyproterone acetate also shows mild glucocorticoid activity (87) and may reduce DHEAS levels (88). Administered in a reverse sequential regimen (cyproterone acetate 100 mg/day on days 5 to 15, and ethinyl estradiol 30–50 mg/day on cycle days 5 to 26), this cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (89).

Side effects of cyproterone acetate include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when ethinyl estradiol is added. Cyproterone acetate administration has been associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration for use in the United States.

Flutamide

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than spironolactone or cyproterone acetate, larger doses (250 mg given two or three times daily) may compensate for the reduced potency. Flutamide is also a weak inhibitor of testosterone biosynthesis.

In a single, 3-month study of flutamide alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (90). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of flutamide and low-dose OCs in women who did not respond to OCs alone (91). The side effects of flutamide treatment combined with a low-dose OC use included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast tenderness (92).

In hyperinsulinemic, hyperandrogenemic nonobese adolescents with PCOS taking a combination of metformin (850 mg/day) and flutamide (62.5 mg/day), a low-dose OC containing drospirenone was more effective than an OC with gestodene in reducing total and abdominal fat excess (93). The combination of ethinyl-drospirenone, metformin, and flutamide is effective in reducing excess total and abdominal fat as well as attenuating dysadipocytokinemia in young women with the hyperinsulinemic PCOS. The antiandrogen flutamide appeared to exert critical effects (94).

Many patients taking flutamide (50%–75%) report dry skin and a blue-green discoloration of urine. The risk of liver enzyme elevation may preclude flutamide as a routine
option for the treatment of hirsutism. Flutamide should not be used in women desiring pregnancy.

**Cimetidine**

*Cimetidine* is a histamine H₂ receptor antagonist that has demonstrated a weak antian-drogenic effect as a result of its ability to occupy androgen receptors and inhibit DHT binding at the level of the hair follicles. Although *cimetidine* has been reported to reduce hair growth in women with hirsutism (95), two later studies show no beneficial effect (96,97).

**Finasteride**

*Finasteride* is a specific inhibitor of type 2 5α-reductase enzyme activity that has been approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia and at a 1-mg dose to treat male pattern baldness. In a study in which *finasteride* (5 mg daily) was compared with *spironolactone* (100 mg daily) (98), both drugs resulted in similar significant improvement in hirsutism despite differing effects on androgen levels. Most of the improvement in hirsutism occurred after 6 months of therapy with 7.5 mg of *finasteride* daily (99). The improvement in hirsutism in the presence of rising testosterone levels serves as convincing evidence that it is the binding of DHT and not testosterone to the androgen receptor that is responsible for hair growth. *Finasteride* does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs used in combination with *finasteride* are more effective in reducing hirsutism than *finasteride* alone. As with *spironolactone* and *flutamide*, *finasteride* could theoretically feminize a male fetus; therefore, both of these agents should be used only with additional contraception.

**Ovarian Wedge Resection**

Bilateral ovarian wedge resection is associated with only a transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (100,101). In patients with hirsutism and PCOS who have had wedge resection, hair growth was reduced by approximately 16% (5,102). Although Stein’s original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and an increased incidence of periovarian adhesions (103).

**Laparoscopic Electrocautery**

Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to *clomiphene citrate*. In a recent series (104), ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to aid in entry and 40-W coagulating current to treat each microcyst over 2 seconds (8-mm needle in ovary). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who had undergone a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary only in four points led to a similar pregnancy rate (105), with a miscarriage rate of 14%. Most series report a decrease in both androgen and LH concentrations and an increase in FSH concentrations (106,107). Unilateral diathermy has been shown to result in bilateral ovarian activity (108). The risk of adhesion formation should be discussed with the patient.

**Physical Methods of Hair Removal**

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. *Eflornithine hydrochloride* cream, also known as *difluoromethylornithine* (DMFO), irreversibly blocks ornithine decarboxylase (ODC), the
enzyme in hair follicles that is important in regulating hair growth. It also has proved effective in the treatment of unwanted facial hair (109).

Shaving is effective and, contrary to common belief, it does not change the quality, quantity, or texture of hair (110). However, plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (110).

Bleaching removes the hair pigment through the use of hydrogen peroxide (usually 6% strength), which is sometimes combined with ammonia. Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration or skin irritation and is not always effective (109).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can also be an obstacle (111). Laser hair removal destroys the hair follicle through photoablation. These methods are most effective after medical therapy has arrested further growth.

**Insulin Sensitizers**

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Metformin (Glucophage) is an oral biguanide antihyperglycemic drug used extensively for non–insulin-dependent diabetes. Preliminary studies evaluating metformin use in pregnancy (category B status) suggest no teratogenicity and a reduced miscarriage rate but a potential increased risk of preeclampsia and perinatal mortality (112,113). Metformin lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. Metformin enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (114). The hyperandrogenism of PCOS is substantially relieved with metformin therapy, which leads to a drop in insulin levels and improved reproductive function (115,116,117). Metformin (500 mg three times daily) increases ovulation rates both spontaneously and when used in combination with clomiphene citrate in obese patients with PCOS. In this group, a 90% ovulation rate has been achieved (118). In a Cochrane meta-analysis, metformin monotherapy improved the ovulation rate 3.9-fold over placebo, and the combination of metformin and clomiphene citrate improved both the ovulation and pregnancy rates 4.4-fold compared with clomiphene citrate use alone (119).

The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug has caused fatal lactic acidosis in men with diabetes who have renal insufficiency, baseline renal function testing is suggested (120). The drug should not be given to women with elevated serum creatinine levels (114).

In light of the association between the dysmetabolic syndrome and PCOS, it has been suggested that metformin may be an appropriate first-line agent for ovulation induction. Regardless of whether metformin is used as a primary ovulation induction agent or in combination with clomiphene citrate, weight loss should be encouraged.

Current concepts regarding the role of obesity and insulin resistance/hyperinsulinemia in PCOS suggest that the primary intervention should be weight loss (5%–10% of body
weight). In those with an elevated BMI, orlistat has proven to be helpful in initiating and maintaining weight loss. A percentage of PCOS patients will respond to weight loss alone with spontaneous ovulation. In those who do not respond to weight loss alone or who are unable to lose weight, the sequential addition of clomiphene citrate followed by an insulin sensitizer alone, followed by a combination of these agents, may promote ovulation without the need to proceed to injectable gonadotropin therapy.

The increased incidence of spontaneous abortions in women with PCOS is a prevailing concern. Because of the potential reduction afforded by insulin sensitizers, these agents may be beneficial in combination with gonadotropin therapy for ovulation induction or in vitro fertilization (121).

Women with early pregnancy loss have a low level of circulating glycodelin, which has immunomodulatory effects protecting the developing fetus, and of IGF-binding protein (IGFBP)-1. Use of metformin increases levels of both factors, which might explain early findings suggesting it may reduce the high spontaneous abortion rates seen among women with PCOS (122). In an assessment of 68 women treated with metformin during pregnancy versus 31 not treated, early pregnancy loss rates were 6/68 versus 13/31, respectively (123). Information regarding an optimal timing for such treatment is unknown.

Cushing Syndrome

The adrenal cortex produces three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This state causes muscle weakness; osteoporosis; atrophy of the skin with striae, nonhealing ulcerations, and ecchymoses; reduced immune resistance that increases the risk of bacterial and fungal infections; and glucose intolerance resulting from enhanced gluconeogenesis and antagonism to insulin action.

Although most patients with Cushing syndrome gain weight, some lose it. Obesity is typically central, with characteristic redistribution of fat over the clavicles around the neck and on the trunk, abdomen, and cheeks. Cortisol excess may lead to insomnia, mood disturbances, depression, and even overt psychosis. With overproduction of sex steroid precursors, women may exhibit hyperandrogenism (hirsutism, acne, oligomenorrhea or amenorrhea, thinning of scalp hair). Masculinization is rare, and its presence suggests an autonomous adrenal origin, most often an adrenal malignancy. With overproduction of mineralocorticoids, patients may manifest arterial hypertension and hypokalemic alkalosis. The associated fluid retention may cause pedal edema.

Characteristic clinical laboratory findings associated with hypercortisolism are confined mainly to a complete blood count showing evidence of granulocytosis and reduced levels of lymphocytes and eosinophils. Increased urinary calcium secretion may be present.

Causes

The six recognized noniatrogenic causes of Cushing syndrome can be divided between those that are ACTH dependent and those that are ACTH independent (Table 28.4). The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing syndrome is the presence of normal or high plasma ACTH concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing disease, is the most common cause of Cushing syndrome. These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as if they are resistant, to a variable degree, to the feedback effect of cortisol. As with the normal gland, these tumors secrete...
ACTH in a pulsatile fashion; unlike the normal gland, the diurnal pattern of cortisol secretion is lost. **Ectopic ACTH syndrome most often is caused by malignant tumors.** About one half of these tumors are small-cell carcinomas of the lung (124). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include such tumors as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (124). The presence of an ectopic CRH-secreting tumor should be suspected in patients whose dynamic testing suggests pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

The most common cause of ACTH-independent Cushing syndrome is exogenous or iatrogenic (i.e., superphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, such therapy will result in Cushing syndrome. When corticosteroids are taken by the patient but not prescribed by a physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing syndrome focuses on the ability to suppress autonomous cortisol secretion and determine whether ACTH is elevated or suppressed; it is summarized in Figure 28.2, Tables 28.5, and 28.6 (125–131).

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

*ACTH-dependent Cushing syndrome may be caused by pituitary adenoma, basophil hyperplasia, nodular adrenal hyperplasia, or cyclic Cushing syndrome.

Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest. This is because the tumors are relatively inefficient in the synthesis of steroid hormones. In general, tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing syndrome is accompanied by hirsutism or virilization in women, or by feminization in men, adrenal cancer should be suspected.

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy or radiation may be achieved. Most patients with malignancy die within 1 year. When administered
Figure 28.2 The workup of Cushing syndrome. DXM, dexamethasone; ACTH, adrenocorticotropic hormone; CT, computed tomography; MRI, magnetic resonance imaging. CRH,
immediately after surgery, mitotane (O,P-DDD, adrenocorticolytic drug) may be of benefit in preventing or delaying recurrent disease (132). Manifestations of Cushing syndrome in these patients are controlled by administration of adrenal enzyme inhibitors. Adrenal adenomas are smaller than carcinomas and average 3 cm in diameter. These tumors are usually unilateral and infrequently are associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (133,134). If a unilateral, well-circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Because normal function of the hypothalamic–pituitary–adrenal axis is suppressed by autonomous cortisol production, cortisol replacement should follow...
surgery. The dosage is titrated downward over several months, during which recovery of normal adrenal function is monitored.

Treatment of Cushing Disease

The treatment of choice for Cushing disease is transsphenoidal resection. The cure rate is approximately 80% in patients with microadenomas who undergo surgery (128) and is less than 50% in patients with macroadenomas (129). Following surgery, transient diabetes insipidus and enduring compromise of anterior pituitary secretion of growth hormone, gonadotropins, and TSH are common (130).

Radiation Therapy

High-voltage external pituitary radiation (4,200–4,500 cGy) is given at a rate not exceeding 200 cGy/day. Although only 15% to 25% of adults show total improvement (130), approximately 80% of children respond (131).

Medical Therapy

Mitotane can be used to induce medical adrenalectomy during or after pituitary radiation (132). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include aminoglutethimide, metyrapone, trilostane, and etomidate.
A combination of aminogluthethimide and metyrapone may cause a total adrenal enzyme block requiring corticosteroid-replacement therapy. Ketoconazole also inhibits adrenal steroid biosynthesis at the side arm cleavage and 11β-hydroxylation steps. The dose of ketoconazole for adrenal suppression is 600 to 800 mg/day for 3 months to 1 year (135). Ketoconazole is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

Nelson syndrome results from adenomatous progression of ACTH-secreting cells in patients with Cushing syndrome treated by bilateral adrenalectomy. The macroadenoma that causes this syndrome produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels in Nelson syndrome are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation. The offending adenomatous tissue is often resistant to complete surgical removal (136). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Nelson syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment.

**Congenital Adrenal Hyperplasia**

Congenital adrenal hyperplasia is transmitted as an autosomal recessive disorder. Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects:

1. A relative decrease in cortisol production
2. A compensatory increase in ACTH levels
3. Hyperplasia of the zona reticularis of the adrenal cortex
4. An accumulation of the precursors of the affected enzyme in the bloodstream

**21-Hydroxylase Deficiency**

Deficiency of 21-hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from adrenal synthetic enzyme deficiency. The disorder produces a spectrum of conditions of CAH, with or without salt wasting, and milder forms that are expressed as hyperandrogenism of pubertal onset (AOAH). Salt-wasting CAH, the most severe form, affects 75% of patients with congenital manifestations during the first 2 weeks of life, and results in a life-threatening hypovolemic salt-wasting crisis, accompanied by hyponatremia, hyperkalemia, and acidosis. The salt-wasting form arises from a severity of enzyme deficiency sufficient to result in ineffective aldosterone synthesis. With or without salt-wasting and newborn adrenal crisis, the condition is usually diagnosed earlier in affected female newborns than in male newborns because genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course) is apparent at birth.

In simple virilizing CAH, affected patients are diagnosed as virilized newborn girls or as rapidly growing masculinized boys at 3 to 7 years of age. The diagnosis is based on basal levels of the substrate for 21-hydroxylase, 17-hydroxyprogesterone (17-OHP) in cases of congenital adrenal hyperplasia caused by 21 hydroxylase deficiency. In milder forms of the disorder with manifestations later in life (acquired, late-onset, or adult-onset adrenal hyperplasia), the diagnosis depends on basal and ACTH-stimulated levels of 17-OHP.

1. Basal follicular phase 17-OHP less than 200 ng/dL virtually excludes the disorder; no further testing is required.
2. Basal 17-OHP greater than 500 ng/dL establishes the diagnosis; there is no need for further testing (137).

3. Basal 17-OHP greater than 200 ng/dL and less than 500 ng/dL requires ACTH stimulation testing.

4. In the ACTH stimulation test, plasma levels of 17-OHP are checked 1 hour following intravenous administration of a bolus of 0.25 mg ACTH 1-24 (cosynotropin [Cortrosyn]) (Fig. 28.3). 17-OHP levels after ACTH stimulation in adult-onset adrenal hyperplasia are generally greater than 1,000 ng/dL (137) (see Fig. 28.3).

5. Individuals who are heterozygous (carriers) for both adult-onset adrenal hyperplasia and CAH reveal stimulated 17-OHP values less than 1,000 ng/dL. In many cases, an overlap with the values seen in the normal population is observed (138) (see Fig. 28.3).

Nonclassic Adult-onset Congenital Adrenal Hyperplasia

The nonclassic type of 21-hydroxylase deficiency represents partial deficiency in 21-hydroxylation, which produces a late-onset, milder hyperandrogenemia. Its occurrence depends on some degree of functional deficit resulting from mutations affecting both alleles for the 21-hydroxylase enzyme. Heterozygote carriers for mutations in the 21-hydroxylase enzyme will demonstrate normal basal and modestly elevated stimulated levels of 17-OHP but no abnormalities in circulating androgens. Some women with a mild gene defects in both alleles demonstrate modest elevations in circulating 17-OHP concentrations but no clinical symptoms or signs.

Figure 28.3 Basal and stimulated 17-hydroxyprogesterone concentration.
The hyperandrogenic symptoms of AOAH are mild and typically present during or after puberty. Following are the three phenotypic varieties (137):

1. Those with ovulatory abnormalities and features consistent with PCOS (39%)
2. Those with hirsutism alone without oligomenorrhea (39%)
3. Those with elevated circulating androgens but without symptoms (cryptic) (22%)

The need for screening patients with hirsutism for adult-onset adrenal hyperplasia depends on the patient population. The frequency of some form of the disorder varies by ethnicity and is estimated at 0.1% of the general population, 1% to 2% of Hispanics and Yugoslavs, and 3% to 4% of Ashkenazi Jews (139).

Genetics of 21-Hydroxylase Deficiency

1. The 21-hydroxylase gene is located on the short arm of chromosome 6, in the midst of the HLA region.
2. The 21-hydroxylase gene is now termed CYP21. Its homologue is the pseudogene CYP21P (140).
3. Because CYP21P is a pseudogene, the lack of transcription renders it nonfunctional. The CYP21 is the active gene.
4. The CYP21 gene and the CYP21P pseudogene alternate with two genes called C4B and C4A, both of which encode for the fourth component (C4) of serum complement (140).
5. The close linkage between the 21-hydroxylase genes and HLA alleles has allowed the study of 21-hydroxylase inheritance patterns in families through blood HLA typing (e.g., linkage of HLA-B14 was found in Ashkenazi Jews, Hispanics, and Italians) (141).

Prenatal Diagnosis and Treatment

Women with congenital and adult-onset forms of the disorder are at a significant risk for having affected infants because of the high frequency of mutations in 21-hydroxylase mutations in the general population. This fact represents an important rationale for screening hyperandrogenic women for this disorder if they anticipate childbearing. In families at risk for CAH, and in instances in which one partner expresses the congenital or adult-onset form of the disease, first-trimester prenatal screening using chorionic villus sampling is advocated (140). Currently, the fetal DNA is used for specific amplification of the CYP21 gene using polymerase chain reaction (PCR) (142). When there is evidence of fetal involvement, an aggressive and controversial approach involves the use of dexamethasone treatment for all pregnant women at risk of having a child with CAH. The dosage is 20 mg/kg in three divided doses administered as soon as pregnancy is recognized and no later than 9 weeks of gestation. This is done before performing chorionic villus sampling or amniocentesis in the second trimester. Dexamethasone crosses the placenta and suppresses ACTH in the fetus. If the fetus is found to be an unaffected female or a male, treatment is discontinued. If the fetus is an affected female, dexamethasone therapy is continued. When dexamethasone is administered before 9 weeks of gestation and is continued to term, it effectively reduces genital ambiguity in genetic females (140). However, at least two thirds of treated females may still require surgical repair of the genitalia. Although prenatal treatment reduces
virilization in females, the efficacy and safety to both mother and baby have not been verified, and the unnecessary treatment of seven of every eight pregnancies poses a ethical dilemma (143).

11β-Hydroxylase Deficiency

In a small percentage of patients with CAH, hypertension rather than mineralocorticoid deficiency develops. The hypertension responds to corticosteroid replacement (144). Most of these patients have a deficiency in 11β-hydroxylase. In most populations, 11β-hydroxylase deficiency accounts for 5% to 8% of the cases of CAH, or 1 in 100,000 births (145). A much higher incidence, 1 in 5,000 to 7,000, has been described in Moroccan Jewish immigrants (146).

Two 11β-hydroxylase isoenzymes, CYP11-B1 and CYP11-B2, are responsible for synthesis of cortisol and aldosterone, respectively. They are encoded by two genes on the middle of the long arm of chromosome 8 (147,148).

Inability to synthesize a fully functional 11β-hydroxylase enzyme causes a decrease in cortisol production, a compensatory increase in ACTH secretion, and increased production of androstenedione, 11-deoxycortisol, 11-deoxycorticosterone, and DHEA. The diagnosis of 11β-hydroxylase-deficient late-onset adrenal hyperplasia is determined when 11-deoxycortisol levels are higher than 25 ng/mL 60 minutes after ACTH 1-24 stimulation (149).

Patients with 11β-hydroxylase deficiency may present with either a classic pattern of the disorder or symptoms of a mild deficiency. The severe, classic form is found in about two thirds of the patients with mild-to-moderate hypertension during the first years of life. In about one third of the patients, it is associated with left ventricular hypertrophy, with or without retinopathy, and death is occasionally reported from cerebrovascular accident (144). Signs of androgen excess are common in the severe form and are similar to those seen in the 21-hydroxylase deficiency.

In the mild, nonclassic form, children are found to have virilization or precocious puberty but not hypertension. Adult women seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3β-Hydroxysteroid Dehydrogenase Deficiency

Deficiency of 3β-hydroxysteroid dehydrogenase occurs with varying frequency in hirsute patients (150,151). The enzyme is found in both the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming Δ-5 steroids into the corresponding Δ-4 compounds, a step integral to the synthesis of glucocorticoids, mineralocorticoids, as well as testosterone and estradiol. In severe forms, cortisol and mineralocorticoids are deficient. In mild forms, elevated ACTH levels overcome these critical deficiencies, and the diagnosis of this disorder relies on the relationship of Δ-5 and Δ-4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal or mildly elevated testosterone or androstenedione may be a signal to initiate a screening protocol for 3β-hydroxysteroid dehydrogenase deficiency using exogenous ACTH stimulation (150). Following intravenous administration of a 0.25-mg ACTH 1-24 bolus, 17-hydroxypregnenolone levels rise significantly within 60 minutes in women with 3β-hydroxysteroid dehydrogenase deficiency compared with normal women (2.276 ng/dL compared with normal of 1,050 ng/dL). The mean poststimulation ratio between 17-hydroxypregnenolone and 17-OHP is markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). Because of the rarity of this disorder, routine screening of hyperandrogenic patients is not justified (150,151).
In adults with CAH, dexamethasone has been shown to suppress the hypothalamic–pituitary axis better than cortisone acetate or hydrocortisone administered in equivalent doses. It also may induce less fluid retention than other corticosteroids. Evening administration with a dosage of 0.25 to 0.5 mg is most effective (152). In some patients, alternate-day therapy using the same dosage is sufficient. Periodic evaluation of serum cortisol is recommended. If morning serum cortisol concentrations are maintained at greater than 2 μg/dL, oversuppression, with consequent impaired hypothalamic–pituitary–adrenal responsiveness to acute stress, is unlikely (153). Many patients with AOAH undoubtedly are treated, undiagnosed, with therapies for ovarian hyperandrogenism or PCOS, with progestins for endometrial regulation, clomiphene citrate or gonadotropins for ovulation induction, or progestins and antiandrogens for control of hirsutism. These therapies may be appropriate as an alternative to glucocorticoid therapy, even when AOAH is recognized as the cause for the patient’s symptoms.

Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization. All patients with rapidly progressing or severe hyperandrogenism should undergo determination of levels of testosterone and DHEAS. A markedly elevated total testosterone level (2.5 times the upper normal range or >200 ng/dL) is typical of an ovarian androgen-secreting tumor, and a DHEAS level greater than 800 μg/dL is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is less than 3.3 μg/dL after dexamethasone administration (154). The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable (155).

A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of findings suggesting ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor diagnosis and localization (156).

Computed tomography scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors or benign incidental nodules (157). In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors (156,157).

Magnetic resonance imaging is comparable, if not superior, to CT scanning in detecting ovarian neoplasms, but it is neither more sensitive than high-quality ultrasonography nor more useful in clinical decision making when a likely neoplasm is identified by ultrasonography. Nuclear medicine imaging of the abdomen and pelvis after injection with NP-59 ([131-iodine] 6-beta-iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate tumor localization (150). In the rare circumstances when imaging fails to provide clear evidence of a neoplastic source of excess androgens, selective venous catheterization with measurement of site-specific androgen levels to identify an occult source of androgen excess may be utilized (158). If all four vessels are catheterized transfemorally, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values (159). Under such circumstances, specificity approaches 80%, but this rate should be weighed against the 5% rate of significant complications, such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure (160).
Androgen-producing Ovarian Neoplasms

Ovarian neoplasms are the most frequent androgen-producing tumors. Granulosa cell tumors constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (in postmenopausal more frequently than in premenopausal women) (see Chapter 35). Usually associated with estrogen production, they are the most common functioning tumors in children and lead to isosexual precocious puberty (161). Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the treatments of choice. If fertility is desired, in the absence of contralateral ovarian or pelvic node involvement, unilateral salpingo-oophorectomy is justifiable. The malignant potential of these lesions is variable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia (161).

Thecomas are rare and occur in older patients. In one study, only 11% were found to be androgenic, even in the presence of steroid-type cells (luteinized thecomas) (161). The tumor is rarely malignant and rarely bilateral, and a simple oophorectomy is sufficient treatment.

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years (161). A few cases with estrogenic or androgenic manifestations have been reported.

Sertoli-Leydig cell tumors, previously classified as androblastoma or arrhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts (161). Sertoli-Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA (161). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal (162).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTATs) are frequently associated with Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation) (163). Their morphologic features range between those of the granulosa cell and Sertoli cell tumors. Whereas SCTATs with Peutz-Jeghers syndrome tend to be bilateral and benign, SCTATs without Peutz-Jeghers syndrome are almost always unilateral and are malignant in one fifth of cases (161).

Steroid Cell Tumors

Steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific (161). Virilization or hirsutism is encountered with three fourths of Leydig cell tumors, with one half of steroid cell tumors that are not otherwise specific, and with 12% of stromal luteomas.

Nonfunctioning Ovarian Tumors

Ovarian neoplasms that do not directly secrete androgens are occasionally associated with androgen excess resulting from secretion by adjacent ovarian stroma. Such tumors include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas (164). Gonadoblastomas arising
in the dysgenetic gonads of patients with a Y chromosome may be associated with androgen and estrogen secretion (165,166).

**Stromal Hyperplasia and Stromal Hyperthecosis**

*Stromal hyperplasia* is a nonneoplastic proliferation of ovarian stromal cells. Stromal hyperthecosis is defined as the presence of luteinized stromal cells at a distance from the follicles (167). Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with hyperandrogenism, endometrial carcinoma, obesity, hypertension, and glucose intolerance (167). *Hyperthecosis* also is seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate severe clinical manifestations of virilization, obesity, and hypertension. Hyperinsulinemia and glucose intolerance may occur in as many as 90% of patients with hyperthecosis and may play a role in the etiology of stromal luteinization and hyperandrogenism (50). Hyperthecosis is found in many patients with hyperandrogenemia, insulin resistance, and acanthosis nigricans (HAIR-AN syndrome).

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The E₁:E₂ ratio is increased. Unlike in PCOS, gonadotropin levels are normal (168).

Wedge resection for the treatment of mild hyperthecosis has been successful and has resulted in resumption of ovulation and even in a pregnancy (169). However, in cases of more severe hyperthecosis and high total testosterone levels, the ovulatory response to wedge resection is only transient (168). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared (170). Moreover, when a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed (171).

**Virilization during Pregnancy**

*Pregnancy luteomas* are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses postpartum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized female newborns in the presence of a pregnancy luteoma and maternal masculinization (172).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors, serous cystadenomas, endodermal sinus tumors, and dermoid cysts (161).

**Virilizing Adrenal Neoplasms**

The most common virilizing adrenal neoplasms are adrenal carcinomas. When these malignancies virilize, they are invariably associated with elevations in DHEAS, which are usually accompanied by hypercortisolism. These tumors often are large and detectable on abdominal examination. Less commonly, the adrenals are the site for testosterone-secreting adenomas. Therefore, high testosterone levels (in the tumor range), accompanied by normal or only moderately elevated DHEAS levels, should not divert attention from the adrenal gland to the ovary. In fact, patients with these adenomas manifest increased testosterone production following stimulation with human chorionic gonadotropin (hCG) or LH and decreased testosterone secretion following LH suppression.

Of the fewer than 100 reported cases of pure virilizing adrenal neoplasms, 90% were benign. Although the peak age for the diagnosis of adenomas was 20 to 40 years, most of
the pure testosterone-producing tumors occurred in menopausal women. With one exception, all cases of adenomas were unilateral. Fifty percent were palpable abdominally in children; in adults, none was detected solely by physical examination (173).

**Prolactin Disorders**

Prolactin was first identified as a product of the anterior pituitary in 1933 (174). Since that time, it has been found in nearly every vertebrate species. Its presence in humans was long inferred by the association of the syndrome of amenorrhea and galactorrhea in the presence of pituitary macroadenomas, although it was not definitively identified as a human hormone until 1971. The specific activities of human prolactin (hPRL) were defined initially by the separation of its activity from growth hormone (175) and subsequently by radioimmunoassay (176,177). Although the initiation and maintenance of lactation is the primary function of prolactin, many studies have documented roles for prolactin activity both within and beyond the reproductive system.

**Prolactin Secretion**

There are 199 amino acids within human prolactin, with a molecular weight (MW) of 23,000 daltons (Fig. 28.4). Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 13% amino acid sequence homology with prolactin, respectively. In the human genome, a single gene on chromosome 6 encodes prolactin. The prolactin gene (10 kb) has five exons and four introns. Its transcription is regulated in the pituitary by a proximal promotor region and in extrapituitary locations by a more upstream promotor (178).

![Figure 28.4 Amino acid sequence of prolactin](https://example.com/ImageURL)  
Three cysteine disulfide bands are located within the molecule. (From Bondy PK. Rosenberg leukocyte esterase: metabolic control and disease. 8th ed. Philadelphia, PA: WB Saunders, 1980, with permission.)
In the basal state, three forms are released, a monomer, a dimer, and a multimeric species, called little, big, and big-big prolactin, respectively (179–181). The two larger species can be degraded to the monomeric form by reducing disulfide bonds (182). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation (182–185). The heterogeneity of secreted forms remains an active area of research. Overall, studies thus far indicate that little prolactin (MW 23,000 daltons) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression (182,184,185). Clinical assays for prolactin measure little prolactin, and in all but extremely rare circumstances, these measures are sufficient for assessment of diseases of abnormal pituitary production of the hormone. Prolactin and its relatives, growth hormone and placental lactogen, do not require glycosylation for most of their primary activities, as is the case with the gonadotropins and TSH. Glycosylated forms are secreted, however, and glycosylation does affect the bioactivity and immunoreactivity of little prolactin (186–189). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-dalton nonglycosylated form of prolactin (188). Prolactin has more than 300 known biological activities, the most recognized of which include those associated with reproduction (lactation, luteal function, and reproductive behavior) and homeostasis (immune responsiveness, osmoregulation, and angiogenesis) (190). Despite these many activities, the only known disorder associated with deficiency of prolactin secretion is inability to lactate.

To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone. Although this heterogeneity complicates the physiologic evaluation of prolactin’s myriad effects, it is of little importance to the diagnosis and management of hyperprolactinemic states.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor. Dopamine receptors have been found on pituitary lactotrophs (191), and treatment with dopamine or dopamine agonists suppresses prolactin secretion (192–197). The dopamine antagonist metoclopramide abolishes the pulsatility of prolactin release and increases serum prolactin levels (193,194,198). Interference with dopamine transit from the hypothalamus to the pituitary by mass lesions or blockade of the dopamine receptor, which occurs with antipsychotic agents and other medications, increases serum prolactin levels. Thyrotropin-releasing hormone (TRH), when present at supraphysiologic levels (as in primary hypothyroidism), causes prolactin release, but does not appear to play an important modulatory role in the normal physiologic regulation of prolactin secretion. γ-Aminobutyric acid (GABA) and other neurohormones and neurotransmitters also may function as prolactin-inhibiting factors (see Table 28.7) (199–202). Several hypothalamic polypeptides that modulate prolactin-releasing activity are listed in Table 28.7. It appears that dopamine and TRH act as primary neurohormones, whereas others (e.g., neuropeptide Y, galanin, and enkephalin) act as modulators. It is likely that under differing physiologic conditions (e.g., pregnancy, lactation, stress, aging), a modulator may become a principal regulator of hormone secretion.

The prolactin receptor is a member of the class 1 cytokine receptor superfamily and is encoded by a gene on chromosome 5 (203). Transcriptional regulation of the prolactin receptor is accomplished through three tissue-specific promoter regions: promoter I for the gonads, promoter II for the liver, and promoter III, a generic promoter that includes the mammary gland (204).
## Table 28.7 Chemical Factors Modulating Prolactin Release and Conditions that Result in Hyperprolactinemia

### Inhibitory factors
- Dopamine
- γ-Aminobutyric acid
- Histidyl-proline diketopiperazine
- Pyroglutamic acid
- Somatostatin

### Stimulatory factors
- β-Endorphin
- 17β-Estradiol
- Enkephalins
- Gonadotropin-releasing hormone
- Histamine
- Serotonin
- Substance P
- Thyrotropin-releasing hormone
- Vasoactive intestinal peptide

### Physiologic conditions
- Anesthesia
- Empty sella syndrome
- Idiopathic
- Intercourse
- Major surgery and disorders of chest wall (burns, herpes, chest percussion)
- Newborns
- Nipple stimulation
- Pregnancy
- Postpartum (nonnursing: days 1–7; nursing: with suckling)
- Sleep
- Stress
- Postpartum

### Hypothalamic conditions
- Arachnoid cyst
- Craniopharyngioma
- Cystic glioma
- Cysticercosis
- Dermoid cyst
- Epidermoid cyst
- Histiocytosis
- Neurotuberculosis

Acute stress or painful stimuli. The most common cause of elevated prolactin levels is likely pharmacologic; most patients using antipsychotic medications, and many others using agents with antidiopaminergic properties, have moderately elevated prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require direct intervention to normalize prolactin levels.

**Evaluation**

Plasma levels of immunoreactive prolactin are 5 to 27 ng/mL throughout the normal menstrual cycle. Samples should not be obtained soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to about 9 pulses per 24 hours in the late luteal phase. There also is a diurnal variation, with the lowest levels occurring in midmorning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5:00 and 7:00 AM (205,206). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases (207–209). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is obtained midmorning and not after a stressful event, previous venipuncture, breast stimulation, or physical examination, all of which transiently increase prolactin levels.

When prolactin levels are found to be elevated, hypothyroidism and medication use should first be ruled out as a cause. Prolactin and TSH determinations are basic evaluations in infertile women. Infertile men with hypogonadism also should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, amenorrhea with galactorrhea, hirsutism with amenorrhea, anovulatory bleeding, and delayed puberty (Fig. 28.5).

**Physical Signs**

Elevations in prolactin may cause amenorrhea or galactorrhea. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women (210–212). The cessation of normal ovulatory processes resulting from elevated prolactin levels primarily is due to the suppressive effects of prolactin, via hypothalamic mediation, on GnRH pulsatile release (192,210,211,213–221). In addition to inducing a hypogonadotropic state, prolactin elevations may secondarily impair the mechanisms of ovulation through a number of actions: causing a reduction in granulosa cell number and FSH binding (222), inhibiting granulosa cell 17β-estradiol production by interfering with FSH action (222–224), and causing inadequate luteinization and reduced luteal secretion of progesterone (225–227). Other causes of amenorrhea are detailed in Chapter 27.

Although isolated galactorrhea is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients (228–230) (see Fig. 28.5). In such cases, whether because of a prior transient episode of hyperprolactinemia or other unknown factors, the sensitivity of the breast to the lactotrophic stimulus engendered by normal prolactin levels is sufficient to result in galactorrhea. This situation is similar to that observed in breastfeeding mothers in whom milk secretion, once established, continues and even increases despite progressive normalization of prolactin levels. Repeat testing may be helpful in detecting hyperprolactinemia. Approximately one third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia often occurs in the absence of galactorrhea (66%), possibly as a result of inadequate estrogenic or progestational priming of the breast.

In patients with both galactorrhea and amenorrhea (including the syndromes described and named by Forbes, Henneman, Griswold, and Albright in 1951, Argonz and del Castilla in 1953, and Chiari and Frommel in 1985), approximately two thirds will have hyperprolactinemia; of those, approximately one third will have a pituitary adenoma (231).
Figure 28.5  Workup for hyperprolactinemia. TSH, thyroid-stimulating hormone; MRI, magnetic resonance imaging; CT, computed tomography; HRT, Hormone Replacement Therapy; OCPs, Oral Contraceptive pills; CNS, central nervous system.
In anovulatory women, 3% to 10% of women diagnosed with polycystic ovary disease have coexistent and usually modest hyperprolactinemia (232,233) (Fig. 28.6). Prolactin and TSH levels should be measured in all patients with delayed puberty. Pituitary abnormalities, including craniopharyngiomas and adenomas, should be considered in all cases of delayed puberty accompanied by low levels of gonadotropins, regardless whether prolactin levels are elevated. When prolactin-secreting pituitary adenomas are present, the condition of multiple endocrine neoplasia type 1 (MEN-1) syndrome (gastri
toma, insulinoma, parathyroid hyperplasia, and pituitary neoplasia) should be considered, although symptoms of pituitary adenoma are rarely the presenting symptom. Patients who have a pituitary adenoma and a family history of multiple adenomas warrant special attention (234). Prolactinomas are noted in approximately 20% of patients with MEN-1. The MEN-1 gene is localized to chromosome 11q13 and appears to act as a constitutive tumor.

**Figure 28.6** Prolactin levels in 235 patients with galactorrhea. Among patients with a tumor, open triangles denote associated acromegaly, and solid circles and solid triangles denote previous radiotherapy or surgical resection, respectively. (From Kleinberg DL, Noel GL, Frantz AG. Galactorrhea: a study of 235 cases, including 48 with pituitary tumors. *N Engl J Med* 1977;296:589–600.)
suppressor gene. An inactivating mutation results in development of the tumor. It is thought that prolactin-secreting pituitary adenomas that occur in patients with MEN-1 may be more aggressive than sporadic cases (235).

Once an elevated prolactin level is documented and medications or hypothyroidism excluded as the underlying cause, knowledge of neuroanatomy as well as imaging techniques and their interpretation are required for further evaluation (see Chapter 7). Pituitary hyperprolactinemia is most often caused a microadenoma, and the results of imaging studies usually are normal. These patients can be reassured that the course of their condition generally is benign. Macroadenomas or juxtasellar lesions are less common and require more complex evaluation and treatment, including surgery, radiation, or both. Levels of TSH should be measured in all patients with hyperprolactinemia (see Fig. 28.5).

### Imaging Techniques

In patients with larger microadenomas and macroadenomas, prolactin levels usually are higher than 100 ng/mL. However, levels lower than 100 ng/mL may be associated with smaller microadenomas, macroadenomas that produce a “stalk section” effect, and suprasellar tumors that may be easily missed on a “coned-down” view of the sella turcica. Modest elevations of prolactin can, therefore, be associated with microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities. Imaging of the pituitary gland must be considered in the presence of otherwise unexplained and persistent elevation of prolactin (Table 28.8). In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, imaging is not necessary unless it is accompanied by symptoms suggesting a mass lesion (headache, visual field deficits). Magnetic resonance imaging of the sella and pituitary gland with gadolinium enhancement appears to provide the best anatomic detail (236) (Fig. 28.7). The cumulative radiation dose from multiple CT scans may cause cataracts, and the “coned-down” views or tomograms of the sella are very insensitive and likewise expose the patient

| Table 28.8 Sellar and Suprasellar Tumors and Conditions that May Result in Hyperprolactinemia |
|-----------------------------------------------|--------------------------------------------------|
| Abscess                                      | Lipoma                                           |

| Ectopic neurohypophysis                      | Osteocartilaginous tumor                         |
| “Empty” sella                               | Pars intermedia cysts                            |
| Epidermoid tumor                            | Pituitary adenoma                                |
| Germinoma                                   | Rathke’s cleft cyst                              |
| Hamartoma (tuber cinereum/hypothalamus)     | Sarcoidosis                                      |
| Histiocytosis                               |                                                  |
| Hyperplasia                                 |                                                  |
| Hypophysitis                                |                                                  |

1107
to radiation. For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma, as well as to identify other potential sellar or suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas.

In more than 90% of untreated women, microadenomas do not enlarge over a 4- to 6-year period. For that reason, the argument that medical therapy will prevent a microadenoma from growing is false. Additionally, although prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If prolactin levels increase significantly or central nervous system symptoms (e.g., headache, visual changes) occur, repeat imaging may be indicated.

Hypothalamic Disorders

Dopamine was the first of many substances demonstrated to be produced in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin.
release in the anterior pituitary. Lesions that disrupt dopamine release can result in hyperprolactinemia. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, as well as from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the hypothalamic–pituitary region can disrupt dopamine release and cause hyperprolactinemia (see Table 28.8).

### Pituitary Disorders

**Microadenoma**

Autopsy series reveal that 25% of the U.S. population has microadenomas, and approximately 40% stain positively for prolactin. Clinically significant pituitary tumors requiring some type of intervention affect only 14 per 100,000 individuals.

In more than one third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (less than 1 cm) is found. Release of pituitary stem-cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas are monoclonal in origin. Genetic mutations are thought to release stem-cell growth inhibition and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor, or both. Recently, the heparin-binding secretory transforming (HST) gene has been noted in a variety of cancers as well as in prolactinomas (237). Patients with microadenomas can generally be reassured of a benign course, and many of these lesions gradually regress spontaneously (238,239).

Both microadenomas and macroadenomas are monoclonal in origin. Pituitary prolactinomas or lactotrope adenomas are sparsely or densely granulated histologically. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns. Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem-cell adenomas can be associated with hyperprolactinemia with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk of progression for microadenoma to a macroadenoma is only 7% (240). Treatments include expectant, medical, or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extraocular muscle palsies. Formal visual field testing is rarely helpful unless imaging suggests compression of the optic nerves.

**Expectant Management**  In women who do not desire fertility, expectant management can be used for both microadenomas and hyperprolactinemia in the absence of an adenoma if menstrual function remains intact. Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteopenia (241). Therefore, estrogen replacement with hormone regimens or hormonal contraceptives is indicated for patients with amenorrhea or irregular menses. Patients with drug-induced hyperprolactinemia can also be managed expectantly with attention to the risks of osteoporosis. In the absence of symptoms of pituitary enlargement, imaging may be repeated in 12 months and, if prolactin levels remain stable, less frequently thereafter to assess further growth of the microadenoma.
Medical Treatment  Ergot alkaloids are the mainstay of therapy. In 1985, bromocriptine was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. These agents act as strong dopamine agonists, thus decreasing prolactin levels. Effects on prolactin levels occur within hours, and lesion size may decrease within 1 to 2 weeks. Bromocriptine decreases prolactin synthesis, DNA synthesis, cell multiplication, and overall size of prolactinomas. Treatment results in normal prolactin blood levels or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids such as bromocriptine are excreted via the biliary tree, it should be used with caution in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting, headaches, nasal congestion, and constipation. Many patients tolerate bromocriptine when dose is increased gradually, by 1.25 mg (one half tablet) daily each week until prolactin levels are normal or a dose of 2.5 mg twice daily is reached. A proposed regimen is as follows: one half tablet every evening (1.25 mg) for 1 week, one half tablet morning and evening (1.25 mg) during the second week, one half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and every evening during the fourth week and thereafter (2.5 mg twice a day). The lowest dose that maintains the prolactin level in the normal range is continued (1.25 mg twice daily often is sufficient to normalize prolactin levels in individuals with levels <100 ng/mL). Pharmacokinetic studies show peak serum levels occur 3 hours after an oral dose, with a nadir at 7 hours. Because little detectable bromocriptine remains in the serum by 11 to 14 hours, twice-a-day administration is required. Prolactin levels can be checked soon (6–24 hours) after the last dose is taken.

One rare but notable adverse effect of bromocriptine is a psychotic reaction. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve with discontinuation of the drug (242). Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with bromocriptine compared with those not receiving bromocriptine (240).

An alternative to oral administration is the vaginal administration of bromocriptine tablets, which is well tolerated and actually results in increased pharmacokinetic measures (243). Cabergoline, another ergot alkaloid, has a very long half-life and can be given orally twice per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as bromocriptine in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than bromocriptine. Very rarely, patients experience nausea and vomiting or dizziness with cabergoline; they may be treated with intravaginal cabergoline, as with bromocriptine. Although cabergoline appears to be safe to use during pregnancy, more extensive data regarding the use of bromocriptine in pregnancy is available; therefore bromocriptine is preferred for pregnant patients. A gradually increasing dosage helps avoid the side effects of nausea, vomiting, and dizziness. Cabergoline at 0.25 mg twice per week is usually adequate for hyperprolactinemia with values less than 100 ng/mL. If required to normalize prolactin levels, the dosage can be increased by 0.25 mg per dose on a weekly basis to a maximum of 1 mg twice weekly.

When bromocriptine or cabergoline cannot be used, other medications such as pergolide or methergoline may be used. In patients with a microadenoma who are receiving bromocriptine therapy, a repeat MRI scan may be performed if indicated 6 to 12 months after prolactin levels are normal. Normal prolactin levels and resumption of menses should not be considered absolute proof of tumor response to treatment. Further MRI scans should be performed if new symptoms appear.
Discontinuation of *bromocriptine* therapy after 2 to 3 years may be attempted in a select group of patients in whom normal prolactin levels have been maintained with therapy (244,245). Discontinuation of *cabergoline* therapy has also been successful in patients treated for 3 to 4 years who have maintained normal prolactin levels (246). In general, recurrence rates are higher for macroadenomas (as compared with microadenomas or hyperprolactinemia without adenoma) after cessation of either bromocriptine or cabergoline, warranting close follow-up with serum prolactin assessment and MRI after cessation of therapy. In patients with macroadenomas, withdrawal of therapy should proceed with caution because tumors may re-expand rapidly.

**Macroadenomas**

Macroadenomas are pituitary tumors that are larger than 1 cm. *Bromocriptine* is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes and, rarely, diabetes insipidus and blindness.

**Medical Treatment**

Treatment with *bromocriptine* decreases prolactin levels and the size of macroadenomas; nearly one half show a 50% reduction in size, and another one fourth show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in more than 60% of cases after discontinuation of *bromocriptine* therapy, long-term therapy is usually required.

After stabilization of tumor size is documented, an MRI scan is repeated 6 months later and, if stable, yearly for several years. This examination may be performed earlier if new symptoms develop or if there is no improvement in symptoms. Serum prolactin levels are measured every 6 months. Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is prudent. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment.

**Surgical Intervention**

Tumors that are unresponsive to *bromocriptine* or that cause persistent visual field loss require surgical intervention. Some neurosurgeons have noted that a short (2-week) preoperative course of *bromocriptine* increases the efficacy of surgery in patients with larger adenomas (243). Unfortunately, despite surgical resection, recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

**Metabolic Dysfunction and Hyperprolactinemia**

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. Thyroid replacement therapy can reduce pituitary enlargement and normalize prolactin levels (247).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Hemodialysis does not lower prolactin levels, but levels become normal with transplantation (248–250). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS (251).

**Drug-induced Hyperprolactinemia**

Numerous drugs interfere with dopamine secretion and can therefore be responsible for hyperprolactinemia and its attendant symptoms (see Table 28.7). If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt. If not,
endocrine management should be directed toward replacing estrogen and normalizing menses for those with disturbed or absent ovulation. Treatment with dopamine agonists may be utilized if ovulation is desired and the drug inducing hyperprolactinemia cannot be discontinued.

**Use of Estrogen in Hyperprolactinemia**

In rodents, pituitary prolactin-secreting adenomas occur with high-dose estrogen administration (252). Elevated levels of estrogen, such as those that occur in pregnancy, are responsible for hyper trophy and hyperplasia of lactotrophic cells and account for the progressive increase in prolactin levels in normal pregnancy. The increase in prolactin during pregnancy is physiologic and reversible, however, and adenomas are not fostered by the hyperestrogenemia of pregnancy. Pregnancy may even have a favorable influence on pre-existing prolactinomas (253,254). Estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to the status of an adenoma (255–258). For these reasons, estrogen replacement or OC use is appropriate for hypoestrogenic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.

**Monitoring Pituitary Adenomas During Pregnancy**

Prolactin-secreting microadenomas rarely create complications during pregnancy. However, monitoring of patients with serial gross visual field examinations and funduscopic examination is recommended. If persistent headaches, visual field deficits, or visual or funduscopic changes occur, MRI scanning is advisable. Because serum prolactin levels progressively rise throughout pregnancy, prolactin measurements are rarely of value.

For those women who experience return of spontaneous ovulation and become pregnant while taking bromocriptine, discontinuation of bromocriptine is recommended. This does not, however, preclude subsequent use of bromocriptine during the pregnancy to treat symptoms (visual field defects, headaches) that arise from further enlargement of the microadenoma (259–262). Bromocriptine has not exhibited teratogenicity in animals, and observational data do not suggest it is harmful to the pregnancy or the fetus in humans.

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored additionally with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. Breastfeeding is not contraindicated in the presence of microadenomas or macroadenomas (259–262). The use of bromocriptine and presumably other dopamine-ergic agents that may cause blood pressure elevation during the postpartum period is contraindicated (263–267).

**Thyroid Disorders**

Thyroid disorders are 10 times more common in women than men (268). Approximately 1% of the female population of the United States will develop overt hypothyroidism. Even before the discovery of the long-acting thyroid stimulator (LATS) in women with Graves disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology (269).

**Thyroid Hormones**

Iodide is a critical component of the class of hormones known as thyronines, among which the most important are triiodothyronine and thyroxine (T3 and T4). Iodide obtained from dietary sources is actively transported into the thyroid follicular cell for synthesis of these
hormones. Sodium–iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide from the circulation into the thyrocyte against an electrochemical gradient. Sodium–iodide symporter requires energy that is supplied by Na-K ATPase. Uptake is stimulated by TSH. The enzyme thyroid peroxidase (TPO) then oxidizes iodide near the cell–colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). Triiodothyronine (T₃) and thyroxine (T₄), formed by secondary coupling of MIT and DIT, are also catalyzed by TPO. The membrane-bound, heme-containing oligomer, TPO, is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and on the follicular cell surface. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T₃ and T₄, and the remainder is present in MIT and DIT or found as unbound iodine. Thyroglobulin provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The thyroid antimicrosomal antibodies found in patients with autoimmune thyroid disease are directed against the TPO enzyme (270,271).

Thyroid-stimulating hormone regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis as a component of iodide uptake, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T₄, T₃, and reverse T₃. T₄ is released from the thyroid at 40 to 100 times the concentration of T₃. The concentration of reverse T₃, which has no intrinsic thyroid activity, is 30% to 50% of T₃ secretion and 1% of T₃ concentration. Of thyroid hormones released, 70% are bound by circulating thyroid-binding globulin (TBG). Although T₃ is present in the circulating storage pool in the highest concentrations, it has a slow turnover rate (about 7 days). Compared with T₄, the concentration of T₃ is lower and has a higher turnover rate. Approximately 30% of T₄ is converted to T₃ in the periphery. Reverse T₃ participates in regulation of the conversion of T₄ to T₃. T₃ is the primary physiologically functional thyroid hormone at the cellular level. T₃ binds the nuclear receptor with 10 times the affinity of T₄. Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate. It balances fuel efficiency with performance, much as a carburetor functions in an engine. Hyperthyroid states result in excessive fuel consumption with marginal performance.

**Iodide Metabolism**

Normal function of the thyroid gland depends on iodine. The present recommended daily allowance by the U.S. National Research Council is 150 to 300 mg/day. Present daily consumption in the United States averages 200 to 600 mg/day and is largely assured by virtue of addition of iodine to many common foodstuffs. Iodine is usually ingested in the form of iodized salt (100 mg of potassium iodide/kg of salt) (272).

In regions where dietary iodine is insufficient, goitrous hypothyroidism among adults and the consequences of inadequate fetal thyroxine are common (endemic goiter and endemic cretinism). Paradoxically, sufficiency of iodine appears to be associated with the development of autoimmune thyroid disorders (273,274) and reduced remission rates in patients treated for Graves disease (275). Animal studies suggest that iodine stimulates immunoglobulin production by B lymphocytes, activates macrophages, and increases the immunogenic potential of thyroglobulin because of the higher iodide content (276–279).

**Risk Factors for Autoimmune Thyroid Disorders**

Environmental factors that have been associated with the occurrence of autoimmune thyroid diseases include pollutants (plasticizers, polychlorinated biphenyls, and coal-processing pollutants) (280,281) and antibodies to *Yersinia enterocolitica* (282). The female hormonal milieu and its effects on immune surveillance undoubtedly play a role in the increased risk (10-fold) for women to develop autoimmune thyroid disease.
The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies present (stimulating versus blocking, complement fixing, and noncytotoxic) combine to create the clinical spectrum of autoimmune thyroid diseases that may affect reproductive function.

**Evaluation**

**Thyroid Function**

Total serum $T_4$ is measured by radioimmunoassay, and these measurements are indifferent to the fraction of $T_4$ that is bound to its specific binding protein, TBG. Levels of TBG are variable, and many conditions cause elevations in them (e.g., pregnancy, OC use, estrogen therapy, hepatitis, and genetic abnormalities of TBG). Thus, indirect estimation of the unbound (“free”) $T_4$ or its direct measurement are required for clinical evaluation.

The $T_3$ resin uptake determines the fractional binding of radiolabeled $T_3$ that is added to a serum sample in the presence of a resin that competes with TBG for $T_3$ binding. The binding capacity of TBG in the sample is inversely proportional to the amount of labeled $T_3$ bound to the artificial resin. Therefore, a low $T_3$ resin uptake indicates high TBG $T_3$ receptor site availability and implies high circulating TBG levels.

The free $T_4$ index (FTI) is obtained by multiplying the serum $T_4$ concentration by the $T_3$ resin uptake percentage, yielding an indirect estimate of the levels of free $T_4$:

$$T_3 \text{ RU } \% \times T_4 \text{ total} = \text{free } T_4 \text{ index}$$

A high $T_3$ resin uptake percentage indicates reduced TBG receptor site availability and high free $T_4$ index and thus hyperthyroidism, whereas a low $T_3$ resin uptake percentage is a result of increased TBG receptor site binding and thus hypothyroidism. Equilibrium dialysis and ultrafiltration techniques may be used to determine directly the free $T_4$. Free $T_4$ and $T_3$ may also be determined by radioimmunoassay.

Because levels of TSH are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. Current TSH sandwich immunoassays are extremely sensitive and capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. Thus, TSH measurements provide the best way to screen for thyroid dysfunction (283) and accurately predict thyroid hormone dysfunction in about 80% of cases.

**Immunologic Abnormalities**

Many antigen–antibody reactions affecting the thyroid gland can be detected. A number of recognized thyroid autoantigens are listed in Table 28.9. Antibody production to thyroglobulin obviously depends on a breach in normal immune surveillance (273,274). The incidence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in Table 28.10.

Antibodies to thyroglobulin are restricted to one minor and two major epitopes. Antibodies are mainly noncomplement-fixing immunoglobulin G (IgG) polyclonal antibodies (275). Antithyroglobulin antibodies are found in patients with Hashimoto thyroiditis, Graves disease, acute thyroiditis, nontoxic goiter, and thyroid cancer. They also appear in normal women.

Antithyroid peroxidase antibodies (anti-TPO antibodies), previously referred to as antimicrosomal antibodies, are directed against TPO and are found in Hashimoto thyroiditis,
Graves disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. Antimicrosomal antibodies correlate with the histologic appearance of lymphocytic thyroiditis (259,260). These antibodies can cause artifacts in the measurement of thyroid hormone levels.

Another group of antibodies important in autoimmune thyroid disease binds the TSH receptor. These antibodies often create the signs and symptoms that lead to an evaluation. Thyroid-stimulating hormone receptor antibodies (TSHR-Ab or TRAb) are pathogenic and capable of activating or blocking TSH receptor functions. These antibodies are detected using two approaches—competitive and functional assays. The competition between antibody and TSH for binding to the TSH receptor is the basis for the measurement of TSH-binding inhibitory immunoglobulin (TBII). The functional assay approach is based on the status of the receptor induced by the antibody-receptor interaction. This functional assay measures the production and accumulation of cAMP, thyroid hormone or thyroglobulin secretion, or iodide uptake in thyroid epithelial cells, or Chinese hamster ovary cells transfected with the human TSH receptor. Whereas the competitive assay does not indicate any functional activity of the antibody, the functional assay identifies whether the antibody is agonistic (thyroid-stimulating antibody [TSAb] or antagonistic TSH stimulation–blocking antibody [TSHBAb]). Both types of antibodies may be present in the same patient, and the effect is the algebraic sum of the two levels of activity (agonistic and antagonistic) (Fig. 28.8).

Thyroid-stimulating antibody or thyroid-stimulating immunoglobulin (TSI) activates the TSH receptor (Table 28.11). Long-acting thyroid stimulators are monoclonal or limited polyclonal TSAb, which mimic TSH action. They are quantified by their ability to stimulate human thyroid cell cultures to produce cyclic adenosine monophosphate or to release T₃. Thyroid-stimulating hormone-binding inhibitory immunoglobulin is detectable in two

TSH, thyroid-stimulating hormone.
varieties: those that block TSH binding and those that block both pre- and postreceptor processes. Several investigators have detected such blocking antibodies in patients with primary hypothyroidism who have atrophic thyroid glands (277–279). The nomenclature and detection assay of TSH receptor antibodies are listed in Table 28.11.

Thyroid growth-promoting immunoglobulins (TGI) stimulate growth but not hormone release (250–259). Their immunologic antagonists are the TGI-blocking antibodies that are capable of inhibiting TSH-mediated growth responses in patients who may have had thyroid damage by immune destruction.

Antibodies to the NIS are prevalent in a number of thyroid conditions. Increased expression of NIS protein and NIS mRNA is found in patients with autonomous thyroid adenomas and Graves disease. They are decreased in Hashimoto thyroiditis, cold nodules, and thyroid carcinoma.

Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced (284). The various antigen–antibody reactions result in the wide clinical spectrum of these disorders.
Transplacental transmission of some of these immunoglobulins may affect thyroid function in the fetus. The presence of autoimmune thyroid disorders, particularly Graves disease, is associated with other autoimmune conditions: Hashimoto thyroiditis, Addison disease, ovarian failure, rheumatoid arthritis, Sjögren syndrome, diabetes mellitus (type I), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura. Other factors associated with the development of autoimmune thyroid disorders include low birth weight, iodine excess and deficiency, selenium deficiency, parity, OC use, reproductive age span, fetal microchimerism, stress, seasonal variation, allergy, smoking, radiation damage to the thyroid, and viral and bacterial infections (285).

Certain groups of individuals, including infertile and pregnant women, should undergo an assessment of thyroid function at least once (286). Testing is also recommended for women with atrial fibrillation, hyperemesis gravidarum, and hyperlipidemia. Periodic assessment of thyroid function is indicated in patients who receive amiodarone and lithium. Epidemiologists recommend that all women with diabetes be tested annually for thyroid dysfunction. Women with type I diabetes are three times more likely to experience postpartum thyroid dysfunction, and it is recommended that all pregnant women with diabetes be screened with TSH in the first trimester. Any woman with a history of postpartum thyroiditis should also be offered annual surveillance of thyroid function. Because there is a high prevalence of hypothyroidism in women with Turner and Down syndrome, an annual check of thyroid function is recommended. Periodic TSH screening in mature women is advisable.

**Hashimoto Thyroiditis**

Hashimoto thyroiditis or chronic lymphocytic thyroiditis, which was first described in 1912, can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antimicrosomal and antithyroglobulin antibody are usually present. Typically, glandular hypertrophy is found, but atrophic forms are also present. The composition of various antibodies (i.e., TBII, causing the atrophic form and congenital hypothyroidism in some neonates, and TGI, causing the goitrous variety) results in varied physical findings.
Three classic types of autoimmune injury are found in Hashimoto thyroiditis: (i) complement-mediated cytotoxicity, (ii) antibody-dependent cell-mediated cytotoxicity, and (iii) stimulation or blockade of hormone receptors, which results in hypo- or hyperfunction or growth (see Fig. 28.8).

The histologic picture of Hashimoto thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves disease and Hashimoto thyroiditis may cause very similar histologic findings manifested by a similar mechanism of action. Nearly all patients with Hashimoto thyroiditis and about two thirds of patients with Graves disease have sera demonstrating antibody-dependent cell-mediated cytotoxicity. Thyroid antibody positivity is detected in 16.8% of white women and in 10.2% of men in the United States (287).

Clinical Characteristics and Diagnosis of Hashimoto Thyroiditis

Most patients with Hashimoto thyroiditis are relatively asymptomatic with painless goiter and hypothyroidism. The goiter can also involve the pyramidal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable manifestations of hypothyroidism include cold intolerance, constipation, carotene deposition in the periorbital region, carpal tunnel syndrome, dry skin, fatigue, hair loss, lethargy, and weight gain. Hashitoxicosis, the hyperthyroid manifestation of Hashimoto thyroiditis, may represent a variant of Graves disease. This form is estimated to occur in 4% to 8% of patients with Hashimoto thyroiditis. These patients often become hypothyroid during the course of treatment.

In many cases, an elevated serum level of TSH is detected during routine screening. Elevated serum antithyroglobulin and antimicrosomal antibody elevation confirm the diagnosis. The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered as listed in Table 28.12. In light of the annual risk of hypothyroidism (5%) and the potential adverse

effects on the neuropsychological development of the fetus, most clinicians treat women who have elevated serum TSH concentrations and positive thyroid antibody tests, even in the absence of symptoms (subclinical hypothyroidism) (284). If the serum TSH alone is elevated, in the absence of positive thyroid antibody titers, the annual risk for hypothyroidism drops to less than 3% per year.

Treatment

Thyroxine replacement is initiated in patients with symptomatic hypothyroidism, patients who have a goiter that is cosmetically or physically bothersome and are subclinically hypothyroid, and patients who are undergoing fertility therapy and are subclinically hypothyroid. Regression of gland size usually does not occur, but treatment prevents further growth. All pregnant patients with an elevated TSH level should be treated with levothyroxine. Treatment does not slow progression of the disease. Replacement therapy is monitored by TSH determinations at least 6 weeks after a change in dose. Aluminum hydroxide (antacids), cholestyramine, iron, and sucralfate may interfere with absorption. The half-life of levothyroxine is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dose change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from ovulatory difficulties and possibly with spontaneous abortion (288–291). A meta-analysis of case-control and longitudinal studies performed since 1990 reveals a possible association between miscarriage and thyroid antibodies with an odds ratio of 2.73 (2.20–3.40, 95% confidence interval). This association may be explained by a heightened autoimmune state affecting the fetal allograft, or, alternatively, a slightly higher age of women with antibodies compared with those without antibodies (0.7 ± 1 year, P <0.001) (292). Studies also suggest that early subclinical hypothyroidism may be associated with menorrhagia (293).

Severe primary hypothyroidism is associated with amenorrhea or anovulation (294,295). Enhanced sensitivity of the prolactin-secreting cells to TRH and defective dopamine turnover resulting in hyperprolactinemia associated with a deficiency of thyroid hormone are the apparent explanations for the hyperprolactinemia (296–299). Hyperprolactinemia-induced luteal phase defects also are associated with less severe forms of hypothyroidism (300,301). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects (302,303).

Combined thyroxine and triiodothyronine therapy is no more effective than thyroxine therapy alone (304). In patients with Hashimoto thyroiditis and subclinical hypothyroidism, a daily dose of 0.025 to 0.075 mg of levothyroxine is usually adequate to normalize TSH values.

Graves Disease

Graves disease, characterized by exophthalmos, goiter, and hyperthyroidism, was first identified as an association of findings in 1835. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to multiple epitopes of the thyrotropin receptor. This activity induces a B-cell–mediated response (301), resulting in the clinical features of Graves disease. The generic TSAb bind to conformational epitopes in the extracellular domain of the thyrotropin receptor and are detected in the serum of 90% of patients with Graves disease. The epitopes make up discontinuous areas that overlap the thyrotropin binding site. Human leukocyte antigen (HLA) class II antigens DR, DP, DQ, and DS can present antigens to T cells and are expressed on thyroid epithelial cells. Antibodies to the TSH receptor (TSHR–Ab) are produced when this immunogen (TSH receptor) is presented to helper T lymphocytes with the D locus antigens (302).
The class II antigens are upregulated by chronic stimulation of the TSH receptor, reduction in the iodinating capacity of thyroid tissue, viral transformation, and interferon-α (302,303). The clinical use of interferon-α has been associated with autoimmune thyroid disease. Graves disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. Human leukocyte antigen and the CTLA-4 gene region have been established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes. The rate of concordance for Graves disease is only 20% in monozygotic twins and even lower in dizygotic twins, consistent with a multifactorial inheritance pattern highly influenced by environmental factors. Graves disease is associated with polymorphisms of the cytotoxic T-lymphocyte antigen 4 (CTLA-4) gene in several populations. Linkage analysis has identified loci on chromosomes 14q31, 20q11.2, and Xq21 that are associated with susceptibility to Graves disease (305).

Clinical Characteristics and Diagnosis

The classic triad of exophthalmos, goiter, and hyperthyroidism in Graves disease is associated with symptoms of hyperthyroidism: frequent bowel movements, heat intolerance, irritability, nervousness, palpitations or tachycardia, tremor, weight loss, and lower extremity swelling. Physical findings include lid lag, nontender thyroid enlargement (2 to 4 times normal), onycholysis, palmar erythema, proptosis, staring gaze, and thick skin. A cervical venous bruit and tachycardia are usually noted. The tachycardia does not respond to increased vagal tone produced with a Valsalva maneuver. Severe cases may demonstrate acropathy, chemosis, clubbing, dermopathy, exophthalmos with ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves disease and many of those previously treated have elevated T₃ and normal T₄ levels. Therefore, assessment of T₄, T₃, and TSH values is indicated. The TSH levels are suppressed, and levels may remain undetectable for some time even after the initiation of treatment. This assessment is useful in evaluating medical treatment and prognosis, and anticipating fetal complications such as neonatal thyrotoxicosis. Autonomously functioning, benign thyroid neoplasms that exhibit a similar clinical picture include toxic adenomas and toxic multinodular goiter. Very rare conditions causing thyrotoxicosis include hCG-secreting choriocarcinoma, TSH-secreting pituitary adenomas, and struma ovarii. Factitious ingestion of thyroxine or desiccated thyroid should be considered in patients with eating disorders. Other potential causes of hyperthyroidism are listed in Table 28.13. Smoking appears to be an independent risk factor for relapse after medical therapy and should be considered when planning treatment.

Treatment

**Iodine-131 Ablation**  Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient’s needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy.

A single dose of radioactive iodine-131 (¹³¹I) is an effective cure in about 80% of cases and is the most commonly used definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of ¹³¹I. Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism (cretinism) as a result of treatment during the first trimester have been reported (306,307). Nuclear medicine professionals
provide expertise in the administration of the radioactive isotope, and suppressive medical treatment is provided for 6 to 12 weeks after administration of $^{131}$I. Medical therapy is the main component of therapy even when radioactive $^{131}$I or surgery is eventually planned. Postablative hypothyroidism develops in 50% of patients within the first year after $^{131}$I therapy and in more than 2% of patients per year thereafter.

A higher rate of miscarriage has been noted in women treated with $^{131}$I therapy in the year preceding therapy, but there has been no reported increase in the rate of stillbirths, preterm birth, low birth weight, congenital malformation, or death after therapy (308). Many thyroidologists and nuclear medicine specialists ascribe the higher rates of miscarriage to unrecognized post $^{131}$I induced hypothyroidism and are now more willing to allow pregnancy earlier than 1 year after therapy if patients receive replacement therapy with levothyroxine.

**Thyroid-stimulating Receptor Antibody in Graves Disease** The level of TSHR-Ab (TBII) grossly parallels the degree of hyperthyroidism as assessed by the serum levels of thyroid hormones and total thyroid volume. Studies suggest that the combination of a small goiter volume (<40 mL) and a low TBII level (<30 units/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (309). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (>70 mL) and a higher TBII level (>30 units/L). Thus, the subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Although it is not necessary for the diagnosis of Graves disease, except in some cases of multinodular goiter, a TSHR-Ab measurement may be a useful marker of disease severity. Used in combination with other clinical factors, it may contribute to initial decisions regarding treatment. See Table 28.11 for a review of the nomenclature and assay methods for TSHR-Ab.

Measurements of TSHR-Ab (TBII) during treatment with antithyroid drugs also are predictive of subsequent outcome. In one series, 73% of TBII-negative patients had remission compared with only 28% of TBII-positive patients who had achieved remission after 12 months of antithyroid drug therapy (310). Furthermore, the duration of a course of antithyroid drug therapy can be modified according to the TSHR-Ab status. In patients whose TSHR-Ab status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSHR-Ab positive (311). Regardless of the rapidity of the disappearance of TSHR-Ab, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the
risk of relapse. TSHR-Ab status also appears to determine, in an inverse relationship, the reduction in thyroid volume after radioactive iodine therapy.

Recently, a second generation assay has been developed for assessment of TSHR-Ab using recombinant human TSH receptor (312). This new assay has nearly 100% sensitivity and specificity in the diagnosis of Graves disease. Its utility in monitoring treatment is being evaluated. Many patients with Graves disease have or will develop antineutrophil cytoplasmic antibodies (ANCA), but the significance of this finding is still being studied.

**Antithyroid Drugs** Antithyroid drugs of the thioamide class include *propylthiouracil* (PTU) and *methimazole*. Low doses of either agent block the secondary coupling reactions that form T₃ and T₄ from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. *Propylthiouracil* additionally blocks the peripheral conversion of T₂ to T₃. Approximately one third of patients treated by this approach alone go into remission and become euthyroid (309).

*Propylthiouracil* causes a reduction of hyperthyroid symptoms at a dose of 100 mg taken every 8 hours over 1 month. Adequate control of thyrotoxic symptoms may require considerably higher doses. *Propylthiouracil* blocks the intrathyroid synthesis of T₂ and the peripheral conversion of T₃ to T₂, but does not cross the placenta as easily as *methimazole*; therefore, it is the drug of choice during pregnancy. Drug efficacy is monitored weekly by evaluation of appetite, emotional lability, insomnia, and tremor. A general rule is to lower the dosage by 50% when thyroid function returns to normal, which frequently correlates with the return to a normal heart rate and, subsequently, normalization of TSH levels. Thyroxine is usually the first value to become normal.

Pruritus affects 3% to 5% of treated patients. Serious adverse reactions include agranulocytosis (occurring 1–2 months after therapy in 0.02%) and a generalized drug eruption accompanied by arthralgia, fever, and sore throat. A complete blood count determination is performed if the patient develops an upper respiratory tract infection. If adverse reactions occur, *methimazole* may be used.

*Methimazole* (10 mg) is given every 8 to 24 hours. Its dosage is reduced in a manner similar to that used with *PTU*. It is not the drug of choice in pregnant women because it does not block peripheral conversion and crosses the placenta more readily than *PTU*. Its use in pregnancy is associated in some instances with the development of characteristic skin lesions in the fetus, aplasia cutis congenita. It does, however, have fewer adverse reactions, a longer dosing interval, and a lower cost than *PTU*; therefore, it is most often prescribed in nonpregnant women.

Other medical therapies include *iodide* and *lithium*, both of which reduce thyroid hormone release and inhibit the organification of iodine. *Iodide* also leads to the secondary coupling of T₁ and T₄. These medications are rarely used in women of reproductive age because of their risks to the fetal thyroid and to fetal development (*iodine* causes congenital goiter; *lithium* causes Ebstein’s anomaly).

**Surgery** A subtotal thyroidectomy is less commonly used primarily but is used routinely if medical treatment fails or if a patient is hypersensitive to medical therapy. Surgery is the most rapid and consistent method of achieving a euthyroid state in Graves disease that avoids the possible long-term risks of radioactive iodine. Children, young women, pregnant women, and patients with coexistent thyroid nodules are potential candidates for thyroidectomy. It is felt to be the treatment of choice for a patient with significant Graves ophthalmology. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.
**β-Blockers**  Propranolol is occasionally used before surgery in patients who prove to be hypersensitive to other medical therapy. It provides relief of symptoms while awaiting a reduction in T₄ caused by PTU or methimazole.

---

**Thyroid Storm**

In severe hypothyroidism, physiologic stress—including childbirth, systemic infection, or surgery—may provoke a life-threatening spectrum of symptoms. These include diarrhea, vomiting, and fever, with associated dehydration, as well as altered mental status that may proceed to coma. Patients with poorly controlled hyperthyroidism are most susceptible. Beta-blocker agents, glucocorticoids, PTU (the action of which includes inhibition T₄-T₃ conversion), and iodides are key elements of therapy.

---

**Hyperthyroidism in Gestational Trophoblastic Disease and Hyperemesis Gravidarum**

Because of the weak TSH-like activity of hCG, conditions with high levels of hCG, such as molar pregnancy, may be associated with biochemical and clinical hyperthyroidism. Symptoms regress with removal of the abnormal trophoblastic tissue and resolution of elevated levels of hCG. In a similar fashion, when hyperemesis gravidarum is associated with high levels of hCG, mild biochemical and clinical features of hyperthyroidism may be seen (313,314). Gestational trophoblastic disease is reviewed in Chapter 37.

---

**Thyroid Function in Pregnancy**

High levels of hCG at the end of the first trimester are sufficient to contribute to the thyrotropic effects of TSH, and TSH levels may show transient depression as a result of this phenomenon. Thyroid hormone requirements in pregnancy increase moderately. Patients depending on replacement thyroid hormone require monitoring to determine the need for increases in thyroid hormone replacement (estimated at 30%) commencing in the first weeks of pregnancy. Evidence suggests that optimal fetal and infant neurodevelopmental outcomes may require careful titration of replacement thyroxine that meets the frequently increased requirements of pregnancy (315,316).

---

**Reproductive Effects of Hyperthyroidism**

High levels of TSAb in women with Graves disease have been associated with fetal-neonatal hyperthyroidism (317,318). Despite both the inhibition and elevation of gonadotropins seen in thyrotoxicosis (319), most women remain ovulatory and fertile (320). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis. An increased incidence of congenital anomalies, particularly aplasia cutis, occurs in the offspring of women treated with methimazole (321).

Autoimmune hyperthyroid Graves disease may improve spontaneously, in which case antithyroid drug therapy may be reduced or stopped. Nevertheless, TSHR-Ab production may persist for several years after radical radioactive iodine therapy or surgical treatment for hyperthyroid Graves disease. In this circumstance, there is a risk of exposing a fetus to TSHR-Ab. Fetal–neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous diagnosis of Graves disease, secondary to the transplacental passage of maternal TSHR-Ab. This is a serious condition with a 16% neonatal mortality rate as well as a risk of intrauterine fetal death, stillbirth, and skeletal developmental abnormalities, such as craniosynostosis. Caution against overtreatment with antithyroid medication is also warranted as these medications may cross the placenta in sufficient quantities to induce fetal goiter. Guidelines for TSHR-Ab testing during pregnancy in women with previously treated Graves disease are found in Table 28.14. Fetal goiters and the associated fetal hypo- or hyperthyroid status have been diagnosed accurately in mothers with Graves disease using a combination of fetal ultrasonography of the thyroid with Doppler, fetal heart rate monitoring, bone maturation, and maternal TSHR-Ab and antithyroid drug status (322).
SECTION VII  Reproductive Endocrinology

Table 28.14  Guidelines for TSHR-Ab Testing During Pregnancy with Previously Treated Graves Disease

1. In the woman with antecedent Graves disease in remission after ATD treatment, the risk for fetal-neonatal hyperthyroidism is negligible, and systematic measurement of TSHR-Ab is not necessary. Thyroid function should be evaluated during pregnancy to detect an unlikely but possible recurrence. In that case, TSHR-Ab assay is mandatory.

2. In the woman with antecedent Graves disease previously treated with radioiodine or thyroidectomy and regardless of the current thyroid status (euthyroidism with or without thyroxine substitution), TSHR-Ab should be measured early in pregnancy to evaluate the risk for fetal hyperthyroidism. If the TSHR-Ab level is high, careful monitoring of the fetus is mandatory for the early detection of signs of thyroid overstimulation (tachycardia, impaired growth rate, oligohydramnios, goiter). Cardiac echography and measurement of circulatory velocity may be confirmatory. Ultrasonographic measurements of the fetal thyroid have been defined from 20 weeks gestational age but require a well-trained operator, and thyroid visibility may be hindered because of fetal head position. Color Doppler ultrasonography is helpful in evaluating thyroid hypervascularization. Because of the potential risks of fetal-neonatal hyperthyroid cardiac insufficiency and the inability to measure the degree of hyperthyroidism in the mother because of previous thyroid ablation, it may be appropriate to consider direct diagnosis in the fetus. Fetal blood sampling through cordocentesis is feasible as early as 25 to 27 weeks gestation with less than 1% adverse effects (fetal bleeding, bradycardia, infection, spontaneous abortion, in utero death) when performed by experienced clinicians. ATD administration to the mother may be considered to treat the fetal hyperthyroidism.

3. In the woman with concurrent hyperthyroid Graves disease, regardless of whether it has preceded the onset of pregnancy, ATD treatment should be monitored and adjusted to keep free T4 in the high-normal range to prevent fetal hypothyroidism. TSHR-Ab should be measured at the beginning of the last trimester, especially if the required ATD dosage is high. If the TSHR-Ab assay is negative or the level low, fetal-neonatal hyperthyroidism is rare. If antibody levels are high (TBII ≥ 40 U/L or TSAb ≥ 300%), evaluation of the fetus for hyperthyroidism is required. In this condition, there is usually a fair correlation between maternal and fetal thyroid function such that monitoring the ATD dosage according to the mother's thyroid status is appropriate for the fetus. In some cases in which a high dose of ATD (>300 mg/d of propylthiouracil [PTU] or >20 mg/d of methimazole) is necessary, there is a risk of goitrous hypothyroidism in the fetus, which might be indistinguishable from goitrous Graves disease. The correct diagnosis relies on the assay of fetal thyroid hormones and TSH, which allows for optimal treatment.

4. In any woman who has previously given birth to a newborn with hyperthyroidism, a TSHR-Ab assay should be performed early in the course of pregnancy.

TSHR-Ab, thyroid-stimulating hormone receptor antibodies; ATD, autoimmune thyroid disease; T4, thyroxine; TBII, TSH-binding inhibitory immunoglobulin; TSAb, thyroid-stimulating antibody.

Postpartum Thyroid Dysfunction

This clinical entity is much more common than recognized; it is often difficult to diagnose, because its symptoms appear 1 to 8 months postpartum and often are confused with postpartum depression and difficulties adjusting to the demands of the neonate and infant. Following are criteria for the diagnosis of postpartum thyroiditis: (i) no history of thyroid hormonal abnormalities either before or during pregnancy, (ii) documented abnormal TSH level (either depressed or elevated) during the first year postpartum, and (iii) absence of a positive TSH-receptor antibody titer (Graves disease) or a toxic nodule. An incidence of approximately 5% has been documented (323). A number of studies now describe clinical and biochemical evidence of postpartum thyroid dysfunction in 5% to 10% of new mothers (324). These women have a 25% chance of becoming permanently hypothyroid.

Histologically, lymphocytic infiltration and inflammation are found. Antimicrosomal antibodies are also present in this disorder (325,326). Women who are at greatest risk of developing this disorder are those with a personal or family history of the disorder, those with an autoimmune thyroid disorder, or those with an autoimmune disease.

Clinical Characteristics and Diagnosis

Postpartum thyroiditis usually begins with a transient hyperthyroid phase between 6 weeks and 6 months postpartum followed by a hypothyroid phase. However, only one fourth of the cases follow this classic clinical picture, whereas more than one third
have either hyperthyroidism or hypothyroidism alone. Individuals with type 1 diabetes are 3 times more likely to develop postpartum thyroiditis, and women with a history of postpartum thyroiditis in a previous pregnancy have nearly a 70% chance of recurrence in a subsequent pregnancy. Numerous case reports demonstrate a possible association between postpartum thyroiditis and other autoimmune disorders. Postpartum thyroiditis appears to be caused by the combination of a rebounding immune system in the postpartum state and the presence of thyroid autoantibodies. Although psychotic episodes are rare, postpartum thyroid dysfunction should be considered in all women with postpartum psychosis. The thyrotoxic phase may be subclinical and overlooked, particularly in areas where iodine intake is low (327). Unlike patients with Graves disease, those with the hyperthyroidism caused by postpartum thyroiditis have a low level of radioactive isotope uptake.

The absence of thyroid tenderness, pain, fever, elevated sedimentation rate, and leukocytosis helps to rule out subacute thyroiditis (de Quervain thyroiditis). Evaluation of TSH, \(T_4, T_3, T_3\) resin uptake, and antimicrosomal antibody titer confirm the diagnosis.

### Treatment

Most patients are diagnosed during the hypothyroid phase and require 6 to 12 months of \(T_4\) replacement if they are symptomatic. Because approximately 10% to 30% of women develop permanent hypothyroidism, TSH should be evaluated following discontinuation of replacement therapy.

Rarely, patients are diagnosed during the hyperthyroid phase (328). Antithyroid medications are not routinely used for these women. Propranolol may be used for relief of symptoms. Approximately two thirds of these patients return to a euthyroid state, and one third return to a hypothyroid state.

### Antithyroid Antibodies and Disorders of Reproduction

Women who have antithyroid autoantibodies before and after conception appear to be at an increased risk for spontaneous abortion (329,330). Nonorgan-specific antibody production and pregnancy loss are documented in cases of antiphospholipid abnormalities (331). The concurrent presence of organ-specific thyroid antibodies and nonorgan-specific autoantibody production is not uncommon (331–333). In cases of recurrent pregnancy loss, thyroid autoantibodies may serve as peripheral markers of abnormal T-cell function and further implicate an immune component as the cause of reproductive failure (334). The clinical implications of these findings in the management of patients with recurrent pregnancy is not known. Recurrent pregnancy loss is covered in Chapter 31.

### Thyroid Nodules

Thyroid nodules are a common finding on physical examination and are demonstrated by ultrasonography in more than 50% of patients (335). Occasionally such nodules are functional, and clinical and laboratory evaluation should be applied to distinguish these nodules from nonfunctional nodules, which are occasionally malignant. For nonfunctional “cold” nodules, fine-needle biopsy and aspiration are required to rule out malignancy. In the case of indeterminate aspirates, 2% to 20% are malignant; therefore, surgical biopsy often is indicated (336).

### Gonadal Dysgenesis and Down Syndrome

Patients with gonadal dysgenesis (Turner syndrome, and other forms of hypergonadotropic hypogonadism associated with abnormalities of the second sex chromosome) exhibit a high prevalence of autoimmune thyroid disorders. Approximately 50% of adult patients with Turner syndrome have antithyroid peroxidase (anti-TPO) and antithyroglobulin (anti-TG) autoantibodies. Of these patients, approximately 30% will develop subclinical or clinical hypothyroidism. The disorder is indistinguishable from Hashimoto thyroiditis. A susceptibility locus for Graves disease is noted on chromosome X (337).
Down syndrome, caused by an extra chromosome 21, is characterized by an atypical body habitus, mental retardation, cardiac malformations, an increased risk of leukemia, and a reduced life expectancy. The extra chromosome is almost always of maternal origin. Autoimmune thyroid disorders are more common in patients with Down syndrome than in the general population. The gene for autoimmune polyglandular syndrome I (APECED) has been mapped to chromosome 21 and is thought to be a transcription factor involved in immune regulation (AIRE). This gene may play a role in the development of autoimmune thyroid disease in these patients (338). Hashimoto thyroiditis is the most common type of thyroid disease in individuals with Down syndrome. Hypothyroidism develops in as many as 50% of patients older than age 40 with Down syndrome. These clinical syndromes and other evidence suggest part of the genetic susceptibility to Hashimoto thyroiditis may reside on chromosomes X and 21.

SECTION VII  Reproductive Endocrinology

CHAPTER 28 Endocrine Disorders

SECTION VII Reproductive Endocrinology

CHAPTER 28 Endocrine Disorders

Endometriosis is defined as the presence of endometrial tissue (glands and stroma) outside the uterus. The most frequent sites of implantation are the pelvic viscera and the peritoneum. Endometriosis varies in appearance from a few minimal lesions on otherwise intact pelvic organs to massive ovarian endometriotic cysts that distort tubo-ovarian anatomy and extensive adhesions often involving bowel, bladder, and ureter. It is estimated to occur in 7% of reproductive-age women in the United States and often is associated with
pelvic pain and infertility. Considerable progress has been made in understanding the pathogenesis, spontaneous evolution, diagnosis, and treatment of endometriosis.

Etiology

Although signs and symptoms of endometriosis have been described since the 1800s, its widespread occurrence was acknowledged only during the 20th century. Endometriosis is an estrogen-dependent disease. Three theories have been proposed to explain the histogenesis of endometriosis:

1. Ectopic transplantation of endometrial tissue
2. Coelomic metaplasia
3. The induction theory

No single theory can account for the location of endometriosis in all cases.

Transplantation Theory  The transplantation theory, originally proposed by Sampson in the mid-1920s, is based on the assumption that endometriosis is caused by the seeding or implantation of endometrial cells by transtubal regurgitation during menstruation (1). Substantial clinical and experimental data support this hypothesis (2,3). Retrograde menstruation occurs in 70% to 90% of women (4,5), and it may be more common in women with endometriosis than in those without the disease (5). The presence of endometrial cells in the peritoneal fluid, indicating retrograde menstruation, has been reported in 59% to 79% of women during menses or in the early follicular phase (6,7), and these cells can be cultured in vitro (7). The presence of endometrial cells in the dialysate of women undergoing peritoneal dialysis during menses supports the theory of retrograde menstruation (8). Endometriosis is most often found in dependent portions of the pelvis—the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the posterior uterus, and the posterior broad ligaments (9).

Endometrium obtained during menses can grow when injected beneath abdominal skin or into the pelvic cavity of animals (10,11). Endometriosis has been found in 50% of Rhesus monkeys after surgical transposition of the cervix to allow intra-abdominal menstruation (12). Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women (13,14) and in baboons (15). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis (16).

Ovarian endometriosis may be caused by either retrograde menstruation or by lymphatic flow from the uterus to the ovary (17). Extrapelvic endometriosis, although rare (1%–2%), potentially may result from vascular or lymphatic dissemination of endometrial cells to many gynecologic (vulva, vagina, cervix) and nongynecologic sites. The latter include bowel (appendix, rectum, sigmoid colon, small intestine, hernia sacs), lungs and pleural cavity, skin (episiotomy or other surgical scars, inguinal region, extremities, umbilicus), lymph glands, nerves, and brain (18).

Coelomic Metaplasia  The transformation (metaplasia) of coelomic epithelium into endometrial tissue has been proposed as a mechanism for the origin of endometriosis. Previously this theory had not been supported by either strong clinical or experimental data. One study evaluating structural and cell surface antigen expression in the rete ovarii and epiophoron reported little commonality between endometriosis and ovarian
surface epithelium, suggesting that serosal metaplasia is unlikely in the ovary (19). In contrast, the results of another study involving the genetic induction of endometriosis in mice suggest that ovarian endometriotic lesions may arise directly from the ovarian surface epithelium through a metaplastic differentiation process induced by activation of an oncogenic \( K-ras \) allele (20).

**Induction Theory**  The induction theory is, in principle, an extension of the coelomic metaplasia theory. It proposes that an endogenous (undefined) biochemical factor can induce undifferentiated peritoneal cells to develop into endometrial tissue. This theory has been supported by experiments in rabbits (21,22) but has not been substantiated in women and primates.

**Genetic Factors**  There is increasing evidence to suggest that endometriosis is at least partially a genetic disease. Recent findings that support this association include evidence of familial clustering in humans and in rhesus monkeys, a founder effect detected in the Icelandic population, concordance in monozygotic twins, a similar age at onset of symptoms in affected nontwin sisters, a 6- to 9-times increased prevalence of endometriosis among first-degree relatives of women compared with the general population, and a 15% prevalence of magnetic resonance imaging (MRI) findings suggestive of endometriosis in the first-degree relatives of women with stage III-IV disease based on the classification of the American Society of Reproductive Medicine (23). The induction of humanlike endometriosis by genetic activation of an oncogenic \( K-ras \) allele lends further support to the genetic basis of this disorder (20).

**Population Studies**  The risk or endometriosis is 7 times greater if a first-degree relative has been affected by endometriosis (24). Because no specific Mendelian inheritance pattern has been identified, multifactorial inheritance has been postulated. A relative risk for endometriosis of 7.2 has been found in mothers and sisters, and a 75% (6 of 8) incidence has been noted in homozygotic twins of patients with endometriosis (25). In another study of twins, 51% of the variance of the latent liability to endometriosis may be attributable to additive genetic influences (26). Other investigators reported that 14 monozygotic twin pairs were concordant for endometriosis, and 2 pairs were discordant (27). Of these twin pairs, 9 had moderate to severe endometriosis.

A relationship has been shown between endometriosis and systemic lupus erythematosus (28), dysplastic nevi, and a history of melanoma in women of reproductive age (29). Endometriosis also is linked to the presence of individual human leukocyte antigens (30–32).

**Mutations**  In women with endometriosis, no mutations were found in the \( TP53 \) and \( RASK \) genes (33). No significant differences were observed in \( N314D \) (galactose-1-phosphate uridyl transferase) mutation frequency between women with endometriosis (18%) and controls (17%) (34).

**Steroid Receptor Genetics**  An association of estrogen receptor gene polymorphisms (two-allele and multiallele polymorphism) with endometriosis has been reported (35). Furthermore, various exon-deleted progesterone-receptor messenger RNAs (mRNAs) have been documented in human endometrium and ovarian endometriosis (36).

**Aneuploidy**  Epithelial cells of endometriotic cysts are monoclonal on the basis of phosphoglycerate kinase gene methylation, but normal endometrial glands are monoclonal (37,38). In a
comparison of endometriotic tissue with normal tissue from the endometrium flow, cytometric DNA analysis failed to show aneuploidy (39). However, more recent studies using comparative genomic hybridization (40) or multicolor in situ hybridization (41) showed aneuploidy for chromosomes 11, 16, and 17 (41), increased heterogeneity of chromosome 17 aneuploidy (42), and losses of 1p and 22q (50%), 5p (33%), 6q (27%), 70 (22%), 9q (22%), and 16 (22%) of 18 selected endometriotic tissues (40).

Loss of Heterozygosity
Microsatellite DNA assays reveal an allelic imbalance (loss of heterozygosity) in p16 (Ink4), GALT, p53, and APOA2 loci in patients with endometriosis, even in stage II of endometriosis (43). Another report (38) found in 28% of endometriotic lesions a loss of heterozygosity at one or more sites: chromosomes 9p (18%), 11q (18%), and 22q (15%).

Immunologic Factors and Inflammation
Although retrograde menstruation appears to be a common event in women, not all women who have retrograde menstruation develop endometriosis. The immune system may be altered in women with endometriosis, and it has been hypothesized that the disease may develop as a result of reduced immunologic clearance of viable endometrial cells from the pelvic cavity (44,45). Endometriosis can be caused by decreased clearance of peritoneal fluid endometrial cells resulting from reduced natural killer (NK) cell activity or decreased macrophage activity (46). Decreased cell-mediated cytotoxicity toward autologous endometrial cells has been associated with endometriosis (46–50). However, these studies used techniques that have considerable variability in target cells and methods (51,52). Whether NK cell activity is lower in patients who have endometriosis than in those without endometriosis is controversial. Some reports demonstrate reduced NK activity (53–57), whereas others have found no increase in NK activity, even in women with moderate to severe disease (48–50,58). There also is great variability in NK cell activity among normal individuals that may be related to variables such as smoking, drug use, and exercise (51).

In contrast, endometriosis can also be considered a condition of immunologic tolerance, as opposed to ectopic endometrium, which essentially is self-tissue (44). It can be questioned why viable endometrial cells in the peritoneal fluid would be a target for NK cells or macrophages. Autotransplantation of blood vessels, muscles, skin grafts, and other tissues is known to be extremely successful (47–49). Furthermore, there is no in vitro evidence that peritoneal fluid macrophages actually attack and perform phagocytosis of viable peritoneal fluid endometrial cells. High-dose immunosuppression can slightly increase the progression of spontaneous endometriosis in baboons (59). There is no clinical evidence, however, that the prevalence of endometriosis is increased in immunosuppressed patients. The fact that women with kidney transplants, who undergo chronic immunosuppression, are not known to have increased infertility problems can be considered indirect evidence that these patients do not develop extensive endometriosis.

Substantial evidence suggests that endometriosis is associated with a state of subclinical peritoneal inflammation, marked by an increased peritoneal fluid volume, increased peritoneal fluid white blood cell concentration (especially macrophages with increased activation status), and increased inflammatory cytokines, growth factors, and angiogenesis-promoting substances. It has been reported in baboons that subclinical peritoneal inflammation occurs both during menstruation and after intrapelvic injection of endometrium (57). A higher basal activation status of peritoneal macrophages in women with endometriosis may impair fertility by reducing sperm motility, increasing sperm phagocytosis, or interfering with fertilization (60,61), possibly by increased secretion of cytokines such as tumor necrosis factor-α (TNF-α) (62–64). Tumor necrosis factor also may facilitate the pelvic implantation of ectopic endometrium (63,64). The adherence of human endometrial stromal cells to mesothelial cells in vitro has been increased by the...
pretreatment of mesothelial cells with physiologic doses of TNF-α (65). Macrophages or other cells may promote the growth of endometrial cells (66–68) by secretion of growth and angiogenic factors such as epidermal growth factor (EGF) (65), macrophage-derived growth factor (MDGF) (69), fibronectin (70), and adhesion molecules such as integrins (71). After attachment of endometrial cells to the peritoneum, subsequent invasion and growth appear to be regulated by matrix metalloproteinases (MMP) and their tissue inhibitors (72,73).

There is increasing evidence that local inflammation and secretion of prostaglandins (PG) is related to differences in endometrial aromatase activity between women with and without endometriosis. Expression of aromatase cytochrome P450 protein and mRNA was present in human endometriotic implants but not in normal endometrium, suggesting that ectopic endometrium produces estrogens, which may be involved in the tissue growth interacting with the estrogen receptor (74). Inactivation of 17β-estradiol has been reported to be impaired in endometriotic tissues because of deficient expression of 17β-hydroxysteroid dehydrogenase type 2, which is normally expressed in eutopic endometrium in response to progesterone (75). The inappropriate aromatase expression in endometriosis lesions can be stimulated by prostaglandin E₂ (PGE₂). This reaction leads to local production of E₂, which also stimulates PGE₂ production, resulting in a positive-feedback system between local inflammation and estrogen-driven local growth of ectopic endometrium (76).

The subclinical pelvic inflammatory status associated with endometriosis is also reflected in the systemic circulation. Increased concentrations of C-reactive protein, serum amyloid A (SAA), TNF-α, membrane cofactor protein-1, interleukin-6, interleukin-8 and chemokine (C-C motif) receptor 1 (CCR1) have been observed in peripheral blood samples of patients with endometriosis when compared with controls (77). This observation can be the basis for the development of noninvasive diagnostic tests.

### Environmental Factors and Dioxin

There is an increasing awareness of potential links between reproductive health, infertility, and environmental pollution. Attention has been directed to the potential role of dioxins in the pathogenesis of endometriosis, but the issue remains controversial. A recent meta-analysis concluded that currently there is insufficient evidence in women or in nonhuman primates that endometriosis is caused by dioxin exposure (78).

### Human Data

A 1976 explosion of a factory in Seveso (Italy) resulted in the highest levels of dioxin exposure recorded in humans (79), but so far no data have been published. The Seveso Women’s Health Study will correlate prospective individual data on exposure to dioxin with reproductive endpoints such as the incidence of endometriosis, infertility, and decreased sperm quality. Thus far, one case-control study has failed to show in the general population an association between endometriosis and exposure to polychlorinated biphenyl and chlorinated pesticides during adulthood. No differences in mean plasma concentrations of 14 polychlorinated biphenyl and 11 chlorinated pesticides were found between women with and those without endometriosis (80). Genetic mechanisms may play a role in dioxin exposure and the development of endometriosis. Transcripts of the *CYP1A1* gene, a dioxin-induced gene, have been reported to be significantly higher (9 times higher) in endometriotic tissues than in eutopic endometrium (81). Other investigators have reported a similar expression of arylhydrocarbon receptor and dioxin-related genes (using semiquantitative reverse transcriptase polymerase chain reaction) in the endometrium from women with or without endometriosis (82). In Japanese women, no association was found between endometriosis prevalence or severity and polymorphisms for arylhydrocarbon receptor repressor, arylhydrocarbon (x2) receptor, and arylhydrocarbon nuclear translocator or *CYP1A1* genes (83). Based on these data, there is insufficient
Evidence supporting the association between endometriosis and dioxin exposure in humans.

**Primates**

An initial retrospective case-control study reported that the prevalence of endometriosis was not statistically different (Fisher exact test, \( p = 0.08 \)) between monkeys chronically exposed to dioxin during 4 years (11 of 14, 79%) and in nonexposed animals (2 of 6, 33%) after a period of 10 years. However, a positive correlation was found between the severity of endometriosis and dioxin dose, serum levels of dioxin, and dioxin-like chemicals (84, 85). Two prospective studies have evaluated the association between dioxin exposure and development of endometriosis in Rhesus monkeys. In the most recent study (86), monkeys exposed over 12 months to low-dose dioxin (0.71 ng/kg/day) had endometriosis implants with smaller maximal and minimal diameters and similar survival rate when compared with endometriotic lesions in unexposed controls, suggesting no effect of dioxin on endometriosis. However, after 12 months of exposure to high-dose dioxin (17.86 ng/kg/day), larger diameters and a higher survival rate of endometriosis implants were observed in exposed Rhesus monkeys compared with nonexposed controls. The second randomized controlled study performed in 80 Rhesus monkeys compared those with no treatment with those treated with 0, 5, 20, 40, and 80 \( \mu g \) of Aroclor (1,254/\( \mu g \)/day) for 6 years. Endometriosis occurred in 37% of controls and in 25% of treated monkeys as determined by laparoscopy and necropsy data (87). No association was observed between endometriosis severity and polychlorinated biphenyl exposure. These data question the importance of dioxin exposure, except at high doses, in the development of endometriosis in primates.

**Rodents**

Continuous exposure to 2,3,7,8-tetrachlorodibenzo-P-dioxin inhibited the growth of surgically induced endometriosis in ovariectomized mice treated with high-dose estradiol. No correlation was observed between the dose of dioxin and survival of endometrial implants, adhesions, and serum E2 levels (88). In ovariectomized mice induced with endometriosis, similar stimulating effects of estrone and 4-chlorodiphenyl ether (4-CDE) were observed on survival rates of endometriotic mice, suggesting an estrogen-like effect of 4-CDE (89). Potential mechanisms mediating dioxin action to promote endometriosis in rodents are complex and probably different in rats and mice, not to mention women. The mouse appears to be a better model to elucidate these mechanisms (90, 91), but both models have important limitations.

**Future Research**

The study of endometriosis is compounded by the need to exclude other causes and to assess symptoms within the context of the pelvic condition (i.e., the presence or absence of pathology). The pathogenesis of endometriosis, the pathophysiology of related infertility, and the spontaneous evolution of endometriosis are being investigated. At the time of diagnosis, most patients with endometriosis have had the disease for an unknown period, making it difficult to initiate any clinical experiments that would determine definitely the etiology or progression of the disease (3). Because endometriosis occurs naturally only in women and primates and invasive experiments cannot be performed easily, it is difficult to undertake properly controlled studies. Thus, there is a need for the development of a good animal model with spontaneous endometriosis.

The main advantage of the rat and rabbit animal models used to study endometriosis is their low cost relative to primates. The disadvantages are numerous, however. Rodents lack a menstrual cycle comparable to that of primates and are not subject to spontaneous endometriosis. Whereas the rat ovulates spontaneously, it has a shorter luteal phase than humans. The reproductive pattern of the rabbit lacks a luteal phase. There is a wide phylogenetic gap between these two species and the human. In both rodent models, the
type of lesions appear to be quite different from the variety of pigmented and nonpigmented lesions observed in women (92–94).

Primates, conversely, are phylogenetically close to humans, have a comparable menstrual cycle, are afflicted with spontaneous endometriosis, and when induced with endometriosis, develop macroscopic lesions that are similar to those found in human disease (12,95–99). Although the great apes are closest to humans in many anatomic and physiologic aspects of reproduction, they are not practical models for study; therefore, Rhesus and cynomolgus monkeys have been used. Baboons may be a better choice for study because they are continuous breeders, are phylogenetically very close to humans, and have similar reproductive anatomy and physiology with regard to menstrual cycle characteristics and regularity, embryo implantation, and fetal development (95). In addition, spontaneous endometriosis in the baboon has been found to be both minimal and disseminated, similar to the different stages of endometriosis in women (95,100,101). Experimental endometriosis can be successfully induced by the intrapelvic injection of menstrual endometrium (11). In recent years, the baboon has been established in about 30 peer-reviewed articles as an excellent model for endometriosis research (102). Future research on the pathogenesis of endometriosis, using the baboon model, should focus on the early interactions between endometrial and peritoneal cells in the pelvic cavity at the time of menstruation. Proteomic and genomic approaches can detect potential differences between eutopic endometrium and myometrium in women with and without endometriosis. Immunomodulatory drugs inhibiting pelvic inflammation associated with endometriosis may offer new approaches to medical treatment in the future (103).

Prevalence

Endometriosis is predominantly found in women of reproductive age but has been reported in adolescents and in postmenopausal women receiving hormonal replacement (104). It is found in women of all ethnic and social groups. In women with pelvic pain or infertility, a high prevalence of endometriosis (from a low of 20% to a high of 90%) has been reported (2,105). In asymptomatic women undergoing tubal ligation (women of proven fertility), the prevalence of endometriosis ranges from 3% to 43% (5,106–110). This great variation in the reported prevalence may be explained by several factors. First, it may vary with the diagnostic method used: laparoscopy, the operation of choice for diagnosis, is generally accepted to be a better method than laparotomy for diagnosing minimal to mild endometriosis. Second, minimal or mild endometriosis may be more thoroughly evaluated in a symptomatic patient being given general anesthesia than in an asymptomatic patient during tubal sterilization. Third, the experience of the surgeon is important because there is a wide variation in the appearance of subtle endometriosis implants, cysts, and adhesions. Most studies that evaluate the prevalence of endometriosis in women of reproductive age lack histologic confirmation (5,106,107,110–115).

Diagnosis

Clinical Presentation

Endometriosis should be suspected in women with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. However, these symptoms can also be associated with other diseases. Endometriosis may be asymptomatic, even in some women with more advanced disease (ovarian or deeply invasive rectovaginal endometriosis).

Risk factors for endometriosis include short cycle length (116), heavier menstruation, and longer flow duration (16,117), probably related to a higher incidence of retrograde
menstruation. Patient height and weight are positively and negatively, respectively, associated with the risk of endometriosis (118).

Endometriosis can be associated with significant gastrointestinal symptoms (pain, nausea, vomiting, early satiety, bloating and distention, altered bowel habits). A characteristic motility change (ampulla of Vater–duodenal spasm, a seizure equivalent of the enteric nervous system), along with bacterial overgrowth, has been documented in most women with the disease (119). Women of reproductive age with endometriosis are not osteopenic (120).

The average delay between onset of pain symptoms and surgically confirmed endometriosis is quite long: ±8 years in the United Kingdom and ±9 to 12 years in the United States (121). Similar durations have been observed in Scandinavia (122) and in Brazil (123). A delay in diagnosis of endometriosis of 6 and 3 years in women with pain and women with infertility, respectively, has been reported. Over the past two decades, there has been a steady decrease in the delay in diagnosis and a decline in the prevalence of advanced endometriosis at first diagnosis (124). Concurrently, patient awareness of endometriosis has increased. For many patients, quality of life is affected by pain, emotional impact of subfertility, anger about disease recurrence, and uncertainty about the future regarding repeated surgeries or long-term medical therapy and its side effects. Therefore, endometriosis should be perceived as a chronic disease, at least in a subset of highly symptomatic women, and quality-of-life issues should be evaluated using reliable and valid questionnaires (125).

**Pain**

In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Dysmenorrhea often starts before the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain-free menses. The distribution of pain is variable but most often is bilateral.

Local symptoms can arise from rectal, ureteral, and bladder involvement, and lower back pain can occur. Most studies have failed to detect a correlation between the degree of pelvic pain and the severity of endometriosis (108). Some women with extensive disease have no pain, whereas others with only minimal disease may experience severe pelvic pain. Severe pelvic pain and dyspareunia may be associated with deep infiltrating subperitoneal endometriosis (105,115,126). The character of pelvic pain is related to the anatomic location of deeply infiltrating endometriotic lesions (127).

Possible mechanisms causing pain in patients with endometriosis include local peritoneal inflammation, deep infiltration with tissue damage, adhesion formation, fibrotic thickening, and collection of shed menstrual blood in endometriotic implants, resulting in painful traction with the physiologic movement of tissues (115,128).

In rectovaginal endometriotic nodules, a close histologic relationship has been observed between nerves and endometriotic foci and between nerves and the fibrotic component of the nodule (129).

**Subfertility**

An association between endometriosis and subfertility is generally accepted, but most of the studies suggesting this link have been based on retrospective or cross-sectional analysis (130). When endometriosis is moderate or severe, involving the ovaries and causing adhesions that block tubo-ovarian motility and ovum pickup, it is associated with subfertility (131). This effect has also been shown in primates, including cynomolgus monkeys and baboons (98,132). Although numerous mechanisms (ovulatory dysfunction, luteal insufficiency, luteinized unruptured follicle syndrome, recurrent abortion,
altered immunity, and intraperitoneal inflammation) have been proposed (133), the association between fertility and minimal or mild endometriosis remains controversial (130,131).

**Infertility** Based on the number of asymptomatic women who are found to have endometriosis during tubal ligation, it would appear that the prevalence of endometriosis is not necessarily higher in infertile than in fertile women with endometriosis (5). In fertile women, endometriosis has been reported to be minimal or mild in 80% and moderate or severe in 20% (5,106–110).

In women with mild disease, some studies have reported a lower spontaneous monthly fecundity rate (MFR), which is the total number of pregnancies divided by the number of months of pregnancy exposure (i.e., 5%–11% compared with 25% in a normally fertile population) (133). Other studies using artificial insemination with donor semen have reported that the MFR in women with minimal and mild endometriosis is either reduced (4%) or normal (20%) (134–137). Fertility is not reduced in baboons with spontaneous minimal endometriosis (132,138). In one study, the fecundity rate (probability of becoming pregnant in the first 36 weeks after laparoscopy and carrying the pregnancy to 20 weeks or more) was 18% in infertile women with minimal to mild endometriosis and 23.7% in women with unexplained infertility (no significant difference). None of these women had been surgically treated for endometriosis during the diagnostic laparoscopy. However, 10% of women in each group had been treated with intrauterine insemination, in vitro fertilization (IVF), or cystectomy–myomectomy (139). It remains unclear whether the mere presence of peritoneal endometriosis directly correlates with infertility.

**Spontaneous Abortion** A possible association between endometriosis and spontaneous abortion has been suggested in mostly uncontrolled or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion have important methodologic shortcomings: heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups (140–142). Based on controlled prospective studies, there is no evidence that endometriosis is associated with (recurrent) pregnancy loss (143), or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate (144,145).

</thead>
<tbody>
<tr>
<td>Endometriosis has been associated with anovulation, abnormal follicular development with impaired follicle growth, reduced circulating E₂ levels during the preovulatory phase, disturbed luteinizing hormone (LH) surge patterns, premenstrual spotting, the luteinized unruptured follicle syndrome, and galactorrhea and hyperprolactinemia (146). Increased incidence and recurrence of the luteinized unruptured follicle syndrome has been reported in baboons with mild endometriosis, but not in primates with minimal endometriosis or a normal pelvis (147). Luteal insufficiency with reduced circulating E₂ and progesterone levels, out-of-phase endometrial biopsies, and aberrant integrin expression has been reported in the endometrium of women with endometriosis by some researchers (146,148), but these findings have not been confirmed by other investigators (149). Therefore, no convincing data exist to conclude that the incidence of these endocrinologic abnormalities is increased in women who have endometriosis.</td>

<tbody>
<tr>
<td>Extrapelvic endometriosis, although often asymptomatic, should be suspected when symptoms of pain or a palpable mass occur outside the pelvis in a cyclic pattern. Endometriosis involving the intestinal tract (especially colon and rectum) is the most common site of extrapelvic disease and may cause abdominal and back pain, abdominal distention, cyclic rectal bleeding, constipation, and obstruction. Ureteral involvement can</td>
</tr>
</tbody>
</table>
lead to obstruction and result in cyclic pain, dysuria, and hematuria. Pulmonary endometriosis can manifest as pneumothorax, hemothorax, or hemoptysis during menses. Umbilical endometriosis should be suspected when a patient has a palpable mass and cyclic pain in the umbilical area (18).

**Clinical Examination**

In many women with endometriosis, no abnormality is detected during the clinical examination. The vulva, vagina, and cervix should be inspected for any signs of endometriosis, although the occurrence of endometriosis in these areas is rare (e.g., episiotomy scar). Other possible signs of endometriosis include uterosacral or cul-de-sac nodularity, lateral or cervical displacement caused by uterosacral scarring (150), painful swelling of the rectovaginal septum, and unilateral ovarian (cystic) enlargement. In more advanced disease, the uterus is often in fixed retroversion, and the mobility of the ovaries and fallopian tubes is reduced. Evidence of deeply infiltrative endometriosis (deeper than 5 mm under the peritoneum) in the rectovaginal septum with cul-de-sac obliteration or cystic ovarian endometriosis should be suspected by clinical documentation of uterosacral nodularities during menses, especially if CA125 serum levels are higher than 35 IU/mL (151–153).

The clinical examination may have false-negative results. Therefore, the diagnosis of endometriosis should be confirmed by biopsy of suspicious lesions that are obtained laparoscopically.

**Imaging and Endometriosis**

The presence of filling defects (presence of hypertrophic or polypoid endometrium) detected by hysterosalpingography (154) has a significant positive correlation with endometriosis. The positive predictive value of this finding is 84% and negative predictive value is 75%.

Gynecologic transvaginal (155) or transrectal ultrasonography (156) is an important diagnostic tool (157) in the assessment of ovarian endometriotic cysts (differentiation from other adnexal masses) and of rectovaginal endometriosis (sensitivity, 97%; specificity, 96%).

Other imaging techniques, including computed tomography (CT) and MRI, can be used to provide additional and confirmatory information, but they cannot be used for primary diagnosis (158,159). These techniques are more costly than ultrasonography, and their added value is not clear.

**CA125**

There is no blood test available for the diagnosis of endometriosis. Levels of CA125, a marker found on derivatives of the coelomic epithelium and common to most nonmucinous epithelial ovarian carcinomas, have been found to be significantly higher in women with moderate or severe endometriosis and normal in women with minimal or mild disease (160,161). During menstruation, an increase in CA125 levels has been shown in women with and without endometriosis (162–166). Other studies have not found an increase during menses (167,168) or have found an increase only with moderate to severe endometriosis (169,170). The levels of CA125 vary widely, not only in patients without endometriosis (8–22 U/mL in the nonmenstrual phase) but also in those with minimal to mild endometriosis (14–31 U/mL in the nonmenstrual phase) and in those with moderate to severe disease (13–95 U/mL in the nonmenstrual phase). Compared with laparoscopy, measurement of serum CA125 levels has no value as a diagnostic tool (171).
The reason CA125 levels are increased in moderate to severe endometriosis is unclear. It has been hypothesized that endometriosis lesions contain a greater amount of CA125 than normal endometrium and that the associated inflammation could lead to an increased shedding of CA125 (161).

The specificity of CA125 has been reported to be higher than 80% in most studies. This high level of specificity is achieved in selected women with infertility or pain who are known to be at risk for endometriosis. The low level of sensitivity of CA125 (20%–50% in most studies) poses limitations for the clinical use of this test for diagnosis of endometriosis. Theoretically, the sensitivity might increase during the menstrual period, when the increase in CA125 levels is more pronounced in women who have endometriosis. However, studies using cutoff levels of 35 U/mL (169,170) or 85 U/mL (172) have not found a significant improvement in sensitivity. A sensitivity of 66% was found when CA125 was determined during both the follicular phase and the menstrual phase in each patient and when the ratio of menstrual versus follicular values (>1.5) was used instead of one CA125 level (170). More recent studies reported that the value of CA125 in diagnosis of endometriosis is limited but higher for moderate to severe disease, especially if serum CA125 concentrations are measured during the midfollicular phase (171,173).

Serial CA125 determinations may be useful to predict the recurrence of endometriosis after therapy (174,175). CA125 levels decrease after combined medical and surgical therapy or during medical treatment of endometriosis with danazol, gonadotropin-releasing hormone (GnRH) analogues, or gestrinone, but not with medroxyprogesterone acetate (MPA) or placebo (176–178). Levels of CA125 have been reported to increase to pretreatment levels as early as 3, 4, or 6 months after the cessation of therapy with danazol, GnRH analogs, or gestrinone (166,177–181). Posttreatment increases in CA125 levels have been reported to correlate with endometriosis recurrence (165,175,182). However, other studies have not substantiated a correlation between posttreatment CA125 levels and disease recurrence (176,179,183).

Laparoscopic Findings

Unless disease is visible in the vagina or elsewhere, laparoscopy is the standard technique for visual inspection of the pelvis and establishment of a definitive diagnosis (159). During diagnostic laparoscopy, the pelvic and abdominal cavity should be systematically investigated for the presence of endometriosis. This examination should include a complete inspection and palpation, in a clockwise or counterclockwise fashion with a blunt probe, of the bowel, bladder, uterus, tubes, ovaries, cul-de-sac, and broad ligament (Fig. 29.1). The type, location, and extent of all lesions and adhesions should be documented in the operative notes; ideally, the findings should be recorded on video or DVD (159). There is insufficient evidence to justify performing the laparoscopy at a specific time in the menstrual cycle, but to avoid underdiagnosis, it should not be performed during or within 3 months of hormonal treatment (159).

Characteristic findings include typical (“powder-burn” or “gunshot”) lesions on the serosal surfaces of the peritoneum. These lesions are black, dark brown, or bluish nodules or small cysts containing old hemorrhage surrounded by a variable degree of fibrosis (Fig. 29.2). Endometriosis can appear as subtle lesions (Fig. 29.3), including red implants (petechial, vesicular, polypoid, hemorrhagic, red flamelike), serous or clear vesicles, white plaques or scarring, yellow-brown discoloration of the peritoneum, and subovarian adhesions (93–95,184,185). Histologic confirmation of the laparoscopic impression is essential for the diagnosis of endometriosis (186), not only for subtle lesions but also for typical lesions reported to be histologically negative in 24% of cases (187).
of ovarian endometrioma (greater than 3 cm in diameter) and deeply infiltrating disease, histology should be obtained to identify endometriosis and to exclude rare instances of malignancy (159).

Mild forms of deep endometriosis may only be detected by palpation under an endometriotic lesion or by discovery of a palpable mass beneath visually normal peritoneum, most notably in the posterior cul-de-sac (152) (Fig. 29.4). At laparoscopy, deeply infiltrating endometriosis may have the appearance of minimal disease, resulting in an underestimation of disease severity (188). Reduced Douglas depth and volume in women with deep endometriosis suggests that such lesions develop not in the rectovaginal septum but intraperitoneally and that burial of anterior rectal wall adhesions creates a false bottom, giving an erroneous impression of extraperitoneal origin (189).

The diagnosis of ovarian endometriosis is facilitated by careful inspection of all sides of both ovaries, which may be difficult when adhesions are present in more advanced stages of disease (Fig. 29.5). With superficial ovarian endometriosis, lesions can be both typical and subtle. Larger ovarian endometriotic cysts (endometrioma) are usually located on the anterior surface of the ovary and are associated with retraction, pigmentation, and adhesions to the posterior peritoneum. These ovarian endometriotic cysts often contain a thick, viscous dark brown fluid (“chocolate fluid”) composed of hemosiderin derived from previous intraovarian hemorrhage. Because this fluid may also be found in other conditions, such as in hemorrhagic corpus luteum cysts or neoplastic cysts, biopsy and preferably removal of the ovarian cyst for histologic

confirmation are necessary for the diagnosis in the revised endometriosis classification of the American Society for Reproductive Medicine. If that is not possible, the presence of an ovarian endometriotic cyst should be confirmed by the following features: cyst diameter of less than 12 cm, adhesion to pelvic sidewall or broad ligament, endometriosis on surface of ovary, and tarry, thick, chocolate-colored fluid content (190). Ovarian endometriosis appears to be a marker for more extensive
pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having mostly extensive pelvic or intestinal endometriosis (191).

**Histologic Confirmation**

*Histologic confirmation is essential in the diagnosis of endometriosis.* In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This approach resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77% (192).

Microscopically, endometriotic implants consist of endometrial glands and stroma, with or without hemosiderin-laden macrophages (Fig. 29.6). It has been suggested, however, that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis (2). Furthermore, problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands (193). The presence of stromal endometriosis, which contains endometrial stroma with hemosiderin-laden macrophages or hemorrhage, has been reported in women (186,187) and in baboons (101) and may represent a very early event in the pathogenesis of endometriosis. Isolated endometrial stromal cell nodules, immunohistochemically positive for vimentin and estrogen receptor, can be found in the absence of endometrial glands along blood or lymphatic vessels (194).

Different types of lesions may have different degrees of proliferative or secretory glandular activity (193). Vascularization, mitotic activity, and the three-dimensional structure of endometriosis lesions are key factors (195–197). Deep endometriosis has been described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue (115). However, smooth muscles are
Figure 29.4 Laparoscopic excision of deep endometriosis from the cul-de-sac (photographs kindly donated by Dr Christel Meuleman, Leuven University Fertility Center, Leuven University Hospitals, Leuven, Belgium). also frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uterosacral ligaments (198).

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is believed to be important in the histogenesis of endometriosis and its recurrence after treatment (199,200). The clinical relevance of microscopic endometriosis is controversial because it has not been observed uniformly. Using undefined criteria for what constitutes normal peritoneum, peritoneal biopsy specimens of 1 to 3 cm were obtained during laparotomy from 20 patients with moderate to severe endometriosis (200). Examination of the biopsy results with low-power scanning electron microscopy revealed unsuspected microscopic endometriosis in 25% of cases not confirmed by light microscopy. Peritoneal endometriotic foci have been demonstrated by light microscopy in areas that show no obvious evidence of disease (201).

In serial sections of laparoscopic biopsies of normal peritoneum, 10% to 15% of women were shown to have microscopic endometriosis, and endometriosis was found in 6% of those without macroscopic disease (185,202,203).

In contrast, other studies have been unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum (92,204–206). Examination of larger samples (5–15 mm) of visually normal peritoneum has revealed microscopic endometriosis in only 1 of 55 patients studied (207). Similarly, a histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis is a rare occurrence (208). Therefore, it appears that macroscopically appearing normal peritoneum rarely contains microscopic endometriosis (207).

**Classification**

The current classification system of endometriosis by the American Society of Reproductive Medicine is the former American Fertility Society (AFS) system (see...
Fig. 29.5, which has been revised without major changes (131). It is based on the appearance, size, and depth of peritoneal and ovarian implants; the presence, extent, and type of adnexal adhesions; and the degree of cul-de-sac obliteration. In the new classification system, the morphology of peritoneal and ovarian implants should be categorized as red (red, red-pink, and clear lesions), white (white, yellow-brown, and peritoneal defects), and black (black and blue lesions).
This system reflects the extent of endometriotic disease but has considerable intraobserver and interobserver variability (209,210). Because the revised classification of endometriosis is the only internationally accepted system, it appears to be the best available tool to describe objectively the extent of endometriosis and relate it to spontaneous evolution and to therapeutic outcomes (pain relief, enhancement of fertility).

The classification system has also been criticized because several investigators failed to find a correlation between it and endometriosis-related pain or infertility. This topic will be reviewed in “Results of Surgical Treatment.”

Figure 29.6 Histologic appearance of endometriosis: endometrial glandular epithelium, surrounded by stroma in typical lesion and clear vesicle.

Spontaneous Evolution

Endometriosis appears to be a progressive disease in a significant proportion (30%–60%) of patients. During serial observations, deterioration (47%), improvement (30%), or elimination (23%) was documented over a 6-month period (211). In another study, endometriosis progressed in 64%, improved in 27%, and remained unchanged in 9% of patients over 12 months (212). A third study of 24 women reported 29% with disease progression, 29% with disease regression, and 42% with no change over 12 months. Follow-up studies in both baboons and women (213–215) with spontaneous endometriosis over 24 months have demonstrated disease progression in all baboons and in 6 of 7 women. Several studies have reported that subtle lesions and typical implants may represent younger and older types of endometriosis, respectively. In a cross-sectional study, the incidence of subtle lesions decreased with age (216). This finding was confirmed by a 3-year prospective study that reported that the incidence, overall pelvic area involved, and volume of subtle lesions decreased with age, but in typical lesions, these parameters and the depth of infiltration increased with age (105). Remodeling of endometriotic lesions (transition between typical and subtle subtypes) has been reported to occur in women and in baboons, indicating that endometriosis is a dynamic condition (217,218). Several studies in women, cynomolgus monkeys, and rodents have shown that endometriosis is ameliorated after pregnancy (218–221).
The characteristics of endometriosis are variable during pregnancy, and lesions tend to enlarge during the first trimester but regress thereafter (222). Studies in baboons have revealed no change in the number or surface area of endometriosis lesions during the first two trimesters of pregnancy (223). These results do not exclude a beneficial effect that potentially may occur during the third trimester or in the immediate postpartum period. Establishment of a “pseudopregnant state” with exogenously administered estrogen and progestins was based on the belief that symptomatic improvement may result from decidualization of endometrial implants during pregnancy (224). This hypothesis, however, has not been substantiated.

**Treatment**

Treatment must be individualized, taking into consideration the clinical problem in its entirety, including the impact of the disease and the effect of its treatment on quality of life (159). Pain may persist despite seemingly adequate medical or surgical treatment of the disease. In such circumstances, a multidisciplinary approach involving a pain clinic and counseling should be considered early in the treatment plan (159). It also is important to involve the woman in all decisions, to be flexible in considering diagnostic and therapeutic approaches, and to maintain a good relationship with the patient. It may be appropriate to seek advice from more experienced colleagues or to refer the woman to a center with the necessary expertise to offer all available treatments in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy (159). Because the management of severe or deeply infiltrating endometriosis is complex, referral is strongly recommended if disease of such severity is suspected or diagnosed (159).

**Prevention**

No strategies to prevent endometriosis have been uniformly successful. Although a reduced incidence of endometriosis has been reported in women who engaged in aerobic activity from an early age (16), the possible protective effect of exercise has not been investigated thoroughly. There also is insufficient evidence that oral contraceptive use offers protection against the development of endometriosis. In contrast, a recent report (225) showed an increased risk for endometriosis development in a select population of women taking oral contraceptives.

Regardless of the clinical profile (subfertility, pain, asymptomatic findings), treatment of endometriosis may be justified because endometriosis appears to progress in 30% to 60% of patients within a year of diagnosis and because it is not possible to predict in which patients it will progress (212). Unfortunately, elimination of the endometriotic implants by surgical or medical treatment often provides only temporary relief. Therefore, in addition to eliminating the endometriotic lesions, the goal should be, more importantly, to treat the sequelae (pain and subfertility) often associated with this disease.

**Surgical Treatment**

In most women with endometriosis, preservation of reproductive function is desirable. Therefore, the least invasive and least expensive approach that is effective should be used. Depending on the severity of disease, diagnosis and removal of endometriosis should be performed simultaneously at the time of surgery provided preoperative consent has been obtained (159,226–229). The goal of surgery is to excise all visible endometriotic lesions and associated adhesions—peritoneal lesions, ovarian cysts, deep rectovaginal endometriosis—and to restore normal anatomy. In most women, laparoscopy can be used, and this technique decreases cost, morbidity, and the possibility of recurrence of adhesions postoperatively. **Laparotomy should be reserved for patients with advanced-stage**
disease who cannot undergo a laparoscopic procedure and for those in whom fertility conservation is not necessary.

**Peritoneal Endometriosis** Endometriosis lesions can be removed during laparoscopy by surgical excision with scissors, bipolar coagulation, or laser methods (CO₂ laser, potassium-titany-phosphate laser, or argon laser). Although some surgeons claim that the CO₂ laser is superior because it causes only minimal thermal damage, no evidence is available to show the superiority of one technique over another. Comparable cumulative pregnancy rates have been reported after treatment of mild endometriosis with laparoscopic excision and electrocoagulation (230).

**Ovarian Endometriosis** Superficial ovarian lesions can be vaporized. Small ovarian endometrioma (<3 cm in diameter) can be aspirated, irrigated, and inspected with ovarian cystoscopy for intracystic lesions; their interior wall can be vaporized to destroy the mucosal lining of the cyst (231). Large (>3 cm in diameter) ovarian endometrioma should be aspirated, followed by incision and removal of the cyst wall from the ovarian cortex. To prevent recurrence, the cyst wall of the endometrioma must be removed, and normal ovarian tissue must be preserved.

Although as little as one tenth of an ovary is enough to preserve function and fertility (232), there is increasing concern that ovarian cystectomy with concomitant removal or destruction of primordial follicles may reduce ovarian volume and reserve and diminish fertility. A recent study reported reduced follicular response in natural and clomiphene citrate-stimulated cycles, but not in gonadotropin-stimulated cycles, in women younger than 35 years of age who underwent cystectomy compared with controls of similar age with normal ovaries (233). Therefore, it has been proposed to replace cystectomy by fenestration and coagulation of the inner wall of the endometriotic ovarian cyst. In one study, cumulative clinical pregnancy rates and recurrence rates were comparable in women treated with cystectomy and with fenestration and coagulation after 36 months, but conception occurred more quickly in the fenestration and coagulation group (234). A more recent case-control study in 231 patients reported a lower cumulative reoperation rate in the cyst excision group than in the fenestration and coagulation group after 18 (6% versus 22%) and 42 (24% versus 59%) months of follow-up (235). A randomized controlled trial demonstrated that pain and subfertility caused by ovarian endometrioma were improved more by cystectomy than by fenestration and coagulation (236). A reduced recurrence of pain after 2 years (odds ratio [OR], 0.2; confidence interval [CI], 0.05–0.77), an increased pain-free interval after operation (19 months versus 9.5 months), and an increased pregnancy rate (67% versus 23%) were found in the cystectomy group when compared with the fenestration and coagulation group (236). In another recent study (237), coagulation or laser vaporization of endometriomas without excision of the pseudocapsule was associated with a significantly increased risk of cyst recurrence. Laparoscopic cystectomy for ovarian endometriomas greater than 4 cm diameter improves fertility compared with drainage and coagulation (238,239).

Therefore, based on the current evidence, ovarian cystectomy appears to be the method of choice.

**Adhesiolysis** The removal of endometriosis-related adhesions (adhesiolysis) should be performed carefully. Routine use of pharmacologic or liquid agents to prevent postoperative adhesions after fertility surgery cannot be recommended based on evidence from randomized controlled trials (240).

**Preoperative Hormonal Treatment** In patients with severe endometriosis, it has been recommended that surgical treatment be preceded by a 3-month course of medical treatment to reduce vascularization and nodular size (152). However, a recent randomized study comparing 3 months of preoperative treatment with GnRH and no treatment in 75 women with moderate to severe endometriosis failed to show a significant difference in ease of surgery between the two groups (241).
Deep Rectovaginal and Rectosigmoidal Endometriosis  The surgical excision of deep rectovaginal and rectosigmoidal endometriosis is difficult and can be associated with major complications. Postoperative bowel perforations with peritonitis have been reported in 2% to 3% of cases (242).

Preoperative investigations, including gynecologic ultrasonography, intravenous pyelography (to exclude ureteral endometriosis), and colon contrast radiography (to exclude transmural rectosigmoidal endometriosis), are essential, and MRI may be useful in specific cases. Preoperative laxatives, starch-free diet, and full bowel preparation are needed to allow perioperative bowel suturing, if needed. To allow complete excision of rectovaginal endometriosis, 6% of patients needed bowel wall resection, and 14% required partial resection of the posterior vaginal fornix (242). Segmental rectosigmoid resection can be performed by laparotomy, laparoscopy with intracorporeal suturing, or by laparoscopically assisted vaginal technique (243). The latter technique appears to be faster than laparoscopy with intracorporeal suturing and cheaper than laparotomy because of decreased hospital stay and lower operating room charges (243), but more studies are needed to confirm this impression. Ureter stents may be required before excision of peritoneal endometriosis surrounding the ureter. A multidisciplinary approach involving gynecologic and gastroenterologic surgeons and urologists is desirable. More long-term follow-up after surgery for colorectal endometriosis is needed to document complications, recurrences, and long-term effects on pain and fertility.

Oophorectomy and Hysterectomy  Radical procedures such as oophorectomy or total hysterectomy are indicated only in severe situations and can be performed either laparoscopically or, more commonly, by laparotomy. However, it is important to note that women aged 30 years or younger at the time of hysterectomy for endometriosis-associated pain are more likely than older women to have residual symptoms, to report a sense of loss, and to report more disruption from pain in different aspects of their lives (244). If a hysterectomy is performed, bilateral salpingo-oophorectomy should be considered as well (245), and all visible endometriotic tissue should be removed at the same time (246).

Postoperative Hormone Therapy  Postoperative hormone therapy with estrogen is required after bilateral oophorectomy, and there is a negligible risk for renewed growth of residual endometriosis (247). To reduce this risk, hormone therapy should be withheld until 3 months after surgery. The addition of progestins to this regimen protects the endometrium. However, the decision to start hormone therapy with a combination of estrogen and progestin should be balanced against the increased risk of breast cancer and heart disease associated with hormone therapy.

Some cases of adenocarcinoma have been reported, presumably arising from endometriosis lesions remaining in women treated with unopposed estrogen (232).

Results of Surgical Treatment

Pain  The outcome of surgical therapy in patients with endometriosis and pain is influenced by many psychological factors relating to personality, depression, and marital and sexual problems. There is a significant placebo response to surgical therapy: diagnostic laparoscopy without complete removal of endometriosis may alleviate pain in 50% of patients (248–250). Similar results have been reported using oral placebos (251). Although some reports have claimed pain relief with laser laparoscopy in 60% to 80% of patients with very low morbidity, none was prospective or controlled and, thus, did not allow a definitive conclusion regarding treatment efficacy (152,252–255).

Endometriosis Stage and Pain Relief after Surgery  In patients with pain, the endometriosis stage was not related to pain symptoms in several studies (256,257).
However, more recent studies reported a positive correlation between endometriosis stage and endometriosis-related dysmenorrhea or chronic pelvic pain (258,259).

In a prospective, controlled, randomized, double-blind study, surgical therapy (ablation of endometriotic lesions and laparoscopic uterine nerve ablation [LUNA]) was shown to be superior to expectant management 6 months after treatment of mild and moderate endometriosis (248). In women with mild and moderate disease treated with laser, 74% achieved pain relief. Treatment was least effective in women with minimal disease. There were no reported operative or laser complications (248). There is no evidence that LUNA is a necessary part of this treatment (260) because LUNA by itself has no effect on dysmenorrhea associated with endometriosis (237). One year later, symptom relief was still present in 90% of those who responded initially (213,248). Patients with severe disease were not included (248) because it had previously been shown that surgery resulted in pain relief in 80% of patients who did not respond to medical therapy (261).

These results suggest that laser laparoscopy may be effective for the treatment of pain associated with mild to severe endometriosis. In women with minimal endometriosis, laser treatment may limit progression of disease.

Effect of Preoperative and Postoperative Treatment

Hormonal therapy before surgery improves endometriosis scores, but there is insufficient evidence that it has any effect on pain relief after the operation (262).

Some evidence from randomized controlled trials supports the postoperative medical treatment of pain associated with endometriosis for 6–12 months. Postoperative GnRH treatment resulted in reduced pain scores and in a delay of pain recurrence for more than 12 months if the agonists were given for 6 months but not if they were only administered for 3 months (263–265). Similarly, postoperative hormonal treatment with danazol, 100 mg/day (low dose), for 12 months after surgery for moderate to severe endometriosis resulted in a significantly lower pain score in the treated group when compared with the placebo group. In contrast, postoperative high-dose danazol, 600 mg/day for 3 months, was not superior to expectant management with respect to pain recurrence in an identical patient population (266). According to a recent Cochrane review (262), compared with surgery alone or surgery plus placebo, postoperative hormonal treatment does not reduce pain recurrence at 12 or 24 months and has no effect on disease recurrence 263–266, 268, 270, 271, 273.

Subfertility

Advanced Endometriosis and Pregnancy Outcome after Surgery

When endometriosis causes mechanical distortion of the pelvis, surgery should be performed to achieve reconstruction of normal pelvic anatomy. Laparoscopic cystectomy for ovarian endometriomas greater than 4 cm diameter improves fertility compared with drainage and coagulation (238,239).

The success of surgery in relieving infertility is probably related to the severity of endometriosis. A recent retrospective multicenter analysis (271) reported cumulative pregnancy rates of 39%, 31%, 30%, and 25% in patients with endometriosis stages I, II, III, and IV, respectively, 12 months after surgical treatment. Although there appeared to be a negative correlation between stage of endometriosis and fertility outcome, no significant difference was found between the four groups in this study. However, the study had many limitations, including retrospective design, lack of well-defined definition of male factor infertility as potential bias, multicenter data with significant interobserver variability, inclusion of only a limited number of patients with substantial adhesive disease, variable infertility treatment after 6 months of follow-up, and absence of a control group.
A somewhat higher cumulative intrauterine pregnancy rate has been reported in 30 women with deep uterosacral endometriosis after surgery: 48% after 12 months (47% for AFS stages I to II and 46% for AFS stages III to IV) (276). A cumulative pregnancy rate of 24% was reported in patients 9 months after undergoing reoperation for stage III to IV endometriosis (277).

Other investigators reported a negative correlation between stage of endometriosis and fertility after surgical treatment. In an older study, using an older classification system, a significant decrease in fecundability was seen in women with severe or extensive endometriosis compared with women with mild or moderate disease (278,279). In a more recent study (280), the negative correlation between the stage of endometriosis and the spontaneous cumulative pregnancy rate after surgical removal of endometriosis was statistically significant. Other studies have reported a significant negative correlation between endometriosis stage and pregnancy rate and decreased pregnancy rates when the revised scores exceeded 70 (281,282).

**Preoperative and Postoperative Medical Treatment**

Preoperative medical treatment with danazol, GnRH agonists, or progestins may be useful to reduce the extent of endometriosis in patients with advanced disease. Postoperative medical treatment is rarely indicated because it does not work based on randomized trials, because it prevents pregnancy, and because the highest pregnancy rates occur during the first 6 to 12 months after conservative surgery (264,265). If pregnancy does not occur within 2 years of surgery, there is little chance of subsequent fertility (283).

**Minimal to Mild Endometriosis and Fertility after Surgery**

Surgical management of infertile women with minimal to mild endometriosis is controversial. The cumulative pregnancy rate after 5 years without therapy has been reported to be as high as 90% in women with minimal or mild endometriosis (284). This is comparable to the 93% rate reported in women who do not have endometriosis. Laparoscopic destruction of endometriosis has been reported to improve fertility in patients with minimal to mild disease (285–287), but not all investigators share this conclusion (288–290). It has been hypothesized that the MFR is higher during the first 6 to 12 months after laparoscopic surgery than with expectant management (291,292).

Two randomized controlled studies have evaluated the effect of surgical treatment of endometriosis on fertility parameters (144,145). One study (144) reported that laparoscopic surgery enhanced fecundity in infertile women with minimal or mild endometriosis. They studied 341 infertile women, 20 to 39 years of age, with minimal or mild endometriosis. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They were followed for 36 weeks after the laparoscopy or, for those who became pregnant during that interval, for up to 20 weeks of pregnancy. The study objects were recruited among infertile women scheduled for diagnostic laparoscopy with strict eligibility criteria. The women in the study had no previous surgical treatment for endometriosis and no medical treatment for endometriosis in the previous 9 months and no other medical or surgical treatment for infertility in the previous 3 months. They had no history of pelvic inflammatory disease and no severe pelvic pain precluding expectant management. The diagnosis of endometriosis required the presence of one or more typical bluish or black lesions. The stage of endometriosis was determined according to the revised American Society of Reproductive Medicine classification. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They found that resection or ablation of minimal and mild endometriosis increased the likelihood of pregnancy in infertile women. In the treated group, 31% of the patients became pregnant, compared with 18% in the nontreated group ($P = 0.006$).
In a multicenter study in Italy, a similar study design was used to compare the effect of diagnostic laparoscopy with surgical resection and ablation of visible endometriosis (on fertility parameters) in infertile women with minimal to mild endometriosis (145). Eligible patients were women aged less than 36 years who were trying to conceive and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis. None of the women had had therapy for endometriosis or infertility. Treatment was randomly allocated during laparoscopy. There was a follow-up period of 1 year after the laparoscopy. The results of this study did not show a beneficial effect of surgery regarding fertility. During the follow-up period after laparoscopy, no statistically significant differences in conception and live-birth rates were observed in the treated group (24% and 20%, respectively) and in the control group (29% and 22%, respectively).

### Prognosis with Surgical Treatment

Based on the aforementioned studies, and taking into account the larger patient population in the Canadian multicenter study, surgical treatment of minimal to mild endometriosis appears to offer a small but significant benefit with regard to fertility outcome (130,159,289). Furthermore, the surgical removal of peritoneal endometriosis may also be important to prevent progression of endometriosis. However, care is needed to prevent adhesion formation that could result as a consequence of overenthusiastic excision of minimal to mild endometriosis.

### Medical Treatment

#### Empirical Treatment

If the patient desires treatment of pain symptoms suggestive of endometriosis in the absence of a definitive diagnosis, a therapeutic trial of a hormonal medication to reduce menstrual flow is appropriate. Empirical treatment for pain presumed to be due to endometriosis in the absence of a definitive diagnosis includes counseling, analgesia, nutritional therapy, progestins, or combined oral contraceptives. It is unclear whether combined oral contraceptives should be taken in a conventional, continuous, or tricycle regimen. A GnRH agonist may be taken, but this class of drug is more expensive and associated with more side effects and concerns about bone density than oral contraceptives (159).

### Dysmenorrhea

Generally, women suffering from dysmenorrhea are treated with analgesics; many women treat themselves with over-the-counter oral analgesics. In a recent systematic Cochrane review evaluating the use of nonsteroidal anti-inflammatory drugs (NSAIDs) for primary dysmenorrhea (290), primary dysmenorrhea was described as menstrual pain without organic pathology (see Chapter 15). Exclusion of pelvic pathology was based on physical examination alone. It can be argued that some of these women with so-called primary dysmenorrhea probably in fact had endometriosis. It was concluded that NSAIDs, except niflumic acid, were more effective than placebo for pain relief (290), but there was insufficient evidence to suggest whether any individual NSAID was more effective than another. In another review, selective cyclo-oxygenase-2 inhibitors rofecoxib and valdecoxib were found to be as effective as naproxen and more effective than placebo for the treatment of primary dysmenorrhea (291). However, concerns have been raised about the safety of these medications, and its manufacturers have recently withdrawn rofecoxib from the market.

According to a systematic review (292) based on two relatively small randomized controlled trials comparing paracetamol and co-proxamol with placebo, respectively, co-proxamol (paracetamol 650 mg and dextropropoxyphen 65 mg) but not paracetamol...
(500 mg 4 times daily) was more effective than placebo in reducing pain. This observation can possibly be explained by the suboptimal dosage of paracetamol used.

**Pain**

Considering that endometriosis is a chronic inflammatory disease, anti-inflammatory drugs would appear to be effective for treatment (see Chapter 15). Nonsteroidal anti-inflammatory drugs may be effective in reducing endometriosis-associated pain (159,293–295). Although NSAIDs have been used extensively and have often been the first-line therapy for reduction of endometriosis-related pain, the analgesic effect of NSAIDs has not been studied extensively. Only one small, double-blind, placebo-controlled, four-period, crossover clinical study has been published (294). This study showed complete or substantial pain relief of endometriosis-related dysmenorrhea in 83% of cases treated with naproxen compared with 41% in cases treated with placebo. Women who received naproxen needed significantly fewer supplemental analgesics compared to women taking placebo.

Endometriosis-related pain is nociceptive (296), but persistent nociceptive input from endometriotic lesions leads to central sensitization manifested by somatic hyperalgesia and increased referred pain. The effectiveness of NSAIDs in the reduction of endometriosis-related pain may be explained by both a local antinociceptive effect and a reduced central sensitization in addition to the anti-inflammatory effect. However, NSAIDs have significant side effects, including gastric ulceration and possible inhibition of ovulation. Prostaglandins also are involved in the follicle rupture mechanism at ovulation, which is why women who wish to become pregnant should not take NSAIDs at the time of ovulation (297).

**Nonhormonal Medical Therapy**

**Modulation of Cytokines** In rats with experimental endometriosis, recombinant human TNF-α–binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (298). Similarly, a recent prospective randomized placebo- and drug-controlled study in baboons showed that recombinant human TNF-α–binding protein effectively inhibits the development of endometriosis and endometriosis-related adhesions (57) and is effective in the treatment of spontaneous endometriosis in baboons (299).

In mice with experimental endometriosis, a placebo-controlled double-blind study showed that intraperitoneal or subcutaneous injection of recombinant interferon-α2b resulted in smaller endometriotic lesions when compared with the placebo control group (300). In rats with experimental endometriosis, regression of endometrial explants was observed after treatment with immune-enhancing modulators toxoribine and levamisole (301).

**Anti-inflammation** In the future, leukotriene receptor antagonists could be of use in patients with endometriosis who do not respond to prostaglandin synthetase inhibitors (302). In humans, a randomized placebo-controlled trial of oral pentoxifylline, 800 mg/day for 12 months, reported after life-table analysis a similar overall pregnancy rate in treated patients (31%) and in controls (18.5%) (303).

**Inhibition of Matrix Metalloproteinase** In nude mice, suppression of MMPs by progesterone or by a natural inhibitor slows the establishment of ectopic lesions by human endometrium (304). Thus far, no clinical reports have been published.

**New Developments** Many substances potentially capable of modulating immunologic or inflammatory mechanisms involved in the onset or progression of the disease could be the targets for future research in endometriosis (305,306).
Because estrogen is known to stimulate the growth of endometriosis, hormonal therapy has been designed to suppress estrogen synthesis, thereby inducing atrophy of ectopic endometrial implants or interrupting the cycle of stimulation and bleeding. Implants of endometriosis react to gonadal steroid hormones in a manner similar but not identical to normally stimulated ectopic endometrium. Ectopic endometrial tissue displays histologic and biochemical differences from normal ectopic endometrium in characteristics such as glandular activity (proliferation, secretion), enzyme activity (17β-hydroxysteroid dehydrogenase), and steroid (estrogen, progestin, and androgen) hormone receptor levels.

There is strong evidence that suppression of ovarian function for 6 months reduces pain associated with endometriosis. Combined oral contraceptives danazol, gestrinone, medroxyprogesterone acetate, and GnRH agonists are all equally effective but their side-effect and cost profiles differ (159,306–309).

The use of diethylstilbestrol, methyltestosterone, or other androgens is no longer advocated because they lack efficacy, have significant side effects, and pose risks to the fetus if pregnancy occurs during therapy. A new generation of aromatase inhibitors, estrogen receptor modulators, and progesterone antagonists may offer new hormonal treatment options in the future. Recent progress in the understanding of the pathogenesis of endometriosis has led to the expectation that new pharmaceutical agents affecting inflammation, angiogenesis, and MMP activity may prevent or inhibit the development of endometriosis.

**Oral Contraceptives**

**Continuous Administration**

Manipulation of the endogenous hormonal milieu is the basis for the medical management of endometriosis. The treatment of endometriosis with continuous low-dose monophasic combination contraceptives (one pill per day for 6–12 months) was originally used to induce pseudopregnancy caused by the resultant amenorrhea and decidualization of endometrial tissue (224). Kistner was the first to introduce the concept of an adynamic endometrium through elimination of the normal cyclic hormonal changes characteristic of the menstrual cycle (310). This induction of a pseudopregnancy state with combination oral contraceptive pills has been shown to be effective in reducing dysmenorrhea and pelvic pain. In addition, the subsequent amenorrhea induced by oral contraceptives could potentially reduce the amount of retrograde menstruation (one of the risk factors proposed in the etiology of endometriosis), decreasing the risk for disease progression. Pathologically, oral contraceptive use is associated with decidualization of endometrial tissue, necrobiosis, and possibly absorption of the endometrial tissue (311). Unfortunately, there is no convincing evidence that medical therapy with oral contraceptives offers definitive therapy. Instead, the endometrial implants survive the induced atrophy and, in most patients, reactivate after termination of treatment.

Any low-dose combination oral contraceptive containing 30 to 35 μg of ethinyl estradiol used continuously can be effective in the management of endometriosis. The objective of the treatment is the induction of amenorrhea, which should be continued for 6 to 12 months. Symptomatic relief of dysmenorrhea and pelvic pain is reported in 60% to 95% of patients (312,313). After a first-year recurrence rate of 17% to 18%, a 5% to 10% annual recurrence rate has been observed. In addition, a posttreatment pregnancy rate of up to 50% can be expected. Although oral contraceptives are effective in inducing a decidualized endometrium, the estrogenic component in oral contraceptives may potentially stimulate endometrial growth and increase pelvic pain in the first few weeks of treatment. The long-term significance of this effect remains to be determined. Oral contraceptives are less costly than other treatments and may be helpful in the short-term management of endometriosis with potential long-term benefits in some women.
Cyclic Administration

There is no convincing evidence that cyclic use of combination oral contraceptives provides prophylaxis against either the development or recurrence of endometriosis. Estrogens in oral contraceptives potentially may stimulate the proliferation of endometriosis. The reduced menstrual bleeding that often occurs in women taking oral contraceptives may be beneficial to women with prolonged, frequent menstrual bleeding, which is a known risk factor for endometriosis (16). Further research is warranted to assess the effect of low-dose oral contraceptives in preventing endometriosis and in treating associated pain. In a randomized controlled study, a cyclic 21-day oral contraceptive (ethinyl estradiol 20 µg plus desogestrel 0.15 mg) combined with very-low-dose danazol (50 mg/day) was less effective in relief of dysmenorrhea than depot medroxyprogesterone acetate (150 mg every 3 months) (314).

Progestins

Progestins may exert an antiendometriotic effect by causing initial decidualization of endometrial tissue followed by atrophy. They can be considered as the first choice for the treatment of endometriosis because they are as effective as danazol or GnRH analogues and have a lower cost and a lower incidence of side effects than these agents (315).

There is no evidence that any single agent or any particular dose is preferable to another. The effective doses of several progestins are summarized in Table 29.1. In most studies, the effect of treatment has been evaluated after 3 to 6 months of therapy. MPA has been the most studied agent. It is effective in relieving pain starting at a dose of 30 mg/day and increasing the dose based on the clinical response and bleeding patterns (316,317). However, a recent randomized placebo-controlled study reported a significant reduction in

PO, oral; SC, subcutaneous; IM, intramuscular; IN, intranasal.
stages and scores of endometriosis in both the placebo group and the group treated with MPA, 50 mg/day, and placebo at laparoscopy within 3 months after cessation of therapy (318). These findings raise questions about the need for medical therapy.

Medroxyprogesterone acetate (150 mg) given intramuscularly every 3 months is also effective for the treatment of pain associated with endometriosis, but it is not indicated in infertile women because it induces profound amenorrhea and anovulation, and a varying length of time is required for ovulation to resume after discontinuation of therapy. Megestrol acetate has been administered in a dose of 40 mg/day with good results (319). Other treatment strategies have included dydrogesterone (20 to 30 mg/day, either continuously or on days 5 to 25) and lynestrenol (10 mg/day). The effectiveness of natural progesterone has not been evaluated.

Side effects of progestins include nausea, weight gain, fluid retention, and breakthrough bleeding caused by hypoestrogenemia. Breakthrough bleeding, although common, is usually corrected by short-term (7-day) administration of estrogen. Depression and other mood disorders are a significant problem in about 1% of women taking these medications.

Intraterine Progesterone Treatment

Local progesterone treatment of endometriosis-associated dysmenorrhea with a levonorgestrel-releasing intruterine system for 12 months has resulted in a significant reduction in dysmenorrhea, pelvic pain, and dyspareunia; a high degree of patient satisfaction; and a significant reduction in the volume of rectovaginal endometriotic nodules (320,321). These promising results have been confirmed in other studies (322), even after 3 years of treatment (323). This type of local treatment may become a more important option if a long-term medical suppression of endometriosis is needed.

Progesterone Antagonists

Progesterone antagonists and progesterone receptor modulators may suppress endometriosis based on their antiproliferative effects on the endometrium, without the risk for hypoestrogenism or bone loss that occurs with GnRH treatment. These products are soon to be introduced in the United States, but their clinical effectiveness remains to be proved.

Mifepristone Mifepristone (RU-486) is a potent antiprogestagen with a direct inhibitory effect on human endometrial cells and, in high doses, an antiglucocorticoid action (324). The recommended dose for endometriosis is 25 to 100 mg/day. In uncontrolled studies, mifepristone, 50 to 100 mg/day, reduced pelvic pain and induced 55% regression of the lesions without significant side effects (325,326). In an uncontrolled pilot study, mifepristone, 5 mg/day, resulted in pain improvement, but there was no change in endometriosis lesions, suggesting that this dosage is probably too low (327).

Onapristone Progesterone antagonists onapristone (ZK98299) and ZK136799, used in the treatment of rats with surgically induced endometriosis, resulted in a remission in 40% to 60% of treated animals. In animals with persistent endometriosis, growth inhibition was obtained in 48% and 85% of endometriotic lesions after therapy with onapristone and ZK136799, respectively (328).

Other Progesterone Antagonists The chemical synthesis and pharmacologic characterization of a highly potent progesterone antagonist, ZK230211, have been reported, with little or no other endocrinologic effects. ZK230211 is active on both progesterone receptors A and B (329). In primates, this drug has been reported to block ovulation and menstruation at all effective doses (330), whereas another progesterone antagonist, ZK137316, allowed ovulation but blocked menstruation in a dose-dependent fashion. All progesterone antagonist–treated animals maintained normal follicular phase concentration
of estradiol and returned to menstrual cyclicity within 15 to 41 days after treatment (330). Both progesterone antagonists block unopposed estrogen action on the endometriosis through their antiproliferative effect.

**Gestrinone**

Gestrinone is a 19-nortestosterone derivative with androgenic, antiprogestogenic, antiestrogenic, and antigonadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone–binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). Gestrinone causes cellular inactivation and degeneration of endometriotic implants but not their disappearance (331). Amenorrhea occurs in 50% to 100% of women and is dose dependent.

Resumption of menses generally occurs 33 days after discontinuing the medication (332,333). An advantage of gestrinone is its long half-life (28 hours) when given orally. The standard dose has been 2.5 mg twice a week. Although it has been reported that 1.25 mg twice weekly is equally effective (334), a more recent randomized study demonstrated in women with mild to moderate endometriosis that 2.5 mg gestrinone, twice weekly for 24 weeks, is more effective and has a better effect on bone mass (+7% versus −7%) when compared with 1.25 mg gestrinone, 2 times weekly for 24 weeks (335).

The clinical side effects of gestrinone are dose dependent and similar to but less intense than those caused by danazol (332). They include nausea, muscle cramps, and androgenic effects such as weight gain, acne, seborrhea, and oily hair and skin.

In a multicenter, randomized, double-blind study, gestrinone was as effective as GnRH for the treatment of pelvic pain associated with endometriosis (336). However, gestrinone has fewer side effects and has the added advantage of twice-weekly administration. Pregnancy is contraindicated while taking gestrinone because of the risk for masculinization of the fetus.

**Danazol**

Danazol is not more effective than other available medications to treat endometriosis. Recognized pharmacologic properties of danazol include suppression of GnRH or gonadotropin secretion, direct inhibition of steroidogenesis, increased metabolic clearance of estradiol and progesterone, direct antagonistic and agonistic interaction with endometrial androgen and progesterone receptors, and immunologic attenuation of potentially adverse reproductive effects (337,338). The multiple effects of danazol produce a high-androgen, low-estrogen environment (estrogen levels in the early follicular to postmenopausal range) that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding of implants from the uterus into the peritoneal cavity.

The immunologic effects of danazol have been studied in women with endometriosis and adenomyosis and include a decrease in serum immunoglobulins, a decrease in serum C3, a rise in serum C4 levels, decreased serum levels of autoantibodies against various phospholipid antigens, and decreased serum levels of CA125 during treatment (165,166,178–181,339,340). Danazol inhibits peripheral blood lymphocyte proliferation in cultures activated by T-cell mitogens but does not affect macrophage-dependent T-lymphocyte activation of B lymphocytes (338). Danazol inhibits interleukin-1 and TNF production by monocytes in a dose-dependent manner, and suppresses macrophage- and monocyte-mediated cytotoxicity of susceptible target cells in women with mild endometriosis (341,342). These immunologic findings may be important in the remission of endometriosis with danazol treatment and may offer an explanation of the effect of danazol in the treatment of a number of autoimmune diseases, including hereditary
angioedema (343), autoimmune hemolytic anemia (344), systemic lupus erythematosus (345), and idiopathic thrombocytopenic purpura (346,347). Doses of 800 mg/day are frequently used in North America, whereas 600 mg/day is commonly prescribed in Europe and Australia. It appears that the absence of menstruation is a better indicator of response than drug dose. A practical strategy for the use of danazol is to start treatment with 400 mg daily (200 mg twice a day) and increase the dose, if necessary, to achieve amenorrhea and relieve symptoms (333).

The significant adverse side effects of danazol are related to its androgenic and hypoe-strogenic properties. The most common side effects include weight gain, fluid retention, acne, oily skin, hirsutism, hot flashes, atrophic vaginitis, reduced breast size, reduced libido, fatigue, nausea, muscle cramps, and emotional instability. Deepening of the voice is another potential side effect that is nonreversible. Although danazol can cause increased cholesterol and low-density lipoprotein levels and decreased high-density lipoproteins levels, it is unlikely that these short-term effects are clinically important. Danazol is contraindicated in patients with liver disease because it is largely metabolized in the liver and may cause hepatocellular damage. Danazol is also contraindicated in patients with hypertension, congestive heart failure, or impaired renal function because it can cause fluid retention. The use of danazol is contraindicated in pregnancy because of its androgenic effects on the fetus.

Because the many side effects of oral danazol limit its use, alternative routes of administration have been studied. In an uncontrolled pilot study, local danazol treatment using a vaginal danazol ring (1,500 mg) has been shown to be effective for pain relief in deeply infiltrative endometriosis. This treatment did not cause the classic danazol side effects or detectable serum danazol levels, and it allowed ovulation and conception to occur (348).

**Gonadotropin-releasing Hormone Agonists**

Gonadotropin-releasing hormone agonists bind to pituitary GnRH receptors and stimulate LH and FSH synthesis and release. However, the agonists have a much longer biologic half-life (3–8 hours) than endogenous GnRH (3.5 minutes), resulting in the continuous exposure of GnRH receptors to GnRH agonist activity. This exposure causes a loss of pituitary receptors and downregulation of GnRH activity, resulting in low FSH and LH levels. Consequently, ovarian steroid production is suppressed, providing a medically induced and reversible state of pseudomenopause. A direct effect of GnRH agonists on ectopic endometrium is also possible, because expression of the GnRH receptor gene has been documented in ectopic endometrium and because direct inhibition of endometriosis cells has been shown in vitro (349). Furthermore, in rat models used to study surgical adhesion formation and endometriosis, GnRH agonist therapy decreased activity of plasminogen activators and matrix MMPs and increased the activity of their inhibitors, suggesting potential GnRH agonist–regulated mechanisms for reducing adhesion formation (350).

Various GnRH agonists have been developed and used in treating endometriosis. These agents include leuprolide, buserelin, nafarelin, histrelin, goserelin, deslorelin, and triptorelin. These drugs are inactive orally and must be administered intramuscularly, subcutaneously, or by intranasal absorption. The best therapeutic effect is often associated with an estradiol dose of 20 to 40 pg/mL (75–150 pmol/L). These so-called depot formulations are attractive because of the reduced frequency of administration and because nasal administration can be complicated by variations in absorption rates and problems with patient compliance (333). The results with GnRH agonists are similar to those with danazol or progestin therapy. Treatment for 3 months with a GnRH agonist is effective in improving pain for 6 months (263).

Although GnRH agonists do not have an adverse effect on serum lipids and lipoproteins levels, their side effects are caused by hypoestrogenism and include hot flashes, vaginal
dryness, reduced libido, and osteoporosis (6%–8% loss in trabecular bone density after 6 months of therapy). Reversibility of bone loss is equivocal and therefore of concern (351,352), especially because treatment periods of longer than 6 months may be required. The goal is to suppress endometriosis and maintain serum estrogen levels of 30 to 45 pg/mL. More extreme estradiol suppression will induce bone loss (351). The dose of daily GnRH agonist can be regulated by monitoring estradiol levels, by the addition of low-dose progestin or estrogen–progestin in an add-back regimen, or by draw-back therapy. The goal of add-back therapy is to treat endometriosis and endometriosis-associated pain effectively while preventing vasomotor symptoms and bone loss related to the hypoestrogenic state induced by GnRH analogues. Add-back therapy can be achieved by administering progestins only, including norethisterone, 1.2 mg, and norethindrone acetate, 5 mg, but bone loss is not prevented by medrogestone, 10 mg/day (352–354). Add-back therapy can also be achieved by tibolone, 2.5 mg/day (353,356) or by an estrogen–progestin combination (i.e., conjugated estrogens, 0.625 mg, combined with medroxyprogesterone acetate, 2.5 mg, or with norethindrone acetate, 5 mg, estradiol, 2 mg, and norethisterone acetate, 1 mg) (353–357). However, some concern remains about the long-term effects of GnRH analogues on bone loss. In one report, bone mineral density reduction occurred during long-term GnRH agonist use and was not fully recovered up to 6 years after treatment (358). Use of add-back therapy (2 mg estradiol and 1 mg norethisterone acetate) did not affect this process (358). Therefore, GnRH agonists should not be prescribed to girls who have not yet attained their maximal bone density.

Draw-back therapy has been suggested as an alternative in a study showing that 6 months of intake of 400 µg/day of nafarelin was as effective as a draw-back regimen consisting of 1 month of intake of 400 µg/day of nafarelin followed by 5 months of 200 µg/day of nafarelin, with similar estradiol levels (30 pg/mL) but less loss of bone mineral density (359).

Aromatase Inhibitors

Treatment of rats with induced endometriosis using the nonsteroidal aromatase inhibitor fadrozole hydrochloride (360) or YM511 (361) resulted in a dose-dependent volume reduction of endometriosis transplants. In one case report (362), treatment of severe postmenopausal endometriosis with an aromatase inhibitor, anastrozole, 1 mg/day, and elemental calcium, 1.5 g/day for 9 months, resulted in hypoestrogenism, pain relief after 2 months, and after 9 months a 10-fold reduction in the 30-mm diameter size of red, polypoid vaginal lesions, along with remodeling to gray tissue. In a pilot study (363), preliminary data were generated suggesting a potential future use of this drug, but randomized controlled trials are needed to confirm these data.

Selective Estrogen Receptor Modulators

In animal models, raloxifene therapy resulted in regression of endometriosis. The effect was seen in both a surgically prepared, rat uterine explant model and in Rhesus macaques diagnosed with spontaneous endometriosis before exposure (364).

### Efficacy of Medical Treatment

**Pain** Medical treatment with progestins, danazol, gestrinone, or GnRH agonists is effective in treating pain associated with endometriosis, as shown in several prospective, randomized, placebo-controlled double-blind studies (211,250,365,366). Based on published studies, medroxyprogesterone acetate, danazol, gestrinone, and GnRH agonists have similar efficacy in resolution of the laparoscopically documented disease and in pain alleviation (332). **Postoperative medical therapy may be required in patients with**
incomplete surgical resection and persistent pain. Treatment should be continued at least 3 to 6 months, and pain relief may be of short duration, presumably because endometriosis recurs. Disadvantages of medical therapy over surgical therapy include the high cost of hormone preparations, the high prevalence of side effects, and the higher recurrence rate of endometriosis.

Subfertility Conception is either impossible or contraindicated during medical treatment of endometriosis. There is no evidence that medical treatment of minimal to mild endometriosis leads to better chances of pregnancy than expectant management (211,280,365–371).

Adolescent Endometriosis The incidental finding of minimal to mild endometriosis in a young woman without immediate interest in pregnancy is a common clinical problem. Seventy percent of girls with chronic pelvic pain unresponsive to oral contraceptives or NSAIDs are affected by endometriosis (372). Mild disease can be treated by surgical removal of implants at the time of diagnosis, followed by continuous administration of low-dose combination oral contraceptives to prevent recurrence. More advanced disease can be treated medically for 6 months, followed by continuous oral contraceptives to prevent progression of disease. Gonadotropin-releasing hormone agonists with add-back therapy can be considered for adolescents older than 16 years of age who have completed pubertal maturation (372).

Recurrence Endometriosis tends to recur unless definitive surgery is performed. The recurrence rate is about 5% to 20% per year, reaching a cumulative rate of 40% after 5 years. The rate of recurrence increases with the stage of disease, the duration of follow-up, and the occurrence of previous surgery (373–377). The likelihood of recurrence appears to be lower when endometriosis is located only on the right side of the pelvis than when the left side is involved (378).

In a recent randomized controlled trial, postoperative low-dose cyclic oral contraceptive use resulted in a significantly lower cumulative recurrence rate after 1 year, but not after 2 to 3 years (271). In women treated with a second operation for recurrent endometriosis, the cumulative recurrence rate was comparable to those rates after laparoscopy or laparotomy (379).

The recurrence rates reported in women 5 years after therapy with various GnRH agonists were 37% for minimal disease and 74% for severe disease (373). In women treated with GnRH agonists or danazol for endometriosis associated with pelvic pain, the recurrence rates of endometriosis were similar, and associated pain symptoms usually returned after cessation of therapy (380). Pain recurs within 5 years in about one in five patients with pelvic pain treated by complete laparoscopic excision of visible endometriotic lesions (381).

Assisted Reproduction and Endometriosis The treatment of endometriosis-related infertility is dependent on the age of the woman, the duration of infertility, the stage of endometriosis, the involvement of ovaries, tubes, or both in the endometriosis process, previous therapy, associated pain symptoms, and the priorities of the patient, taking into account her attitude toward the disease, the cost of treatment, her financial means, and the expected results. Assisted reproduction—including controlled ovarian hyperstimulation with intrauterine insemination, IVF, and gamete intrafallopian transfer—may be options for infertility treatment in addition to surgical reconstruction and expectant management. IVF is the method of choice when distortion of the tubo-ovarian anatomy
contraindicates the use of superovulation with intrauterine insemination or gamete intrafallopian transfer.

**Intrauterine Insemination**

Endometriosis-associated infertility can be successfully treated with intrauterine insemination, but only if it is done in combination with ovarian stimulation (382). A randomized study (382) compared controlled ovarian hyperstimulation with FSH and intrauterine insemination with no treatment during 311 cycles in 103 couples with minimal to mild endometriosis as the only infertility factor. In this study, a significantly higher live-birth rate per cycle was reported in the treated group (11%) than in the control group (2%) (OR, 5.6; 95% CI, 1.8–17.4). However, there is clear evidence that the pregnancy rate in an insemination program is lower in women with endometriosis than in women with unexplained infertility (383, 384). A recent meta-analysis of 5,214 cycles by stepwise logistic regression (385) evaluated the effectiveness of ovulation induction and intrauterine insemination in the treatment of persistent infertility. The odds ratio for pregnancy associated with endometriosis was 0.45 (95% CI, 0.27–0.76) and for male factor was 0.48 (95% CI, 0.37–0.61).

**In Vitro Fertilization**

Based on several retrospective studies (141, 146), investigators have suggested that the pregnancy rate after IVF may be lower in women with endometriosis than in women without the disease. In earlier studies, this finding had been attributed to lower oocyte quality and decreased fertilization rate in women with endometriosis. However, these findings were not confirmed in more recent studies that reported a normal fertilization rate but a reduced implantation rate per embryo transferred in women obtaining oocytes from donors with endometriosis (386, 387). This reduced implantation rate could be related to increased interleukin-6 levels in follicular fluid of women with endometriosis when compared with controls (388). A more recent case-control study in an IVF egg-donation program compared oocyte receptors in patients with endometriosis stage III or IV (cases) with oocyte receptors in patients without endometriosis (controls). Similar rates of implantation, miscarriage, and pregnancy were observed in cases and controls, suggesting that there is no endometrial implantation problem in women with endometriosis stage III or IV treated with IVF (389). In another case-control study, the cumulative pregnancy rate and live-birth rates were comparable after five cycles of IVF in women with ovarian endometriosis and those with tubal infertility. The cumulative pregnancy rates were 63% and 63%, respectively, and the cumulative live-birth rates were 47% and 51%, respectively, but women with ovarian endometriosis had poorer responses and needed higher doses of gonadotropin therapy (390).

When endometriosis was assigned a stage, the pregnancy rate after IVF was decreased in patients with stage IV endometriosis but normal in women with less advanced disease (381, 391–396). However, some studies have been unable to demonstrate a significant negative correlation between either the presence or stage of endometriosis and the pregnancy rate per cycle (397, 398). The best evidence probably is provided by a recently published meta-analysis (399) showing that IVF pregnancy rates are lower in patients with endometriosis than in those with tubal infertility, even when women with minimal to mild endometriosis were analyzed separately. The use of **danzol**, gestrinone, or GnRH agonists in women with endometriosis before IVF has been reported to improve the pregnancy rate by some (396, 400, 401) but not all investigators (398). Prolonged treatment with a GnRH agonist before IVF in moderate to severe endometriosis can be considered and discussed with patients; although improved pregnancy rates have been reported (402, 403), the long duration of treatment may limit the practical application of this treatment.

Laparoscopic ovarian cystectomy is recommended if an ovarian endometrioma 4 cm or more in diameter is present to confirm the diagnosis histologically. This procedure
may reduce the risk of infection, improve access to follicles, and possibly improve ovarian response (159). The woman should be counseled regarding the risks of reduced ovarian function after surgery (404) and the loss of the ovary.

### Intracytoplasmic Sperm Injection

A recent well-controlled study in patients undergoing intracytoplasmic sperm injection (ICSI) (400) reported a reduced number of oocytes recovered after ovarian aspiration but a normal fertilization rate, implantation rate, and pregnancy rate in women with endometriosis when compared with controls. These normal fertilization, implantation, and pregnancy rates also were reported in another recent study of ICSI (405).

### Gamete Intrafallopian Transfer

The use of gamete intrafallopian transfer in patients with endometriosis is reported to result in a higher monthly fecundity rate (25%) than with IVF (14%). This difference may be related to selection bias because less severe forms of endometriosis may have been more likely to be treated with gamete intrafallopian transfer, reserving IVF for more advanced stages of disease (288). In one study, the gamete intrafallopian transfer pregnancy rate in patients with a primary diagnosis of endometriosis (32.5%) was lower than in matched controls (406).

The current evidence suggests that patients with endometriosis have a poorer ovarian response and need a higher dose of gonadotropin therapy in IVF or ICSI programs, but endometrial implantation is not reduced. Future studies evaluating the association between endometriosis and reproductive outcome after assisted reproduction should be prospective and should include the following components (142):

- Accurate and recent laparoscopic description of the stage of endometriosis
- Date, number of procedures, and interval between surgical procedures
- Ultrasonographic evidence of endometriosis, confirmed by cytology or histology when endometriotic cysts are aspirated during oocyte aspiration
- Effectiveness of interim suppressive therapy between diagnosis and treatment with assisted reproduction
- Reliability and date of negative diagnosis
- Clear definition of implantation rate, pregnancy rate, abortion rate, and live-birth rate per started cycle, per oocyte aspiration, and per embryo transfer

### Coping with Disease

**Coping with endometriosis as a chronic disease is an important component of management.** According to guidelines for the management of endometriosis (159), evidence from two systematic reviews suggests that high frequency transcutaneous electrical nerve stimulation (TENS), acupuncture, vitamin B1, and magnesium may help to relieve dysmenorrhea (407). Whether such treatments are effective in endometriosis-associated dysmenorrhea is unknown. Many women with endometriosis report that nutritional and complementary therapies such as reflexology, traditional Chinese medicine, herbal treatments, and homeopathy improve pain symptoms. Although there is no evidence from randomized controlled trials to support the effectiveness of these treatments in endometriosis, they should not be ruled out if the woman feels they work in conjunction with more traditional therapies or that they could be beneficial to her overall pain management and quality of life. Patient self-help groups
can provide invaluable counseling, support, and advice. The Web site www.endometriosis.org/support.html provides a comprehensive list of all the self-help groups in the world (159).

SECTION VII Reproductive Endocrinology

Use of nafarelin versus placebo after reductive laparoscopy.

The physician’s initial encounter with the infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment.

The main causes of infertility include male factor, decreased ovarian reserve, ovulatory disorders (ovulatory factor), tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions), uterine factors, systemic conditions (including infections or chronic diseases such as autoimmune conditions or chronic renal failure), cervical and immunologic factors, and unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions).

The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency.

Male factor is the only cause of infertility in 20% of infertile couples, but it may be a contributing factor in as many as 30% to 40% of cases. Treatment of reversible endocrine or infectious causes of subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques. Intracytoplasmic sperm injection (ICSI) has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional in vitro fertilization (IVF) treatment.

An association between the age of the woman and reduced fertility has been well documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s.
Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility.

The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS).

Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. Uterine pathologies constitute the etiologic factor in infertility in as many as 15% of couples seeking treatment and are diagnosed in as many as 50% of infertile patients. Leiomyomas have not been shown to be a direct cause of infertility.

All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined.

Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications.

Fortunately, recent studies have not shown an increased risk for breast, uterine, or ovarian cancer secondary to medications used for superovulation in the treatment of infertility.

Information on the Society for Assisted Reproductive Technology (SART) and registered ART clinics are accessible by the public at http://www.sart.org.

Infertility is defined as 1 year of unprotected intercourse without pregnancy. This condition may be further classified as primary infertility, in which no previous pregnancies have occurred, and secondary infertility, in which a prior pregnancy, although not necessarily a live birth, has occurred. Fecundability is the probability of achieving pregnancy within a single menstrual cycle, and fecundity is the probability of achieving a live birth within a single cycle. The fecundability of a normal couple has been estimated at 20% to 25% (1). On the basis of this estimate, about 90% of couples should conceive after 12 months of unprotected intercourse.

Epidemiology

Infertility affects about 10% to 15% of reproductive-age couples in the United States. Data from the U.S. National Survey of Family Growth indicate that the prevalence of infertility among women who had not been surgically sterilized was 13.3% in 1965, 13.9% in 1982, and 13.7% in 1988 (2). In 1990, about 1 in 3 women in the United States reported 12 consecutive months of unprotected coitus without pregnancy at some time in her life (3). A number of demographic variables, including age and socioeconomic status, have been associated with infertility. As a result of the delay in childbearing in the United States population, more older reproductive-age women are attempting to conceive. Thus, although the overall prevalence of infertility in the United States has not changed since 1965, the percentage of women with primary infertility has increased significantly. In 1965, only one of six infertile women was nulliparous, whereas in 1988, more than half of infertile women had never been pregnant (4).
Although the prevalence of infertility has been stable, the demand for infertility care has increased significantly over the past few decades. Between 1968 and 1984, the number of office visits for infertility increased nearly threefold to 1.6 million visits annually (5). In 1995, it was estimated that about 2% of women (1.2 million) had a medical visit related to their infertility, whereas 13% (7.6 million) had sought medical attention for infertility in their lifetime (6). The increase in the use of infertility medical care stems from many factors, including a heightened awareness that infertility is a medical condition that may be treated in many cases, and sociologic changes that have led to delayed childbearing. Still, despite an increased awareness of available therapies, only 43% of infertile couples seek treatment, and only 24% seek specialized care. Fewer than 2% use in vitro fertilization (IVF) or other forms of assisted reproductive technology (ART) (7). Although infertility is more prevalent among women of relatively low socioeconomic status, patients seeking treatment for infertility are predominantly of high socioeconomic status (4). The women most likely to obtain specialized treatment are 30 years of age or older, white, married, and of relatively high socioeconomic status (7). Familiarity with and access to infertility services among the affluent and better-educated patients probably account for their greater use of these medical resources.

Initial Assessment

The physician’s initial encounter with the infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. The male partner should be present at this first visit because his history is a key component in the selection of diagnostic and therapeutic plans. It cannot be overemphasized that infertility is a problem of the couple. The presence of the male partner, beginning with the initial evaluation, involves him in the therapeutic process. This essential involvement demonstrates that the physician is receptive to the male partner’s needs as well as to those of the female partner and allows the male partner an opportunity to ask questions and to voice any concerns.

The physician should obtain a complete medical, surgical, and gynecologic history from the woman. Specifically, information regarding menstrual cyclicity, pelvic pain, and previous pregnancy outcomes is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID), intrauterine device use, or pelvic surgery, should be reviewed. A history of intrauterine exposure to diethylstilbestrol (DES) is significant. In addition, a review of systems relevant to pituitary, adrenal, and thyroid function is useful. Questions regarding galactorrhea, hirsutism, and changes in weight are particularly relevant. A directed history, including developmental defects such as undescended testes, past genital surgery, infections (including mumps orchitis), previous genital trauma, and medications should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is also important, as is information about coital frequency, dyspareunia, and sexual dysfunction. Finally, information should be obtained on any family history of infertility, premature ovarian failure, congenital or developmental defects, mental retardation, and hereditary conditions relevant to preconceptional planning, such as cystic fibrosis, thalassemia, and Tay Sachs disease.

The initial interview provides the physician with the opportunity to assess the emotional impact of infertility on the couple. It further gives the physician a chance to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In some cases, referral to a trained social worker or psychologist may be beneficial.
The physical examination of the woman should be thorough, with particular attention given to height, weight, body habitus, hair distribution, thyroid gland, and pelvic examination. Referral of the man to a urologist for examination often is beneficial if historic information or subsequent evaluation suggests an abnormality. This initial encounter also provides an opportunity to outline the general causes of infertility and to discuss subsequent diagnostic and treatment plans (Figs. 30.1–30.3).

### Causes of Infertility

The main causes of infertility include:

1. Male factor
2. Decreased ovarian reserve
3. Ovulatory disorders (ovulatory factor)
CHAPTER 30 Infertility

**Figure 30.2** Diagnostic and treatment algorithm: anovulation. FSH, follicle-stimulating hormone; LH, luteinizing hormone; E2, estradiol; TSH, thyroid-stimulating hormone; T4, thyroxine; GH, growth hormone; ACTH, adrenocorticotropic hormone; BMI, body mass index; MRI, magnetic resonance imaging; GnRH, gonadotropin-releasing hormone. ART, assisted reproductive technology. (From Yao M. Clinical management of infertility. Washington, DC: The Advisory Board: 2000, with permission.)

4. Tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions)

5. Uterine factors

6. Systemic conditions (including infections or chronic diseases such as autoimmune conditions or chronic renal failure)

7. Cervical and immunologic factors

8. Unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions)
Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment. The relative prevalence of the different causes of infertility varies widely among patient populations (Table 30.1). In many cases, no specific cause is detected despite a thorough evaluation, and the couple’s infertility is categorized as unexplained. Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of reproductive structures in either partner. In these specific instances, couples should be counseled regarding their options of adoption, the use of donor gametes, or surrogacy. However, most couples that have difficulty conceiving have subfertility. According to this fundamental concept, most couples could conceive spontaneously in time, but because of known or unidentifiable causes, their spontaneous fecundity rate is so low that medical management is warranted. Another reason to seek medical attention, particularly among older women, is that as time passes with unsuccessful spontaneous attempts, fecundability will be compromised further by increasing age and concomitantly decreasing ovarian reserve. Although identification of apparent causes of subfertility (such as anovulation or oligospermia) allows treatment to be targeted, effective empiric treatments also greatly increase the chance of a pregnancy even when no distinct cause is identified. Overall, these treatments aim at increasing the probability of conception and implantation by optimizing gamete (sperm and oocyte) and uterine factors.

The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency. Some treatments, especially ART, are indicated for more than one diagnosis and are discussed in greater detail. Often, more than one cause is identified in a couple. For this reason, multiple approaches to investigation and treatment may be undertaken simultaneously.

### Male Factor

Male factor is the only cause of infertility in 20% of infertile couples, but it may be a contributing factor in as many as 30% to 40% of cases (8). However, the combined effects of our increased understanding of genetic causes in male factor infertility and the efficacy of intracytoplasmic sperm injection (ICSI) in ART have revolutionized modern treatment of male factor infertility. For men, semen analysis is inexpensive and noninvasive, and remains fundamental to the infertility evaluation. The value and interpretation of the semen analysis and other tests for male infertility should be considered within the context of male reproductive physiology.
The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. The testes contain two cell types: the Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis), and the Leydig cells (the site of androgen synthesis). In the man, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which act on the testes. The former (LH) stimulates the synthesis and secretion of testosterone by the Leydig cells, and the latter (FSH) stimulates the Sertoli cells to secrete inhibin. Both FSH and testosterone act on the seminiferous tubules to stimulate spermatogenesis. In humans, the development from spermatogonia stem cells to the mature sperm cells takes about 75 days. Spermatogonia undergo mitotic division to give rise to spermatocytes. These spermatocytes subsequently undergo meiosis to produce spermatids, which contain 23 (rather than 46) chromosomes. Upon maturation, spermatids become spermatozoa, which enter the epididymis, where they continue to mature and become progressively more motile during the 12 to 21 days that is required to traverse this tortuous structure.

During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands. The semen released is a gelatinous mixture of spermatozoa and seminal plasma; however, it thins out 20 to 30 minutes after ejaculation by a process called liquefaction. Liquefaction occurs secondary to the presence of proteolytic enzymes within the prostatic fluid. The released spermatozoa are not usually capable of fertilization. Instead, a series of complex biochemical and electrical events, termed capacitation, must take place within the sperm’s outer surface membrane before fertilization can occur. Normally, capacitation occurs in the cervical mucus; however, it can occur in physiologic media in vitro. Finally, as part of fertilization, the sperm must undergo the acrosome reaction, in which the release of enzymes of the inner acrosomal membrane results in the breakdown of the outer plasma membrane and its fusion with the outer acrosomal membrane (9). The acrosome reaction and binding of sperm and ovum surface proteins are important for the penetration of the ovum’s zona pellucida and subsequent fusion between the ovum and sperm. As the sperm penetrates the egg, it initiates a hardening of the zona pellucida (cortical reaction), which prevents penetration by additional sperm (9,10).

The concept of a global decline in sperm counts needs to be reassessed (11,12). A number of recent analyses reported no decrease in sperm counts over time (13–15). Geographic differences in the results of semen analyses do seem to exist, but a global trend toward decreasing semen quality does not (16–18). Furthermore, the rate of male factor infertility has not increased significantly in recent decades. Thus, even if semen characteristics are changing, these changes do not appear to be having a dramatic clinical effect. Nevertheless, exposures to environmental toxins may certainly be harmful to sperm, and the incidence of some exposures (e.g., phytosterogens) may be on the rise. Marijuana and cocaine use can reduce sperm concentration (19,20). Certain drugs may reduce sperm count or function or cause ejaculatory dysfunction (Table 30.2). Finally, consumption of...
caffeine, alcohol, and smoking has been associated with diminished semen quality or fecundity in a dose-related fashion (21,22).

**Semen Analysis**

The basic semen analysis measures semen volume, sperm concentration, sperm motility, and sperm morphology. In addition, many laboratories measure pH, fructose levels, and white blood cell counts within the semen. Normal values suggested by the World Health Organization (WHO) are listed in Table 30.3 (23). These values represent only general guidelines, and normal values should be established by individual andrology laboratories.

**Specimen Collection**  The method used for semen specimen collection is important to the achievement of accurate results. The optimal period of abstinence before semen collection is unknown; however, because a decrease in sperm concentration is associated with frequent ejaculation, a period of 2 to 3 days usually is recommended. The specimen should be obtained by masturbation and collected in a clean container. Because the presence of spermicidal agents, collection into condoms is generally unacceptable, although special sheaths that do not contain spermicides are available for semen collection. All semen specimens should be kept at body temperature and taken to the laboratory within one-half to one hour of collection. Even when the specimen is obtained under optimal circumstances, interpretation of the results of the semen analysis is complicated by variability within the same individual, wide differences in normal semen parameters, and their relativity to the minimum parameters required for conception (11). Semen parameters also may vary widely from one man to another and among men with proven fertility. In many circumstances, several specimens are necessary to verify an abnormality.

**Sperm Volume**  The normal ejaculated volume of semen is 1.5 to 5 mL. Volumes may be abnormally low in cases of retrograde ejaculation, and high volumes usually reflect relatively long periods of abstinence or inflammation of the accessory glands. Absence of fructose or high pH may be associated with ejaculatory tract obstruction or seminal vesicle dysfunction.

**Sperm Concentration**  Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate. Establishing a lower limit of normal for sperm concentration is difficult. Historically, cutoffs of 60 million sperm per milliliter for normal fertility have been advocated, but most WHO laboratories recognize the value of 20 million sperm per milliliter as a lower limit of normal.

**Sperm Motility**  An equally important parameter in the semen analysis is sperm motility, which is defined as the percentage of progressively motile sperm in the ejaculate. Lower limits of normal vary considerably and depend on the local laboratory’s experience. A reduction in sperm motility is referred to as asthenozoospermia. The WHO and many laboratories use a cutoff of 50% motility as the lower limit of normal, whereas others use less than 40% motility as a criterion for defining asthenospermia. Computer-assisted semen analysis, in which computer-generated images of sperm specimens quantify both sperm counts and sperm motility, may yield results very different from those of nonautomated semen analyses. Regardless of how motility is assessed, the interpretation of sperm motility—as with sperm concentration—is hampered by both significant variability among repeat samples obtained from a single individual and poor correlation between values for normal motility and fertility potential.

**Sperm Morphology**  An abnormality of sperm morphology is known as teratozoospermia. The WHO uses a fairly permissive visual assessment of sperm within a semen specimen to assess morphology value, with greater than 30% normal forms defined as acceptable. More stringent criteria have evolved from other sources. The strict Tygerberg criteria were introduced by Kruger et al. in 1986 to assess sperm morphology. Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal. Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards. One advantage of these strict criteria, however, is that the Tygerberg classification correlates with prognosis in IVF treatment. For example, greater than 14% normal morphology is associated with normal rates of fertilization in IVF programs; 4% to 14% normal morphology is associated with a “good prognosis.” Values of less than 4% normal sperm morphology are associated with poor prognosis for fertilization and pregnancy in IVF. In some studies, this sperm morphology classification has also been found to be predictive of pregnancy outcomes after intrauterine insemination (IUI) treatment, especially when the total motile sperm count is less than $1 \times 10^6$. The disparity in criteria for assessment of semen morphology mandates that to interpret semen analysis results properly, the clinician must thoroughly understand the methodology used by the local andrology laboratory.

**White Blood Cells**  Although measurements of semen volume, sperm concentration, sperm motility, and sperm morphology make up the standard semen analysis, some laboratories also report numbers of round cells. These cells, which may be lymphocytes, can signify the presence of prostatitis or, alternatively, may actually be immature germ cells. These two cell types can be distinguished by an immunoperoxidase-staining technique that identifies leukocytes (Endtz test). The WHO views ejaculates with more than 5 million round cells per milliliter or more than 1 million leukocytes per milliliter as abnormal. However, the prognostic significance of leukocytes in the semen is controversial. The presence of immature sperm cells in the ejaculate suggests a defect in spermatogenesis and, therefore, may signify a relatively poor prognosis for fertilization.
Although the standard semen analysis and associated tests provide a fairly reasonable picture of semen quality, they yield little information about sperm function. These specialized tests may be pursued to assess sperm viability, fertilization potential (zona-free hamster oocyte test), the presence of antisperm antibodies, and the effect of cervical mucus on sperm viability and function (postcoital test). In general, these tests are not currently considered part of the standard assessment because their prognostic value and impact on management are limited by poor specificity, poor reproducibility, or controversial interpretation of the results (31,32).

**Further Evaluation**  If abnormalities in the semen are detected, further evaluation of the male partner by a urologist is indicated to diagnose the defect (31). Table 30.4 lists the differential diagnoses for male factor infertility (33). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 30.5 (34,35). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (35). The figures include data from cases in which the male partner was normal and the presumed

cause of the couple’s infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (34). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently.

**Treatment**

Significant deviations from the normal range of sperm count, concentration, motility, and morphology indicate the presence of male factor infertility. Treatment of male factor infertility may be classified as medical, surgical, or ART-related therapies. The diagnosis and treatment of azoospermia (no sperm on semen analysis) will be discussed separately from other forms of male factor infertility.

Treatment of reversible endocrine or infectious causes of subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. However, medical therapies for other causes of male factor infertility are severely limited. Clomiphene citrate, an estrogen agonist and partial antagonist, has often been used to treat male infertility of idiopathic origin. Clomiphene citrate acts on the hypothalamic–pituitary axis and, in men, increases serum levels of LH, FSH, and testosterone (36). Most studies have shown that clomiphene citrate treatment yields little improvement in semen parameters and no improvement in pregnancy rates (37), whereas treatment with pure FSH during ART has resulted in significant increases in fertilization rates (38).

**Varicocele**

A varicocele is an abnormal dilation of the veins within the spermatic cord. Varicoceles nearly always occur on the left side, presumably because of the direct insertion of the spermatic vein into the renal vein on that side. The pathophysiologic effects of varicocele on testicular function are uncertain but appear to be mediated by an associated rise in testicular temperature or a reflux of toxic metabolites from the left adrenal or renal veins (39). In either event, the effect on sperm production is bilateral. Understanding of the role of varicoceles in infertility is complicated by the prevalence of varicoceles in fertile men and the efficacy of varicocele repair in infertile men.

*More than 100% because of multiple factors.*

One WHO study found varicocele to be present in 25.4% of men with abnormal semen analyses, as opposed to 11.7% of men with normal semen (40). This study failed to demonstrate a difference in the frequency of spontaneous pregnancies among couples in which the men had varicoceles versus those who did not. When compared with fertile men with or without varicoceles, however, infertile patients with varicoceles have higher levels of FSH, smaller testes, and lower sperm concentration and motility (41).

Varicocele repair, which involves interruption of the internal spermatic vein, is commonly performed in the 40% of infertile men with clinically evident varicoceles. Currently, it is performed as an outpatient procedure and may involve laparoscopy, open surgery, or the injection of embolizing agents. Despite its widespread use, the therapeutic benefits of varicocele repair remain controversial. Two multicenter trials have shown that pregnancy rates are significantly increased after varicocelectomy (42,43). However, the validity of the control groups in each of these trials has been criticized (44). A more recent meta-analysis of four randomized, controlled trials involving a total of 385 patients failed to demonstrate significantly altered pregnancy rates after varicocelectomy (44–48).

Artificial Insemination

Artificial insemination encompasses a variety of procedures. All involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm–ovum interaction in the absence of intercourse. The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed except in cases of severe coital dysfunction. Currently, all of the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor. Artificial insemination has mainly been used to treat unexplained infertility (usually combined with superovulation) and male factor infertility. The efficacy of each type of insemination method should be assessed separately for each of these two diagnoses.

Types of Insemination for Unexplained Infertility  Many techniques for artificial insemination have been described, but only intracervical and intrauterine insemination have been routinely employed. Intrauterine insemination is the best studied and most widely practiced of all the insemination techniques. It involves placement of about 0.3 to 0.5 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization. In contrast with IUI, intracervical insemination may be performed either with unwashed or with processed specimens. The success rates with intracervical insemination are consistently lower than those with IUI and are further discussed under “Unexplained Infertility” (49).

Processing Semen  Two important issues regarding the use of artificial insemination procedures are the mode of semen processing and the number and timing of inseminations. Many protocols have been developed for sperm preparation. Seminal fluid usually is prevented from reaching the intrauterine cavity and intra-abdominal space by the cervical barrier. The introduction of seminal fluid past this barrier may be associated with severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins. Thus, protocols for processing whole semen include the washing of specimens to remove seminal factors and to isolate pure sperm. Some semen preparation methods attempt to further enhance sperm motility or morphology by using additional separation protocols. These methods include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures. Finally, phosphodiesterase inhibitors, such as pentoxifylline, have been used during semen processing in an attempt to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (50).

Intrauterine Insemination as Treatment for Male Factor Infertility  Studies of the efficacy of IUI in the treatment of male factor infertility have been difficult to assess
because of variations in inclusion criteria and the limitations of sperm function tests. Considering these limitations, the benefits of IUI in male factor infertility have been accepted because IUI appears to result in higher pregnancy rates than natural intercourse or intracervical insemination (OR 2.20, 95% CI, 1.43–3.39) (51). However, the IUI pregnancy rates are generally lower in couples with male factor infertility than in couples with unexplained infertility (4.8% versus 11.6%) (51). A retrospective analysis of 1,841 couples undergoing 4,056 cycles of IUI for male factor infertility found that pregnancy rates were related to total motile sperm count. Optimal pregnancy rates (>8.2% per cycle) were reached with initial total motile sperm counts of greater than or equal to $5.0 \times 10^6$. Higher counts did not necessarily yield higher pregnancy rates. The minimal total motile sperm count that resulted in a pregnancy was $1.6 \times 10^6$ (52). Some couples with male factor infertility do not achieve pregnancy with artificial insemination, whereas others have initial semen parameters that make insemination a suboptimal approach. In these couples, the use of ART, especially with ICSI, may be superior treatment options. Because ICSI is highly effective and requires only that viable sperm be present, almost all cases of male factor infertility can be treated successfully. Because the IUI success rates are extremely low if the total motile sperm count is less than $0.5 \times 10^6$, ICSI should be considered in such cases (53). Finally, ICSI should be recommended after a maximum of three IUI cycles have failed in a couple with male factor infertility.

Azoospermia: Classification and Treatment

Azoospermia is the absence of spermatozoa in the ejaculate. Azoospermia is found on semen analysis in about 5% of all couples being investigated for infertility (54), and its incidence is 1% in all men and 10% to 15% among infertile men (55,56). The classification of azoospermia reflects the etiology, prognosis, and treatment and differentiates the causes as pretesticular, testicular, and posttesticular (57).

Pretesticular Azoospermia

Pretesticular azoospermia represents those conditions in which the hypothalamic–pituitary axis fails to stimulate spermatogenesis within the tests. Congenital, acquired, and idiopathic etiologies of hypogonadotropic hypogonadism are included in this category. A full endocrine history, including information on puberty and growth and a review of endocrine systems, should guide the physician in the evaluation of the patient with hypogonadotropic hypogonadism. Laboratory investigations of particular benefit in this population include measurement of serum LH, FSH, testosterone, and prolactin levels and imaging of the pituitary gland. Low levels of gonadotropins (LH and FSH) and low serum levels of testosterone are characteristic of hypogonadotropic hypogonadism.

Hormonal treatment of hypogonadotropic hypogonadism is effective. Administration of pulsatile gonadotropin-releasing hormone (GnRH) therapy is both conceptually indicated and effective in infertile men with hypothalamic dysfunction (58), including those patients with Kallmann syndrome. Infertile males with hypogonadotropic hypogonadism secondary to panhypopituitarism also may respond to GnRH therapy (59). An alternative treatment uses human chorionic gonadotropin (hCG), 1,000–2,500 IU twice a week, with the dose titrated to maintain serum testosterone and estradiol levels within the normal range. Treatment with hCG is then combined with human menopausal gonadotropin (hMG), which is given at a dose of 150 IU three times weekly (60,61). Spermatogenesis and pregnancy can be achieved in as many as 80% to 88% of patients after 1 year of therapy (60,61).

Testicular Azoospermia

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be congenital or genetic (e.g., Klinefelter syndrome, microdeletion of Y chromosome), acquired (e.g., radiation therapy, chemotherapy, testicular torsion, or mumps orchitis), or
developmental (e.g., testicular maldescent). The latter disorder may be associated most closely with male factor infertility in the absence of complete testicular azoospermia. A large observational cohort study suggested that infertility was, in fact, associated with congenital bilaterally maldescended testes, but that men with congenital unilaterally maldescended testes did not have decreased fertility when compared with controls (62).

Men with hypergonadotropic hypogonadism (elevated levels of LH and FSH with low serum levels of testosterone) generally have primary gonadal failure. A karyotype should be obtained in such cases to detect chromosomal abnormalities such as Klinefelter syndrome (47,XXY). Acquired causes of primary gonadal failure are usually evident based on the history, but the diagnosis should be confirmed by assessment of the serum hormonal profile and biopsy. If the diagnosis of gonadal failure is confirmed on biopsy, endocrine therapy is contraindicated.

It is becoming increasingly evident that some cases of male factor infertility that have previously been categorized as idiopathic are actually the result of genetic defects on the Y chromosome (Table 30.6). The two most commonly implicated candidate gene families are the RNA-binding motif (RBM) and the “deleted in azoospermia” (DAZ) families, but microdeletions at various loci on the Y chromosome have been described. For example, microdeletions in Yq11.23 can occur in one or more of three regions: AZFa (proximal), AZFb (central), and AZFc (distal). Microdeletions in the Y chromosome have been identified in 10% to 20% of men with idiopathic azoospermia or severe oligospermia (63,64) and in 7% of 200 infertile men (65). Semen analyses in affected men varied between oligospermia and azoospermia. Microdeletions in the Y chromosome occur in 2% of fertile men. These microdeletions can be transmitted to the male offspring, who may then suffer from infertility. Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that genetic counseling can be provided before treatment. Testicular azoospermia is treated by surgical retrieval of spermatozoa with subsequent fertilization of the oocyte by ICSI.

**Intracytoplasmic Sperm Injection** This micromanipulation technique is performed to increase the fertilization rate of oocytes retrieved during ART by direct injection of a live sperm into the oocyte, thereby theoretically bypassing limitations imposed by sperm motility, defective capacitation or acrosome reaction, and sperm binding the zona pellucida. This technique was first reported to result in human pregnancies in 1992 (66). The procedure involves stripping the aspirated cumulus complex of all

surrounding granulosa cells so that micromanipulation can be performed on the egg itself. A viable sperm is then inserted into the cytoplasm of the egg (ooplasm).

In general, ICSI has allowed couples with male factor infertility to achieve ART pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional IVF treatment. The indications of ICSI have evolved since its introduction and will continue to evolve as more is learned about its risks and benefits. One absolute indication for ICSI is severe male factor infertility as demonstrated by total progressively motile sperm counts (0.5 × 10^6/mL and <3% normal morphology according to strict Tygerberg criteria) (53). Sperm counts of less than 0.5 × 10^6/mL are associated with poor fertilization rates in IVF, and this finding alone is also an indication for ICSI (67). Other indications for ICSI include the sole presence of spermatozoa lacking an acrosome or those that are completely immotile, as well as the use of surgically recovered epididymal or testicular sperm. Other absolute indications for ICSI are non-male factor–related and include a history of fertilization failure with conventional IVF and the fertilization of oocytes before preimplantation genetic diagnosis (68). The benefit of combined IVF/ICSI in ART for unexplained infertility also is described under “Unexplained Infertility.”

Micromanipulation is a highly skilled technique. When performed by specially trained embryologists, the immediate risk for damaging the manipulated oocyte is less than 10% (53). Because the particular spermatozoa used for ICSI might otherwise be incapable of fertilization, concerns have been voiced regarding possible increased risks for congenital abnormalities among ICSI offspring. Several large series have followed 1,987, 1,139, and 730 children born after ICSI (69). Each has reported no increase in major or minor congenital malformations among offspring produced by ICSI when compared with the general population (69–71) and when adjusted for multiple gestation (70). However, an increased incidence of sex chromosome karyotypic abnormalities (69,72) and hypospadias (70) has been suggested. Because the prevalence of sex chromosome karyotypic abnormalities and other genetic factors is increased in infertile men with severe oligospermia or azoospermia, genetic counseling should be offered before treatment with ART (73).

Posttesticular Azoospermia

In posttesticular azoospermia, the hypothalamic–pituitary axis and spermatogenesis are normal. No sperm appear in the ejaculate secondary to congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunctions, including retrograde ejaculation. Although low seminal pH (6.7–8.0) or low seminal fructose may signal the congenital absence or obstruction of the vas deferens, the diagnosis is confirmed by vasography. In some cases, testicular biopsy may be indicated to differentiate between primary testicular damage and outflow obstruction. Congenital bilateral absence of the vas deferens (CBAVD) is found in 1% to 2% of infertile men and 95% of men with cystic fibrosis (74). Common mutations of the cystic fibrosis transmembrane conductance regulator gene (CFTR), which encodes a cyclic adenosine monophosphate (cAMP)-regulated chloride channel, can be found in some infertile men with CBAVD, despite the absence of clinical symptoms of cystic fibrosis. Therefore, screening for mutations in the CFTR gene is indicated if men with CBAVD plan to undergo sperm retrieval and ICSI to conceive using their own sperm. One cost-effective screening method addressing this problem involves screening the female partner for the three most common mutations in the CFTR gene. If negative, the couple has a risk of less than 1 in 1,500 for conceiving a child with cystic fibrosis, regardless of the paternal genotype (33).

Prior vasectomy is probably the most common cause of posttesticular azoospermia in infertile men. Vasectomy can be reversed effectively using microsurgical vasoepididymostomy. In one study, vas deferens patency was obtained in 86% of cases, and pregnancy was
achieved in 52% of cases after primary procedures (75). Rates of patency and pregnancy vary inversely with the length of time from vasectomy. For those patients with azoospermia 3 months after the reversal procedure, either the reanastomosis has failed or the epididymis is obstructed. However, repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (75).

Epididymal obstruction is diagnosed by finding normal spermatogenesis on testicular biopsy. Vasography can be used to determine the level of obstruction, but because of its risk of increased scarring, it is done only if reconstructive surgery is performed with the procedure. Alternatively, transrectal ultrasonography (TRUS) findings, in conjunction with the presence of large numbers of sperm in the seminal vesicle aspiration, strongly suggest ejaculatory duct obstruction without the high risk of scarring (76).

There are two approaches to the treatment of posttesticular obstruction if the use of donor sperm is not being considered. Epididymal aspiration proximal to the obstruction may be used to obtain sperm for use in ART in cases of epididymal or vas deferens obstruction. Alternatively, microsurgical vasoepididymostomy is associated with patency rates of 70% and postoperative pregnancy rates of 44% at 1 year if no other infertility factor is present (77).

Some men with reduced semen volume may have retrograde ejaculation, in which sperm is propelled into the bladder during ejaculation rather than through the urethra. This diagnosis can be confirmed by examination of a urine specimen that is obtained by voiding after ejaculation or catheterization. This condition occurs in rare cases of patients with diabetes mellitus, in certain neurologic conditions, and after bladder or prostatic surgery. For subfertile men with retrograde ejaculatory dysfunction, α-adrenergic agonists such as phenylephrine have been reported to strengthen internal urethral sphincter tone (78). Sperm may also be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (79).

Surgical Sperm Recovery for Intracytoplasmic Sperm Injection Among the many surgical methods for sperm recovery, the most widely described are microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called fine-needle aspiration, or FNA) (80). The choice of surgical sperm recovery method depends on the underlying diagnosis, whether the goal of the procedure is diagnostic or therapeutic, and whether isolated sperm will be used immediately or will be cryopreserved.

In cases of posttesticular azoospermia, in which spermatogenesis is expected to be normal, all four methods give successful sperm recovery greater than 90% (81). Both MESA and TESE are open surgical procedures performed with an operating microscope and general or regional anesthesia, whereas TESA and PESA are noninvasive, blind aspiration procedures that are performed with 19- to 21-gauge needles. Alternatively, a 14-gauge Trucut needle, which gives a higher sperm yield, can be used in these procedures (82). Because MESA allows for diagnosis and possibly reconstruction, and usually yields very large numbers of sperm, cryopreservation and avoidance of repeat surgery may be possible (83). Although PESA and TESA appear less invasive, there is increased risk of bleeding, epididymal injury, and postsurgical fibrosis, which can lead to failure of sperm recovery in repeat procedures (84,85).

A meta-analysis found no difference in the rates of fertilization, implantation, or ongoing pregnancy between epididymal and testicular sperm for patients with the same diagnosis (86). Fertilization and implantation rates have been reported to be similar in a retrospective analysis comparing TESA with open biopsy using TESE (81). Further, cryopreservation of spermatozoa within testicular tissues for use in subsequent ICSI treatment...
cycles has been reported (87). Fresh and frozen-thawed epididymal (88) or testicular spermatozoa (89) appear to have comparable fertilization and ongoing pregnancy rates when used for ICSI.

In contrast to posttesticular azoospermia, patients with testicular azoospermia require the use of TESE or TESA, and possibly multiple biopsies, for sperm retrieval (90). The use of TESE followed by ICSI has resulted in ongoing pregnancies, even for patients with 47,XXY Klinefelter syndrome (91,92). However, the sperm recovery rate with TESE is only about 50% and is even lower with TESA. Further, ICSI after TESE has variable clinical outcomes in patients with testicular azoospermia.

Following ICSI, fertilization and pregnancy rates are significantly lower with testicular azoospermia than with posttesticular azoospermia (86,93). Moreover, embryos derived from testicular sperm retrieved from men with testicular azoospermia have higher aneuploidy rates and lower developmental competence (94). In comparison with patients who have normal testicular histology, all measures of success are lower in the presence of an associated histologic diagnosis of testicular aplasia, Sertoli cell–only syndrome, or spermatogenesis arrest (92,95,96). Despite these findings, the histologic diagnosis alone should not be used to exclude patients from ICSI treatment because 15% of cases with no sperm identified on histology were found to have sperm on retrieval (97). Among patients with testicular azoospermia, surgically recovered sperm may be at various stages of maturation arrest (i.e., round spermatid, elongated spermatid, and motile and immotile spermatozoa). Although sperm at all stages have been used to establish successful pregnancies using ICSI (53,98), the fertilization and pregnancy rates associated with maturation-arrested spermatid are very low, and couples should be counseled regarding their prognosis and alternative options (99–101).

**Donor Insemination** For men with azoospermia, couples with significant male factor infertility who do not desire ART, or women without a male partner who are seeking pregnancy, therapeutic donor insemination offers an effective option. A number of important issues surround the use of this form of artificial insemination. First, despite reports that the use of fresh donor semen is associated with higher pregnancy rates than the use of frozen specimens (102), both the Centers for Disease Control and Prevention and the American Society for Reproductive Medicine recommend the use of frozen samples (103). This recommendation stems from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seroconversion. Currently, semen donors are screened for HIV infection, hepatitis B, hepatitis C, syphilis, gonorrhea, chlamydia, and cytomegalovirus infections, all of which may be transmitted through semen. All cryopreserved samples are quarantined for 6 months, and the donor is retested for HIV before clinical use of the specimen. Donors are likewise questioned about any family history of genetically transmitted disorders, including both mendelian (e.g., hemophilia, Tay-Sachs disease, thalassemia, cystic fibrosis, congenital adrenal hyperplasia, Huntington disease) and polygenic–multifactorial conditions (e.g., mental retardation, diabetes, heart malformation, spina bifida). Those with a positive family history of these conditions are eliminated as donor candidates.

A second issue surrounding the use of therapeutic donor insemination—that which is most important to the patient—is the success rate of treatment. In patients younger than 30 years of age who have no other infertility factors, conception rates approach 62% after 12 cycles of treatment with frozen sperm (104). In several prospective randomized or crossover trials, IUI was superior to intracervical insemination for donor insemination. Overall, the cycle fecundity rates ranged from 9.7% to 24% for IUI, to 3.9% to 17.9% for intracervical insemination (105–111). A meta-analysis concluded that IUI had a significantly higher cycle fecundity rate when compared with ICSI (OR 2.4, 95% CI, 1.5–3.8) (112). Moreover, the concomitant use of clomiphene citrate or gonadotropin...
(hMG) for controlled ovarian hyperstimulation (COH) did not result in higher fecundity rates (112). In addition, the length of recommended treatment also should be considered. When frozen donor semen is used, more than 80% of subsequent pregnancies will occur during the first 12 months of treatment (113). Thus, patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or proceed with alternative forms of therapy.

Last, but not least, one must consider the psychosocial aspects of pregnancies involving donor gametes. Among patients without a male partner, the potential repercussions of becoming a single mother and the issue of telling others about the father of the child should be considered. If the couple is married, it is imperative that the husband is aware of the process of using donor gametes. Most programs require that the husband sign a consent form. A skilled infertility social worker or psychologist can be immeasurably helpful in addressing these concerns.

**Age and Decreased Ovarian Reserve**

An association between the age of the woman and reduced fertility has been well documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s. Chronologic age is the strongest determinant of reproductive success in both spontaneous and ART cycles because it is a predictor of ovarian reserve (114,115). However, age has traditionally not been regarded as a cause of infertility per se, likely because it represents a physiologic rather than a pathologic progression.

In rural Senegal, where each woman gives birth to an average of 7.9 children, fertility rates peak at 25 years of age and decline steeply after 35 years of age (116). Similarly, among the Hutterites, a communal sect living in the Dakotas and Montana that practiced no contraception and had large families, fertility peaked by 25 years of age, and one third of women were no longer fertile by 40 years of age (117). In one study, the fecundability of women who underwent donor insemination because of azoospermia in their husbands provided insight into the effects of age on their fertility. It was found that fertility rates began to drop after 30 years of age. The pregnancy rate after 1 year of inseminations was 74% in women aged 30 years and younger, 62% in women aged 30 to 35 years, and 54% in women older than 35 years of age (118).

Oocyte donation programs provide insight into the physiology of declining fertility in older women (Fig. 30.4). When embryos produced from oocytes retrieved from younger women were transferred into older women, the pregnancy rates among the older women approximated those of the younger women (119), and variations in pregnancy rates were directly dependent on the age of the donors rather than that of the recipients (119–121). In fact, among 260 egg donors (mean age of 30 years) who underwent COH with exogenous gonadotropins, the number of oocytes retrieved per cycle decreased steadily at the rate of 0.24 oocyte per year of increasing age (121). In another study, the use of oocytes from young donors provided cycle fecundity rates of 50% per cycle. The accumulated pregnancy and live birth rates in this investigation reached 95% and 89%, respectively, after up to four cycles of ART (122). These observations strongly support that it is the age of the oocyte, rather than the age of the endometrium, that accounts for the age-related decline in female fertility. This oocyte-related decline in fertility is also known as decreased ovarian reserve.

Ovarian reserve refers to the size of the nongrowing, or resting, primordial follicle population, which presumably determines the number of growing follicles and the “quality” or reproductive potential of their oocytes. Ovarian reserve is thought to affect how the ovaries respond to pharmacologic doses of exogenous gonadotropins in terms of follicle count, oocytes produced, serum estradiol levels, duration of stimulation, and the quantity of exogenous gonadotropins required. Although age is the best predictor of
ovarian reserve, approximately 10% of women have an accelerated loss of ovarian reserve by their mid-30s, whereas others respond well to COH and achieve pregnancies despite their advanced age. Because of this imperfect correlation between chronological age and ovarian biological age, assays have been developed to assist in the prediction of ovarian responsiveness to COH.

Screening tests used in the prediction of ovarian responsiveness to COH include assessments of serum day 3 FSH, serum inhibin B, serum mullerian-inhibiting substance (MIS), the clomiphene citrate challenge test (CCCT), and transvaginal ultrasound parameters such as antral follicle count and mean ovarian volume measurement (123–125). Measurement of day 3 FSH is based on evidence that small increases in basal serum FSH levels correlate with the decreased fecundability seen among women in their late 30s. For IVF treatment following pituitary desensitization, basal FSH assessment proved to be a better predictor of ovarian response than age (126).

Clomiphene citrate is thought to have antiestrogenic effects on the hypothalamic–pituitary axis, resulting in a decrease in the suppression of FSH production by the pituitary. The CCCT involves the measurement of serum FSH and estradiol on day 3, and again on day 10 after administration of clomiphene citrate (100 mg orally each day) from days 5 to 9.

Because FSH levels vary by the assay used and by the population screened, it is recommended that each ART center set its own reference range for evaluating the FSH levels. In a general infertility patient population, the incidence of an abnormal CCCT rises from less than 10% in patients younger than 35 years of age to 26% in patients older than 40 years of age (127). Basal day 3 FSH testing has a sensitivity of 8% in identifying women who will not conceive with subsequent IVF treatment, and the addition of the CCCT to a day 3 FSH only increases the sensitivity of this prediction to 26% (128–130). Both day 3 FSH and CCCT results display high specificity (96%) in the prediction of IVF outcome. In one study, 5% of 435 women beginning their first IVF cycle had a day 3 FSH level greater than 15 IU/L (131). These women proved 3.9 times
more likely to have an unsuccessful treatment cycle. Similarly, among 175 IVF cycles involving women older than 40 years of age, no pregnancies resulted when testing revealed a day 3 FSH greater than 11.1 mIU/mL or a day 10 FSH greater than 13.5 mIU/mL after CCCT (132). Although it is reasonable to advise women with advanced age (greater than 40 years) and abnormal basal day 3 FSH or CCCT results to limit the number of IVF cycle attempts based on their poor prognosis, abnormal day 3 FSH and CCCT tests are more difficult to interpret in women younger than 40 years of age with regular menstrual cycles. One retrospective study demonstrated an ongoing pregnancy rate of 47% in women with regular cycles who had FSH levels ranging from 10 to 15 IU/L and 28% in those with FSH levels greater than 15 IU/L (133). These results indicate that high basal FSH values should not be used as the sole basis for excluding women from consideration for ART.

Given the imperfect nature of FSH as a screening test before COH, the search for other assays has intensified. Serum inhibin B is secreted by ovarian granulosa cells starting at the preantral follicle stage (134). Inhibin B secretion increases during the luteal-follicular transition between menstrual cycles (135), and reflects the overall granulosa cell function of the cohort of follicles that is recruited to undergo gonadotropin-dependent growth. This finding provided the impetus to investigate the potential use of inhibin B as a prognostic marker for ovarian responsiveness in ART cycles. Inhibin B suppresses the production of FSH by the pituitary gland. In the CCCT, the main mechanism for suppression of FSH is inhibin B production by granulosa cells. Although the use of basal inhibin B levels as a predictor of pregnancy outcomes is debatable (114), several studies have shown the value of stimulated inhibin B in the management of COH cycles. The largest of these studies evaluated the inhibin B level after 4 days of gonadotropin stimulation in 54 patients undergoing IVF (136). Patients with serum inhibin B levels less than 400 pg/mL had significantly lower numbers of follicles and oocytes. This threshold indicates that stimulated inhibin B yielded a positive predictive value of 86.7% in the prediction of ovarian response to exogenous gonadotropins.

Recently, MIS, also known as antimullerian hormone (AMH), has been investigated as a marker for ovarian reserve and for ovarian responsiveness to stimulation. This substance is produced by the granulosa cells of preantral and small antral follicles and inhibits the initiation of primordial follicle growth (137). The serum level of MIS in women with normal cycles declines with age and becomes undetectable by the time of menopause (138). As the ovarian primordial follicle count decreases, the serum MIS concentration also decreases, making this hormone an ideal candidate for the early detection of ovarian reserve depletion. Decreased levels of MIS in the early follicular phase correlate with poor ovarian response in ART cycles (139). A retrospective study comparing normal and poor responders with gonadotropin stimulation established a threshold value of 8.1 pmol/L, which predicted poor ovarian response during a subsequent IVF cycle with a sensitivity of 80% and a specificity of 85% (140).

The ideal marker for ovarian reserve is one that can be performed in a basal state with high sensitivity and specificity for identifying patients who will have live pregnancy outcomes. Ongoing efforts to identify such a prognostic test are warranted so patients can be counseled regarding various treatment options.

Spontaneous Abortion

Another factor contributing to decreased fecundity among older reproductive-age women is the increased risk of spontaneous abortion in this population. A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous abortion for various age groups to be 13.3% (12–19 years), 11.1% (20–24 years), 11.9% (25–29 years), 15.0% (30–34 years), 24.6% (35–39 years), 51.0% (40–44 years), and 93.4% (greater than 45 years) (141). In addition, using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they
could be clinically diagnosed (142). This proportion is thought to be increased among older women attempting pregnancy, making subclinical spontaneous pregnancy loss a significant consideration among older women who are thought to be having difficulty conceiving.

One major cause for the increase in spontaneous losses among older women is their increased incidence of chromosomally abnormal conceptuses. A cytogenetic analysis of 750 spontaneous abortions revealed that the increase in chromosomally abnormal conceptuses seen with increased maternal age was mainly due to an increase in the incidence of chromosomal trisomies. In particular, the incidence of trisomies 16, 21, 22, 18, and 20 were significantly increased, with 18 and 20 being the most dramatic. In contrast, the risk for monosomy X and polyploidy did not increase with advanced maternal age (143). In conclusion, an increased spontaneous loss rate, coupled with a reduced conception rate, significantly decreases the chance of a live birth among women older than 40 years of age.

**Age of Male Partner**

There is little doubt that increasing age is accompanied by reduced female fecundity. However, the age-related decline in fecundity for men is more controversial. Male fertility peaks at about 35 years of age and declines sharply after 45 years of age. Yet, men have reportedly fathered children into their 80s (4). Studies using chromosome-specific probes on ejaculated sperm reveal a slight but statistically significant increase in aneuploid sperm with advanced paternal age greater than 55 years (144,145). However, it is not known whether this finding corresponds to an increase in liveborn aneuploidy. Several studies describe an increase in the rate of autosomal recessive disorders among the progeny of men 35 years of age and older (146,147). More recently, advancing paternal age has been associated with an increased incidence of several autosomal dominant diseases, Apert syndrome and achondroplasia, and an increased incidence of schizophrenia (148,149). These findings suggest an age-related decline in gamete quality among men, albeit one that is subtler than that observed in women.

**Ovulatory Factor**

Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility. The normal length of the menstrual cycle in reproductive-age women varies from 25 to 35 days, and most women have cycle lengths of 27 to 31 days. Figure 30.5 shows the fluctuations of estradiol, progesterone, FSH, and LH in a normal, 28-day ovulatory cycle. Women who have regular monthly menses (about every 4 weeks) with moliminal symptoms, such as premenstrual breast swelling and dysmenorrhea, almost invariably have ovulatory cycles. Because ovulation is prerequisite to conception, ovulation must be documented as part of the basic assessment of the infertile couple. Initial diagnoses among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligo-ovulation (infrequent ovulation).

**Methods to Document Ovulation**

**Luteinizing Hormone Monitoring** Documentation of the LH surge represents a remarkably reproducible method of predicting ovulation. Ovulation occurs 34 to 36 hours after the onset of the LH surge and about 10 to 12 hours after the LH peak (150,151). Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISA) using 40 mIU/mL as the threshold for detection (152,153). The positive and negative predictive values of these kits have been described to be 90% and 96%, respectively.
A 100% correlation between urinary LH prediction of ovulation and transvaginal ultrasound diagnosis of ovulation has further confirmed the value of urine LH detection kits for home ovulation detection (155). Still, this ELISA test cannot detect urinary LH in up to 5% to 10% of women, probably either because of failed recognition by the antibody used or because their peak urinary LH concentration does not rise above the threshold set by the kit manufacturers. Serum LH measurements may be necessary to predict ovulation in such cases.

**Basal Body Temperature**  
The least expensive method of confirming ovulation is for the patient to record her temperature each morning on a basal body temperature (BBT) chart. The oral or rectal temperature should be determined before the patient arises, eats, or drinks. Smoking is forbidden before temperature measurement, and irregular sleep patterns can interfere with the test results. Patients monitoring their BBT record their temperature daily as well as times when they have coitus. Use of a BBT thermometer is preferred over use of a conventional thermometer because of the instrument’s precision in the temperature range under consideration. The principle behind temperature charting as a means to document ovulation is based on the thermogenicity of progesterone. Significant progesterone secretion by the ovary generally occurs only after ovulation. The secretion of progesterone causes a temperature increase of about 0.58°F over the baseline temperature of 97° to 98.8°F typically recorded during the follicular phase of the menstrual cycle. Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles. Frequently, a nadir in charted BBT is noted at the time of the LH surge, but this finding is inconsistent. A normal luteal phase is characterized by a documented temperature elevation lasting at least 10 days.

**Charting BBT to document ovulation, although simple, has several drawbacks.**  
Presumptive ovulation can be identified only retrospectively (i.e., the test merely confirms rather than predicts ovulation). Even retrospectively, the exact time of ovulation is difficult to determine using BBTs, although in most instances, it is probably 1 day before documented temperature elevation. An unequivocal temperature rise generally occurs 2 days after the LH surge and correlates with serum progesterone levels of 0.4 ng/mL (156). In a small percentage of patients, BBT charts are monophasic, despite the documentation of

![Figure 30.5 Relative hormonal fluctuations in a normal, ovulatory, 28-day menstrual cycle.](image-url)
ovulation by other methods. Furthermore, BBT charting is correlated with transvaginal ultrasound evidence of ovulation in only 30.4% of cases (155). Despite its limitations, for many patients, BBT charting is a simple way to document ovulation, and unequivocal biphasic cycles are almost certainly ovulatory. Patients with monophasic cycles require confirmation of ovulation using alternative methods.

**Midluteal Serum Progesterone**  Elevations in serum levels of progesterone constitute indirect evidence of ovulation. When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21–23 of an ideal 28-day cycle). The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 nmol/L) typically confirms ovulation. However, interpretation of isolated luteal-phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone (157). Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels of progesterone are not necessarily diagnostic of anovulation.

**Ultrasound Monitoring**  Ovulation can also be documented by monitoring the development of a dominant follicle by ultrasound until ovulation takes place. Ovulation is characterized both by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac (158). It most often occurs when follicular size reaches about 21 to 23 mm, although it may occur with follicles as small as 17 mm or as large as 29 mm (159,160). Because of the inconvenience and expense of serial measurements, routine use of ultrasound for documenting ovulation is discouraged. Instead, its use should be confined to the monitoring of ovulation induction or superovulation.

**Follow-up Tests**  If test results confirm that a patient is anovulatory or oligo-ovulatory, the differential diagnoses of hypothalamic–pituitary disorder, hypothyroidism, anorexia nervosa, polycystic ovarian syndrome (PCOS), and premature ovarian failure should be considered. In addition to history and physical examination, the basic investigations typically used to assess these potential diagnoses further include serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing. These three investigations are often sufficient to guide the initial management plan.

**Polycystic Ovarian Syndrome**

The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is PCOS. The diagnosis of PCOS is determined by exclusion of other medical conditions and the presence of two of the following conditions (161):

- Oligo-ovulation or anovulation (manifested as oligomenorrhea or amenorrhea)
- Hyperandrogenemia (elevated levels of circulating androgens)
- Hyperandrogenism (clinical manifestations of androgen excess)
- Polycystic ovaries detected by ultrasonography

The exclusion of pregnancy, hypothalamic–pituitary disorders, or other causes of hyperandrogenism (e.g., androgen-secreting tumors or nonclassical congenital adrenal hyperplasia) may be indicated in some patients presenting with presumptive ovulatory disorders and infertility. However, once other causes of oligo-ovulation or anovulation have been excluded, biochemical evidence consistent with PCOS—including elevated serum LH:FSH ratios and hyperinsulinemia—is not required before initiation of infertility treatment. Before initiating therapeutic changes in such women, differential diagnoses should be reviewed and endocrinologic investigations repeated if necessary. Because oligomenorrheic women with PCOS are at risk for endometrial hyperplasia, it may
be prudent to perform an endometrial biopsy before beginning ovulation induction therapy.

**Ovulation Induction in Women with Polycystic Ovarian Syndrome**

Despite the use of similar medications, the indications and goals of ovulation induction should be distinguished from those of superovulation. **Ovulation induction refers to the therapeutic restoration of the release of one egg per cycle in a woman who either has not been ovulating regularly or has not been ovulating at all.** Although it is usually acceptable for ovulation induction to result in the release of two eggs, one should avoid the ovulation of more than two eggs in an effort to minimize the risk of ovarian hyperstimulation syndrome (OHSS) and multiple gestation. **In contrast, superovulation is indicated for the treatment of unexplained infertility in women who have been unable to conceive despite regular, monthly ovulation. The explicit goal of superovulation is to cause more than one egg to be ovulated, thereby increasing the probability of conception.**

Ovulation induction can be achieved either medically or surgically in women with PCOS. There is no fixed protocol on how to approach ovulation induction in these patients, although it is reasonable to progress from the least to the most invasive therapies. Appropriate patient selection for various therapies can be a significant determinant of the success of ovulation induction among PCOS patients.

Regardless of which treatment is employed, one important concept to convey to couples is that pregnancy is a cumulative probability. Once ovulation has been documented for a particular treatment, patients should be mentally prepared to continue with that regimen for at least three cycles because, for most treatments, the rate of a pregnancy occurring per therapeutic cycle is the same for each of the first three cycles. **When counseling patients, it is often helpful to remind them that even a couple with no fertility problems has a fecundity rate of only 20% to 25% per cycle (1).** A good rule of thumb involves review of the patient management plan at least once every 2 to 3 cycles and more frequently if side effects are present. This plan should be discussed explicitly with patients, thereby promoting education, communication, and informed compliance.

**Weight Loss**  A body mass index (BMI) above 27 kg/m² is considered excessive; moreover, an increase in BMI is associated with an increased risk for insulin resistance.

There are several excellent reasons for recommending weight loss for infertile patients who are overweight. Weight loss of 20 kg (mean pretreatment weight, 77 kg) through the use of hypocaloric diets in one study and 10 kg (mean pretreatment BMI, 32 kg/m²) in another study resulted in a decrease in plasma testosterone, androstenedione, LH, and fasting insulin levels (162,163). Significant improvement in these parameters, which are thought to play a role in the pathogenesis of PCOS, helps restore spontaneous ovulation in many patients. In a study of 67 overweight women who had a mean weight loss of 10.2 kg/m², spontaneous ovulation and pregnancy occurred in 90% and 30%, respectively (164).

Obese patients are at increased risk for medical conditions such as diabetes, hypertension, and cardiovascular disease. Because obesity also is a risk factor for obstetric complications, there should be tremendous incentive for infertile patients to lose weight (165). As with any other lifestyle change, promotion of weight loss can be difficult and frustrating for both patient and practitioner. Weight loss often requires multidisciplinary efforts, including the involvement of an experienced dietician and promotion of an effective exercise program. However, because weight loss is a gradual process, and other factors may be contributing to infertility concomitantly, it is reasonable to pursue medical options in conjunction with lifestyle changes.

**Clomiphene Citrate**  Traditionally, clomiphene citrate (Clomid, Serophene) has been the first-line intervention for medical induction of ovulation in PCOS patients.
Clomiphene citrate is a weak synthetic estrogen that mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation. A functional hypothalamic–pituitary–ovarian axis is required for appropriate clomiphene citrate activity. More specifically, clomiphene citrate is thought to bind and block estrogen receptors in the hypothalamus for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop (166). This blockade increases GnRH pulse amplitude in some anovulatory women (167). Increased GnRH levels lead to increased pituitary secretion of gonadotropins, which promotes ovarian follicular development. Clomiphene citrate also may affect ovulation through direct action on the pituitary or the ovary (168,169). Unfortunately, the antiestrogenic effects of clomiphene citrate at the level of the endometrium or the cervix may have adverse effects on fertility in a minority of individuals (170,171).

Use of clomiphene citrate for ovulation induction is generally associated with excellent outcomes. In fact, in some populations, 80% to 85% of treated women will ovulate and 40% will conceive (172,173). Discrepancies between ovulatory rates and conception rates are most likely associated with the number of cycles attempted or are secondary to the presence of additional, nonovulatory infertility factors among treated women. Most pregnancies resulting from induction of ovulation with clomiphene citrate occur during the first 6 months of therapy (172). Side effects of clomiphene citrate therapy include infrequent OHSS, vasomotor flushes, nausea, pelvic discomfort, and breast pain (174). In the presence of visual abnormalities, clomiphene citrate should be discontinued promptly. Use of clomiphene citrate is associated with a 35% to 60% incidence of multiple follicular recruitments (175). However, the incidence of multiple gestation with this agent is only about 5% to 8%. Most of these multiple gestations are twin pregnancies, and triplet pregnancies occur infrequently. Rates of spontaneous abortion and teratogenicity in humans are not increased with the use of clomiphene citrate (176).

Clomiphene citrate is typically used for ovulation induction in the following manner:

1. The drug is supplied in 50-mg tablets; the usual starting dosage is 50 mg/day. A baseline transvaginal ultrasound should be performed on days 1 to 3 to confirm the absence of ovarian cysts before treatment. Therapy is typically begun within the first 5 days after the onset of a spontaneous or progesterone-induced menses and is continued for 5 days (i.e., treatment on days 2–6, 3–7, or 5–9 of the menstrual cycle) (177). Some patients respond to a dosage as low as 25 mg/day.

2. Ovulation should be documented using a home urine LH kit in conjunction with ultrasound monitoring of follicular development or confirmation by serum progesterone at approximately 7 days following the LH surge. This information is valuable for future therapeutic planning because failure to conceive despite successful ovulation has different implications than failure to conceive because of failed ovulation induction. If ovulation does not occur at the initial dosage of clomiphene citrate, the dosage is increased in each subsequent cycle by 50 mg/day. The U.S. Food and Drug Administration recommends a maximum dosage of 100 mg/day; however, in patients who ovulate as a result of clomiphene citrate treatment, 11.8% do so only at doses of 150 mg/day or more (172). Considerable clinical experience with clomiphene citrate indicates that a dosage of up to 250 mg/day is safe.

3. Ovulation is expected to occur 5 to 10 days after the last day of therapy; thus, with standard clomiphene citrate regimens, ovulation testing should begin on day 12 or 13 and continue daily until results are positive. Once a pattern is established, ovulation testing can be confined to a better defined 5-day
period in subsequent months. Daily intercourse for 3 days beginning on the day of a positive urine LH test may maximize the chance of a pregnancy.

4. Ultrasound monitoring can be used to determine the number and size of follicles that are developing. If a dominant follicle develops, but there is no spontaneous LH surge, hCG (Profasi 10,000 units given intramuscularly, or Ovidrel 250 μg given subcutaneously) can be used to induce final follicular maturation and ensure that ovulation is timed optimally with respect to follicular growth and timed intercourse or IUI. The number of clomiphene citrate-treated and ovulatory cycles should not exceed six. The maximum cumulative pregnancy rate should be achieved by the six-cycle mark, and further treatment with clomiphene citrate is of minimal predicted benefit at that point.

Despite the high therapeutic success rates of clomiphene citrate in most anovulatory women, treatment has relatively low success in inducing ovulation in women with PCOS and insulin resistance in whom obesity or elevated BMI also is evident. There is increasing evidence that insulin sensitizers are particularly effective in inducing ovulation in women with PCOS who are insulin resistant.

**Insulin Sensitizers** The etiology of PCOS is currently viewed as multifactorial, with contributions from different genetic causes and environmental factors (see Chapter 28) (178). **Insulin resistance is thought to play a central role in the pathogenesis of PCOS in the subset of patients who have increased BMI, hyperinsulinemia, and significant hyperandrogenism** (Table 30.7) (178). It is also thought that a different form of insulin resistance intrinsic to PCOS is part of the underlying disease mechanism in thin women with PCOS (179,180). Therefore, the therapeutic roles of insulin sensitizers, metformin and rosiglitazone, in ovulation induction have been extensively investigated.

**Metformin** is an oral biguanide that is approved for the treatment of non–insulin-dependent diabetes. Metformin acts by several mechanisms, including inhibition of gluconeogenesis in the liver and an increase in the uptake of glucose in the periphery (181). **When women with PCOS, hyperandrogenism, and hyperinsulinemia are treated with metformin for 12 weeks, their fasting insulin and total testosterone levels, free testosterone index, BMI, waist-to-hip ratio, hirsutism, and acne all decrease significantly** (182). Moreover, among women who have PCOS, a BMI greater than 28 kg/m², and hyperandrogenemia, 89% ovulate after treatment with a combination of metformin and clomiphene citrate (182). This rate is significantly higher than the 12% of patients who ovulated with combined clomiphene citrate and placebo treatment (183). A meta-analysis of studies involving ovulation induction of PCOS patients by metformin versus placebo, metformin versus clomiphene citrate, and metformin plus clomiphene citrate versus placebo plus clomiphene citrate showed that the combined regimen of metformin and clomiphene citrate increased the success of ovulation induction by three- to fourfold when compared with clomiphene citrate alone (184).

Similarly, *rosiglitazone*, an insulin sensitizer belonging to the class of thiazolidinediones, has been shown to induce ovulation within 2 months of treatment in obese, *clomiphene citrate*-resistant patients with PCOS at a rate of 33% when used alone and 77% when combined with *clomiphene citrate* (185). Furthermore, *rosiglitazone* significantly decreases fasting insulin and glucose levels, total testosterone, free testosterone, and dehydroepiandrosterone sulfate (DHEAS) and increases sex hormone-binding globulin (SHBG) (186). Because BMI is not improved by treatment, its ovulation induction effects are presumed to be the result of improved insulin resistance and ovarian androgen profiles (186). The use of *metformin* or *rosiglitazone* alone has been shown to induce ovulation and improve androgen levels in PCOS patients who have normal BMI and insulin sensitivity profiles, although there is no added benefit to combining *metformin* and *rosiglitazone* (187). Thus, the use of insulin sensitizers is not restricted to obese and insulin-resistant PCOS patients. It is anticipated that ongoing investigations in the next few years will further guide patient selection for *clomiphene citrate*, *metformin*, *rosiglitazone*, or combined regimens involving these medications.

Unlike *troglitazone*, which was withdrawn from the market because of its risk of fatal liver failure (1 in 50,000), this newer generation of thiazolidinediones, including *rosiglitazone* and *pioglitazone*, have good safety profiles, especially with respect to liver toxicity (188–190). *Metformin* also has an excellent safety profile, but gastrointestinal symptoms are common side effects, and isolated cases of fatal lactic acidosis have been reported in patients with underlying renal compromise. *Metformin* typically is discontinued once pregnancy has been established; however, it is a category B drug, and its administration during pregnancy is not known to confer specific risk to the fetus. Prospective, nonrandomized studies have reported that the continuation of *metformin* in pregnancy appeared safe and may decrease the risk of gestational diabetes (191,192). However, these findings need to be confirmed by a prospective, randomized trial with neonatal and pediatric outcomes before this practice is widely adopted (193).

**A typical treatment regimen using metformin, with or without clomiphene citrate, for ovulation induction in PCOS patients follows (179):**

1. **Select PCOS patients.** Failure of ovulation induction with *clomiphene citrate* alone is an indication but not a requirement for the use of metformin.

2. **Confirm normal liver and renal function.** Serum hCG testing to exclude pregnancy, followed by a progestin withdrawal-induced menses, can be undertaken if indicated.

3. **Start metformin** therapy as follows:
   - *Metformin*, 500 mg once a day with breakfast for 4 days
   - *Metformin*, 500 mg twice a day with breakfast and dinner for 4 days
   - *Metformin*, 500 mg with breakfast and 1,000 mg with dinner for 4 days

4. **Thereafter, metformin, 1,000 mg twice a day (at breakfast and dinner).**

5. **If a trial of metformin alone is chosen, evaluate single serum progesterone levels weekly to detect the occurrence of ovulation.** It may take up to 2 months of therapy for spontaneous ovulation to occur.

6. **If metformin plus clomiphene citrate is the desired regimen, add clomiphene citrate at the usual starting dosage of 50 to 100 mg once a day from days 5 to 9 when the full dose of metformin has been reached if spontaneous ovulation has not occurred.** Home LH detection kits can then be used to predict ovulation and time intercourse.
7. **Clomiphene citrate** can be increased incrementally by 50 mg once a day in subsequent cycles if ovulation still does not occur. Once ovulation occurs, the ovulatory dosage of **clomiphene citrate** can be used in combination with **metformin** for as many as 3 to 6 cycles (in conjunction with ovulation detection and timed intercourse or inseminations).

If the combination of **metformin** and **clomiphene citrate** fails to induce ovulation, the diagnosis should be reviewed. Alternatively, the aromatase inhibitor **letrozole** has been reported to be efficacious in inducing ovulation in **clomiphene citrate**-resistant patients (194). In patients who have elevated serum DHEAS, **dexamethasone**, 0.5 mg/day at bedtime, combined with typical **clomiphene citrate** regimens may induce ovulation (195). At this low dosage, **dexamethasone** therapy is associated with minimal adverse effects. Other treatment options, including gonadotropin therapy and surgical ovarian diathermy, may be considered.

**Gonadotropin Therapy for Polycystic Ovarian Syndrome Patients** Anovulatory PCOS patients who fail to ovulate or conceive after medical treatment with anti-estrogen or insulin sensitizing agents should be considered for ovulation induction with gonadotropin therapy, either alone or in combination with **clomiphene citrate** or **letrozole**. This treatment involves daily injection of gonadotropins, close monitoring of serum estradiol levels and monitoring of follicular development by transvaginal ultrasound. Intrauterine insemination often is recommended in conjunction with ovulation induction to optimize the chances of pregnancy. It is important to remember that PCOS patients tend to have a high number of small antral follicles in the unstimulated state. These follicles can potentially be stimulated by exogenous gonadotropin therapy. This effect could be problematic because the goal of gonadotropin therapy in these patients, unlike that in ovulatory patients with unexplained infertility, is not to produce many eggs but rather to induce the release of only 1 to 2 oocytes. Treatment should be monitored by an experienced physician because the risks of OHSS and multiple gestation are significantly increased when using gonadotropins in this patient population.

**Surgical Treatment** Pathophysiologic changes in the polycystic ovary have been the subject of many years of intense investigation. As early as 1935, with the initial description of the syndrome, ovarian surgical treatment of PCOS was considered (196). Initially, surgical management of PCOS involved wedge resection of the ovaries in an effort to reduce the volume of androgen-producing tissue and thereby alleviate hyperandrogenic abnormalities. In fact, ovarian wedge resection does decrease circulating levels of testosterone (197), and this therapy is associated with resumption of menses in **91% of treated PCOS patients** (198). Unfortunately, many patients treated with ovarian wedge resection suffer from postoperative intrapelvic adhesions, often leading to iatrogenic tubal factor infertility (198,199).

Laparoscopic techniques for treating PCOS appear to be associated with less adhesion formation in the pelvis than noted after ovarian wedge resection by laparotomy (200,201), while maintaining similar improvements in hormonal profiles (202,203). Compared with controls, patients undergoing laparoscopic ovarian diathermy (or ovarian drilling) have higher rates of subsequent ovulation and a lower resistance to standard ovulation induction agents (204,205). In further support of this concept, 112 women with PCOS and anovulatory infertility in whom previous ovulation induction attempts using **clomiphene citrate** (up to 200 mg once a day) were unsuccessful were treated with laparoscopic ovarian diathermy. This surgical therapy resulted in a significant decrease in serum levels of LH, testosterone, DHEAS, and androstenedione as well as in the LH:FSH ratio (206). Furthermore, 73% of these patients ovulated spontaneously, 24% ovulated with **clomiphene citrate** therapy, and 1.8% required gonadotropin use alone. The cumulative probabilities of pregnancy were 54%, 68%, and 82% at 12, 18, and 24 months of follow-up, respectively. The median time to conception was 10.2 months. Thus,
laparoscopic ovarian diathermy may have particular application in ovulation induction among PCOS patients who are resistant to treatment with clomiphene citrate.

Laparoscopic ovarian diathermy appears to affect IVF outcomes as well. In a prospective trial comparing IVF outcomes in PCOS patients with and without prior surgical intervention, both a higher ongoing pregnancy rate and lower peak estradiol levels were documented in those who had prior laparoscopic ovarian diathermy (207). If these results are interpreted as an indication that laparoscopic ovarian diathermy favorably alters the response of PCOS patients to COH with gonadotropin therapy, then its effect on reducing the risk for OHSS among PCOS patients treated with these medications warrants further investigation. It is of interest that laparoscopic ovarian diathermy has been linked to a decrease in the elevated rates of spontaneous abortions documented in PCOS patients (206, 207).

A variety of techniques have been described for laparoscopic destruction of ovarian tissue in the treatment of PCOS, including the use of laser, unipolar cautery, and bipolar cautery. Although no single technique has been proved superior using randomized studies, recent reports have advocated diathermy by electrocautery (206–208). In this technique, the ovary is immobilized, and an insulated needle is inserted into the ovary in a direction perpendicular to the ovarian surface using a short duration of cutting current at 100 W. Coagulating current at 40 W is then applied for about 2 seconds. The needle is withdrawn, and the process is repeated at up to 15 puncture sites per ovary. At the end of the procedure, the ovaries are lavaged with copious amounts of normal saline (206).

In addition to the usual risks associated with laparoscopic surgery, laparoscopic ovarian diathermy involves the rare but potential risk of surgically induced premature ovarian menopause via inadvertent disruption of ovarian vascular supply. More common, however, is the possible formation of adnexal adhesions, which may further compromise fertility.

Of patients who had second-look laparoscopy after laparoscopic ovarian diathermy, 19% had adhesions (201). In a series of 112 PCOS patients (206), filmy adhesions confined to the ovarian surface were reported in 4 of 15 women who had not conceived at 1 year and who underwent second-look laparoscopy. At present, the impact of postsurgical adhesion formation on subsequent fertility and defined indications for use of second-look laparoscopy in treated patients is undetermined.

Ovulation Induction for Other Anovulatory Disorders

**Hyperprolactinemia** Hyperprolactinemia can be associated with ovulatory factor infertility. After exclusion of a pituitary macroadenoma or other intracranial pathology, correction of the hyperprolactinemic state with bromocriptine is followed by restoration of ovulation in 90% of patients (209). Cabergoline has similarly high efficacy, but it has the advantage of a twice-weekly dosing schedule. More controversial is the use of bromocriptine alone or the addition of bromocriptine to clomiphene citrate therapy in non-galactorrheic patients with normal or minimally elevated serum prolactin levels. Such therapy has, however, been associated with improved pregnancy rates among normoprolactinemic women with unexplained infertility and galactorrhea (210).

**Hypogonadotropic Hypogonadism** Anovulation in the presence of low serum LH, FSH, and estradiol levels defines hypogonadotropic hypogonadism and reflects dysfunction within the hypothalamic–pituitary axis. Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space-occupying lesions, should be excluded using magnetic resonance imaging.
Low BMI is thought to cause anovulation and infertility in women, possibly by disrupting hypothalamic function (211). Examples of conditions characterized by low BMI include anorexia nervosa, rigorous athletic training, and malnutrition. In recent years, the female athlete triad, which consists of secondary amenorrhea, eating disorder or disordered eating, and osteopenia or osteoporosis, has become more widely recognized (212). It is important to understand that the female athlete triad is not restricted to professional athletes, but affects women who train for recreational purposes also. In most patients with this condition, weight gain is the ideal treatment for ovulatory dysfunction, thus avoiding the use of ovarian stimulatory medications and their complications. Other health benefits, including the reduction of pregnancy complications such as intrauterine growth restriction and osteoporosis, can result from correction of an abnormally low BMI. In one study, increased caloric intake and weight gain alone resulted in the resumption of menses in 90% patients with amenorrhea related to low BMI, with 73% conceiving spontaneously conception (213). In another study, a mean weight gain of 3.6 kg was sufficient to promote the resumption of spontaneous ovulation (214).

There is now increasing evidence linking genetic and physiologic mechanisms to the regulation of body fat content, caloric intake, and hypothalamic control of reproduction. In humans, abnormalities in leptin receptor function lead to early-onset morbid obesity and the absence of pubertal development, presumably secondary to defective hypothalamic function (215). Further, in women with hypothalamic amenorrhea secondary to strenuous exercise or low BMI, daily administration of recombinant human leptin increased LH pulse frequency and mean LH levels within 2 weeks and successfully induced follicular growth or ovulatory cycles within 3 months (216). Leptin, produced by peripheral adipocytes and reflects energy stores, and its receptor have critical functions in body mass regulation, glucose homeostasis, and reproductive function at the level of the hypothalamus (215).

Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (Kallmann syndrome), can be treated using pulsatile GnRH therapy if the pituitary–ovarian axis is intact. Gonadotropin therapy should be chosen for patients with pituitary dysfunction, such as those with empty sella syndrome. Each of these treatment modalities is discussed in greater detail under “Gonadotropin Therapy.”

Hypothyroidism The prevalence of abnormal TSH levels in the general infertility population has been reported to be 6.3%, 4.8%, 2.6%, and 1.5% for women in couples diagnosed with anovulatory infertility, unexplained infertility, tubal infertility, and male infertility, respectively (217). This diagnosis is significant in the management of infertility. For instance, one study reported that among 171 women with hypothyroidism, 23% had irregular menses, likely resulting from anovulation (218). Spontaneous ovulatory cycles typically resume when euthyroid status is achieved using thyroxine supplementation.

In contrast to the causal relationship between hypothyroidism and anovulation, the association between hypothyroidism or thyroid antibodies and spontaneous abortion is still unclear. Although hypothyroidism has been associated with increased fetal wastage in some studies (219,220), the association between thyroid antibody status and recurrent pregnancy loss or success rates in ART is controversial (221–224). In any case, because even very mild or subclinical hypothyroidism can have adverse effects on fetal brain development and subsequent intelligence quotient, it is prudent to screen and treat women with thyroid hormone abnormalities before commencing infertility treatment (225).

Tubal, Paratubal, and Peritoneal Factors

Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Tubal factors include damage or obstruction of the fallopian tubes and usually are associated with previous PID or previous pelvic or tubal surgery. Peritoneal factors include
peritubal and periovarian adhesions, which generally result from PID, surgery, or endometriosis. The risk of infertility after a single episode of PID is significant and increases rapidly with subsequent episodes. In fact, the incidence of tubal infertility has been reported to be 12%, 23%, and 54% after one, two, and three episodes of PID, respectively (226). Still, about one half of patients with documented tubal damage have no identifiable risk factors for tubal disease (227). Most of these women are presumed to have had subclinical chlamydial infections.

**Hysterosalpingography** The initial diagnostic test used to assess tubal patency, hysterosalpingography (HSG) has a sensitivity of 85% to 100% in identifying tubal occlusion. The specificity of HSG in identifying PID-related tubal occlusion approaches 90% (228,229). Other causes of apparent tubal blockage include salpingitis isthmica nodosa, benign polyps within the tubal lumen, tubal endometriosis, tubal spasm, and intratubal mucous debris (230). Bilateral tubal pathology documented on HSG is associated with significantly reduced fecundity rates and warrants further evaluation using fallopscopy, selective salpingography, or laparoscopy.

HSG usually is performed between cycle days 6 and 11. During menses, HSG should be avoided because there is increased incidence of vascular intravasation caused by dilatation of periuterine veins. Additionally, there is the theoretical risk of retrograde dispensation of menstrual endometrium into the peritoneum with attendant risk of infection and endometriosis. The risk of infectious sequelae after HSG is 0.3% to 1.3%; in high-risk populations, this incidence can be as high as 3% (231,232). Therefore, known hydrosalpinxes, current PID or cervicitis, and palpable adnexal masses or tenderness on bimanual examination all constitute contraindications to HSG. Because there is a high prevalence of current or past chlamydial infection among infertile women and complications of HSG-associated pelvic infection could further compromise fertility, it is reasonable to prescribe antibiotic prophylaxis to patients scheduled for HSG. A recommended prophylactic regimen consists of doxycycline, 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. Other rare complications of HSG include cervical laceration, uterine perforation, hemorrhage, vasovagal reaction, and allergic response to the contrast dye. The procedure often causes uterine cramping; prophylaxis with a nonsteroidal anti-inflammatory medication taken 30 minutes before the procedure may minimize this discomfort.

The performance of the HSG procedure is fairly straightforward. After vaginal cleansing, an acorn (Jarcho) cannula or other injection device is introduced into the uterine cervix. A paracervical anesthetic block is not routinely necessary, but may be used in selected patients. Either a water-soluble or a low-viscosity oil-based (i.e., Ethiodol) dye is used for the procedure. Water-soluble contrast material is more rapidly absorbed than oil-based dyes and does not carry the risk for either lipid embolism caused by dye extravasation or lipid granuloma formation. Conversely, oil-based dyes are associated with less uterine cramping, better resolution of tubal architecture, and a higher postprocedure pregnancy rate (233). In a randomized controlled trial of oil versus water-soluble dye, there was a 33% pregnancy rate with oil and a 17% pregnancy rate with water-soluble dye within nine ovulatory cycles after HSG (234). A meta-analysis found that the use of oil-soluble media to flush the tubes during HSG significantly increases subsequent pregnancy rates (OR 1.8, 95% CI, 1.29–2.50) (235). Most pregnancies occurred within 7 months of the HSG. A potential mechanism to explain this therapeutic benefit entails flushing of inspissated mucus and debris from the tubal lumen, which allows fertilization to occur. Careful and slow initial injection of 3 to 4 mL of contrast media should give a clear outline of the uterine cavity. Further injection of about 5 to 10 mL of contrast media usually is sufficient to demonstrate bilateral tubal patency or tubal obstruction.

It is not unusual for unilateral tubal fill and spill to occur at the time of HSG. If the tube that fills and spills demonstrates normal architecture and prompt spillage, then it is
possible that the hydrostatic dye column is following the path of least resistance out of the open tube. Additionally, unilateral or bilateral proximal occlusion may be secondary to procedure-related spastic constriction of the fallopian tubal lumen, which would result in a misdiagnosis of tubal nonpatency. To alleviate the potential for tubal spasm, premedication with diazepam 30 minutes before the procedure has been advocated. If proximal spasm is suspected during the procedure, subcutaneous terbutaline in the amount of 0.25 mg can be administered.

Successful evaluation of proximal tubal obstruction using selective salpingography has been described. Based on techniques derived from coronary angioplasty, salpingography uses a small guidewire to permit selective tubal cannulation and radiographic visualization under fluoroscopy.

Other Diagnostic Modalities Falloposcopy is based on principles similar to selective salpingography but allows direct fiberoptic visualization of tubal ostia and intratubal architecture. Falloposcopy allows the visual identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction. In fact, a tubal disease scoring system based on falloposcopic examination has been suggested to identify patients with poor prognoses for spontaneous conception (236). Complications associated with falloposcopy include a 5.1% rate of pinpoint perforations of the tube.

Alternatively, sonohysterography with contrast media offers a much less invasive method of diagnosing fallopian tubal obstruction while maintaining a sensitivity and specificity similar to that of laparoscopic chromotubation (237). Further prospective evaluation and cost analyses are necessary to determine the utility of tubal cannulation and sonohysterography with contrast media.

Laparoscopy The most thorough technique for diagnosing tubal and peritoneal disease is laparoscopy. It allows visualization of all pelvic organs and permits detection of intramural and subserosal uterine fibroids, peritubal and periovarian adhesions, and endometriosis. Abnormal findings on HSG can be validated by direct visualization on laparoscopy. Chromopertubation involves the transcervical installation of a dye, such as methylene blue or indigo carmine. Tubal patency is assessed by direct laparoscopic visualization of the dye extruding through the fimbrial openings of the tubes. Unlike HSG, laparoscopy allows careful assessment of the external architecture of the tubes and, in particular, visualization of the fimbria. Identified abnormalities, including tubal obstruction, pelvic adhesions, and endometriosis, can be treated at the time of diagnosis.

Treatment of Tubal Factor Infertility Therapies that directly correct tubal factor infertility are entirely surgical and include (i) correction of periadnexal disease; (ii) correction of proximal, distal, or combined tubal disease; and (iii) correction of iatrogenic tubal abnormalities (e.g., tubal sterilization). As success rates for ART continue to improve, the indications for surgical approaches in the treatment of tubal factor infertility have become increasingly limited. Still, many of the principles underlying surgical management remain important. Surgical treatment of periadnexal disease distorting tubo-ovarian relationships has been proved to be effective, regardless of whether the approach is by laparotomy or laparoscopy (238). Adhesion prevention, however, becomes particularly vital when surgery is used to treat prior adhesive disease causing infertility. The relative value of laparotomy versus laparoscopy for the treatment of tubal infertility has received considerable attention, as have their respective effects on postoperative adhesion formation. For example, one study comparing laparoscopy and laparotomy for the treatment of ectopic pregnancy demonstrated that adhesion formation occurred more frequently after laparotomy, even when meticulous technique was maintained during all procedures (239). Although many adjuncts for
Postoperative adhesion prevention have been proposed, none has consistently deterred postoperative adhesion formation. Thus, the microsurgical principles of careful hemostatic technique, minimization of tissue trauma, and judicious use of the laparoscopic approach are essential in the surgical management of tubal factor infertility.

**Proximal Tubal Occlusion**  Tubal spasm, temporary mucous plugging, and underfilling of the tube may cause a false-positive finding by HSG when proximal obstruction is demonstrated. The false-positive rate for proximal tubal obstruction may be as high as 15%. Consequently, confirmation of proximal occlusion by repeat HSG or laparoscopic chromopertubation should be considered. Salpingitis isthmica nodosa, the pathologic sequela of inflammation in the fallopian tube, accounts for 23% to 60% of histologically confirmed cases of proximal occlusion (240,241). **Proximal tubal occlusion can be corrected at the time of diagnosis by HSG.** Selective salpingography performed under fluoroscopy may be used to inject contrast media directly into the tubal lumen in an attempt to overcome obstruction resulting from mucous plugging. If selective salpingography fails to recreate tubal patency, proximal tubal cannulation can be performed using a guidewire under radiologic guidance. Proximal tubal cannulation has a reported success rate of 85% in establishing tubal patency. Reocclusion occurs in 30% of cases. The risk for tubal perforation with cannulation ranges from 3% to 11%, but tubal damage is usually mild and heals spontaneously (230). The ongoing pregnancy rates for selective salpingography and fluoroscopic tubal cannulation in studies averages 26% (230,242–246).

Microsurgical tubocornual anastomosis is the primary surgical approach, with postsurgical ongoing pregnancy rates averaging 47.4% in five reported series involving 175 patients (230,247–250). Hysteroscopic cannulation appears to have similar efficacy, with a 48.9% ongoing pregnancy rate among 133 patients treated in four series (230,251–254). Although ongoing pregnancy rates with microsurgical tubocornual anastomosis and hysteroscopic cannulation appear comparable, cannulation is significantly less invasive and has fewer complications. Microsurgery, however, provides access to other pelvic structures, allowing the surgeon to assess the distal fimbriae and to lyse any peritubal adhesions that may be compromising normal tubo-ovarian relationships. The success of the surgical approach is enhanced by the possibility of subsequent pregnancies without additional treatment. In a study of 102 patients who underwent microsurgical treatment for proximal tubal disease, nearly one half of the women who wanted a second child succeeded over a 2-year period (255).

**Distal Tubal Occlusion and Hydrosalpinx**  Distal tubal disease and occlusion can be secondary to a variety of inflammatory conditions including infection, endometriosis, or prior abdominal or pelvic surgery. Because of the secretory capacity of cells lining the oviductal lumen, fluid can accumulate within the occluded fallopian tube. The deleterious impact of a hydrosalpinx extends beyond mere blockage of the fallopian tube. The fluid within such a hydrosalpinx may contain substances that are directly embryotoxic or that impede efficient embryo implantation. A meta-analysis of 14 studies and 1,004 patients with hydrosalpinx concluded that IVF pregnancy rates were significantly lower in cases of hydrosalpinx (256).

Patients should be selected carefully for surgical correction of distal tubal disease via fimbrioplasty or neosalpingostomy. **Fimbrioplasty** is the lysis of fimbrial adhesions or the dilation of fimbrial phimosis, whereas **salpingostomy** (also known as salpingo-neostomy) involves the creation of a new tubal opening in an occluded fallopian tube (257). The efficacy of neosalpingostomy or fimbrioplasty as treatment for distal tubal occlusion depends on the extent of tubal and peritubal disease as assessed by HSG and laparoscopy. Poor prognostic factors for successful pregnancy after tubal corrective surgery include hydrosalpinx greater than 30 mm in diameter, thickened tubal walls, absence of visible fimbriae, and dense pelvic or adnexal adhesions (258). The appearance of the tubal
mucosa has added prognostic significance for the fertility outcome of laparoscopic tuboplasty for distal tubal occlusion (259). Patients with both proximal and distal tubal disease represent the poorest candidates for surgical management of tubal infertility (260). A study of a series of 194 cases of laparoscopic fimbrioplasty and neosalpingostomy resulted in an intrauterine pregnancy rate of 27.3% and an ectopic pregnancy rate of 4.1% (261). Patients younger than 35 years of age with mild distal tubal disease, normal tubal mucosa, and absent or minimal pelvic adhesions may be considered for corrective microsurgery. Otherwise, the extent of disease may render surgery less effective than ART, and the patient should be considered for IVF treatment.

Given the deleterious impact of hydrosalpinges on IVF outcome, the paradoxical situation is presented whereby tubal removal or proximal interruption may actually improve fertility. Removal of a hydrosalpinx that is visualized on transvaginal ultrasound before IVF treatment has been shown to significantly improve outcomes. In a randomized trial of 204 women with ultrasonographic findings consistent with a hydrosalpinx, the live birth rate was 29% in women who had salpingectomy before IVF and 16% in women who underwent IVF alone (262). A subsequent Cochrane review of three randomized studies confirmed that salpingectomy for hydrosalpinx significantly increases IVF pregnancy rates (263). A technically simpler alternative to salpingectomy is proximal tubal occlusion via cautery or clip device. Comparative studies indicate that tubal occlusion is as effective as salpingectomy for improving IVF pregnancy rates in patients with hydrosalpinx (264).

**Sterilization Reversal**  
About 0.2% of women who choose surgical tubal sterilization request reversal procedures (265,266). The success of tubal reanastomosis depends on the method of sterilization, the site of anastomosis, and the presence of other infertility factors. Pregnancy rates are lowest (49%) after the reversal of sterilization procedures involving unipolar electrocautery. In contrast, postprocedure pregnancy rates rose to 67% when the sterilization technique involved Fallope rings or spring-loaded clips and 75% when Pomeroy tubal ligation was employed. The prognosis is best when anastomotic sites have no significant differences in tubal diameter (e.g., isthmic–isthmic or cornual–isthmic anastomoses). Tubal length is also an important prognostic consideration: Final anastomosed tubal lengths of less than 4 cm are associated with low pregnancy rates (267). Pregnancy rates higher than 40% have been reported after microsurgical fimbriectomy correction (268). Laparoscopy to assess surgical prognostic factors, such as potential final tubal length, site of reanastomosis, method of sterilization (if not previously known), and presence of associated pelvic pathology, is often performed before microsurgical fallopian tubal reanastomosis by laparotomy.

Historically, all sterilization reversal procedures have involved laparotomy. More recently, excellent pregnancy rates have been reported after laparoscopic tubal anastomosis. In one study of 186 patients followed after laparoscopic tubal anastomosis with a two-layer closure, cumulative postprocedure pregnancy rates were 60.3%, 79.4%, and 83.3% at 6, 12, and 18 months, respectively (269). In another study, laparoscopic tubal reanastomosis was performed on 102 women, of whom 70% conceived and 65% had ongoing intrauterine pregnancies during the 15-month follow-up period (270). Rates of ectopic pregnancy were similar (3% and 7%) in both series (269,270). The surgical time of laparoscopic tubal reanastomosis depended on the surgeon’s experience as well as the number of layers involved in tubal closure.

Recently, successful robotic-assisted laparoscopic microsurgical tubal anastomosis on humans has been reported. The reported procedures had a mean duration of 159 ± 33.8 minutes and were performed solely using robotic arms that were remotely controlled by surgeons with previous extensive experience with microsurgical tubal anastomosis by laparotomy. The reported postprocedure tubal patency rate was 89% at 6 weeks, and the ongoing pregnancy rate was 50% (271). Despite advances in surgical technology, however, IVF
should be considered for patients with prior sterilization and poor prognostic characteristics. Likewise, IVF is indicated for those patients whose tubal reanastomoses have not yielded a pregnancy by 12 to 18 months postoperatively.

Cervical and Immunologic Factors

Postcoital Test Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. The classic test for evaluation of the potential role of cervical factor in infertility is the postcoital test (PCT). The PCT is designed to assess the quality of cervical mucus, the presence and number of motile sperm in the female reproductive tract after coitus, and the interaction between cervical mucus and sperm. The test does not yield sufficient information on sperm count, motility, or morphology to allow assessment of semen quality. The PCT should be performed 1 to 2 days before the anticipated time of ovulation because sufficient estrogenization of the cervical mucus is critical to the interpretation of the results. Intercourse after 2 days of abstinence and about 2 to 12 hours before the PCT should be sufficient for testing purposes. Inexpensive and easily performed, the PCT involves both gross assessment of the cervical mucus and microscopic assessment of the sperm–mucus interaction. A small amount of cervical mucus is withdrawn by means of oval forceps or via an angiocatheter syringe. Cervical mucus is assessed for clarity and for spinnbarkeit (i.e., stretchability), with normal estrogen-stimulated mucus stretching 8 to 10 cm when pulled from the cervix. The mucus is placed on a glass slide and covered with a cover slip. A small trail of mucus may be left to dry outside the cover slip so that ferning can be assessed. Estrogenized mucus is clear and watery with a characteristic ferning pattern, whereas progesterone results in mucus that is opaque, thick, and lacking ferning. The presence of sperm, number per high-power field, and motility are assessed by the examination of several microscopic fields. Although the number of motile sperm per high-power field should be documented, normal values have not been established. Some authors suggest that virtually any number of motile sperm seen on the PCT is normal (272), whereas others require greater than 20 sperm per high-power field (273).

There are several potential causes for an abnormal PCT. The most common is incorrect timing of the test within the menstrual cycle, leading to the production of cervical mucus that is suboptimal for sperm penetration. Other causes of poor mucus quality include anovulation, anatomic factors (e.g., prior cervical conization or cryotherapy), infection, and use of certain medications. Clomiphene citrate may exert detrimental effects on cervical mucus by its antiestrogenic action on cervical glands. Poor PCT results may, of course, reflect suboptimal mucus–sperm interactions. The observation of shaking or uniformly dead sperm on PCT may suggest the presence of antisperm antibodies.

Although there is a plausible biologic rationale for the PCT, this test has been accepted without critical review of its prognostic value or of its impact on the overall management plan of the subfertile couple. The PCT lacks reproducibility, standard methodology, and uniform criteria for assessment. These factors, in conjunction with poor correlation between PCT results and pregnancy outcome, argue against the use of PCT as a standard investigational tool in infertility patients (273–276). For example, one study reported no difference in pregnancy outcomes among women whose cervical mucus contained 0 to 11 motile sperm per high-power field (274), whereas another reported abnormal PCTs in 20% of fertile couples (273). A review of the world’s English-language literature challenged the validity of the PCT, and found the sensitivity (the ability to detect infertility) of the test to be 9% to 71% and the specificity (the ability to identify fertility) to be 62% to 100% (275). The PCT has no bearing on the management of patients with unexplained infertility because the accepted treatment of superovulation with IUI bypasses
the cervical mucus. In a prospective, randomized controlled study, couples who underwent PCT as part of their infertility evaluation had cumulative pregnancy rates identical to those of a control group not undergoing PCT after 24 months of therapy (277). These findings indicate that PCT testing has no effect on treatment outcomes.

**Antisperm Antibodies** Both men and women have the capability to mount a humoral response to sperm. Either allogenic or autoimmune response could, in turn, adversely affect fertility. Antisperm antibodies (ASA) are most commonly limited to immunoglobulin G (IgG), IgM, and IgA isotypes, and each subclass has characteristic anatomic localization. Systemically produced IgG molecules may be found in serum as well as in cervical mucus and semen. Agglutinating antibodies of the IgA class are typically found in cervical mucus and seminal plasma. The larger IgM antibodies have difficulty traversing the genital tract mucosa and therefore are found exclusively in serum. Antisperm antibodies have also been detected in ovarian follicular fluid (278). In addition to subclassification by isotype, antisperm antibodies can be free, agglutinating, bound to sperm that is motile, or bound to sperm that is immobilized. Further complexity arises in that sperm-bound antisperm antibodies can bind to different parts of the outer sperm plasma membrane, including the head, body, or tail. One major challenge in understanding antisperm antibodies is to determine the relative importance of each of these factors with respect to disease pathogenesis, impact on fertility, and prognosis. Though ASA are present in up to 9% to 12.8% of infertile couples (279), they are also found in up to 2.5% of fertile men (280) and 4% of fertile women (281). These findings would indicate that these antibodies may contribute to subfertility rather than result in absolute infertility.

Many causes have been proposed to explain the formation of antisperm antibodies (271). In women, coital trauma that disrupts the vaginal epithelium could theoretically expose immune effector cells to sperm antigens, thereby leading to antisperm antibody formation. However, it remains unclear why most women, who are repeatedly exposed to millions of spermatozoa, do not exhibit this immune response. In men, the blood–testis barrier normally shields the serum from exposure to sperm and their antigens. Conditions that cause breaks in this barrier could activate autoimmunity. Testicular trauma or torsion, occlusion of the vas deferens secondary to childhood inguinal herniorrhaphy or cystic fibrosis, vasectomy reversal, and genital tract infections have been suggested to elicit antisperm antibody formation.

The mechanisms by which antisperm antibodies might adversely affect fertility remain a subject of debate and ongoing investigation. One or more of these mechanisms could be involved in a particular infertile couple. Adverse antibody-mediated effects on semen quality (either before ejaculation or upon contact of ejaculate with the female reproductive tract) present obvious potential for subfertility. Other purported mechanisms include antisperm antibody–mediated interference with capacitation, acrosome reaction, sperm–egg fusion, and cleavage of the early embryo (282). A recent comprehensive review of the English language literature identified 20 trials examining the effect of ASA on fertilization (32). Of these trials, 14 showed a decrease in fertilization rate, two showed equivocal effect, and four showed no effect.

A number of assays, both indirect and direct, are available for the detection of antisperm antibodies. Sperm agglutination tests (Kibrick’s or Franklin-Dukes) and sperm complement-dependent immobilization tests (Isojoma’s) have largely been replaced by the immunobead or mixed agglutination tests. The immunobead test uses commercially available anti-IgG–, anti-IgA–, or anti-IgM–coated polyacrylamide beads. Washed spermatozoa are exposed to the labeled beads, and sperm binding is assessed. The test yields specific information on both the immunoglobulin class of the antisperm antibody and the site of binding to the involved sperm (283). In the mixed agglutination reaction, human red blood cells sensitized with human IgG are mixed with the male’s semen. The presence of antibody-coated spermatozoa results in the formation of mixed agglutinates with the red
Uterine Factors

Uterine pathologies are the cause of infertility in as many as 15% of couples seeking treatment (289) and are diagnosed in as many as 50% of infertile patients (290–292). For patients undergoing in vitro fertilization, lower pregnancy rates are observed in the presence of uterine cavity anomalies (293,294). The correction of these anomalies has been associated with improved pregnancy rates (292). Therefore, the evaluation of the couple with infertility should include an assessment of the endometrial cavity. Most endometrial pathologies implicated in infertility result in both structural and functional impairment. Endometrial molecular mechanisms of implantation and gestation are exquisitely controlled and remarkably complex. Consequently, even subtle defects in endometrial progression from the peri-implantation, luteal phase to the mature decidua supporting a placenta and fetus can result in infertility or early pregnancy loss.

Diagnostic Imaging for Uterine Pathology

Uterine abnormalities that have been implicated in infertility include endometrial polyps, submucous fibroids, intrauterine adhesions, mullerian anomalies, prior exposure to diethylstilbestrol (DES), and possibly luteal phase defect. The diagnosis and treatment of these entities may prove crucial to the successful management of the infertile couple. Insofar as it allows assessment of both tubal and uterine pathology, HSG is a reasonable initial imaging technique to use in the basic infertility evaluation. Although HSG has 85% to 100% sensitivity for detecting tubal pathology (228,229), it is only 44% and 75% sensitive in documenting uterine malformations and intrauterine adhesions, respectively (295).

Sonohysterography appears to be superior to HSG in the detection of uterine malformations, correctly identifying 90% of abnormalities in infertile patients (296). These
data are consistent with those observed in patients with abnormal uterine bleeding in the general gynecologic setting, where sonohysterography has sensitivities of 87% and 93% in the detection of intrauterine pathology and endometrial polyps, respectively (297,298). Compared with conventional transvaginal ultrasound, sonohysterography has both higher sensitivity (93% versus 65%) and specificity (94% versus 76%) for the detection of endometrial polyps in the patient with abnormal bleeding (298). The use of contrast medium (i.e., Echovist) at the conclusion of saline sonohysterography was initially developed to afford a sono- graphic assessment of tubal status. When sonographic contrast medium is employed, the study is referred to as hysterosalpingo-contrast sonography, or HyCoSy. A prospective study investigating the use of HyCoSy as an initial screening study in the infertility evaluation of 103 women demonstrated a 90% concordance between this technique and HSG for the detection of endometrial pathology, but only a 72% concordance in the detection of tubal blockage (299).

Office hysteroscopy has been proven to have superior sensitivity (100%) and specificity (95%) in the evaluation of the endometrial cavity (300). In many practices, diagnostic hysteroscopy is the preferred procedure for the diagnosis of uterine pathology in infertile patients. To optimize visualization of the endometrial cavity during hysteroscopy, the procedure should be performed during the early- to midfollicular phase of the cycle. This also minimizes the possibility of pregnancy. Although excellent acceptance of diagnostic hysteroscopy using a 5-mm scope without analgesia has been reported (301), patient tolerance of office hysteroscopy has been optimized by advancements in pain-control medication regimens. The most important benefit to office hysteroscopy is the ability to immediately treat most pathology that is encountered. Significantly, these operative procedures can be performed using electrolyte distention media. Studies have shown success rates of 98% to 100% with office hysteroscopic procedures (302,303).

### Congenital Anomalies of the Uterus

Congenital uterine anomalies may be associated with infertility, spontaneous pregnancy loss in the first or second trimester, or late-trimester pregnancy complications. In women with didelphic, unicornuate, and septate uteri, the rates of spontaneous abortion and preterm delivery are highly increased at 25% to 38% and 25% to 47%, respectively (304). Endometrial dysfunction during the luteal phase may result in infertility, whereas dysfunction occurring after implantation may result in pregnancy loss. Pregnancy outcome in the presence of a uterine anomaly may depend on the location of blastocyst implantation in a particular cycle. This may explain why a woman with a septate uterus might encounter recurrent pregnancy loss after having delivered a term infant. With the exception of a septate uterus, infertility associated with most congenital uterine anomalies is not readily amenable to surgical treatment (305,306). Laparoscopic-guided hysteroscopic septoplasty can decrease significantly the risk of spontaneous abortion in women with septate uteri, and surgical therapy is indicated in patients with known uterine septi who have recurrent spontaneous abortion (307). Indications for surgical correction of congenital uterine anomalies when the presenting symptom is infertility are less obvious. Among seven series of hysteroscopic metroplasties performed for infertility, the overall pregnancy rate after treatment was 48% (307). It is still reasonable to consider surgical management in some infertile patients with uterine septi because septoplasty may maximize the chance of having a live birth by decreasing the associated risks for spontaneous abortion and preterm labor.

### In Utero Exposure to Diethylstilbestrol

Exposure to DES in utero increases a woman’s risk for congenital reproductive tract malformations and obstetric complications, including preterm labor and cervical incompetence (308). In one study, almost 70% of women exposed to DES in utero were noted to have uterine malformations on HSG. The most common malformation was the T-shaped uterus (309). Whether DES-exposed women also have higher rates of infertility remains unclear (310). One investigator reported that decreased fertility in these women was
particularly prevalent when constriction of the upper segment of the reproductive tract was present (311). This question is difficult to study, however, because there is great variation in the degree of congenital uterine, tubal, and cervical anomalies associated with exposure. Furthermore, some abnormalities may promote other infertility factors. For instance, cervical anomalies may promote production of suboptimal cervical mucus, or cervical stenosis may promote retrograde menstruation and the subsequent development of endometriosis. In fact, a recent large prospective cohort study of patients with laparoscopically confirmed disease identified a significantly elevated risk (RR 1.8, CI, 1.2–2.8) of endometriosis among women exposed to DES (312). Overall, when a DES-exposed woman has uterine anomalies on HSG and greater than 1 to 2 years of primary infertility, her prognosis for future pregnancy is extremely poor (313). Metroplasty for correction of T-shaped and hypoplastic DES-exposed uteri has unproven value and is not recommended. Results of IVF treatment are generally poor in infertile, DES-exposed women. Although ovarian response rates to COH are comparable in DES-exposed women and nonexposed women with unexplained infertility, DES exposure is associated with significantly lower implantation rates in IVF (314).

Acquired Abnormalities
of the Uterus

Leiomyomas  Among women with infertility and uterine leiomyomas, many variables may affect pregnancy rates, including leiomyoma size, location, and number (solitary versus multiple) as well as the presence of symptoms associated with these tumors. Leiomyomas have not been shown to be a direct cause of infertility. It has been suggested, however, that uterine leiomyomas might alter uterine contractility and thereby disrupt normal sperm migration. Alternatively, the presence of leiomyomas might adversely affect vascular and molecular profiles of sites of implantation (315). No prospective, randomized trial comparing expectant management with myomectomy in infertile patients with uterine leiomyomas has yet been conducted. However, one recent case-control study compared pregnancy outcomes among 106 women who had laparoscopic myomectomy for fibroids, 106 women with uterine fibroids who did not have surgery, and 106 women who had unexplained infertility but no fibroids. Reported live birth rates were significantly different among the study populations: 42% for the laparoscopic surgery group, 11% for the group with myomas but no surgery, and 25% for the unexplained infertility group (316). A meta-analysis of 12 prospective series involving a total of 138 women who underwent abdominal myomectomy for infertility showed that cumulative postprocedure pregnancy rates at 1 year were 57% to 67%. Not surprisingly, pregnancy rates for those women who had no other factor contributing to their infertility were higher than for women with additional causes of infertility (61% versus 38%). Women who were treated for submucous fibroids had a postoperative pregnancy rate of 70% at 1 year (317). One study reported 24-month cumulative conception rates of 87%, 66%, and 47% in patients younger than 30 years of age, 30 to 35 years of age, and older than 35 years, respectively, after abdominal myomectomy in 138 infertile women (318). The presence of other causes of infertility and duration of infertility were factors associated with worst prognosis, whereas the size, number, or site of fibroids did not affect pregnancy outcomes. Others have reported success rates after abdominal myomectomy that are comparable to the 65% pregnancy rate and 50% live delivery rate reported for laparoscopic myomectomy (319). The success of laparoscopic myomectomy, however, is contingent on a number of factors, including stringent criteria for patient selection and the surgeon’s experience with the procedure. In addition, appropriate closure of the created uterine defect is essential to minimize the complication of uterine rupture during subsequent pregnancy (320,321). In short, both myomectomy and superovulation/IUI are reasonable treatment options for women with uterine fibroids and otherwise unexplained infertility, particularly if the leiomyomas are large, submucous, solitary, or distorting the uterine cavity.
Endometrial Polyps  Even in the absence of abnormal uterine bleeding, endometrial polyps may be discovered in women with infertility. The incidence of asymptomatic endometrial polyps in women with infertility has been reported to range from 10% to 32% (303,322). Because of the influence of circulating estrogen on the development of endometrial polyps, the higher incidence seen in the infertility population may be related to the hyperestrogenemia associated with prior cycles of COH. A recent prospective study of 224 infertile women who underwent hysteroscopy suggested a 50% pregnancy rate achieved with polypectomy (323). Timing hysteroscopic evaluation and treatment immediately before COH has proven benefit (292). In contrast, of 83 patients who were diagnosed with an endometrial polyp during COH for IVF and who underwent hysteroscopy immediately after oocyte retrieval, only 58% had histopathologic confirmation of the diagnosis (324). Although pregnancy rates in these women were similar to those of other IVF patients, spontaneous abortion rates appeared higher in those patients with polyps (324). The threshold of parameters, such as size and number of polyps, at which infertility or miscarriage risk is elevated have not been well described. Nonetheless, the evidence to date indicates that the targeted removal of endometrial polyps to optimize fertility outcomes is prudent.

Intrauterine Synechiae or Asherman Syndrome  About 13% of 78 infertile women scheduled for IVF treatment were found to have intrauterine adhesions when evaluated with diagnostic hysteroscopy (323). Causes of intrauterine adhesions are often iatrogenic, with patient histories typically involving intraoperative or postoperative complications of uterine evacuations for menorrhagia, pregnancy termination, or postpartum hemorrhage. Other causes of intrauterine synechiae include intrauterine infection with pathogens such as schistosoma and mycobacteria. In some Third World countries, tuberculous endometritis may be an important cause of uterine factor infertility (325). Tuberculous endometritis differs from most other types of endometrial infection, and uterine scarring and infertility are significant sequelae even after treatment (326). Because intrauterine adhesions may interfere with embryo implantation, severe forms of Asherman syndrome have been associated with amenorrhea, menstrual irregularities, spontaneous abortion, and recurrent pregnancy loss.

Hysteroscopic resection is the method of choice for the management of intrauterine synechiae. Postoperative prevention of reformation of adhesive disease may involve estrogen therapy alone or in combination with intraoperative placement of an intrauterine device such as a pediatric Foley catheter for 1 week. It is thought that estrogens will rapidly rebuild the endometrial lining after surgery and thereby prevent the development of scar tissue. A typical regimen consists of conjugated estrogen at a dosage of 2.5 mg to 5 mg per day for 1 to 2 months. The surgical management of intrauterine adhesions is reported to be very effective, with pregnancy rates higher than 80% among patients treated for mild to moderate disease (327).

Disorders of Endometrial Function and Luteal-phase Defect  There are few areas of greater controversy in the field of infertility than those surrounding the existence, diagnosis, and treatment of inadequate luteal phase or luteal-phase defect (LPD). The controversy has been fueled by disagreements about both the definition of this entity and the efficacy of its treatment. Although variously defined, most agree that luteal-phase defect is present when two endometrial biopsies show a delay of more than 2 days beyond the actual cycle day in the histologic development of the endometrium (328). The actual cycle day has conventionally been calculated by assigning the onset of the menses following biopsy as day 28 and counting backward to the day of biopsy.

Compromising the reliability of endometrial histology in the diagnosis of LPD are the significant inter- and intraobserver variability in the results of histologic dating (329), the intercycle variation of biopsy results, and debate concerning the proper timing of the
biopsy. In a collection of serial luteal-phase endometrial biopsy specimens from normally fertile women, investigators documented isolated out-of-phase specimens in 31.4% of participants with normal cycles and sequential out-of-phase specimens in 6.6%, suggesting that out-of-phase endometria are common in women with regular cycles (330). Others have reported that the frequency of out-of-phase endometrial specimens among infertile patients is no greater than the rate that would occur by chance alone (331,332).

In light of the discomfort and inconvenience associated with the multiple endometrial biopsies needed to confirm the diagnosis of luteal-phase defect, investigators have attempted to identify alternative markers for the diagnosis of LPD. In addition to delayed endometrial maturation, LPD can also be characterized by histologic asynchrony between endometrial epithelial and stromal compartments. A variety of factors could be responsible for such histologic alterations, including inadequate follicular development, inadequate FSH or LH secretion, hyperprolactinemia, and inadequate progesterone production by the corpus luteum (333).

Although some studies have advocated the use of a threshold luteal-phase serum progesterone level, data that convincingly associate either single or summed midluteal-phase serum progesterone levels with proposed luteal-phase abnormalities are lacking because of the characteristic pulsatile secretion of progesterone (334). Given the concerns over the accuracy of diagnosing LPD, attempts to diagnose this disorder should be confined to infertile patients who lack other identifiable diagnoses and to those in whom treatment specifically directed at luteal-phase defect is being contemplated.

In recent years, a temporal and functional “implantation window” of maximal uterine receptivity has been proposed to occur during the midluteal phase of the human menstrual cycle. Studies of IVF and embryo transfer indicate that the implantation window lasts from day 5.5 to day 9.5 postovulation (335). Using a ratio of urinary estrogen metabolites to progesterone metabolites to time ovulation, the percentage of pregnancy losses associated with implantation on postovulation days 9, 10, 11, and beyond day 11 were 13%, 26%, 52%, and 82%, respectively (336).

Luteal-phase defect has been proposed as a cause of a nonreceptive endometrial environment. Specifically, LPD may result in an aberrant molecular profile within the endometrium, which in turn can adversely affect endometrial receptivity to blastocyst implantation. Given the aforementioned concerns regarding histologic dating, recent studies have been directed toward defining more objective molecular markers of endometrial receptivity. To this end, both the presence of pinopodes and molecular markers, such as the expression of integrins, have been proposed as indicators of uterine receptivity (337,338). Although αβ3 integrin expression and pinopode formation appear to be more reliable markers of the implantation window than histologic dating (339), the clinical utility of testing for their presence is questionable because of the significant intercycle variability and poor reproducibility in their expression (340). The value of αβ3 integrin expression as a predictor of pregnancy outcome has been recently refuted in a cohort of 100 consecutive infertile patients who underwent mid- and late luteal, endometrial biopsy-based histologic dating and immunohistochemistry for αβ3 expression (341).

Current treatments for presumed LPD in infertile patients are empiric and reflect the hypothesis that progesterone insufficiency is causal. Treatment, therefore, involves the administration of vaginal micronized (400–600 mg/day) or intramuscular progesterone (50–100 mg/day) beginning 3 days after documentation of an LH surge. After ART with protocols involving a GnRH agonist, supplementation via vaginal administration may be preferred (342). Progesterone supplementation is typically continued until the first day of the next menstrual cycle or until documentation of a negative serum quantitative hCG
value. If a patient becomes pregnant while on therapy, progesterone is continued until 8 to 10 weeks of gestation. Studies supporting progesterone supplementation for LPD have reported improved pregnancy rates after intervention (343). However, these studies have been small and poorly controlled with varied diagnostic criteria. Therefore, a prospective, randomized trial studying the impact of progesterone supplementation on pregnancy rates and outcomes in infertility patients accurately diagnosed with luteal-phase defect is warranted. Until such a study documents unequivocal clinical relevance, the existence of LPD as an entity will remain controversial.

Infectious Factors

The relationship between subclinical infection and fertility has received considerable attention. Particular interest has focused on two potential pathogens: *Chlamydia trachomatis* and *Mycoplasma* species. The association of chlamydia with PID is well established. Chlamydia is the predominant pathogen detected in about 20% of cases of acute salpingitis in the United States. *Chlamydia* may produce asymptomatic infection in the female genital tract, and it is likely that some women experience silent tubal infection. Despite few if any symptoms, these infections may result in significant tubal damage. A possible link between infection and infertility is suggested by evidence that the prevalence of positive chlamydial cultures may be higher among infertile patients than among controls (344). In a study of 286 women undergoing 344 oocyte retrieval procedures, seropositivity for chlamydia and the presence of bacterial vaginosis were highly associated with tubal disease. Reproductive outcomes of IVF, however, were no different than those of controls (345).

In a study of 771 patients undergoing egg retrieval as part of IVF treatment, the incidence of bacterial vaginosis was 25%. Although their pregnancy rates were not affected, patients with bacterial vaginosis had a significantly higher risk for spontaneous abortion than matched controls, even after adjusting for smoking history, maternal age, the presence of polycystic ovaries, history of recurrent miscarriage, and history of previous live birth (346). It remains to be determined which factors directly caused this increased rate of spontaneous pregnancy loss. Likewise, it is not known whether treatment of bacterial vaginosis before or during IVF treatment would alter the rate of spontaneous abortion.

*Mycoplasma* species are pleuropneumonialike organisms. Both *Mycoplasma hominis* and *Ureaplasma urealyticum* have been recovered from the cervical mucus and semen of infertile couples. There also appear to be higher rates of mycoplasma infection among infertile couples than among fertile couples. The effect of these organisms on fertility is unclear. For example, mycoplasma organisms have been isolated from the cervix of the female partner in 47% of previously infertile couples who conceived and 53% of couples who remained infertile (347). The role of treating these infections in an infertile population also is controversial. In one study, 60% of infertile men who tested positive for ureaplasma and whose infection was subsequently treated by antibiotic treatment impregnated their partners; the rate was only 5% among men whose infection was not treated (348). In contrast, a double-blind study of doxycycline treatment for mycoplasma infection failed to show an effect on conception rates (347). Until a clear association has been established between mycoplasma infection or its treatment and fertility outcomes, routine testing for this organism during an infertility evaluation is not warranted.

Systemic Illness

In general, any severe systemic illness, such as renal failure, liver failure, or metastatic cancer, can lead to disruption of the hypothalamic–pituitary–ovarian axis and cause infertility. However, because sporadic ovulation is always possible, even after a period of
anovulation, use of contraception should be advised if pregnancy is not desired. If a patient
with severe systemic illness wishes to conceive, careful preconceptional assessment and
counseling is advisable because the risks of fertility treatment and pregnancy can be
substantial.

The association of antiphospholipid antibodies, particularly anticardiolipin antibod-
ies and the lupus anticoagulant, with recurrent pregnancy loss led to the investigation
of a role for these antibodies in infertility. These antibodies are more prevalent in the
infertility population (349). However, the presence of antiphospholipid antibodies has
not been found to adversely affect IVF outcomes in a prospective study or in a meta-analy-
sis of seven studies (350,351). These findings do not support a role for the routine
testing of antiphospholipid antibodies in the infertility evaluation.

Unexplained Infertility

The laboratory assessment of an infertile couple is relatively simple and should be
performed rapidly to establish a diagnosis and initiate appropriate therapy (see
Figs. 30.1–30.3). Evaluation of the man by semen analysis in an accredited laboratory
skilled in andrology testing is essential. Ovulation should be documented in women
using over-the-counter ovulation detection kits. If uncertainty surrounding the inter-
pretation of such tests exists, the midluteal serum progesterone level can be assessed to
confirm ovulation. Unless laparoscopic surgery is already planned for some other indica-
tion, tubal obstruction should be excluded using HSG. If laparoscopy is indicated, laparo-
scopic chromopertubation can be performed at the time of surgery. Any previous infertility
investigations should be reviewed and repeated if the results are in doubt. If the basic eval-
uation reveals normal semen parameters, evidence of ovulation, patent fallopian tubes, and
no other obvious cause of infertility, the couple is diagnosed with unexplained infertility.
This diagnosis accounts for up to 30% of couples with infertility (352). In six random-
ized studies of couples with unexplained infertility, the cycle fecundity in untreated
controls was 3.8%, significantly lower than the 25% fecundity rate observed in
normal fertile couples (353).

Role of Diagnostic Laparoscopy

A controversial issue in the management of unexplained infertility concerns the
potential role for laparoscopy in the evaluation of this condition. Previously unsus-
pected conditions that may be detected during laparoscopy include uterine leiomyomas,
peritubal adhesions, and endometriosis. These entities can result in infertility via the
distortion of normal tubo-ovarian relationships. Prospective studies have demonstrated
HSG to be highly sensitive in the evaluation of tubal patency; thus, laparoscopy is not felt
to be necessary to evaluate tubal status when HSG findings are normal. However, retro-
spective studies of laparoscopy in infertile patients reveal abnormal findings in 21%
to 68% of cases after HSG with normal results (354). Although the prevalence of
pathology exposed by laparoscopy is impressive, the value of the procedure depends on
whether it influences treatment decisions or fertility outcomes. In a retrospective review of
the laparoscopic surgical reports of 495 couples planned for IUI treatment, laparoscopy
revealed abnormalities that changed the treatment decision in 25% of cases (355). The
most common disorders encountered in descriptive series include endometriosis (43%)
and peritubal adhesive disease (34%) (354).

Whether laparoscopic management of these disorders enhances fertility outcomes
remains largely uncertain. In the case of peritubal adhesions, a single nonrandomized
study comparing open adhesiolysis versus no treatment showed a significant increase in
the cumulative pregnancy rate at 12 months follow-up (32% versus 11%) (356). Although
laparoscopic adhesiolysis has not been studied, it is expected to similarly restore normal
tubo-ovarian relationships and optimize fertility outcomes. Validation by a prospective
randomized study is warranted.
Endometriosis

The main reason for performing diagnostic laparoscopy in women with unexplained infertility and normal HSG findings is the possibility of identifying and treating endometriosis. The value of diagnosing endometriosis in the absence of tubal obstruction and of its treatment in women with unexplained infertility is an area of considerable debate. It is generally thought that there is a higher prevalence of endometriosis in women with infertility (357). Clinical evidence linking the presence of endometriosis to infertility exists, but the mechanisms remain unclear. In severe stages of endometriosis, distorted anatomy may explain the association. In cases of minimal or mild disease with normal tubo-ovarian relationships, endometriosis is purported to have a deleterious effect on fertility via associated elevations in a variety of cytokines, including tumor necrosis factor. These soluble mediators of inflammation may alter the peritoneal, intratubal, or intrauterine environment and adversely affect fertilization, early embryo development, or implantation (358–360). Data on the effect of endometriosis on ART pregnancy rates indicate either no significant changes or lower pregnancy rates (361–363). The fact that pregnancy rates do not appear to correlate with disease stage (according to the Revised American Society for Reproductive Medicine’s classification of endometriosis) further clouds arguments about the importance of endometriosis diagnosis and treatment among infertile couples (364).

Medical therapies for endometriosis that involve hormonal suppression (e.g., combination oral contraceptive pills, GnRH agonists, or danazol) are generally reserved for the treatment of pelvic pain because these treatments preclude pregnancy. Subfertility associated with endometriosis requires alternative, nonsuppressive approaches. In a prospective cohort trial involving 168 infertile women with minimal or mild endometriosis on diagnostic laparoscopy and 263 women with unexplained infertility, the Canadian Collaborative Group on Endometriosis found that fecundity rates were similar in both populations (18.2% versus 23.7%) during 36 weeks of expectant postoperative follow-up (365). The same group performed a randomized trial comparing 172 women who had ablation or resection of minimal or mild endometriosis with 169 women who were not laparoscopically treated for similar operative diagnoses at diagnostic laparoscopy. Cumulative pregnancy rates were significantly different between treated and control groups at 30.7% and 17.7%, respectively. By 36 weeks of follow-up, fecundity rates were 4.7 and 2.4 per 100 person-months, respectively. The rates of spontaneous abortion (20.6% and 21.6%, respectively) were nearly identical (366). In contrast, the Gruppo Italiano per lo Studio dell’Endometriosi reported that, after 1 year of follow-up, 54 women with otherwise unexplained infertility who underwent resection or ablation of minimal to mild endometriosis had pregnancy rates similar to 47 women whose endometriosis was not treated (24% versus 29%, respectively) (367). It is possible that any improvement in pregnancy rates resulting from ablation or resection of endometriosis has been so small that a very large trial would be required to document posttreatment differences. It is important to interpret these data in a clinically relevant context. Based on the Canadian prospective randomized trial, it is calculated that one pregnancy would result from the laparoscopic treatment of every 7.7 patients with minimal to mild endometriosis (368). Assuming that 30% of couples with unexplained infertility and otherwise negative findings have mild to minimal endometriosis, 25.4 patients would need to undergo laparoscopy to yield one pregnancy that can be attributed to the treatment of endometriosis (368). In summary, although surgery appears effective for the treatment of endometriosis-associated infertility, the inclusion of a laparoscopic examination in the routine diagnostic evaluation of every infertile patient is subject to debate.

In view of the available evidence, it is reasonable to initiate fertility treatment empirically in women with unexplained infertility and normal HSG findings without assessment of the pelvis by diagnostic laparoscopy. This conclusion is based on a number of issues, including the debated value of diagnostic laparoscopy, known surgical
risks of laparoscopy, and proven efficacy of empiric treatment. The optimal timing of laparoscopy is undetermined, and diagnostic laparoscopy can be performed if initial treatments are unsuccessful. If laparoscopy is performed, visible endometriotic lesions should either be ablated or resected. A retrospective study has reported electrocoagulation and resection of endometriosis to have an indistinguishable effect on postprocedure pregnancy outcome (369). The best overall approach to patients with unexplained infertility involves a discussion of the options of empiric therapy or diagnostic laparoscopy and allowing the patient to actively participate in decisions regarding the course of treatment.

Treatment of Unexplained Infertility

As requirements for both diagnostic laparoscopy and prior exclusion of endometriosis become less stringent in the diagnosis of unexplained infertility, the potential impact of this broader definition on treatment efficacy must be considered. In a retrospective analysis, 131 women with more than 2 years of unexplained infertility were managed expectantly while waiting for IVF. Their pregnancy rate was only 0.9% per exposure cycle, whereas a similar group of 119 women receiving IVF treatment had a 17% pregnancy rate per cycle (370). The low spontaneous pregnancy rate in these patients warrants the abandonment of expectant management and the rapid initiation of empiric therapies. These therapies are aimed at increasing the chances of conception by increasing the available numbers and proximity of healthy gametes.

Treatment typically involves superovulation (increasing female gametes); collecting, washing, and concentrating the semen (increasing motile sperm); and bypassing a potential cervical factor using IUI. Superovulation with clomiphene citrate and IUI is usually the initial treatment regimen employed. This therapy is fairly efficacious in many couples with unexplained infertility and is less invasive, less expensive, and associated with fewer complications than other forms of treatment. However, if clomiphene citrate with IUI is unsuccessful after 3 months of treatment, then COH using gonadotropin therapy should be undertaken in conjunction with IUI (COH/IUI). If both these approaches fail to result in pregnancy, IVF or ICSI can be performed.

Clomiphene Citrate and Intrauterine Insemination

The rationale for using clomiphene citrate to increase the fecundity rate in ovulatory women with unexplained infertility is that of superovulation. Use of IUI has become a standard part of the clomiphene citrate regimen in treating these women. The degree of superovulation using clomiphene citrate is mild and most commonly results in the release of two eggs in ovulatory women. This low degree of superovulation limits complications such as multiple gestation, but it also limits efficacy. In fact, multiple pregnancy occurs in only 10% of patients treated with clomiphene citrate, and most of these are twin pregnancies. A meta-analysis of six randomized controlled trials has shown the use of clomiphene citrate in women with unexplained infertility to be superior to placebo in increasing the clinical pregnancy rates per patient (OR 2.37, CI, 1.22–4.62) and per treatment cycle (OR 2.5, CI, 1.35–4.62) (371).

In couples with unexplained infertility, IUI significantly improves fertility outcome when performed in clomiphene citrate–treated cycles. A literature review of eight studies involving 932 cycles revealed cycle fecundity rates of 5.6% with clomiphene citrate alone compared with 8.3% with combined clomiphene citrate and IUI (353). Presumably, IUI bypasses the cervical mucus, which may be suboptimal because of the antiestrogenic effects of clomiphene citrate. However, clomiphene citrate may result in a thin endometrium, for which estradiol administered orally or vaginally improves outcome. In a randomized, double-blind study involving 64 patients with unexplained infertility undergoing superovulation with clomiphene citrate, the addition of ethinyl estradiol (0.05 mg daily for 5 days starting on day 8) resulted in a thicker endometrium and a higher ongoing pregnancy rate (37.5% versus 6.25%) (372).
An alternative to clomiphene citrate is the aromatase inhibitor, letrozole. A prospective randomized trial involving 238 superovulation/IUI cycles in couples with unexplained infertility found that the pregnancy rates are similar for clomiphene citrate and letrozole (8.9% and 11.5%, respectively) (373). However, the rate of spontaneous miscarriage appeared lower in the letrozole group (373). Letrozole is reported to result in a luteal phase endometrium that is in phase and has normal thickness with pinopodes (374). Further, the incidence of a thin endometrial echo on ultrasound (≤5 mm) is suggested to be rare in letrozole cycles when compared with clomiphene citrate cycles (194).

Controlled Ovarian Hyperstimulation and Intrauterine Insemination  IUI is considered a standard adjunct to any superovulation treatment in unexplained infertility. A meta-analysis of prospective, randomized trials comparing IUI and timed intercourse in women with unexplained infertility undergoing treatment with gonadotropins determined that the pregnancy rate is higher with IUI (20% versus 11.4%; OR, 1.84; 95% CI, 1.30–2.62) (375). Given the relative imprecision in the prediction of ovulation, the number and timing of intrauterine inseminations has received considerable study. Traditionally, IUI is timed at 3.6 hours after hCG injection, which is close to the time of ovulation; statistically similar pregnancy rates are achieved when the IUI is timed from 32 to 40 hours after hCG (376). When ovulation detection kits are used, the IUI is performed 24 hours after a spontaneous LH surge. A meta-analysis of six prospective, randomized trials comparing one versus two intrauterine inseminations showed no statistically significant improvement in pregnancy rates with two inseminations (377).

However, a subanalysis by mode of ovarian stimulation revealed that when clomiphene citrate is used, two IUIs were superior to one (15.2% versus 10.3%; \( P = 0.03 \)) in the optimization of pregnancy rates. In the case of gonadotropin-based ovarian stimulation, two IUIs did not demonstrate statistically significant improvement over a single, well-timed IUI.

In a multicenter, prospective, randomized trial involving 932 couples with unexplained infertility, the combination of COH with gonadotropins and IUI proved superior to IUI alone, intracervical insemination (IC) alone, or COH/IC (49). The National Cooperative Reproductive Medicine Network reported that the pregnancy rate was significantly higher in couples who were treated with COH/IUI (33%) than those treated with IUI alone (18%), COH/IC (19%), or IC alone (10%) (49). However, the multiple pregnancy rates also were increased.

Pregnancy rates using IVF have been reported to be higher than those using COH/IUI in the treatment of unexplained infertility (353,378). However, the risks and costs associated with IVF treatment are appreciably higher, making it standard practice to treat these couples with COH/IUI before attempting IVF (353). The question of how many COH/IUI cycles should be attempted before conversion to IVF can be a challenging one, especially because this decision is affected by financial as well as medical factors. The relatively low degree of invasiveness and low costs of COH/IUI must be balanced against the potential decrease in ovarian reserve that can compromise IVF success if treatment is delayed. This is a particularly important consideration for the older, infertile couple. Therefore, it is good practice to recommend, a priori, a maximum number of COH/IUI cycles that will be attempted. This definition of treatment expectations may help to temper reactions to unsuccessful therapeutic interventions and foster a sense of control among patients.

It has been recommended that patients with unexplained infertility experience no more than three to six COH/IUI cycles before therapy is discontinued or changed (379–381). One study recommended a maximum of three trials of COH/IUI, based on the cycle fecundity and cumulative pregnancy rates observed in historical controls involving 594 patients with unexplained infertility. In this study, the investigators reported a mean fecundity rate per cycle of 16.4% and a cumulative pregnancy rate of 39.2% during the first three COH/IUI cycles. Cycles 4 to 6 yielded a mean fecundity rate per cycle of 5.6%.
and a cumulative pregnancy rate of 48.5%, a value only 9.3% higher than the rate achieved with three cycles. Alternatively, a historical control group consisting of 131 patients who failed three cycles of COH/IUI had a cycle fecundity rate of 36.6% in their first attempt of IVF/ICSI treatment (382). Thus, the benefit of continuing COH/IUI treatment beyond three cycles appears to be minimal for patients with unexplained infertility, unless a move to IVF/ICSI treatment is not feasible for the couple.

The low rates of pregnancy in patients with unexplained infertility using COH/IUI beyond three cycles might be an indication that two (or more) subsets of populations of patients with unexplained infertility exist. The fact that a significant proportion of these patients with unexplained infertility will exhibit complete failure of in vitro fertilization of oocytes suggests that some of these couples may have major defects in fertilization (383). The rates of complete failure of fertilization with conventional IVF have been reported to be 11.4% and 17.6% in two studies of couples with unexplained infertility (383,384). The overall pregnancy rate, however, was not increased with the use of ICSI, compared with IVF, in patients with unexplained infertility in a prospective, randomized trial (384). Nonetheless, in this context, IVF might be considered diagnostic in identifying those patients with fertilization defects. Because of their high risk for nonfertilization with conventional IVF protocols, it appears reasonable to offer a split of IVF and ICSI on sibling oocytes within a single cycle for couples with unexplained infertility. This approach would prevent the disappointment and loss of potential pregnancy faced by couples with complete fertilization failure discovered during the first IVF cycle (384).

### Treatment Options

**Gonadotropin Therapy**

Medical preparations of gonadotropins (LH, FSH) can be used to stimulate ovarian follicular development or induce ovulation in the treatment of several conditions:

1. **Ovulation induction in anovulatory PCOS that is resistant to ovulation induction by metformin and clomiphene citrate**
2. **Ovulation induction in hypogonadotropic hypogonadism or pituitary dysfunction**
3. **Superovulation or COH combined with IUI in the treatment of unexplained infertility**
4. **COH in IVF/ICSI**

Exogenous gonadotropins supplement or replace the woman’s own gonadotropins. Functional ovarian tissue is required for successful treatment because the major actions of gonadotropins are directed at the ovary itself. Recapitulating spontaneous ovulatory cycles, FSH and LH are presumed to act in concert to stimulate folliculogenesis; FSH acts primarily on the granulosa cells, and LH acts on the thecal lutein cells. When the follicles grow to a certain size, treatment with hCG typically is given to promote oocyte maturation, induce ovulation, and allow appropriate corpus luteum formation and function.

The key differences in the various preparations lie in the methods of extraction or synthesis of FSH and LH, the proportion of each hormone in the preparation, and the route of administration (Table 30.8). Two prospective, randomized controlled trials that compared hMG and recombinant FSH for ovulation induction in PCOS patients and COH/IUI in patients with unexplained infertility, respectively, found that the type of gonadotropin used did not affect pregnancy rates. However, the cost was significantly higher when recombinant FSH was used (385,386).
The response to gonadotropins varies from person to person. Even the same individual may respond differently to the same gonadotropin regimen in different cycles. Therefore, one of the advantages of using recombinant FSH is an improved batch-to-batch consistency, allowing a more predictable response to the same gonadotropin dosage. However, since the recombinant forms may not elicit optimal response in patients with particular FSH receptor variants, a trial of hMG or highly purified urinary FSH should be considered in patients who have suboptimal response to recombinant FSH. Finally, patients should undergo a full evaluation to ensure that there are no contraindications to gonadotropin therapy (Table 30.9).

Regardless of the indication, regimens involving gonadotropin therapy for ovulation induction or COH follow fairly similar protocols. All include close monitoring of folliculogenesis using transvaginal ultrasonography and assessment of serum estradiol levels. Such monitoring allows informed adjustment of gonadotropin dosages, timed hCG injection and IUI, and most importantly, limitation of complications such as OHSS and multiple gestation. Patient age, ovarian reserve, and infertility diagnosis should be considered in determining the initial gonadotropin dose, the maximum allowable number of follicles, and the speed of ovarian stimulation (or cycle length). Many protocols have been proposed and have in common the key issues involved in gonadotropin stimulation in non-IVF/ICSI cycles.

Baseline Transvaginal Ultrasound Scan

Patients begin therapy on cycle day 2 or 3 after the onset of a spontaneous or induced menses (cycle day 1 is defined as the first day of menses). A baseline transvaginal ultrasound is performed before gonadotropin injections are begun to identify uterine abnormalities such as endometrial polyps, submucosal fibroids, or congenital defects. Hormonally responsive disorders, including endometrial polyps and submucosal fibroids, may not be apparent at this point in the menstrual cycle, when tissues are in a hypoestrogenic state. Therefore, a systematic survey should be repeated in subsequent ultrasound examinations throughout the course of the stimulation protocol (387). The two-hand transvaginal ultrasound technique often allows better visualization over the one-hand technique. This technique combines current technology with the traditional bimanual pelvic examination. The nondominant hand of the ultrasonographer can be used to apply gentle abdominal compression.
pressure to improve the definition of pelvic structures (387). The findings of a thin endometrium (<4 mm) and quiescent ovaries on the baseline scan reflect the hypoestrogenic state of the early follicular phase, which is the optimal state with which to commence treatment. Conversely, a thick endometrium represents endogenous hormonal stimulation above normal basal levels, and further testing should be considered to exclude pregnancy and endometrial hyperplasia.

Unilocular, clear cysts may represent functional cysts or unruptured luteinized cysts. Complex ovarian cysts detected at baseline usually reflect old hemorrhagic corpus luteae and are often seen when the patient has been treated with gonadotropins in the previous cycle. Nevertheless, the differential diagnoses, including endometrioma, benign ovarian tumor, or malignancy, must be considered. The management of ovarian cysts present at baseline is controversial. In 174 prospective, non-IVF, COH cycles, a significantly lower cycle fecundity rate was observed with a baseline ovarian cyst larger than 10 mm (388). Confusion may arise secondary to the findings of several IVF studies that reported no adverse effect on pregnancy outcomes associated with the presence of a baseline ovarian cyst (389–391). However, extrapolation of results from IVF studies to non-IVF, COH cycles is not necessarily valid. Regardless, the issue continues to be debated even among IVF studies (392).

Ovarian cysts seen at the baseline scan tend to resolve spontaneously within 1 to 2 months. Low-dose oral contraceptive pills (OCPs) have a lower efficacy than older, high-dose OCPs in preventing the formation of new cysts (393,394). Because OCPs do not affect the speed of resolution of old cysts, they are not indicated in this setting.

### Starting Dose of Gonadotropin

Gonadotropin dosages can be administered every evening, allowing morning measurements of serum estradiol to reflect the steady state. If the patient has had previous gonadotropin treatment, the starting dose should be based on review of ovarian response in previous cycles. The following guidelines can be used for determining the starting dose of gonadotropins in the first COH or ovulation induction cycle:

- With unexplained infertility, the patient’s age may affect ovarian response, though it may be difficult to predict. Other markers of ovarian responsiveness (i.e., FSH level, antral follicle count) can assist in tailoring the dose. Though no strict guidelines exist, one should always start at lower doses and increase the dose on days 6 and 7, if necessary. For example, a maximum of 75 to 100 IU of gonadotropin per day should be used for women younger than 30 years of age with a normal FSH level, whereas women older than 40 years of age can be started at a maximum of 150 to 300 IU per day.
Anovulatory PCOS patients should start at 75 IU of gonadotropin per day. A smaller dose of 50 IU per day sometimes is necessary to minimize the risk for OHSS.

Patients with hypogonadotropic hypogonadism usually begin with 75 IU per day.

Monitoring and Adjustment of Dosage

The dose of gonadotropins is maintained until day 6 or 7, when the serum estradiol level is first measured to document ovarian response. Transvaginal ultrasound also is performed at this time to determine follicular response.

- If these measurements detect no response, the gonadotropin dosage is increased by 50 to 100 IU per day every 2 to 4 days until a response is evident by rising estradiol levels (or until the maximal dosage is reached). The maximal dosage is usually 450 IU per day because higher dosages usually do not increase ovarian response (395).

- Once an ovarian response is obtained, treatment typically is continued without further increase in dose.

Cycle Progression and Monitoring

Transvaginal ultrasound and serum estradiol measurements are performed every 1 to 3 days to evaluate follicular size, number, and quality. Follicles can be predicted to grow 1 to 2 mm per day after they reach 10 mm, and follicular development is believed to be adequate when maximal follicular diameter exceeds 18 to 19 mm. When hMG is used, the serum estradiol level roughly corresponds to 150 to 250 pg/mL per mature follicle. However, serum estradiol levels may not correlate as closely with the number of mature follicles when recombinant FSH is used. In general, the serum estradiol level can be expected to double every 24 hours if the same dosage of gonadotropins is maintained. Therefore, the main reasons for monitoring the estradiol levels are as follows:

1. To detect missed spontaneous ovulation or premature luteinization, which may be reflected by a drop in serum estradiol levels

2. To identify patients at risk for OHSS:
   - Estradiol levels approaching 800 to 1,000 pg/mL indicate increased risk for OHSS. A decrease in gonadotropin dosage should be considered, and 24-hour monitoring is mandated. Withholding gonadotropin in this situation is referred to as “coasting” and is usually followed by a more than 25% decrease in serum estradiol levels while the follicle numbers and diameters increase. If follicle numbers increase to an excessive level, the cycle should be cancelled (396–398).
   - Estradiol levels in the range of 1,500 to 2,000 pg/mL indicate that treatment should absolutely be stopped because of the high risk of OHSS. All medications should be discontinued, and hCG should not be administered. The patient should be asked to abstain from intercourse until menses occurs because she may spontaneously ovulate. Under these conditions, ovulation and intercourse increase the risk of multiple gestation.

Human Chorionic Gonadotropin Administration

When the largest measured follicle reaches a maximum diameter of 18 to 19 mm or more, 10,000 IU of hCG (Profasi) is administered intramuscularly. Alternatively, recombinant hCG (Ovidrel) can be given at 250 µg subcutaneously (399). Optimal pregnancy rates are achieved with IUI performed at 33 to 39 hours after the hCG injection (376).

Pregnancy Test or Plans for Next Cycle

If menses does not ensue after a treatment cycle, testing for pregnancy should be performed about 15 to 16 days after hCG administration. Testing for serum or urinary levels of β-hCG should not be affected by prior administration of exogenous hCG at this
point, and β-hCG should be detectable by either method. If pregnancy does not occur, the cycle should be reviewed. If appropriate follicle size, number, and estradiol levels have been reached, there is no need to change the gonadotropin dosage. The dosage should be changed if COH was inadequate or excessive. If the length of the stimulated cycle was too short (ie, the follicular stimulation was too fast), endometrial maturation could have been suboptimal, and the gonadotropin dosage should be decreased in a subsequent cycle.

**Special Issues of COH/IUI in PCOS**  PCOS patients represent one of the most challenging subpopulations to treat safely and successfully using COH/IUI. The multiple small ovarian antral follicles characteristic of these patients may be very resistant to stimulation, but they are equally likely to respond and grow with minimal increases in gonadotropin dosage. The incidence of multiple pregnancy and OHSS is increased in these patients (400). Up to 30% or more of COH cycles may be canceled as a result of excessive follicular development. Several approaches that have been proposed to avoid complications of COH and cycle cancellation include downregulation with GnRH agonists, dual suppression with oral contraceptives and GnRH agonists, pretreatment with metformin, and surgical ovarian diathermy (206,401–403).

**Hypogonadotropic Hypogonadism**  Therapy with hMG is most successful in patients with hypogonadotropic hypogonadism, yielding cumulative pregnancy rates of 91.2% after six treatment cycles using hMG alone (404). In this particular group of patients, hMG is recommended over purified FSH for ovulation induction because purified FSH has been associated with a significantly higher total dosage requirement, lower estradiol levels, and decreased number of lead follicles (405). Before ovulation induction in these patients, a baseline transvaginal ultrasound should be performed to determine whether the ovaries appear PCO-like, with multiple small antral follicles, thick stroma, or enlarged ovarian volume. A subset of patients with isolated hypogonadotropic hypogonadism have PCO-like ovaries and respond to gonadotropins much like PCOS patients, exhibiting higher serum estradiol levels and a greater number of follicles (406). Based on this finding, in conjunction with the fact that patients with hypogonadotropic hypogonadism typically are younger and have better ovarian reserve than patients with unexplained infertility, it is prudent to start with small doses of hMG in this population to avoid complications of OHSS and multiple gestation.

**Hypothalamic Failure**  In most patients with acquired hypogonadotropic hypogonadism secondary to cranial surgery or radiotherapy for various cranial tumors, hypothalamic failure is the source of their dysfunctional hypothalamic–pituitary axis (407). In these patients, GnRH stimulation testing and the assessment of endogenous pulsatile LH secretion often can confirm whether the hypothalamic–pituitary axis is intact. Patients with hypothalamic failure and subsequent ovulatory factor infertility represent the best candidates for ovulation induction with GnRH agonists. To mimic physiologic hypothalamic–pituitary interactions, GnRH agonists must be administered in a pulsatile fashion, thereby avoiding the downregulation of the GnRH receptors that accompanies continuous GnRH agonist stimulation. Coexistent growth hormone deficiency or prolactin abnormalities do not affect the efficacy of pulsatile GnRH agonist therapy (407). Because GnRH agonists are degraded rapidly by gastric enzymes (and thus ineffective when administered orally), pulsatile GnRH agonists are administered either intravenously or subcutaneously with a minipump delivery system. Adverse effects of pulsatile GnRH agonist therapy are mainly related to pump function and route of delivery (i.e., phlebitis at the needle site). The intravenous route is superior (408), but it is recommended that women with a history of bacterial endocarditis be offered only subcutaneous therapy.

In hypothalamic hypogonadotropic hypogonadism, normal negative and positive feedback mechanisms of the pituitary are functional upon treatment with pulsatile GnRH agonists. In this situation, pulsatile GnRH agonist therapy simulates normal physiology and offers some advantages over hMG as a treatment for ovulatory infertility. More
than two dominant follicles are seen in only 18.9% of patients with hypogonadotropic infertility who are treated with pulsatile GnRH agonist, and more than three follicles are seen in only 5.4% of patients (409). Because OHSS is a rare occurrence, less intensive monitoring is required during GnRH agonist treatment cycles. Moreover, the risk for multiple gestation approximates that associated with clomiphene citrate therapy—only 8% (409). These are important advantages when compared with gonadotropin therapies. Cumulative pregnancy rates among women with hypothalamic hypogonadism approach 80% after 6 treatment cycles and 93% after 12 GnRH agonist treatment cycles (410), with no documented increase in the rates of spontaneous abortion (411).

The optimal dosing interval for pulsatile GnRH agonist therapy is 60 to 90 minutes, and the usual recommended dosage is 75 to 100 ng/kg/pulse (405,406). Increased dosage of up to 250 ng/kg/pulse has been reported to be required in the successful treatment of a patient with known GnRH receptor mutation (412). With typical regimens of pulsatile GnRH, ovulation occurs on day 14 and can be documented by standard LH testing. Patients treated with pulsatile GnRH usually benefit from luteal-phase support through continuation of the GnRH pump, administration of hCG, or progesterone supplementation.

Assisted Reproductive Technologies

All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined in the United States. In 2000, 73,406 cycles of IVF were performed compared with only 549 cycles of GIFT and 763 cycles of ZIFT (413). Consequently, the following discussion will focus primarily on IVF and ICSI. The typical ART cycle (IVF or ICSI) has the following main components:

- COH using gonadotropins, follicular development monitoring with transvaginal ultrasound, and assessment of serum estradiol levels
- Prevention of premature LH surge and ovulation
- Oocyte maturation using hCG
- Oocyte retrieval
- Fertilization by IVF or ICSI
- *In vitro* embryo culture
- Luteal support or endometrial preparation using progesterone supplementation
- Transfer of fresh embryos with possible cryopreservation of excess embryos
- First-trimester pregnancy monitoring

**Folliculogenesis in the Spontaneous Cycle** In unassisted ovulation, the cohort of follicles destined to begin folliculogenesis in any particular menstrual cycle are recruited in the previous cycle’s luteal phase. By about the middle of the next follicular phase, one of these follicles will become dominant, and further development of this dominant follicle suppresses maturation of other follicles within the selected cohort of that particular cycle. Follicular-phase growth of a single dominant follicle in unstimulated cycles induces a series of hormonally regulated feedback loops, resulting in the midcycle LH surge, which is critical for maturation of the oocyte and ovulation. Progesterone production commences just before ovulation and becomes significantly increased after ovulation. Estradiol production during the follicular phase causes proliferation of the endometrial epithelium. Subsequently, progesterone is critical in the final
maturation of the endometrial glands and stroma required for implantation of the blastocyst. In the presence of successful implantation, the hCG-stimulated corpus luteum serves as the primary source of progesterone until the placenta independently produces sufficient amounts of progesterone by 8 to 10 weeks of gestation.

**Controlled Ovarian Hyperstimulation** Typical use of gonadotropins for COH in ART is similar to the superovulation protocol used in COH/IUI for unexplained infertility. There are several key differences:

- **When the GnRH agonist luteal downregulation protocol is used, ovarian suppression should be confirmed by a baseline transvaginal ultrasound examination showing no ovarian cysts larger than 5 cm (389), a thin endometrium, serum estradiol level of less than 50 pg/mL, and serum progesterone level of less than 1.0 ng/mL.** Ovarian suppression usually is achieved after about 10 days of GnRH agonist therapy. Once ovarian suppression is confirmed, COH using gonadotropins can be initiated.

- **In ART, the aim of COH is to recruit more follicles than in COH/IUI.** Unlike COH/IUI, the risk for multiple gestation under ART regimens is strictly dependent on the number of embryos that are transferred and not on the number of follicles recruited.

- **The prevention of a premature LH surge and ovulation is critical to the success of ART.** Spontaneous ovulation is prevented by the routine use of a GnRH agonist, or more recently, a GnRH antagonist. Because these regimens help prevent a premature surge, slightly greater flexibility can be exercised on the day of hCG administration without affecting the pregnancy outcomes (414).

- **The removal of granulosa cells during aspiration of each developing follicle with ART is believed to decrease the risk of subsequent OHSS (415).** Thus, higher serum estradiol levels and larger follicular sizes are allowed before hCG administration in ART protocols. The risk of OHSS does, however, remain a major concern (416).

**Choice of Gonadotropins** In recent years, improved pregnancy rates have resulted from progress in all facets of ART. Concurrent with improvements in embryo culture and embryo transfer techniques has been the introduction of several generations of gonadotropin formulations. The main focus of these improvements has been directed to increasing the purity of the FSH component in new preparations. As a result, current recombinant FSH preparations contain absolutely no LH and no other protein contaminants. A meta-analysis reported that recombinant FSH improved pregnancy rates when compared with use of purified FSH or highly purified FSH (OR 1.20, 95% CI, 1.02–1.42) (417). The effect of recombinant FSH on the incidence of complications in women undergoing ART has been studied. Several randomized, controlled trials have reported a trend toward an elevated incidence of OHSS with the use of recombinant FSH, although this effect has not reached statistical significance (418–420). Collectively, these results suggest an important role for recombinant FSH in ART regimens. This conclusion is based on its characteristic batch-to-batch consistency and subcutaneous route of administration, its possible superiority in outcomes over other gonadotropin preparations used in typical COH, its documented benefits over hMG in PCOS patients, and the small increase in ART pregnancy rates as determined by meta-analysis.

**Role of Low-Dose Aspirin in ART** By decreasing platelet aggregation and inhibiting vasoconstriction, low-dose aspirin is suggested to increase uterine and ovarian perfusion, thereby enhancing outcomes of IVF and ICSI treatments. A prospective, randomized trial demonstrated that the use of aspirin at a dose of 100 mg/day, initiated at the time of GnRH agonist luteal downregulation and continued throughout COH, resulted in
an improvement in ovarian response, implantation, and pregnancy rates in IVF (421). Consequently, low-dose aspirin has become a standard part of ART protocols in many clinics. However, subsequent prospective randomized studies have yielded conflicting results regarding the impact of low-dose aspirin on pregnancy outcomes in patients undergoing IVF (422,423). Significant complications have not been reported with the use of low-dose aspirin in ART.

Recombinant Human Luteinizing Hormone According to the two-cell theory of ovarian hormone production, stimulation of the theca lutein cells by LH is critical to the overall development of the ovarian follicle. Highly purified FSH contains minimal amounts of LH (less than 0.1%), and GnRH agonist suppresses endogenous pituitary LH and FSH production. Therefore, it has been suggested that supplemental LH might improve folliculogenesis and pregnancy rates when highly purified or recombinant FSH is used for COH in ART. A prospective, randomized trial comparing highly purified FSH and highly purified FSH combined with supplemental recombinant human LH has reported a trend toward lower implantation and pregnancy rates when recombinant human LH was added to GnRH agonist–downregulated ovulation induction cycles (424). Although it is possible that some subset of infertility patients might benefit from recombinant human LH supplementation, the generalized use of this hormone in ART currently appears to be limited.

Prevention of Premature Luteinizing Hormone Surge/Ovulation

GnRH-Agonist Downregulation Regimen The use of GnRH agonist has become standard in ART protocols. It prevents spontaneous ovulation, decreases treatment complications, and allows the control of ovulation to rest exclusively on administration of exogenous medications. Commercial preparations of GnRH agonist consist of decapetides that differ from the endogenous GnRH agonist at 2 amino acid residues. These modifications increase both the half-life and the receptor binding affinities of GnRH agonist. When used in a nonpulsatile fashion, GnRH agonist causes an initial agonist effect that is accompanied by upregulation of GnRH receptors within the pituitary gland. This initial activity may be manifested as increased gonadotropin effects, which are referred to as the flare response. However, continued administration of GnRH agonist downregulates GnRH receptors, resulting in minimal basal production of LH and FSH and no stimulation of the ovarian follicles. Therefore, GnRH agonists induces a quiescent hypothalamic–pituitary–ovarian axis and a menopausalike state characterized by low estradiol levels. Consequently, in addition to rash or skin irritation at the subcutaneous injection site, it is not uncommon for patients using GnRH agonist to experience side effects such as hot flashes and moodiness.

The most commonly used regimen for superovulation in ART is called the long, or luteal, downregulation protocol. In this protocol, GnRH agonist is started in the luteal phase (day 21) of the previous cycle, which minimizes its flare effect and prevents the follicular recruitment that is thought to begin in the luteal phase. The couple undergoing treatment is advised to abstain from intercourse during the cycle before the start of COH; however, concomitant use of GnRH agonist in the presence of an unsuspected pregnancy has not been reported to be associated with increased spontaneous abortion, congenital abnormalities, or pregnancy complications.

Before the adoption of GnRH agonists as a standard part of ART cycles, premature luteinization and spontaneous ovulation presented significant challenges to the success of ART. Prospective, randomized trials indicate that use of GnRH agonist under the long protocol offers many benefits when compared with either no GnRH agonist use or use
commencing in the follicular phase of the ART cycle (called the short, or flare, protocol). Use of GnRH agonist in the long protocol significantly lowered the incidence of premature luteinization and spontaneous ovulation, resulting in a lower rate of canceled cycles (425–427). Significantly more oocytes and embryos were yielded using the long protocol, whereas the rate of OHSS decreased (425,427). For logistical reasons, patients preferred the convenience of the long protocol because it requires less frequent monitoring (428). Most importantly, clinical pregnancy rates (425) and live birth rates per retrieval (429) were significantly higher using the long protocol. The benefits of using the long protocol for administration of GnRH agonists greatly outweigh its disadvantages, which include daily administration (for most preparations, e.g., leuprolide acetate), increased requirement for gonadotropins, and an overall increase in the cost of medication. In a meta-analysis reviewing the efficacy of various GnRH agonist regimens, the authors concluded that the addition of GnRH agonist downregulation to ovulation induction regimens for ART was advantageous (430). They noted an improvement in pregnancy rates and a decrease in cancellation rates with no associated increase in spontaneous abortion rates.

The debate concerning the choice of long or short GnRH agonist protocols was mostly settled by a large, prospective, observational, multicenter study involving 1,244 couples receiving their first IVF or GIFT treatment. Although serum estradiol levels were higher in patients using short protocols, these patients had 11% fewer oocytes retrieved. Further, the clinical pregnancy rate was 35% lower using the short protocol when compared with the long protocol, even after adjusting for factors such as age, infertility diagnosis, IVF or GIFT therapy, and year of treatment (431). Currently, the long GnRH agonist protocol is generally recommended for most patients, and use of the short protocol in ART patients with poor ovarian response has not been proved beneficial (431).

Many other regimens have been suggested for the administration of GnRH agonists in gonadotropin-stimulated cycles. Some of the more commonly used protocols and gonadotropins are summarized in Fig. 30.6 and Table 30.8.

**GnRH-Antagonist Regimen**

New GnRH antagonists (Cetrorelix and Ganirelix) have been developed and approved for use in ART protocols. These agents compete with natural GnRH for binding to membrane receptors on pituitary cells and thus control the release of LH and FSH in a dose-dependent manner. The onset of LH suppression is approximately 1 to 2 hours post-administration depending on the dosage used. This suppression is maintained by continuous treatment, and there is a more pronounced effect on LH than on FSH. An initial release of endogenous gonadotropins has not been detected with the use of GnRH antagonists. Because they avoid the flare effect associated with the use of GnRH agonists, they can be started concurrently with gonadotropins and do not require additional time for downregulation. Typically, the antagonist is administered by daily subcutaneous injection, beginning on cycle day 7 or, more commonly, when the lead follicle reaches 14 mm in diameter (432). Alternatively, the medication may be administered as a single bolus dose on approximately cycle day 8. A Cochrane review of five randomized controlled trials comparing GnRH agonist (long protocol) versus antagonist use in ART cycles showed equivalent efficacy of the two protocols in the prevention of premature ovulation (433). However, there were significantly fewer pregnancies with the GnRH antagonist protocol (OR 0.79, 95% CI, 0.63–0.99). A significant reduction in the incidence of severe OHSS was observed in the antagonist regimen compared with the long GnRH-agonist protocol (RR 0.36, 95% CI, 0.16–0.80).

**hCG Injection**

The injection of hCG induces oocyte maturation before retrieval. The dosage of hCG typically is 10,000 IU given intramuscularly or subcutaneously, or 250 μg recombinant hCG given subcutaneously. Different criteria for hCG injection during COH for ART have been described, but all usually include the presence of one or
two leading follicles with mean diameters larger than 16 to 18 mm, at least two other folli-
cles with mean diameters larger than 14 mm, and serum estradiol levels above defined
threshold levels of 300 to 500 pg/mL. Each IVF center sets site-specific criteria based on
its own experience and pregnancy outcomes. The overall goal, however, is to time the hCG
injection in such a way that the probability of pregnancy is maximized while the proba-
bility of premature ovulation is minimized.

Oocyte Retrieval  Oocyte retrieval typically is performed 35 hours after the hCG
injection. Although historically performed by laparoscopy, laparoscopic oocyte
retrieval has now been replaced by the transvaginal ultrasound-guided approach.
Transvaginal ultrasound–guided retrieval is markedly less invasive than its laparoscopic
counterpart, and the use of ultrasound permits the surgeon to visualize the location of the
needle within each ovarian follicle. Intravenous sedation is commonly used for transvagi-

Because the vaginal canal and wall are traversed while using transvaginal ultrasound–
guided oocyte aspiration, the possibility of iatrogenically infecting the patient or her oocytes deserves
particular consideration. Sterile normal saline usually is used for surgical preparation during
oocyte retrieval. In one prospective, randomized trial comparing sterile normal saline to 1% povidone-iodine for this application, the former had higher associated pregnancy rates while maintaining low infection rates (436). Although the exact mechanism for this finding is unclear, it is hypothesized that contact with povidone-iodine could potentially harm oocytes. Therefore, if povidone-iodine is used, it is recommended that the vagina be lavaged with normal saline after preparation. In addition, routine antibiotic prophylaxis is recommended for transvaginal ultrasound procedures. Such prophylaxis reduces the incidence of postprocedure positive microbiology cultures of embryo catheter tips in 78% of patients undergoing embryo transfer. The importance of this effect is suggested by the fact that lower implantation and pregnancy rates are associated with positive microbial catheter-tip cultures (437).

Performance of the retrieval uses a long, 16- or 17-gauge needle, secured by a guide onto the transvaginal ultrasound probe. The needle is used to traverse the upper vaginal wall and enter into a follicle under direct, real-time transvaginal ultrasound guidance. Follicular fluid is then aspirated into sterile, prewarmed culture tubes. This process is repeated until all the follicles are aspirated. At the end of the procedure, a speculum is inserted into the vagina, and the cervix and vaginal walls are inspected for bleeding. Although transvaginal ultrasound–guided oocyte retrieval is both rapid and minimally invasive, all potential risks, albeit rare, should be clearly explained to the patient before IVF treatment begins. These risks include the following:

- Excessive bleeding, possibly requiring blood transfusion
- Potential needle-induced injury to structures in proximity to the ovaries, including bowel, bladder, and major blood vessels, which may require repair by emergency laparotomy, resulting in an abdominal surgical scar
- Late infectious complications, such as abscesses in the peritoneum, bowel, ovary, or uterus, which may require hospitalization for intravenous administration of antibiotics or surgical interventions. (In the specific case of iatrogenic tubo-ovarian abscess, failure of medical treatment may necessitate surgical removal of the tubes and ovaries.)
- Risks associated with intravenous sedation or general anesthesia
- A remote risk that no oocytes will be obtained or fertilized

**IVF and ICSI**  Fertilization of the human oocyte by human sperm in vivo requires the interaction of capacitated spermatozoa with ovulated oocytes, most often within the ampullary portion of the fallopian tube. Capacitation of sperm takes place in the female reproductive tract and involves both changes in sperm motility and changes in the sperm cell membrane that allow the acrosome reaction. Acrosome-reacted sperm are able to penetrate the oocyte’s cumulus oophorus and zona pellucida, binding to the oocyte cell membrane and promoting fertilization. The interaction of spermatozoa and oocyte is not a chance occurrence; complex oocyte–sperm intercommunications appear to play an important role in this process (438).

The mandate of the ART team is to attempt to recreate precisely those processes known to occur in unassisted conception. In all ART procedures, male gametes are initially collected directly by ejaculation into a sterile cup. They are then processed, concentrated, and incubated in protein-supplemented media for 3 to 4 hours before being used for fertilization. This final incubation allows for sperm capacitation. Before fertilization, retrieved oocytes also are cultured in protein-supplemented media for about 6 to 8 hours. For IVF purposes, 50,000 to 100,000 capacitated sperm are placed in culture with a single oocyte; 16 to 20 hours later, fertilization is documented by the presence of two pronuclei within the developing embryo.

Indications for ICSI are discussed under the section of “Male Factor Infertility.” The procedure itself begins by stripping all granulosa cells from the aspirated cumulus complex.
(oocyte and surrounding cells). This is followed by micromanipulation of egg and sperm under magnification. A holding pipette is used to stabilize the egg while an injection pipette is used to insert a viable sperm into the ooplasm of the egg.

**Luteal Support**  The act of retrieving oocytes and associated granulosa cells may adversely affect subsequent corpus luteal function, resulting in subsequent progesterone insufficiency. Therefore, the requirement for luteal support represents yet another way in which ART cycles differ from COH/IUI protocols. **Luteal support is usually initiated on the day after oocyte retrieval for ART.** Commonly used regimens include the following:

- **Progesterone** in oil 50 mg, once a day, intramuscularly
- **Vaginal progesterone** suppositories, 200 mg twice to three times a day
- **Oral micronized progesterone,** 200 mg twice a day

Despite similar levels of circulating progesterone, the oral regimen is associated with decreased per-embryo implantation rates when compared with use of intramuscular progesterone (439).

**Embryo Transfer**  In unassisted conception, the fertilized oocyte traverses through the fallopian tube for 2 to 3 days before entry into the uterus for implantation. This transport is largely dependent on directional ciliary movement within the fallopian tube, although tubal muscular contractions may be involved (440). The embryo is normally at the morular or early blastocyst stage of development when it reaches the uterine cavity. By this time, and under the influence of luteal-phase levels of progesterone, the endometrium has undergone the decidual changes that prepare it for implantation. **The embryo resides in the intrauterine cavity for 2 to 3 days before implantation. During this period, the zona pellucida detaches, allowing implantation to occur 5 to 7 days after fertilization.**

ART protocols for *in vitro* embryo culture and development attempt to recapitulate the timing and conditions of these events, albeit in an incredibly simplified fashion. The development of sequential media has allowed embryos to be grown *in vitro* up to 5 to 6 days after oocyte retrieval. After *in vitro* development, an embryo or multiple embryos are transferred into the cavity of the uterus. Criteria for embryo morphology—including cell number, symmetry, fragmentation, and granularity—are used in most centers to judge the quality of a particular embryo. However, these methods of assessment do not necessarily correlate well with genetic or embryonic developmental potential (441).

In an effort to better assess and select for transfer those embryos that will result in successful pregnancy, investigators have evaluated the advantages of extending the *in vitro* embryo culture period before transfer. **In vitro** culture to day 5 postretrieval allows the evaluation and selection of embryos at the blastocyst stage. It is likely that this extended culture does, in fact, increase the ability to judge appropriately the quality of an embryo. For instance, grading of the blastocyst according to the morphology of the inner cell mass and trophoderm has been correlated with implantation and pregnancy rates (442). Because of its increased implantation rate, extended embryo culture offers the advantage of limiting the number of transferred embryos while maintaining pregnancy rates. The true value of blastocyst transfer may therefore lie in its potential to decrease the rates of high-order multiple gestation resulting from ART. There appears to be an increased risk for monozygotic twinning of embryos cultured to the blastocyst stage (443), although this finding is currently being debated.

**Pregnancy rates resulting from blastocyst transfer range** between 44% for low-scoring blastocysts and 87% for top-scoring ones. Another predictor of the success rate of day 5 transfer is the number of eight-cell embryos on day 3 (443). Extended culture to
the blastocyst stage (day 5) has been advocated by some to be beneficial for all IVF patients, with overall pregnancy rates of up to 43.8% (442,444). Others recommend it only if there are three or more eight-cell embryos on day 3 of in vitro culture (444). The application of extended embryo culture and blastocyst transfer requires laboratory specialization; therefore, the practice is institution specific.

**Technical Aspects of Embryo Transfer** Despite its theoretic simplicity, transcervical embryo transfer into the intrauterine cavity is a procedure that requires significant skill. Correct performance of the procedure is thought to exert a significant impact on clinical outcome. Apart from the skill and experience of the operator, variables such as aspiration of cervical mucus (445), visualization by ultrasound guidance (446), duration of supine position immediately after embryo transfer (447), and type of bacteria cultured from the transfer catheter-tip immediately postprocedure (448) have all been suggested to affect pregnancy outcomes. Microbial contamination of the embryo transfer is especially relevant because it may be prevented by antibiotic prophylaxis at the time of oocyte retrieval and careful handling of the catheter. Pregnancy rates are reduced by half in women with positive catheter-tip cultures (449).

Many different types of catheters have been used to perform embryo transfers, including hard catheters (Erlangen, Tefcat, Tom Cat, Norfolk) and soft catheters (Frydman, Wallace). The Frydman and Wallace catheters are thought to be less traumatic to the endometrium. However, no catheter has been shown to be definitively superior (450,451).

**In women with a history of tubal disease, the difficulty of embryo transfer has been associated with an increased risk of ectopic pregnancy** (452). The number of transfer attempts, the time required for embryo transfer procedures, and the presence of blood inside the transfer catheter after the procedure do not affect clinical outcomes (453). In a series of more than 800 consecutive embryo transfer procedures, 85.9% were easy, 8.4% were difficult, 3.2% needed to be repeated, and 2.5% required cervical dilation. Technical difficulties, repeated embryo transfers because of retained embryos, and cervical dilation for stenosis did not affect the pregnancy rates in this study (454). The timing of the correction of cervical hindrances to embryo transfer may be important. Specifically, although it markedly facilitated the embryo transfers itself, cervical dilation at the time of oocyte retrieval in patients with a history of very difficult embryo transfer was associated with poor pregnancy outcome (1 in 41 cycles) (455). In contrast, surgical treatment of anticipated problems before commencement of IVF/embryo transfer yields good pregnancy rates. For example, hysteroscopic examination of the cervical canal may reveal a ridge, which can be resected (456). Alternatively, transcervical placement of a Malecot catheter at the time of hysteroscopy has been successful in allowing facile entry into the uterine cavity during subsequent embryo transfer or IUI. The Malecot catheter can be left in place for several weeks after hysteroscopy while the patient is maintained on doxycycline 100 mg twice daily. It is easily removed using gentle traction in the office as the day of embryo transfer approaches (457). Good clinical pregnancy outcomes have been reported for both techniques.

**Cryopreservation of Eggs** The success of modern ovulation induction and fertilization regimens often results in embryos in excess of the number appropriate for transfer in a single treatment cycle. Cryopreservation of these embryos permits embryo transfer to the same patient in unstimulated cycles in the future. Some patients receive cryopreserved embryos during “natural” cycles, whereas other patients undergo endometrial preparation with sequential administration of exogenous estrogen and progesterone. Either regimen is significantly less expensive than a gonadotropin-stimulated cycle. More importantly, the risks of surgical complications and OHSS are nonexistent in cycles using cryopreserved embryos. Therefore, pregnancies resulting from transfer of cryopreserved embryos effectively reduce the costs of pregnancy per ovulation stimulation. Conversely, in cryopreserved cycles, not all embryos survive
thawing, and the pregnancy rates are lower than those using fresh embryos. In transfers of cryopreserved embryos using nondonor eggs (eggs from the intended recipient), 90% of thawing procedures resulted in viable embryos for transfer. The rates of pregnancy and delivery were 22.2% and 20.4%, respectively, for cryopreserved embryo transfer procedures (413).

**Pregnancy Testing and Follow-up of Early Pregnancy** The uncertainties surrounding ART treatment and its outcomes can be highly stressful, and treated couples are understandably anxious to obtain a pregnancy test as early as possible (458). *Serial quantitative hCG levels may be obtained starting on day 16 after oocyte retrieval. Serum hCG levels taken earlier than this day may give false-negative or false-positive results.* The latter may reflect the use of intramuscular hCG to trigger ovulation because this exogenous hCG can be detected for up to 14 days after injection (459). Day 16 serum quantitative hCG levels lower than 50 IU/L are associated with a 35% chance of an ongoing intrauterine pregnancy; levels greater than 500 IU/L are predictive of successful outcome in more than 95% of cases (460). *A single serum progesterone level on day 16 does not provide further prognostic value and is therefore not recommended.*

Patients usually undergo serial serum hCG level assessment early in pregnancy, followed by transvaginal ultrasound at 5 to 6 weeks of gestation to document intrauterine location of the pregnancy and the number of gestational sacs. This is especially important for patients with risk factors for ectopic pregnancy, those who are experiencing vaginal bleeding, and those at high risk for higher-order multiple gestation. In addition, such close follow-up in early pregnancy is both indicated and necessary among ART patients because an ongoing pregnancy requires patients to continue daily self-administration of supplemental progesterone (until the luteal-placental shift at about 9 to 10 weeks of gestation). *Transvaginal ultrasound at 7 to 8 weeks for identification of fetal cardiac activity can provide further reassurance.*

**Success Rates** Success rates of IVF vary from program to program. Within a program, the rates of success vary with the patient’s diagnosis and age. *The most comprehensive assessment of the efficacy of ART programs in North America comes from the database of the Society for Assisted Reproductive Technology (SART) (413).* The society’s data collection began in 1985, and its annual summary is published in an effort to improve the quality of statistical reporting on ART. The database attempts to eliminate the effects of interprogram variation. The most recently published report of the society summarizes the results of ART in the United States and Canada for the year 2000, which are depicted in Table 30.10 (413). *Information on SART and registered ART clinics are accessible by the public at http://www.sart.org.* Significant improvements in overall ART outcomes have been made when compared with previously published results. In 2000, a 29.9% (28.4% in 1997 and 16.8% in 1992) rate of delivered pregnancies was reported per oocyte retrieval for standard IVF, with a cancellation rate of 14.3% (21.7% in 1997 and 15.4% in 1992), a pregnancy loss rate of 16.7% (18.1% in 1997 and 20% in 1992), and an ectopic pregnancy rate of 2.1% (0.9% in 1997 and 1.2% in 1992) per transfer. The delivered-pregnancy rate for cryopreserved embryo transfer was 20.4% in 2000 (18.8% in 1997 and 11.6% in 1992). Although the rates of birth defects did not appear to differ from those of the general population, the SART reporting system was not designed to specifically address this issue.

*The age of the woman proved a significant determinant of success in ART (413)* (Table 30.11). Women aged 41 years and older had a delivery rate per retrieval of only 10.5%. The increase in cancellation rates with age—most likely the result of poor ovarian response—was consistent with significantly decreased ovarian reserve in older women. With the high efficacy of ICSI as a treatment for male factor infertility, the delivery rates per retrieval among couples with male factor infertility were comparable to those achieved in couples without male factor for a given female age group.
Treatment with Donor Oocytes  Women with premature ovarian failure have very few reproductive options. The use of donor oocytes may represent the only proven method by which most of these patients can become pregnant. Other patients to be considered for donor oocyte technology may include those with poor oocyte quality (including some patients with failed fertilization), those with poor ovarian response to stimulation, and those with a history of multiple failed ART cycles. Using embryos fertilized from donor eggs in 418 fresh embryo transfers involving 276 recipients, pregnancy and delivery rates were 36.2% and 29.3%, respectively. The cumulative pregnancy rate after four cycles reached 87.9% (461).

Treatment with donor oocytes is available in many ART programs. **The method of donor selection is an important consideration.** Some patients may wish to find their own donor in a sister or friend. Others may choose to use an agency to identify a donor, who can remain anonymous. Although some ART programs may choose to be excluded from the matching process, most will assume the responsibility of screening the donor for medical, reproductive, and psychological fitness. **Like semen donors, potential oocyte donors must be stringently assessed, including screening for transmittable infectious or genetic diseases.** Unlike semen, however, oocytes cannot presently be cryopreserved and quarantined. Hence, the risk for transmission of infectious agents cannot be completely averted. Moreover, because oocyte donation involves COH, a donor is exposed to the same intensive monitoring and significant potential complications inherent to this intervention. Potential donors must be provided with detailed educational information, and meticulous informed consent is mandatory. In addition to undergoing medical screening, oocyte donors are subjected to a comprehensive psychosocial evaluation before being accepted as program participants. Even with such extensive screening and preparation, there is a significant dropout rate for both anonymous and directed oocyte donors (462). Because many potentially litigious issues arise in the administration of such a program, legal counsel is important in the management of an ovum donation center.

**Considerable coordination is required to ensure that the recipient’s endometrium is appropriately prepared when embryos freshly fertilized from the donor oocytes are ready to be transferred** (463). Regimens for ovulation induction and oocyte retrieval for the oocyte donor follow those of standard IVF protocols (Fig. 30.7). Although the oocyte donor is exposed to many of the adverse effects of COH protocols (OHSS, postoperative pelvic discomfort, surgical and anesthesia risks, and medication side effects), her risk for multiple gestation and ectopic pregnancy can be virtually eliminated if she abstains from intercourse during her stimulation cycle.

To ensure adequate endometrial preparation, many recipients of donor oocytes are taken through a “mock” cycle before their actual treatment cycle. During the mock cycle, all hormonal agents are administered, and endometrial adequacy is documented by timed endometrial biopsies. The impact that the completion of a mock cycle might have on the pregnancy rates of subsequent ART cycles with donor eggs has not been studied in a randomized trial. However, such a cycle allows assessment of important factors such as patient compliance, histologic evidence of endometrial response to exogenous hormones, and the ease of embryo transfer (464). Many regimens for endometrial preparation have been described, although successful pregnancies have also been reported after embryo transfer in natural cycles. **Following is a typical regimen for endometrial preparation in recipients of donor oocytes:**

- If the recipient has no baseline ovarian function, no downregulation or baseline testing is required. However, if the recipient has endogenous ovarian function, GnRH agonist is started on day 21 in the luteal phase of the previous cycle. At onset of menses, downregulation is confirmed by the presence of serum estradiol levels of less than 50 pg/mL or an ultrasound examination documenting absence the of ovarian cysts. Once downregulation is confirmed, the dose of GnRH agonist is reduced.
- Start estradiol administration (Estraderm patches 0.2 mg every 48 hours, or Vivelle patches 0.2 mg every 48 hours, or Estrace 1.0 mg orally once per day).
- Monitor serum estradiol levels every 3 to 7 days and adjust dosage to maintain serum estradiol levels of 150 to 300 pg/mL or continue fixed dose.
- Continue estradiol supplementation for at least 21 days at dosages that maintain these estrogen levels.
- The progesterone start day is scheduled according to the day of embryo transfer (in a therapeutic cycle) or the day of endometrial biopsy (in a mock cycle).
Start progesterone administration, 25 to 50 mg intramuscularly (day 1), then increase to 50 to 100 mg/day intramuscularly the following day.

Discontinue GnRH agonist administration on day 2 of progesterone use.

Mock cycle: Perform endometrial biopsy 10 to 12 days after progesterone is started. Therapeutic cycle: Perform embryo transfer on day 4 of progesterone use.

Measure quantitative hCG 16 days or more after the date of donor oocyte retrieval.

**Figure 30.7** Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient. (hCG, human chorionic gonadotropin; OCP, oral contraceptive pill; GnRH-a, gonadotropin releasing hormone antagonist; TVA, ultrasound-guided transvaginal aspiration of oocytes) (Adapted from Chang PL, Sauer MY. Assisted reproductive techniques. Stenchever MA, ed. Atlas of clinical gynecology, Mishell DR, ed, Reproductive endocrinology. Vol. 3. Philadelphia, PA: Current Sciences Group, 1998, with permission.)
Many controversial issues and much ethical debate surround oocyte donation. Donors’ expectations regarding the process itself, the quality of their medical care, and their level of involvement in decisions can be addressed by a conscientious ART team (465). Other topics, such as methods of donor recruitment and amounts of financial compensation, are much more challenging issues (466,467). Further effort is warranted to help clarify these issues and provide access to this highly efficacious ART treatment.

Complications of Assisted Reproductive Technology

Multiple Gestation

Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications. In recent years, it has been reported that only 20% of higher-order multiple gestations are the result of spontaneous conceptions. The remaining 80% are attributable to reproductive interventions. Of these multiple gestations, one half are attributable to ART and one half to the use of ovulation drugs in non-ART cycles (468). Because the average age of women attempting pregnancy has risen during recent decades and increased maternal age affects the incidence of multiple gestation, rates of higher-order multiple gestation must be adjusted for maternal age when compared over time (469). For decades before 1971, higher-order multiple gestation occurred at a maternal age–adjusted incidence of about 30 per 100,000 live births from spontaneous conceptions (469,470). This incidence rose to 173.6 per 100,000 live births in 1997 (469) (Table 30.12). Because higher-order multiple gestations are predominantly triplets (91.2% were triplets in 1997) (468), this rate represents 6,737 triplets born in the United States in 1997 alone (Table 30.13).

Significant medical risks accompany higher-order multiple gestation. There is an increased incidence of potentially life-threatening obstetric conditions such as acute fatty liver (471) and severe preeclampsia (472). The rate of fetal death during the third trimester is also unacceptably high at almost 17% (473). Obstetrically, triplets are at increased risk for preterm birth, low birth weight (<2,500 g), and very low birth weight (<1,500 g) compared with singletons or twins (474,475). When adjusted for gestational age at birth,

*Per 100,000 live-born infants.

Triplets have the same rates of neonatal morbidity and mortality as twins and singletons (476,477), but triplets typically deliver much earlier. One notable exception is that preterm triplets are at significantly greater risk of severe retinopathy of prematurity, even when they are delivered at the same gestational age as a matched singleton or twin (477). Because of the extensive obstetric and neonatal intensive care required in higher-order multiple gestation pregnancies, enormous expenditures are required to provide medical care to these families (478). Finally, although not fully described, the immediate and long-term emotional and psychological impact on the mother, her partner, and the family unit, including other siblings, is likely to be daunting.

To ameliorate this trend in higher-order multiple gestations, a number of medical and nonmedical causes are being identified. Non-ART COH with gonadotropins is a highly efficacious and commonly used treatment modality for infertile couples. It is significantly less expensive than ART and thereby more accessible to many patients. Unfortunately, it is associated with a 20% incidence of twin gestations and 10% incidence of higher-order multiple gestation (49). Current monitoring protocols for non-ART COH based on assessment of serum estradiol levels and the number of large follicles detected by ultrasound cannot entirely predict the risk for higher-order multiple gestation (479). The risk for higher-order multiple gestation is significantly increased with younger age, peak serum estradiol levels greater than 1,385 pg/mL, and a total number of follicles of seven or more (479). It is difficult to discern the significance of this latter measurement, however, because total follicle number depends on which follicles are measured, and it is unclear what should be the smallest reportable size. Further, a high total number of follicles may result from overstimulation of a patient with normal ovaries but unexpectedly high ovarian response or from treatment of a patient with PCO-like ovaries. Because the prevention and management strategies would differ for these two conditions, further stratification of patients and characterization of the COH cycles may clarify relative risks and direct efforts to more effectively prevent OHSS and multiple gestation. 1250
reduce higher-order multiple gestation in non-ART COH are being explored. None is without cost. One option would promote lowering the dosage of gonadotropins used in COH to aim at a lesser degree of ovarian response. This approach will almost certainly lower pregnancy rates. An alternative would be fewer interventions with non-ART COH and substitution with ART. In ART, the rate of higher-order multiple gestation is determined by the number of embryos transferred, not the ovarian response, which allows greater control of the higher-order multiple gestation rate. This approach would require a dramatic change in the guidelines for insurance company reimbursement of infertility treatments, however, or would necessitate the financing of such treatment by the couple. Currently, there are no accepted criteria guiding when a non-ART cycle should be canceled in an attempt to reduce the risk for higher-order multiple gestation. Informed recommendations for such standardization would be helpful.

More progress is being made toward reduction of higher-order multiple gestation in ART. One approach, discussed under “Embryo Transfer,” would involve broader use of extended embryo culture, in which embryos are allowed to grow to the blastocyst stage in vitro. Blastocysts have been shown to have greater developmental potential and higher implantation rates than day 3 embryos, so that even if fewer (a maximum of one to two) blastocysts are transferred, pregnancy rates remain high (442). Another approach would follow the lead of countries outside the United States that have defined set limits for the maximum number of embryos transferred in a given ART cycle. The American Society of Reproductive Medicine has recently addressed this issue by publishing guidelines for embryo transfer during ART. Briefly, a maximum of two, three, and four embryos can be transferred to women with above-average prognosis (age <35 years), average prognosis (age between 35 and 37 years), and below-average prognosis (age 38–40 years) respectively (480). In donor oocyte cycles, the age of the donor (not the recipient) should be used to determine the number of embryos to be transferred. Data on the efficacy of this protocol are expected to be available in a few years. Others have advocated similarly stringent guidelines, promoting the transfer of a maximum of two embryos in ART cycles to minimize the risk for higher-order multiple gestation (481). Cryopreservation of excess embryos should be encouraged to promote more cycles involving transfer of cryopreserved embryos. Universal application of such changes will force patients and doctors to emphasize cumulative birth rates rather than pregnancy rate per cycle. By focusing on cumulative birth rates, patients can have more realistic expectations, and the demand to have an excessive number of embryos transferred would decrease (482,483). As discussed for non-ART COH, these changes will involve alterations in the entire financial reimbursement structure for ART services. There is no doubt that this approach will present many challenges.

Other factors contributing to the increased rates of higher-order multiple gestation have been identified. It has been suggested that government-mandated annual reporting of clinic-specific pregnancy rates places undue emphasis on pregnancy rate per cycle. This may encourage the promotion of higher pregnancy rates at the expense of higher multiple pregnancy rates. If the goal of infertility therapy is the delivery of a healthy baby, both pregnancy rates and incidence of multiple gestation must be considered in determining treatment efficacy. Financial reimbursement schedules by insurance companies, lack of federal support for IVF research, and insufficient patient education regarding the true risk for higher-order multiple gestation are all being examined (484–487).

On the scientific front, new technologies, such as preimplantation genetic diagnosis, may ultimately eliminate the risk of higher-order multiple gestation. Preimplantation genetic diagnosis is a clinical diagnostic procedure that can be performed on the embryo itself to determine whether a particular genetic abnormality is present before its transfer into the uterus (488). Preimplantation genetic diagnosis has been developed in an effort to improve the chances of having healthy infants in families at high risk for a particular genetic disease. It is most frequently performed using blastomere (a cell from a
day 3 embryo containing six to eight cells) biopsy, followed by genetic testing on the cell obtained. The technique chosen for diagnostic testing depends on the type of genetic defect being investigated. For example, fluorescence in situ hybridization (FISH) can be used to assess aneuploidy, translocation, and other structural chromosomal defects (489). This technique can also be used to exclude transmission of X-linked diseases by identification of X and Y chromosomes, thus allowing transfer of only female embryos (490). Alternatively, familial single gene mutations can be identified by extracting blastomere DNA, followed by polymerase chain reaction, restriction enzyme digest, or sequencing. In a recent study involving 262 ART cycles, the embryos obtained from women with a poor prognosis (characterized by age older than 35 years with previous IVF failures and karyotypic defects) were randomized to preimplantation genetic diagnosis for aneuploidy or a control procedure. Those chromosomes commonly involved in aneuploidies (X, Y, 13, 14, 15, 16, 18, 21, and 22) were assessed using FISH in the study group. Although fewer embryos were transferred in the group undergoing preimplantation genetic diagnosis, higher clinical pregnancy rates (37% versus 27%) and implantation rates (22.5% versus 10.2%) were reported when compared with controls (491). Preimplantation genetic diagnosis may assist in the selection of euploidic embryos, thereby offering tremendous potential in the effort to reduce the risk of higher-order multiple gestation.

As progress is being made to eradicate the complication of higher-order multiple gestation, others have suggested ways to reduce subsequent risks once higher-order multiple gestation has occurred. One option for preventing some of the maternal and fetal complications of higher-order multiple gestation involves the judicious use of selective pregnancy termination or multifetal reduction. Although any higher-order multiple gestation is a candidate for this procedure, the reduction of triplet to twin pregnancies is most common and best studied. Overall, about 14% of triplet pregnancies reduce spontaneously to twin pregnancies after fetal heart activity is documented on transvaginal ultrasound at 8 to 9 weeks of gestation (492,493). Although some studies have not found multifetal reduction to result in significant improvement in gestational length or intrauterine growth restriction (493,494), many centers have reported improved outcomes after reductions to twin gestations. Twin gestations after reduction have similar outcomes when compared with spontaneous twin gestations (495,496). Reduction of triplet to twin gestation has been reported to increase the risk for preterm birth (497), low birth weight (497), preeclampsia (496), and delivery before 36 weeks (496). Specifically, the rates of preterm birth before 28, 32, and 34 weeks of gestation, as well as birth weights of less than 1,000, 1,500, and 2,000 g, were significantly lower in twins after reduction from triplet pregnancy compared with triplets who did not undergo reduction (498). However, any benefits achieved for newborn health often incur tremendous emotional, psychological, and physical costs. The major complications of fetal reduction include a 13% risk for premature rupture of the membranes for triplet to twin reduction (499). There is a 5% to 10% risk of losing the entire pregnancy (500) after reduction has occurred. Further, major depression occurs in 80% of women who lose the pregnancy as a complication of fetal reduction and in one third of women who have live twins after fetal reduction (501).

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome is a medical complication that is both completely iatrogenic and unique to the treatment of infertility. Although the pathophysiology of OHSS is not well understood, the signs and symptoms of this disease can be attributed to local and systemic increase in capillary permeability. These changes, in turn, result in the depletion of intravascular volume at the expense of third-space fluid accumulation.

Ovarian hyperstimulation syndrome has been directly associated with increasing numbers of stimulated follicles and retrieved oocytes (502,503), the presence of PCOS (504–506), and high serum estradiol levels (502,507,508). Despite these associations,
however, hyperestrogenemia is not currently thought to be the main cause of OHSS (509–512). Rather, the increased production of vasoactive substances—such as prorenin, renin, angiotensin-converting enzyme, angiotensin I, angiotensin II, and angiotensinogen—by the hyperstimulated ovaries has been implicated (513–521). Still, it remains possible that hyperestrogenemia, especially in the presence of hemoconcentration, has important effects on the thromboembolic risks demonstrated with OHSS.

Inflammatory responses are certainly present in OHSS patients, with possible roles for cytokines, histamine, and prostaglandins in the disease pathogenesis (522–524). In particular, the link between vascular endothelial growth factor (VEGF) and OHSS has been extensively studied. Vascular endothelial growth factor has been shown to exhibit a dose-related expression in human granulosa cells upon stimulation by hCG (525). Further, serum VEGF levels correlate with OHSS severity (526,527) demonstrating a sensitivity and specificity of 100% and 60%, respectively (527). The central role of an inflammatory response is supported by a number of other findings. For instance, mast cells are abundant in ovulatory follicles (528), and histamine blockade has been reported to ameliorate and, in some cases, even prevent OHSS in animal models (523,529). Furthermore, it is clinically well recognized that allergy or hypersensitivity act as risk factors for the development of OHSS (502). To date, however, scientific evidence for these factors is still considered preliminary, and further investigation is warranted to clarify their true role in OHSS (512).

Recently, a distinction between early- and late-onset OHSS has been described (530). Early OHSS, with onset arbitrarily set within 9 days of oocyte retrieval, is associated with higher serum estradiol levels and follicle numbers during COH. In contrast, late OHSS has onset more than 9 days after oocyte retrieval. Late-onset OHSS has been associated not with measures of follicular response, but with multiple gestation. Early and late OHSS may even reflect somewhat distinct pathophysiological mechanisms. It has been proposed that early OHSS may result from ovarian stimulation by the exogenous hCG given to trigger ovulation, whereas late OHSS may be more closely linked to the endogenous hCG produced when pregnancy ensues (530).

Ovarian hyperstimulation syndrome has a varied spectrum of clinical presentation. An attempt to better understand this heterogeneity led to the development of a staging system for OHSS that would reflect symptom severity. This classification categorizes patients according to mild, moderate, and severe disease (531). In mild OHSS, patients often report mild abdominal distention and soreness, nausea, and vomiting. Ovarian enlargement can be 5 to 12 cm. Moderate disease is marked by the presence of abdominal ascites on ultrasound examination. Severe disease is diagnosed when there are clinical signs of tense ascites, hydrothorax, shortness of breath, hemoconcentration, hypercoagulability, or any complications of OHSS such as renal failure, thromboembolism, or acute respiratory distress syndrome (ARDS).

This classification may serve as a useful guide; however, its application may sometimes be misleading. For example, ovarian enlargement is common after COH and, by itself, is not informative. Furthermore, many patients experience mild pelvic soreness and abdominal bloating after COH, and their ovaries may be enlarged when viewed on transvaginal ultrasound. Whether these patients reflect an abnormal response to COH or merely represent a subset of normal responders is debatable. The fact that reported incidence of OHSS after COH has ranged from 7.3% (mild or moderate disease) and 4.2% (severe disease) to 33% overall may suggest that the staging system is itself open to interpretation (502,531).

Management of OHSS Patients undergoing COH with or without ART should be educated about the signs and symptoms of OHSS. They should be instructed to contact their health care provider if they experience abdominal bloating, abdominal discomfort or pain, early satiety, nausea, vomiting, decreased urine output, or weight gain of more than 2 lb per day. Patients with these initial symptoms should be fully assessed to establish their
baseline condition for future comparisons, if that should become necessary. Pertinent points in the assessment of patients with OHSS are as follows:

**History:**

- Age, history of OHSS in previous infertility treatment, history of PCOS
- Characteristics of COH (dose of gonadotropins, number of follicles, number of eggs for an ART cycle, peak serum estradiol level, date of hCG administration, date of oocyte retrieval, date of embryo transfer, number of embryos transferred at embryo transfer)
- Onset of symptoms, their progression (stable versus rapidly worsening), and their severity

Specific questions should address the presence of the following symptoms:

- Abdominal discomfort, pain, bloating; increased abdominal girth; early satiety
- Shortness of breath, chest pain
- Nausea, vomiting
- Weight gain (total amount gained since start of COH and pounds gained per day)
- Decreased urine output

A complete physical examination should be performed, with specific attention to the following areas:

- Signs of hypotension, hemodynamic instability, and dehydration
- Chest: evidence of pleural edema or effusion, congestive heart failure, limited chest expansion because of ascites
- Abdomen: ascites (mild, moderate, tense), peritoneal signs
- Peripheral exam: pitting edema
- Pelvic exam is contraindicated because enlarged ovaries can be fragile and prone to torsion

The following investigations should be performed:

- Complete blood count, prothrombin time, partial thromboplastin time, serum electrolytes, liver function tests, creatinine, blood urea nitrogen
- Chest x-ray if there is significant shortness of breath or abnormalities on chest exam (shielding the pelvis can protect potential pregnancy from irradiation)
- Transvaginal ultrasound to document the baseline amount of ascites and size of ovaries
- Documentation of oxygen saturation is indicated if there is evidence of respiratory compromise
- Serum hCG on day 16 after oocyte retrieval if embryo transfer has occurred

This initial assessment should enable the clinician to decide whether the patient with OHSS needs to be admitted to the hospital for observation and supportive care. Accepted indications for hospitalization include inability to tolerate oral hydration,
hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation. If the diagnosis and its severity remain in doubt after initial assessment, it is reasonable to observe patients overnight while further assessing fluid balance and the presence of oliguria. The need for more prolonged hospitalization often becomes rapidly evident. The presence of peritoneal signs, such as abdominal rebound tenderness or guarding, in a patient with possible OHSS may indicate ovarian torsion, hemorrhage, or rupture of enlarged ovarian cysts. These signs may also represent those rare cases of post-ovocyte retrieval tube-ovarian abscess. Admission to the hospital is mandatory, and admission to an intensive care setting should be seriously considered, if the patient has complications of OHSS such as renal failure, ARDS, thromboembolic disease, or severe hydrothorax.

The onset of OHSS soon after hCG administration or oocyte retrieval is associated with an increased risk for progression to severe disease. Pregnancy is also known to cause worsening of OHSS, most likely as a result of ovarian stimulation by endogenous hCG. Therefore, in cases of very early-onset OHSS, the benefits of withholding embryo transfer, cryopreserving these embryos, and performing embryo transfer in a future unstimulated cycle should be considered and discussed.

**Outpatient Management** If outpatient management is appropriate, the patient should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L/day of mostly electrolyte-balanced fluid) and output. Daily follow-up by telephone or visit is important because the severity of OHSS may change at any time. The patient should contact her health care provider if she notes worsening of the symptoms or if her weight gain increases to more than 2 lb per day. Reassessment is indicated in these situations.

**Inpatient Management** Inpatient management of patients with OHSS involves meticulous monitoring of vital signs and fluid balances as well as supportive care. This care includes use of intravenous hydration and prevention of complications such as thromboembolic prophylaxis, although more invasive interventions, such as paracentesis, may become necessary. Following is a typical inpatient protocol used for management of patients with moderate to severe OHSS:

The initial assessment should be performed as outlined previously, accompanied by the following assessments:

- Vital signs (including oxygen saturation monitoring if respiratory compromise is present) every 4 hours initially
- Fluid intake and output measurements
- Daily weights and abdominal girth
- Daily hematocrit, leukocyte count, serum electrolytes, renal function tests
- Liver function tests, prothrombin time, partial thromboplastin time obtained on admission and repeated as necessary

**Supportive Care:**

- If hypotension or oliguria is present, a bolus of 1 L of normal saline should be given over 1 hour then maintained with D5 normal saline (or D5/2 normal saline) at 150 mL/h. If hypotension or oliguria is not present, but the hematocrit is greater than 45%, maintenance with D5 normal saline at 150 mL/h should be initiated. The maintenance rate for intravenous fluids can be lowered if the hematocrit is normal. Although administration of intravenous fluids will certainly lead to
an increase in third spacing, it is important to maintain adequate intravascular volume and urine output. The hematocrit may need to be monitored twice a day initially; the intravenous fluid maintenance can be titrated downward as the hematocrit normalizes. This should help to minimize third-spacing side effects. Lactated Ringer’s solution should not be used for intravenous hydration in patients with OHSS.

- **If oliguria persists, a small bolus of 250 to 500 mL of normal saline can be given to increase urine output.** The efficacy of albumin (or other plasma expanders) in the treatment or resolution of OHSS has not been studied in a prospective, randomized fashion. However, it is reasonable to attempt gentle diuresis in a patient who has normal blood pressure and hematocrit but in whom oliguria or weight gain persists. Diuresis may be accomplished using sequential administration of 50 mL of 25% albumin followed by furosemide, 10 mg given intravenously. This combination can be repeated 3 to 4 times per 24 hours as necessary. Serum sodium, potassium, and creatinine must be monitored closely when employing albumin or furosemide diuresis.

- **Small amounts of fluid can be taken orally.** As the OHSS improves, the amount of intake can be increased as the intravenous fluid maintenance decreases. During the resolution of OHSS, a maximum total input of 1 L/day has been recommended to prevent increases in third spacing (512).

- **Paracentesis is indicated if the patient has severe abdominal discomfort and respiratory compromise caused by large volumes of ascites.** Hydrothoraces have also been reported to resolve after paracentesis. The presence of massive ascites, combined with persistent oliguria or hypotension despite medical therapy, is also an indication for paracentesis because diuresis often results after the severe abdominal pressure is relieved. Both abdominal paracentesis under ultrasound guidance and transvaginal ultrasound-guided paracentesis are acceptable practices (532,533).

- **If embryo transfer has already been performed or is scheduled, progesterone supplementation should be given as indicated by the ART protocol.** Administration of progesterone is not thought to affect OHSS adversely. However, pregnancy may cause worsening of OHSS as a result of the stimulation of the ovaries by increasing levels of endogenous hCG.

- **Antiemetics and analgesics (i.e., acetaminophen) can be given to relieve symptoms.**

- **Complications of OHSS, such as ARDS, thromboembolism, and renal failure, should be treated in an intensive care setting when indicated.**

**Preventative Measures:**

- **Hemoconcentration and severe leukocytosis are considered risk factors for thromboembolic disease in patients with OHSS** (512). Therefore, heparin, (unfractionated or low molecular weight) should be considered for all patients with OHSS to prevent thromboembolism. In addition, vascular support stockings should be used in ambulatory patients. Intermittent compression stockings should be used for patients who are not ambulating.

**Prevention of OHSS** Because OHSS can potentially cause severe and sometimes life-threatening complications, prevention is an essential consideration. When high estradiol levels (>3,000 pg/mL) are noted before hCG administration, prevention of OHSS can be attempted by coasting. Coasting involves withholding gonadotropin and delaying hCG until serum estradiol levels decrease or follicular diameter of greater than or equal to 18 mm is seen on transvaginal ultrasound (396–398). Coasting does not completely prevent severe OHSS or cycle cancellation, but it does minimize the risk for severe OHSS.
while maintaining high pregnancy rates. An alternative strategy to minimize OHSS risk involves cryopreservation of embryos at the pronucleate stage and transfer of thawed embryos in a subsequent cycle using endometrial preparation without COH. The strategy of cryopreservation results in excellent pregnancy and live birth rates comparable to similar cycles with fresh embryo transfer. The incidence of severe OHSS appears to be reduced, but more importantly, the duration of severe OHSS may be shortened when cryopreservation strategies are used (534–536).

Unfortunately, even with close monitoring and use of the lowest possible doses of gonadotropins during COH, it still may prove difficult to prevent OHSS. A novel strategy that may remedy these difficulties involves the \textit{in vitro} maturation (IVM) of oocytes. Using IVM, immature follicles are aspirated and the retrieved oocytes are grown \textit{in vitro} until mature. This is potentially advantageous because IVM completely obviates the need to stimulate the ovaries with gonadotropins. Once ICSI is performed on IVM oocytes, embryos are transferred to the uterus, which has been hormonally prepared. \textit{In vitro} maturation is particularly applicable to women with PCOS, who have a known increased risk for OHSS and whose ovaries are characterized by multiple small follicles that can be aspirated in the absence of stimulation. \textit{In vitro} maturation has been reported to yield pregnancy rates of 27.1% to 38% in women with PCOS (537–539). However, data on long term effects on fetal and postnatal development are not yet available.

<th>Ectopic and Heterotopic Pregnancy</th>
</tr>
</thead>
</table>
| \textbf{The incidence of ectopic pregnancy is 2\% in the general population} (540). However, \textbf{its incidence is increased after ART and can be as high as 4\%} (541). The timing of embryo transfer (cleavage stage versus blastocyst stage) does not appear to influence the incidence (542). The main risk factors for ectopic pregnancy in IVF treatment are tubal factor infertility and, possibly, previous myomectomy (541). \textbf{The incidence of heterotopic pregnancy, which is normally rare, is particularly high (1\%) after IVF treatment}. Multiple gestation and high hormonal levels during COH and early pregnancy have been suggested as possible causes. \textbf{It is important to have a high index of suspicion for the occurrence of heterotopic pregnancies because only 40\% to 84\% of cases can be diagnosed with transvaginal ultrasound at the initial presentation} (543,544). After treatment of the heterotopic gestation with laparoscopy, laparotomy, or ultrasound-guided injection of potassium chloride into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is 66\% (543).

<tr>
<th>Risk of Cancer after Fertility Therapy</th>
</tr>
</thead>
</table>
| \textbf{The possibility that ovulation-inducing medications might promote the development of cancers of the reproductive tract, specifically with regard to ovarian cancer, was introduced in the early 1990s} (545). One theory behind this proposed risk is that ovarian cancer may arise, in some cases, as the result of damage to the ovarian epithelium during ovulation. Lactation, oral contraceptives, late onset of menarche, early menopause, and multiparity are known to protect against ovarian cancer. Moreover, each is associated with a reduction in the total lifetime number of ovulatory cycles. The lower risk of ovarian cancer in women with increased length of anovulation raised the question of whether dramatic increase in the number of eggs ovulated during superovulation therapy would, in turn, increase the risk of ovarian cancer. Alternatively, some believe that because gonadotropins (FSH and LH) increase cellular proliferation and division within ovarian follicles, their use might create a predisposition to cancer. Both of the most common hormonal therapies used for induction of ovulation—\textit{clomiphene citrate} and \textit{exogenous gonadotropins}—result in increased gonadotropin stimulation of the ovary. These therapies might, therefore, increase the incidence of ovarian cancer in treated infertility patients. Concern about this potential risk for cancer after fertility therapy has also been extended to other organs, including the uterus and breast.

Currently, several factors prevent an accurate calculation of the true risk for developing cancer of the breast, uterus, or ovary after treatment with ovulation-inducing agents. First, contemporary fertility treatments and their dosages remain relatively new and are usually
used in women younger than 40 to 45 years of age. Because ovarian, uterine, and some breast cancers typically occur in older women, the number of patients who were treated with fertility drugs and are now in their middle to late 60s may still be too small to detect elevations in cancer risk. Second, it is hard to differentiate the effect of fertility treatment from the effect that being infertile itself might have on future development of malignancies of the breast, uterus, or ovary. Finally, most of the studies addressing these risks are clouded by small numbers, intake of a variety of medications, and recall bias. All these factors make the interpretation of data difficult (546).

Two of the more recent studies failed to attribute an increased risk for breast, uterine, or ovarian cancer to medications used for superovulation in the treatment of infertility (547,548). One study evaluated more than 20,000 women with exposure to fertility drugs used for IVF and compared them with nearly 10,000 infertile controls. The authors reported no overall increased incidence of uterine, breast, or ovarian cancers in women exposed to medications used for IVF (548). Two other interesting findings represent some of the limitations to these types of studies. The authors reported that the risk of ovarian and uterine cancer was higher in women with unexplained infertility, regardless of whether they had received ovulation induction medications. This may suggest risks associated with the unexplained infertility itself, or the possibility of undiagnosed cancers causing infertility. In addition, the authors reported an increase in the risk of breast and uterine cancer only within the first year after receiving infertility medications for IVF. Patients undergoing IVF are followed closely and may, therefore, be more likely to report early signs or symptoms of these cancers to their physicians. Alternatively, rather than causing these cancers, fertility medications may only stimulate the growth and subsequent diagnosis of pre-existing tumors.

Psychological Support

Stress, as manifested by anxiety or depression, is thought to be increased in women experiencing infertility. The relationship between stress and infertility is complex and may represent a vicious cycle in which infertility results in stress, which results in further difficulty in conceiving (549–551). Results from a recent prospective, randomized trial support the value of group cognitive-behavioral therapy among infertile couples (552). This therapy uses a variety of approaches, including relaxation training such as yoga, cognitive restructuring, methods for emotional expression, and information on nutrition and exercise with respect to infertility. Although the mechanism by which relaxation therapies aid fertility is unknown and issues such as high dropout rates need to be addressed by further research, the option of psychological support and counseling, on an individual or group basis, should be offered to patients experiencing infertility (553).

Other Considerations

One of the most important aspects of the treatment of patients with subfertility or infertility is the process of deciding when no further treatment will be pursued. This crucial topic must be addressed early in infertility therapy. Patients must be accurately informed of estimated success rates and reasonable expectations for all therapeutic interventions. It is equally important to identify an end point to medical intervention at the outset of treatment. This end point offers patients a mental time frame in which they can make both medical and personal decisions. One viable alternative for many couples is adoption, although the process of adoption has become increasingly complex. Many patients may want to simultaneously explore infertility therapy and adoption. The choice of which course to pursue is a very difficult decision that may be facilitated by both physician input and strong psychosocial counseling and support.

Preservation of Fertility in Cancer Patients

Aside from helping subfertile couples build families, technologic advances in tissue and gamete cryopreservation, in combination with ART, have made future fertility possible for some men and women who are faced with surgery, radiotherapy, or chemotherapy for
Sperm cryopreservation has become a widely available option to allow fertility preservation in young men whose cancer treatment may render them infertile. The wide range of neoplastic disorders for which sperm cryopreservation have been successful include leukemia, lymphoma, Hodgkin’s lymphoma, non-Hodgkin’s lymphoma, and testicular cancer (554). Although most patients with these disorders are systemically ill and therefore exhibit decreased total motile sperm counts when compared with patients who do not have cancer, fewer than 20% have azoospermia, and cryopreservation is possible in most patients (554). Further, cryopreserved sperm from cancer patients tolerate thawing as well as samples obtained from patients without cancer (555).

Unfortunately, the efficacy of oocyte cryopreservation lags behind that of sperm preservation. Married women who are scheduled to undergo sterility-inducing cancer treatments may take the option of completing an IVF cycle so that oocytes can be cryopreserved for transfer later in life. However, an IVF cycle may require 2 weeks to complete, rendering this option unrealistic for patients in whom a delay in cancer treatment would compromise their prognosis. Even patients who are able to undergo IVF treatment usually do not have the time necessary for use of a downregulation protocol. Consequently, these women are usually prescribed the shorter, flare protocol, which may give suboptimal response (431). Use of GnRH antagonists may offer a special advantage in this situation. These agents can induce hypothalamic–pituitary downregulation after being started on day 6 of gonadotropin treatment, which obviates the need for the more time-consuming use of GnRH agonists (556).

Patients who are single or who have medical contraindications to IVF treatment may be candidates for ovarian tissue cryopreservation. Ovarian cortical biopsy specimens containing numerous primordial follicles have been successfully retrieved by a laparoscopic approach in healthy volunteers and in cancer patients (557–559). It remains to be determined whether this promising technology creates a risk for reintroduction of malignant cells after autotransplantation of ovarian tissue and whether thawed immature oocytes should be used in in vitro maturation protocols.

Recurrent Pregnancy Loss

Laura Fox-Lee
Daniel J. Schust

• Isolated spontaneous pregnancy loss is remarkably common. Recurrent pregnancy loss (RPL) affects between 1 in 300 and 1 in 100 couples.

• After several pregnancy losses, the chance of having a viable birth is greater than that of having another loss, even without treatment. Prognosis can improve dramatically with treatment of a known underlying cause of RPL.

• Parental chromosomal abnormalities and antiphospholipid antibody syndrome (APAS) are the only undisputed causes of RPL. Other well-described causes include anatomic, endocrine, thrombotic, and possibly other immunologic factors.

• The state of coagulability is a fine balance between pro- and antithrombotic pathways. The hypercoagulability of pregnancy can be largely attributed to increases in prothrombotic factors and decreases in those that inhibit coagulation.

• The immunologic interactions at the maternal–fetal interface reflect the presence of unique cellular constituents combined with the actions of steroid hormones, protein hormones, and metabolic factors.

• Evaluation of patients with RPL should include a detailed patient and family history, an examination focusing on endocrine and anatomic abnormalities, and laboratory studies limited to evaluating treatable etiologies.

• Early pregnancies in patients with RPL should be monitored with ultrasound examinations, assessment of β-human chorionic gonadotrophin (hCG) levels if indicated, and frequent visits with psychological support. In the event of pregnancy loss, tissues should be obtained for karyotype analysis.

• In treating RPL, there is evidence to support repairing anatomic abnormalities, correcting pre-existing endocrine disorders, and treating APAS and other thrombophilic disorders.
Advances in the ability to document and diagnose early pregnancy have revealed that spontaneous pregnancy loss is a common event. Spontaneous pregnancy loss is, in fact, the most common complication of pregnancy. Approximately 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period (1). Most of these pregnancy losses are unrecognized. Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31% (2). Of pregnancies that are clinically recognized, loss occurs in 15% before 20 weeks of gestation (from last menstrual period) (3,4).

Traditionally, recurrent abortion has been defined as the occurrence of three or more clinically recognized pregnancy losses before 20 weeks from the last menstrual period. Using this definition, recurrent pregnancy loss (RPL) occurs in approximately 1 in 300 pregnancies (2). Clinical investigation of pregnancy loss, however, may be initiated after two consecutive spontaneous abortions, especially when fetal heart activity is identified before any of the pregnancy losses, when the women is older than 35 years of age, or when the couple has had difficulty conceiving. If clinical intervention is undertaken in the form of investigation after two spontaneous abortions, approximately 1% of pregnant women will require evaluation (3). Even with a history of RPL, a patient is more likely to carry her next pregnancy successfully to term than to miscarry. For patients with a history of RPL, the risk of subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses (5). These data make clinical study of RPL and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.

Etiology

Parental chromosomal abnormalities and thrombotic complications of the antiphospholipid antibody syndrome (APAS) are the only undisputed causes of recurrent abortion. However, collectively these abnormalities account for less than 10% to 15% of RPLs. Although the exact proportion of patients diagnosed with a particular abnormality may vary among the populations studied, other associations have been made with anatomic abnormalities (12%–16%), endocrine problems (17%–20%), infections (0.5%–5%), and immunologic factors, including those associated with the APAS (20%–50%). Other miscellaneous factors have been implicated and account for approximately 10% of cases. Even after a thorough evaluation, however, the potential cause remains unexplained in about one third to one half of cases (3,6) (Table 31.1).

Genetic Factors

The most common inborn parental chromosomal abnormalities contributing to recurrent abortion are balanced translocations (7–9). In balanced translocations, one parent carries an overall normal gene content but has a piece of one chromosome inappropriately attached to another. Depending on the nature of the translocation (reciprocal or Robertsonian), the gametes produced by the translocation carrier will be normal (reciprocal only), balanced, or unbalanced for the translocated DNA. If fertilized by a chromosomally normal gamete, the resulting embryo may be chromosomally normal (reciprocal only) or may be a balanced or unbalanced carrier of the translocation. Most gametes and embryos with abnormal chromosomal status will not survive. Of those that do survive, live offspring will either be carriers of a balanced translocation or, for Robertsonian translocations, be monosomic or trisomic for the translocated chromosomal DNA.

*(Continued)*
Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may exhibit mosaicism. Embryonic chromosomal monosomy may be particularly prevalent among patients with histories of RPL who are undergoing in vitro fertilization (10). Compared with monosomies, chromosomal trisomies (e.g., trisomy 13, 18, and 21) appear to be more readily tolerated, although mosaicism may be implicated with these abnormalities as well.

Neither family history nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses (9), the chance of detecting a parental chromosomal abnormality also is increased among couples that have never experienced a live birth. Abnormalities may also be detected by parental karyotype analysis of couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies).

DES, diethylstilbestrol; MTHFR, methylene tetrahydrofolate reductase; APAS, antiphospholipid antibody syndrome.

Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may exhibit mosaicism. Embryonic chromosomal monosomy may be particularly prevalent among patients with histories of RPL who are undergoing in vitro fertilization (10). Compared with monosomies, chromosomal trisomies (e.g., trisomy 13, 18, and 21) appear to be more readily tolerated, although mosaicism may be implicated with these abnormalities as well.

Neither family history nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses (9), the chance of detecting a parental chromosomal abnormality also is increased among couples that have never experienced a live birth. Abnormalities may also be detected by parental karyotype analysis of couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies).
Unfortunately, the use of parental karyotyping in the evaluation of structural chromosomal causes of RPL may ultimately become insufficient. Evidence now suggests that paternal chromosomal abnormalities may be isolated within particular fertilizing spermatozoa (11), and aneuploid spermatozoa may be particularly motile (12).

Other structural chromosome anomalies, such as inversions and insertions, as well as chromosomal mosaicism and single gene defects, may also contribute to recurrent abortion. X-linked disorders can be linked to recurrent abortion in female offspring but uncommonly result in recurrent abortion of male offspring (13). Single gene defects and their resulting disorders (e.g., the delta f 508 mutation and cystic fibrosis) may be recognized through analysis of detailed family histories or the identification of some pattern of anomalies characteristic of a known heritable syndrome.

**Thrombophilias**

The role of inherited thrombophilias in RPL has generated a great deal of interest (14–16). This heterogeneous group of disorders results in increased venous or arterial thrombosis. Their associations with pregnancy loss rest on both proved (17) and hypothetical alterations in placental growth and development, particularly placental vascular development. Abnormal placental vascularization and inappropriate placental thrombosis would link these thrombophilic states to pregnancy loss. Although some thrombophilic states may be acquired, most are heritable. Those heritable thrombophilias most often linked with reference to RPL include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V, deficiencies in proteins C and S, mutations in the prothrombin gene promoter, mutations in prothrombin, and mutations in antithrombin III.

As with spontaneous pregnancy loss, inherited and combined inherited–acquired thrombophilias also are surprisingly common. More than 15% of Caucasians carry an inherited thrombophilic mutation (15). The most common of these are factor V Leiden mutations, mutations in the promoter region of the prothrombin gene, and mutations in the gene encoding methylene tetrahydrofolate reductase (MTHFR). These disorders have been estimated to be present in their heterozygous state in approximately 5%, 2% to 3%, and 11% to 15% of healthy Caucasian populations, based on various studies (16–20). These common mutations are associated with mild thrombotic risks. It remains unclear whether homozygous MTHFR mutations even is associated with vascular disease (21). In contrast, more severe thrombophilic deficiencies, such as those of antithrombin and protein S, are much less common in the general population. These epidemiologic data support the hypothesis that a selective genetic advantage may accompany carriage of common heritable thrombophilias. To illustrate this point, women with activated protein C resistance caused by the factor V Leiden mutation have reduced blood loss at delivery (22), and factor V Leiden carriage has been shown to improve pregnancy rates in intracytoplasmic sperm injection/in vitro fertilization, suggesting a positive role in implantation (23). It is important to note that the epidemiology of factor V Leiden mutations is specific to Caucasian populations. Factor V Leiden and prothrombin gene mutations are rare in African and Asian populations, despite similar incidences of venous thromboembolism (VTE) in these groups (24–27). Protein C, protein S, and antithrombin mutations are the most important risk factors for VTE among many Chinese populations (28). These ethnic and geographic differences are important considerations when faced with decisions concerning diagnostic testing in patients with a history of recurrent fetal loss.

Inherited thrombophilic mutations have been estimated to be causative in 50% of VTE during pregnancy (15). Approximately 40% of episodes of venous or arterial thromboembolic phenomena occur in patients carrying a heritable mutation (29). Associations between thrombophilias and adverse fetal outcomes cover a range of early gestational and obstetric disorders. These disorders include isolated and recurrent, early and late spontaneous pregnancy losses, intrauterine growth restriction (IUGR), intrauterine fetal demise
IUFD), placental abruption, and pregnancy-induced hypertension (PIH). This discussion will focus on pathophysiologic mechanisms, diagnostic testing, and treatment strategies for patients with RPL who may have an inherited or acquired predisposition to thrombosis (excluding the antiphospholipid syndrome).

The basis for the association between adverse fetal outcomes and heritable thrombophilias has focused on the mechanisms of impaired placental development and function secondary to venous or arterial thrombosis at the maternal–fetal interface. These findings have been noted in the placentas of women with adverse fetal outcomes and known inherited thrombophilias, but have occurred likewise in patients with similar outcomes who lack inherited thrombophilic risk (30–34). Discussions of the role of placental thrombosis in early pregnancy losses (<10 weeks of gestation) have been particularly contentious, citing a series of experiments showing that maternal blood does not flow into the intervillous spaces of the human placenta until approximately 10 weeks of gestation (35–38). Before establishment of intervillous circulation, however, nutrient transfer from maternal blood to fetal tissues appears to depend on transudation that, in turn, relies on flow through the uterine vasculature. This finding suggests that maternal or fetal thrombotic episodes in the developing placental vasculature could equally be devastating before or after the establishment of intervillous circulation near 10 weeks of gestation. Timing of fetal demise among patients with pregnancy loss, however, does provide diagnostic clues, and its documentation is important in investigations into the causes and treatment of RPL.

Most preclinical and early clinical pregnancy losses are the result of de novo fetal aneuploidy (39). This is also thought to be true of anembryonic pregnancy losses. The presence of pregnancy losses resulting from de novo fetal aneuploidy, whether early and undocumented or documented through evaluation of chromosomal content in fetal tissues, complicates the results of many published studies. The presence or absence of fetal aneuploidy must be documented in all investigations of RPL, and their potential as a confounding factor should be discussed in any assessment of outcome. The timing of fetal demise and the need for chromosomal analysis of any collected fetal tissue should be carefully weighed when diagnostic and therapeutic investigations into thrombophilia-related causes of RPL are being considered. Very early pregnancy losses (biochemical, anembryonic) and known aneuploid fetal losses may be less likely to be altered by the presence of an underlying thrombophilic state and can reasonably be dismissed as indications for thrombophilia testing among patients with otherwise unexplained RPL.

The coagulation system relies on a complex cascade of prothrombotic enzymatic activations (often via serine proteases) in delicate balance with antithrombotic pathways. Although pregnancy is most simply described as prothrombotic, the alterations in the coagulation system associated with pregnancy represent a state of compensated disseminated intravascular coagulation (DIC) (40). Human hemochorial placentation is unique and inherently unstable. Placental development involves invasion into the maternal decidua and its vasculature and requires precise control of hemostasis and fibrinolysis. Delicate control mechanisms exist locally within the placenta (41) and globally within the pregnant woman. Hormonal and related physiologic changes characteristic of pregnancy affect important components of the clotting cascade, the fibrinolytic cascade, and platelet physiology.

Clot formation can be initiated through two pathways, called the extrinsic and intrinsic clotting cascades (Fig. 31.1). Both respond to blood vessel damage and the release of tissue factor (TF). Tissue factor is a glycoprotein expressed on the surface of cells surrounding blood vessels. It is not expressed on the endothelium of the blood vessel itself, so exposure of blood to TF is a sensitive indicator of vascular damage. The extrinsic clotting cascade begins with the interaction of newly released TF with factor VII of
The complex formed by TF and factor VII can either directly activate factor X or activate factor X via the intrinsic pathway. In the intrinsic pathway, the TF/factor VII complex activates factor IX to factor IXa (activated factor IX). Factor IXa then complexes with factor VIIIa. In combination, factors IXa and VIIIa activate factor X. Activation of factor XII after binding to negatively charged surfaces also can initiate the intrinsic pathway. Via this route, activated factor XII cleaves factor XI, generating factor XIa. Factor XIa can act as an alternate activator of factor IX. Extrinsic and intrinsic clotting cascades converge in the activation of factor X to form the common pathway. For all coagulation factors, the subscript a denotes the activated form of the factor.

To avoid uncontrolled thrombosis in response to tissue damage or alternate activation of the coagulation cascade, a number of antithrombotic control mechanisms are activated in conjunction with clot formation (Fig. 31.2). Important to this discussion are those mechanisms involving antithrombin (formerly antithrombin III), protein C, and protein S. Proteins C and S are vitamin K–dependent factors that are activated on clot formation. Activation is initiated by complexes of thrombomodulin and thrombin at sites of endothelial damage. Complexes of activated protein C and S inactivate factors Va and VIIIa, thereby inhibiting their associated procoagulant activities. Antithrombin is a serine protease that inactivates factors Xa and IIa, thereby limiting their procoagulant activities.
protease inhibitor that binds irreversibly to serine proteases. Proteases that bind antithrombin include factors IXa, Xa, XIa, and XIIa. Antithrombin also accelerates dissociation of factor VIIa tissue factor complexes, thereby inhibiting intrinsic and extrinsic clotting pathways at their points of initiation. Finally, as its name suggests, antithrombin binds to and inhibits thrombin (factor IIa). Fibrinolysis also acts to delimit uncontrolled coagulation (see Fig. 31.2). Mechanisms for fibrinolysis include cleavage of the fibrin clot by plasmin and the formation of fibrin degradation products (FDPs or FSPs). Plasmin activity is, in turn, controlled by plasminogen activator inhibitors (e.g., PAI-1).

Prothrombotic changes associated with pregnancy include increases in the amounts or the activities of factors in the clotting cascade and decreases in those counteracting clotting. The former includes pregnancy-associated elevations in factors VII, VIII, X, XII, von Willebrand’s factor, and fibrinogen levels (40,42,43). All of these factors increase throughout gestation. Factor II, factor V, and factor XIII levels also increase early in pregnancy but return to normal levels after the first trimester (40,44). Normal pregnancy has been associated with the development of activated protein C resistance (acquired APCR)
via mechanisms that remain unclear (45). Changes in balancing antithrombotic control mechanisms during pregnancy also favor clot formation. Whereas the activities of protein C and antithrombin remain fairly constant during the course of pregnancy, those of protein S decrease significantly. Protein S activity decreases in conjunction with pregnancy-induced increases in the production of C4b-binding protein, a complement factor-binding protein that forms a complex with protein S, making it unavailable for interaction with activated protein C (46). This increased binding, however, does not fully explain the level of decrease in protein S activity during pregnancy (46).

**Fibrinolysis is impaired during pregnancy, with decreases in fibrinolytic activity beginning at approximately 11 to 15 weeks of gestation** (40). A significant factor in this impairment is a marked decrease in plasmin activity resulting from placentation production of the plasmin-inhibitor, PAI-2 (47,48). In conjunction with these changes, however, FDP levels rise in pregnancy, beginning at approximately 20 weeks of gestation and continuing their rise throughout pregnancy (40,48). In normal pregnancy, platelet function and turnover is unchanged (Fig. 31.3). In the third trimester, platelet number typically decreases, the result of increased platelet consumption. This benign gestational thrombocytopenia can reach levels less than 80 \times 10^9/L (49). Collectively, pregnancy-associated alterations in the amounts and activities of prothrombotic clotting factors, anticoagulant control mechanisms, and fibrinolysis support the determination of human pregnancy as a state of hypercoagulability. Levels of factors VII, VIII, X, and XII are elevated throughout pregnancy, levels of factors II, V, and XIII rise in the first trimester, then return to normal values. The antithrombotic activity mediated by protein S decreases in pregnancy. The placenta produces PAI-2. For all coagulation factors, the subscript a denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

**Figure 31.3** Alterations coagulation and fibrinolysis during normal pregnancy. Pregnancy is a state of hypercoagulability. Levels of factors VII, VIII, X, and XII are elevated throughout pregnancy, levels of factors II, V, and XIII rise in the first trimester, then return to normal values. FSP, fibrin split products; FDP, fibrin degradation products.
compensated DIC. Although these changes reverse during the 4 to 6 weeks following delivery (40,49), the vascular damage associated with delivery is an additional significant risk factor for thrombosis, making the immediate postpartum period an important continuation of the prothrombotic state associated with pregnancy.

Circulating homocysteine is derived from dietary methionine. Homocysteine, in turn, is metabolized either into cysteine or back into methionine (Fig. 31.4). The latter process involves the enzyme methionine synthase. Methionine synthase requires donation of a methyl group from 5-methyltetrahydrofolate to produce methionine, and the enzyme *methylene tetrahydrofolate reductase* (*MTHFR*) is involved in the production of 5-methyltetrahydrofolate from dietary folate sources (14). The nutritional supplements folic acid, vitamins B2, B6, and B12 are all required for proper metabolism of homocysteine; therefore, their deficiency is associated with acquired elevations in circulating homocysteine levels (15,18,50). Although heritable deficiencies in the enzymes required for metabolism of homocysteine have been described for the pathways leading to cystathionine formation and those involved in reconversion to methionine (14,50–52). Point mutations in *MTHFR* are surprisingly common (16,19), and can be associated with hyperhomocysteinemia and thrombosis (50–52).

Those heritable thrombophilias most often linked to RPL include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V, deficiencies...
These inherited disorders are mainly autosomal dominant and display a wide variation in prevalence and in the severity of morbidity associated with gene carriage. The latter two characteristics have direct reciprocal correlations in the Caucasian population. Consistent with general thrombotic risk, carriage of combinations of two or more inherited thrombophilic defects has particularly strong association with adverse pregnancy outcomes (16,19,53). Acquired thrombophilias associated with RPL include hyperhomocysteinemia and activated protein C resistance. Most of the data linking thrombophilic states to recurrent fetal loss consist of small- to moderate-sized prevalence studies (53–61). Recent attempts to pool these data into meta-analyses have allowed more informed recommendations on the testing of patients presenting with RPL (62–64). Collectively, these studies suggest that testing for the factor V Leiden mutation, protein S levels, prothrombin promoter mutations, homocysteine levels, and global activated protein C resistance is of use in Caucasian patients with a history of repetitive first- or second-trimester losses. These recommendations do not necessarily apply to non-Caucasian patients. Individual studies directly linking hyperhomocysteinemia, folic acid, vitamin B₁₂, and MTHFR mutations to RPL have been contradictory (30,31,51–56). Recent studies that have evaluated pooled data from previous investigations (one via meta-analysis) show these conditions to be linked to risk of RPL (62).

With the recent completion of the human genome project and the rapid development of novel and improved molecular cytogenetic techniques (65), many advances and additional insights into the contribution of parental genetic abnormalities to RPL can be anticipated.

Anatomic Abnormalities

Anatomic abnormalities of the both the uterine cervix and the uterine body have been associated with RPL. These anatomic causes may be either congenital or acquired. During development, the uterus forms via the apposition of a portion of bilateral hollow tubes called the müllerian ducts. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may, therefore, include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well documented that prenatal exposure to maternally ingested diethylstilbestrol (DES) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to both isolated spontaneous pregnancy loss and to RPL (66), although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations (67,68). In fact, women with an intrauterine septum may have as high as a 60% risk for spontaneous abortion (69). Uterine septum-related losses most frequently occur during the second trimester. However, if an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first-trimester losses may occur as well (70). The most common uterine congenital anomaly associated with in utero DES exposure is hypoplasia, which may contribute to first- or second-trimester spontaneous abortions, incompetent cervix, and premature labor (71,72). Congenital anomalies of the uterine arteries also may contribute to pregnancy loss via adverse alterations in blood flow to the implanted blastocyst and developing placenta (73).

Acquired anatomic abnormalities have likewise been linked to both isolated and RPL. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometriosis. Endometrium that develops over an intrauterine synechiae or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (74). This may promote abnormal placentation for any embryo
SECTION VII Reproductive Endocrinology

attempting to implant over such lesions. Although data supporting these concepts are a bit tenuous, this abnormal placentation may lead to spontaneous pregnancy loss. Less clear is the association between intramural fibroids and RPL, but it is suggested that large (greater than 5 cm) intramural fibroids are associated with pregnancy loss and that removal improves outcomes (67,75).

Endocrine Abnormalities

The endocrinology of normal pregnancy is complex. Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that ultimately alter pregnancy maintenance may mediate their effects during the follicular phase of the cycle in which conception occurs, or even earlier. Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. Beginning with ovulation and lasting until approximately 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal–placental shift at about 7 to 9 weeks of gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance (76). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or utilization. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate utilization of progesterone by the uterine decidua. Pregnancy failures may also occur near the time of the expected luteal–placental shift if the trophoblast is unable to produce biologically active progesterone following demise of the corpus luteum.

Endocrinologic factors associated with recurrent abortion include luteal phase insufficiency, diabetes mellitus, hypersecretion of luteinizing hormone (LH), thyroid disease, and potentially insulin resistance and the polycystic ovarian syndrome (PCOS), hyperprolactinemia, and decreased ovarian reserve. Luteal phase insufficiency or luteal phase defects (LPD) are characterized by inadequate luteal milestones. They most likely relate to adverse pregnancy outcome via inadequate or improperly timed endometrial development at potential implantation sites. Luteal phase defect has many causes, some of which are associated with hypersecretion of LH. Although the mechanism underlying the association of elevated LH levels with RPL remains incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dyssynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of PCOS. In fact, some studies report ovarian radiologic evidence of PCOS in as many as 40% to 80% of patients experiencing RPL (77,78). In addition to inappropriately elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although not undisputed (78), both changes have been linked to RPL (77,79), and elevated androgen levels have been shown to adversely affect markers of uterine receptivity in women with a history of RPL (80).

Many women with PCOS have metabolic alterations in glycemic control characterized by insulin resistance (see Chapter 29). This too may be directly or indirectly related to adverse pregnancy outcome, and it may be linked to the mechanisms for spontaneous pregnancy loss among women with type 2 diabetes mellitus (81). Women with overt type 2 diabetes mellitus appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (82,83). In fact, hyperglycemia has now been linked directly to embryonic damage (84). In cases of advanced type 2 diabetes with accompanying vascular complications, subsequent pregnancy loss may result from compromised blood flow to the uterus.
Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and LPD. In addition, the metabolic demands of early pregnancy mandate increased levels of thyroid hormones. It is, therefore, not surprising that hypothyroidism has been associated with spontaneous pregnancy loss and with RPL (85). Whether clinically euthyroid patients with antithyroid antibodies have higher rates of RPL continues to be debated (86–89). The mechanism for an association remains unclear; however, these antibodies may be markers of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Two additional endocrinologic abnormalities have been linked with RPL, although data to support these associations are lacking. Animal models suggest that elevated prolactin levels may adversely affect the function of the corpus luteum; however, this concept is not well supported in humans (90,91). Some have suggested that elevated prolactin levels may promote pregnancy wastage via direct effects on the endometrium or indirect immunomodulatory mechanisms (92). Most recently, attempts have been made to correlate markers of ovarian reserve (day 3 follicle-stimulating hormone and day 3 estradiol response to the clomiphene challenge test) with RPL (78,93,94). At present, no consensus exists concerning this potential association.

Maternal Infection

Infection of the reproductive tract with bacterial, viral, parasitic, zoonotic, and fungal organisms has been linked theoretically to pregnancy loss. The most extensively studied pathogens are mycoplasma, ureaplasma, Chlamydia trachomatis, and β-streptococcus (95,96), and recent data have focused on the roles of some of these proposed organisms in RPL. One prospective comparison trial involving 70 patients with RPL reported no elevations in any markers for present or past infection with C. trachomatis when compared with controls (97). In contrast, a very large, prospective trial has demonstrated a link between the detection of bacterial vaginosis and history of second-trimester pregnancy loss among 500 patients with RPL (98). In this study, the likelihood of detecting bacterial vaginosis positively correlated with cigarette smoking. The mechanism linking specific organisms to either isolated or RPL remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (HSV) (99) and human cytomegalovirus (CMV) (100) can directly infect the placenta and fetus. The resulting villitis and related tissue destruction may disrupt pregnancy. Another theoretic possibility is that infection-associated early pregnancy loss may result from immunologic activation that occurs in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse events that occur later in gestation, such as intrauterine growth restriction (101), premature rupture of membranes, and preterm birth (102). Alternatively, mechanisms that protect the fetus from autoimmune rejection also may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfettered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (103).

Immunologic Phenomena

Although there has been extensive information published on the immunologic aspects of RPL, there is a lack of consensus as to the mechanisms and the impact of therapeutic intervention. The detection of a therapeutic effect is difficult, and studies are complicated by the fact that many patients with RPL seek care after the pregnancy is lost but before the fetus or embryo is expelled. In these cases, the physiologic immune reaction to the presence of nonviable tissue may mask any alternative, underlying immune causes for the demise itself. Finally, it is very likely that there is a wide variety of immune...
alterations that may cause isolated or RPL. At least ten well-supported immune mechanisms, each potentially important in pregnancy maintenance, have been identified (104).

Before launching into the most commonly accepted causes of immune-mediated pregnancy loss, a brief review of some of the important concepts in basic immunology is warranted for reference. These descriptions are presented in general terms here and further defined in Chapter 6.

Immune responses classically are divided into innate and acquired responses. Innate responses represent the body's first line of defense against pathogenic invasion. They are rapid and are not antigen specific. Cell types and mechanisms typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) and natural killer T (NKT) cells and possibly by TCRγδ+ T cells. Acquired immune responses, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further classified as primary (response associated with initial antigen contact) and secondary (rapid and powerful amnestic responses associated with subsequent contact to the same antigen).

Antigen specificity is generally regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans. MHC class I molecules (HLA-A, -B, and -C) are present on the surface of nearly every cell in the human body and are important in defense against oncogenic transformation and intracellular pathogens, such as viral infection. Class I MHC molecules act as important ligands for both the T-cell receptor on CD8+ cytotoxic/suppressor T cells and for a variety of receptors on NK cells (105). Class II MHC molecules (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage and monocytes, B cells, and tissue-specific cells such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for MHC class II is the T-cell receptor on CD4+ T helper cells.

One very important concept in immunology that has particular application to pregnancy is that of immune tolerance. It has been well described that bone marrow-derived T cells pass through the fetal thymus during early development. During this developmental interval, the T cells encounter a process termed thymic education. During thymic education, T cells are chosen that express either the CD4 or the CD8 co-receptor, and autoreactive cells are effectively eliminated. In short, this education promotes T-cell tolerance, allowing selection and survival only of those T cells that can recognize nonself but will not react against self. Recently, a subpopulation of CD4+ T cells has been described that strongly express CD25 on their cell surface. These CD4, CD25+ cells are called regulatory T lymphocytes (T reg cells) (106). T reg cells, when activated by autoantigens, can suppress activated inflammatory cells. They may have particular importance in avoidance of tissue destruction associated with inflammation, possibly with applications to tolerance.

These immunologic characteristics have been most thoroughly described and investigated for the immune effector cells populating the peripheral immune system. The peripheral immune system consists of the spleen and peripheral blood, and it is generally responsible for protection against blood-borne pathogens. Pathogens that enter the host via the extensive surface areas of the lacrimal ducts, respiratory system, gastrointestinal tract, mammary ducts, and genitourinary tract encounter a very distinct and important immune environment—that of the mucosal immune system. Although the mucosal immune system may be responsible primarily for the initial protection against most exogenous pathogens, knowledge of its immune characteristics lags far behind that of the peripheral immune
system. Insight into the specific characteristics of immunity within the reproductive tract is even further limited.

### Cellular Immune Mechanisms

Many of the immune theories surrounding the causes of isolated and recurrent spontaneous pregnancy losses have stemmed from attempts to define immunologic rules as they apply specifically to the mucosal reproductive tract. Four main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

1. Which immune cells populate the reproductive tract, particularly at implantation sites?

2. How do these cells arrive at this mucosal immune site, and are they educated in the same way as those populating the periphery?

3. How do the characteristics of antigen presentation differ at the maternal–fetal interface?

4. What regulatory mechanisms specifically affect reproductive tract immune cells?

#### Resident Cells

Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells (107,108). The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. In fact, around the time of implantation, one particular cell type comprises between 70% and 80% of the total endometrial lymphocyte populations (107,108). This cell type is called a variety of names, including decidual granular lymphocytes (DGL), large granular lymphocytes (LGL), and decidual NK cells. This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. If these cells are considered NK, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. The true function of these cells remains unclear, but their remarkable abundance at the maternal–fetal interface is compelling (109,110). Other immune cells that have been described in the periphery have characteristics of both NK cells and of T cells. These NKT cells have recently been shown to play a role in pregnancy loss in animal models (111). They are present in the decidua in humans and may play an important immunoregulatory role at this site (112).

In the peripheral immune compartment, most T cells express a T-cell receptor made up of an αβ heterodimer (TCRαβ\(^+\)). In addition to TCRαβ\(^+\) T cells, the human reproductive tract also is populated by a subset of T cells with a distinctive T cell receptor composed of the γδ heterodimer (TCRγδ\(^+\)), and the numbers of these cells increases in early pregnancy (113–115). TCRγδ\(^+\) T cells appear to fulfill functions quite distinct from their αβ\(^+\) counterparts; these functions may include direct, non-MHC-restricted recognition of antigens within tissues (116). In fact, TCRγδ\(^+\) T cells may fill a protective niche missed or poorly covered by B cells and TCRαβ\(^+\) T cells. The role and importance of TCRγδ\(^+\) cells in the reproductive tract and, more particularly, in pregnancy maintenance deserves further attention.

Finally, it has been suggested that a subset of macrophage, termed “suppressor” macrophage, may be implicated in pregnancy maintenance. These specific cells differ from typical macrophage in their promotion of anti-inflammatory effects, and they have been detected in normal murine placenta (117). Their presence in human decidual specimens requires further investigation. T reg cells are also of the “suppressor” functional phenotype. In pregnant mice and women, these specialized CD4\(^+\) cells are systemically
expanded in an alloantigen independent fashion (118) and can suppress adverse maternal responses to self (119) and to the fetus (120).

The human decidua is populated by characteristic immune effector cells. Investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome have been hampered by insufficient patient numbers to allow meaningful conclusions. These immune cell populations have been reported to be altered in patients with RPL (121–123) but not in patients experiencing isolated spontaneous pregnancy losses (115).

**Immune Cell Education and Homing to the Reproductive Tract**  The implanting fetus represents the most common model of allograft acceptance. The ability of the maternal immune system to avoid rejection of the implanting fetus in an uncomplicated pregnancy is a manifestation of immune tolerance. This observation raises questions about how the resident decidual immune effector cells are selected and educated, how they are recruited to reproductive sites, and how they are maintained once they reach this destination. Animal studies have suggested that the rules for selection and maintenance of these cells, in terms of their requirement for MHC and their education within the thymus, may be distinct from those governing either peripheral immune cells or cells within other mucosal sites, including the intestine (124). The immunophenotypes of immune cells populating the human reproductive tract are distinct from both the periphery and from other mucosal sites (125,126). The education of TCR cells populating epithelial sites may occur outside the thymus and might involve mechanisms that substitute for or modify interaction with MHC (115,127). The development of MHC specificity among NK cells is undergoing careful dissection in animal models (128,129) with the hope that these investigations will shed light on similar processes in humans and, specifically, on the selection and maintenance characteristics of decidual NK cells.

It is now becoming increasingly evident that the cells populating mucosal immune tissues select these sites through interactions between cell surface molecules on the immune cell (integrins) and cell surface molecules on the endothelial cells of blood vessels within the mucosal tissues (e.g., selectins, VCAM, MECA). This cellular recruitment process, called homing, has been most thoroughly described for the intestine (130,131). However, both murine (130,132) and human (133) reproductive tract tissues express these integrin/vascular ligand pairs, and the extension of these findings to pregnancy maintenance will surely prove fruitful. Understanding the mechanisms of selection, education, and maintenance of reproductive tract immune effector cells in the normal state is of paramount importance to determining the effects of alterations on disorders and their treatment.

**Antigen Presentation at the Maternal-Fetal Interface**  Historically, it was proposed that one method by which the implanting trophoblastic allograft could potentially avoid immune detection by the maternal host would be by making itself antigenically invisible. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as nonself. Although current knowledge of immunology now makes this theory somewhat obsolete (134), the implanting fetus does, in fact, use this strategy to some extent. It is certainly true that placental trophoblast cells do not express MHC class II molecules (135,136).

Unlike nearly every other cell in the human body, trophoblast cells do not express the classical MHC class I transplantation antigens HLA-A and -B. Rather, a subpopulation of placental cells, specifically the extravillous cytotrophoblast cells, express the classical MHC class I HLA-C products and the nonclassical HLA-E and -G products (103,137–141). These extravillous cytotrophoblast cells are of particular interest because they are characterized by remarkable invasive potential (142,143). These cells move from the tips of the anchoring villae of the human placenta and invade deeply into the maternal...
CHAPTER 31 Re却ent Pregnancy Loss

decidua. They can even replace cells within the walls of decidua vascular vessels (142–144).

Although the invasive characteristics of extravillous cytotrophoblast may reflect non-

MHC-related mechanisms, including well-described integrin switching (145), the intimate

contact of these fetal-derived cells with maternal immune effector cells exposes the fetus
to recognition as nonself.

It is not known why all placental cells downregulate expression of HLA-A and -B, whereas

invasive extravillous cytotrophoblast express HLA-C, -E, and -G. Because NK cells of the

innate immune system recognize and kill cells that express no MHC (134), the complete
downregulation of MHC would cause trophoblast cells to act as targets for those NK cells

that are pervasive at sites of implantation. In addition to possible protection from direct

NK cell-mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may

serve a variety of alternative roles. Natural killer cell receptor-mediated interactions with

extravillous cytotrophoblast MHC could modulate cytokine expression profiles at the

maternal–fetal interface (109,110). Major histocompatibility complex expression may

aid in decidual and vascular invasion by the trophoblast, an activity essential for

proper placental development (146). Whereas definitive correlations between placental

MHC class I expression patterns and RPL have yet to be reported, trophoblast expression

of HLA-G has been linked to other disorders of placental invasion, such as preeclampsia

(146,147). Genetic mutations at the HLA-G locus have also been linked to RPL in some

but not all studies (148–151). Finally, soluble or secreted trophoblast MHC products may

aid in the development of maternal immune tolerance to the placenta (152).

Aberrant expression of class II MHC determinants, or enhanced expression of MHC class

I on syncytiotrophoblast occurring in response to IFN-γ (153), could mediate abortion by

enhancing cytotoxic T-cell attack (154). This theory appears unlikely, however, because

the expression of classical MHC antigens does not seem to be induced on aborted tissues

from women experiencing one or more pregnancy losses (155). Finally, MHC class II

genotypes appear to affect susceptibility to a variety of diseases, including diabetes and

other autoimmune diseases. A similar link between MHC class II typing and adverse

pregnancy outcome has been reported for RPL (156).

Regulation of Decidual Immune Cells The characteristics of the interactions between
decidual immune effector cells and the implanting fetus may be determined by factors
other than those already mentioned. Local regulation of the cells that populate the human
decidua will further modify the effects of selection, maintenance, and homing, as well as
the distinctive characteristics of antigen presentation at the maternal–fetal interface. These
regulatory effects are often targets of investigative efforts because they may offer more
direct insight into potential therapies for immune-mediated disorders of pregnancy main-
tenance. Three such regulatory mechanisms include (i) alterations in T-helper cell
phenotypes, (ii) reproductive hormones and immunosuppression, and (iii) trypto-
phan metabolism.

Antigen-stimulated immune responses involving CD4+ T cells can be divided into
two major classes: T helper 1 (TH1) responses and T helper 2 (TH2) responses. This
subclassifcation may be overly simple, but it has been useful in broadly defining types of
immune responses based on the characteristics of the CD4+ cells present, as well as their
associated cytokines. The production of these responses rests on the environment in which
relatively undifferentiated CD4+ TH0 cells become differentiated. Thus, TH0 cells
exposed to IFN-γ become TH1-type cells, and those exposed to interleukin IL-1,-4
become TH2-type cells (157). Responses from TH1 cells are associated with inflamma-
tion and primarily involve interferon (IFN)-γ and IL-2, IL-2, and tumor necrosis factor
(TNF)-β. Responses from TH2 cells are associated with antibody production and the
cytokines IL-10, IL-4, IL-5, and IL-6 (157–159). Although TNF-α can be secreted by both
 TH1 and TH2 cells, it is most often characteristic of a TH1 response (160,161). A recip-
rocating regulating relationship exists between TH1 and TH2 cells and cytokines
Extending these immune regulatory phenomena to pregnancy, the type of CD4+ cellular response to the implanting fetus is controlled not only by the types of cells (e.g., T helper cells) in the decidua, but also by the cytokine environment at the maternal–fetal interface. As mentioned previously, the human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine secretion (165–167). Cytokines may affect reproductive events either directly or indirectly, depending on the specific cytokines secreted, their concentrations, and the differentiation stage of potential reproductive target tissues. It is now well documented that TH1-type cytokines can be harmful to an implanting embryo (168,169). Furthermore, most agree that some patients with RPL exhibit a dysregulation of their T helper cellular immune response to antigens at the site of implantation, with typical shifts toward TH1 inflammatory responses (170,171). Depending on the individual series, 60% to 80% of nonpregnant women with a history of otherwise unexplained recurrent spontaneous abortion have been found to have evidence of abnormal in vitro TH1 cellular immune responses. Fewer than 3% of women with normal reproductive histories demonstrate these responses (171,172). Rather, most women with normal pregnancies have a TH2 immune response to trophoblast antigens (171).

Methods for the documentation of cytokine dysregulation among patients with RPL also vary among investigators; some groups have confirmed this abnormality within the endometrium (173–175) or among immune cells isolated from the decidua (176) of these patients. Others use peripheral blood lymphocytes (PBL) from women with a history of RPL and stimulate them in vitro with trophoblast antigens (171,177). One study documented aberrant cytokine secretion when PBL from patients with RPL were stimulated in vitro by HLA-G bearing cells (178), whereas another study demonstrated that decidual and peripheral immune cells exhibit a shift toward the TH2 phenotype when exposed to HLA-G (179). Whether peripheral cytokine levels reflect T-helper cell dysregulation at the maternal–fetal interface or whether this dysregulation affects peripheral as well as local immune response during pregnancy remains controversial (180,181). Finally, as with all immune theories, there seems to be significant redundancy in the need for particular cytokines and soluble immunoregulatory factors at the site of implantation. To date, animal models with directed gene deletions have shown few of these factors (e.g., leukemia inhibitory factor) to be absolutely essential to pregnancy maintenance (182,183).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in both humans and animals indicates that immune responses to fetal antigens can be detected (184–186). Thus, the regulation of this response at the maternal–fetal interface may be critical. The concept that successful pregnancy requires some form of generalized suppression of maternal immune response is supported by reports that failure to downregulate maternal responses to recall antigens, such as tetanus toxoid and influenza, is associated with poor pregnancy outcome among patients with RPL (187). Regulator T cells as well as reproductive hormones appear important in this respect. Reproductive hormones have dramatic effects on peripheral cell-mediated immunity, as demonstrated by well-documented and notable sex differences in immune responsiveness (188). The levels of these potentially immunosuppressive hormones are elevated in pregnant women. The fact that the levels of these hormones at the maternal–fetal interface may be far above those in the maternal circulation during pregnancy (189) may explain an apparent inconsistency: overall immune responsiveness during pregnancy appears to change little, whereas local suppression at the maternal–fetal interface may be vital.

It has been suggested that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the
semiallogeneic implanting fetus (190). *In vitro* studies have shown that progesterone mediates its suppression of T cell effector function by alterations in membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression (191), and it may be mediated by nonclassical steroid receptors (192) or may not involve a receptor at all (192,193). Progesterone-mediated changes in T cell gene expression have been associated with the development of TH2-type T helper cell responses and with increased leukemia inhibitory factor expression (176,194). Because a shift in the intrauterine immune environment from TH2 to TH1 has been linked with early spontaneous pregnancy loss (171,176), the elevated intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance.

*In vitro* evidence indicates that progesterone can inhibit mitogen-induced proliferation of and cytokine secretion by CD8+ T cells (195) and can alter the expression of a transcription factor that drives the development of TH1 cells (196).

Levels of estrogen increase dramatically during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies has shown that estrogens improve immune responses in males after significant trauma and hemorrhage (197), suppress cell-mediated immunity after thermal injury (198), and protect against chronic renal allograft rejection (199). *In vitro*, estrogens appear to downregulate delayed-type hypersensitivity (DTH) reactions and promote the development of TH2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (200,201).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid tryptophan and its catabolizing enzyme indoleamine 2,3 dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data that T cells need tryptophan for activation and proliferation (202), and that local alterations in tryptophan metabolism at the maternal–fetal interface could either activate or fail to suppress maternal antifetal immunoreactivity (203). Recent studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic fetuses, and that this effect is mediated by lymphocytes (204). Further support lies in studies demonstrating that hamsters fed diets high in tryptophan have increased rates of fetal wastage (205). Extending this theory to humans requires further investigation. The expression of IDO in human uterine decidua (206) and the alterations in serum tryptophan levels with increasing gestational age during human pregnancy (207) suggest a potential local immunoregulatory mechanism.

Although associations between the development of endometriosis and immunologic abnormalities are now being defined (208), the link between endometriosis and RPL is unclear. **The occurrence of RPL in the presence of endometriosis may involve cellular or humoral dysfunction** (209,210).

---

**Humoral Immune Mechanisms**

Pregnancy-specific antigens can elicit humoral responses, and patients with RPL can display altered humoral responses to endometrial and trophoblast antigens (Table 31.2) (171,211). Nevertheless, most literature surrounding humoral immune responses and RPL focus on organ-nonspecific autoantibodies associated with APAS. Historically, these IgG and IgM antibodies were thought to be directed against negatively charged phospholipids. Those phospholipids most often implicated in RPL are cardiolipin and phosphatidylserine. Most recently, however, it has been shown that antiphospholipid antibodies often are directed against a protein cofactor, called β2 glycoprotein 1, that assists antibody association with the phospholipid (212,213). Antiphospholipid antibodies were originally characterized by prolongation of phospholipid-dependent coagulation tests *in vitro* (activated partial thromboplastin time [aPTT], Russell Viper Venum Time) and by thrombosis *in vivo*. The association of these antiphospholipid antibodies with thrombotic complications has been...
### Table 31.2 Concepts in Reproductive Immunology

#### Cellular immunity

1. **Resident endometrial/decidual cells**
   - Few B cells
   - TCR+ and TCRδ+ cells are present, TCRγδ+ cells increase in early pregnancy
   - NK-like, large granular lymphocytes (decidual NK cells) accumulate at sites of implantation
   - NKT cells and “suppressor” macrophage
   - T reg cells

2. **Immune cell education and homing**
   - Thymic versus extrathymic education
   - Possible *in situ* education and maintenance
   - Integrins/vascular ligand pairs and mucosal homing

3. **Antigen presentation**
   - MHC class II molecules are not expressed in the placenta
   - Classical MHC class I molecules HLA-A and HLA-B are not expressed in the placenta
   - Extravillous cytotrophoblast cells express HLA-C, HLA-E, and HLA-G

4. **In situ immunoregulation**
   - Th1/Th2 cytokine microenvironments and dysregulation
   - Hormonal immunomodulation
     - 1. Progesterone
     - 2. Estrogen
     - 3. Human chorionic gonadotropin (hCG)
     - 4. Prolactin
     - 5. Androgens
     - 6. Others
     - c. Tryptophan metabolism and indoleamine 2,3 dioxygenase (IDO)
     - d. Leukemia inhibiting factor (LIF)

#### Humoral immunity

1. **Fetal antigens are recognized by the maternal immune system and humoral responses are mounted**

2. **Organ nonspecific autoantibodies**
   - Anticardiolipin antibodies
   - Lupus anticoagulant
   - Anti-β2 glycoprotein 1 (anti-β2G) antibodies
   - Antiphosphatidylserine antibodies

3. **Organ-specific autoantibodies**
   - Antithyroid antibodies
   - Antisperm antibodies
   - Antitrophoblast antibodies
     - 1. Blocking antibodies
     - 2. HLA sharing
     - 3. Trophoblast/lymphocyte cross-reactive antibodies (TLX)

NK, natural killer; NKT, natural killer T; MHC, major histocompatibility complex.
termed the antiphospholipid syndrome, and although many of these complications are systemic, some are pregnancy specific—spontaneous abortion, stillbirth, intrauterine growth retardation, and preeclampsia (214). A reassessment of the criteria used to diagnose APAS resulted in the development of the Sapporo criteria, which include adverse pregnancy outcomes. These criteria, which have been validated clinically (215,216), are as follows:

**Laboratory Assessment**

For a patient to be diagnosed with APAS, one or more clinical and one or more laboratory criteria must be present:

**Clinical**

1. One or more confirmed episode of vascular thrombosis of any type
   - Venous
   - Arterial
   - Small vessel

2. Pregnancy complications
   - Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation
   - One or more fetal deaths at greater than 10 weeks of gestation
   - One or more preterm births at less than 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency

**Laboratory**

(Testing must be positive on two or more occasions, 6 weeks or more apart.)

1. Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels

2. Positive plasma levels of lupus anticoagulant

The presence of antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) during pregnancy is a major risk factor for an adverse pregnancy outcome (217). In large series of couples with recurrent abortion, the incidence of the APAS was between 3% and 5% (95). The presence of anticardiolipin antibodies among patients with known systemic lupus erythematosus portends less favorable pregnancy outcome (218).

A number of mechanisms whereby antiphospholipid antibodies might mediate pregnancy loss have been proposed. Antibodies against phospholipids could increase thromboxane and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (219–221). Alternatively, *in vitro* evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytial trophoblast (222), which is required for proper placental function. One study demonstrated that both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize β2 glycoprotein 1, the essential cofactor for antiphospholipid antibody binding (223). Although it gives insight into pathophysiology, the prognostic value of serum levels of specific antibodies against β2 glycoprotein 1 with respect to pregnancy outcome among RPL patients is poorer than that of standard anticardiolipin antibodies (224,225). Some have proposed that sera from antibody-positive patients with RPL are particularly adept at inhibiting trophoblast adhesion to endothelial cells *in vitro* (226). Others have noted rapid development
of atherosclerosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibodies (227). Finally, still others have suggested that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villi from those women with RPL who test positive for antiphospholipid antibody (228). However, placental pathologic evidence supporting causal involvement of APAS in pregnancy loss often is equivocal. The lesions characteristic of this syndrome (placental infarction, abruption, and hemorrhage) often are missing in women with antiphospholipid antibodies (229), and these same lesions can be found in placentae from women with recurrent abortion who do not have biochemical evidence of antiphospholipid antibodies (230).

One additional group of autoantibodies that have been linked to RPL is the antithyroid antibodies (ATA). Although the overall significance of these antibodies is unclear (231,232), one large retrospective study showed an increased prevalence of these antibodies among women with a history of RPL, even in the absence of thyroid endocrinologic abnormalities (89). However, another study reported that the presence of serum ATA had no effect on pregnancy outcome in euthyroid pregnant patients with a history of RPL (87).

Other antibody-mediated mechanisms for recurrent abortion have been proposed, including antisperm and antitrophoblast antibodies, as well as blocking antibody deficiency. Although each hypothesis has been shown to have minimal relevance to RPL (95,154), their discussion is warranted because therapies aimed at these disorders persist. Historically, the blocking antibody deficiency hypothesis has received the most attention. This hypothesis is based on a supposition that blocking factors (presumably antibodies) were required to prevent a maternal, cell-mediated, antifetal immune response that was believed to occur in all pregnancies. It was therefore proposed that in the absence of these blocking antibodies, abortion occurred (233). This supposition has never been substantiated (234,235). For example, maternal hyporesponsiveness in mixed lymphocyte culture with paternal stimulator cells was originally proposed to identify women with deficient blocking activity (233). Investigations based on this type of testing were continued by others (236,237), who proposed that parental HLA sharing resulted in a predisposition to blocking antibody deficiency. These reports were limited by small sample size, retrospective nature, and lack of population-based controls. One prospective, population-based control study conclusively demonstrated that HLA heterogeneity was not essential for successful pregnancy (238). However, follow-up studies have now shown that, in the exceedingly rare case of complete sharing of the entire HLA region, spontaneous pregnancy losses do increase (239). This particular 10-year prospective trial concluded, however, that HLA typing is of no use in outbred populations because only isolated and significantly inbred populations have such HLA homogeneity. Further evidence refuting the blocking antibody hypothesis for recurrent abortion comes from reports of successful pregnancies both among women who do not produce serum factors capable of mixed lymphocyte culture inhibition (233) and among women who do not produce antipaternal cytotoxic antibodies (234). Those mixed lymphocyte culture results that demonstrate hyporesponsiveness in some patients with RPL are now believed to represent the effect of the pregnancy loss rather than the cause of recurrent abortion (186,233–235).

One final theory that arose out of the blocking antibody investigations involved a novel HLA-linked alloantigen system. The finding that polyclonal rabbit antisera could recognize both lymphocytes and trophoblast cells suggested the existence of trophoblast–lymphocyte crossreactive alloantigens (called TLX) (240). These TLX were, in turn, linked to maternal blocking antibody deficiency and RPL. The TLX hypothesis is now of historical relevance only. The theory was invalidated when TLX was found to be identical to CD46, a complement receptor that is thought to protect the placenta from complement-mediated attack (241). CD46 was not a novel alloantigen. It can be found on a wide variety of cells, thus explaining the cross-reactive nature of the original rabbit antisera.
CHAPTER 31 Recurrent Pregnancy Loss

It is important to conclude this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss by suggesting that pregnancy may not require an intact maternal immune system at all. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (242). Furthermore, viable births also occur in women with severe immune deficiencies, and in murine models that lack T and B cells (severe combined immunodeficiency [SCID] mice), and in those that display a congenital absence of a thymus (nude mice). Immune factors may play important roles in a significant proportion of patients with recurrent pregnancy loss, however, and their presence is the subject of immense research to better define this role.

Other Factors

The implantation of the blastocyst within the uterine decidua represents an exquisitely scripted crosstalk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, RPL has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors (VEGF) on the developing placenta and their requisite receptors within the maternal decidua (243). Cellular and extracellular matrix adhesion properties may also be involved in this dialogue. The concept of uterine receptivity has been emboldened by the description of endometrial integrins and the timing of integrin switching during implantation (244). Others have reported decreased levels of endometrial mucin secretion (245) and reductions in the endometrial release of soluble intercellular adhesion molecule I (246) among women with histories of RPL. Programmed cell death (apoptosis) may also play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl2—have been linked to RPL and poor pregnancy outcome (104,247).

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform because, in humans, they must all be retrospective, and they are all confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogestogens, antineoplastic agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially heavy metals (248–251). Exposure to heavy metals has recently been shown to have both endocrine and immune effects that could lead to poor placentation and subsequent pregnancy loss (252). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) have not been substantiated (253,254). There is no compelling evidence that moderate exercise during pregnancy is associated with spontaneous abortion. In the absence of cervical anatomic abnormalities or incompetent cervix, coitus does not appear to increase the risk of spontaneous pregnancy loss (255,256). Exposure to three particular substances—alcohol, cigarettes, and caffeine—deserves specific attention. Although some conflicting data exist (257,258), one very large epidemiologic study has shown that alcohol consumption during the first trimester of pregnancy, at levels as low as 3 drinks per week, is associated with an increased incidence of spontaneous pregnancy loss (259). Cigarette smoking has also been linked to early spontaneous pregnancy loss (260,261); however, this is also not without controversy (262). Alcohol and tobacco intake in the male partner correlates with the incidence of domestic violence, which in turn is associated with early pregnancy loss (263). Finally, a growing body of literature suggests that consumption of coffee and other caffeinated beverages during early pregnancy is related to adverse pregnancy outcome (261,264). One highly publicized report casts doubt on the definition of a lower limit for safe use of caffeine in the first trimester of pregnancy (261). Obesity (265), stress (266), and use of nonsteroidal
SECTION VII Reproductive Endocrinology

anti-inflammatory agents during early pregnancy (267,268) have all been linked to an increased rate of isolated spontaneous pregnancy loss.

Preconception Evaluation

Evaluation of recurrent spontaneous abortion should include obtaining a thorough history from both partners, performing a physical assessment of the woman (with attention to the pelvic examination), and a limited amount of laboratory testing (Table 31.3).

History

A description of all prior pregnancies and their sequence, as well as whether histologic assessment and karyotype determinations were performed on previously aborted tissues, is an important aspect of the history. Approximately 60% of abortuses lost before 8 weeks of gestation have been reported to be chromosomally abnormal (269); most of these pregnancies are affected by some type of trisomy, particularly trisomy 16 (270). The most common single chromosomal abnormality is monosomy X (45X), especially among anembryonic conceptuses (271). Aneuploidy may be detected less often in miscarriage specimens when the couple experiencing recurrent abortions is euploidic. Alternatively, some investigators have suggested that because aneuploidy is common among miscarriage specimens from patients experiencing both isolated and recurrent spontaneous pregnancy losses, the documentation of aneuploidy in tissues from patients with RPL does not affect their prognosis for future pregnancy maintenance (9).

Most women with RPL tend to experience spontaneous abortion at approximately the same gestational age in sequential pregnancies. Unfortunately, the gestational age when pregnancy loss occurs, as determined by last menstrual period, may not be informative because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion (272). The designation of couples into primary or secondary categories also is not helpful for either the diagnosis or management in most cases. Approximately 10% to 15% of couples cannot be classified into either primary or secondary categories, because although their first pregnancy resulted in a loss, it was followed by a term delivery before subsequent losses.

It is important to elicit any history of subfertility or infertility among couples with RPL. This condition is defined by the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples will meet this criteria; this number increases to 33% among couples with RPL. Because many pregnancies are lost before or near the time of missed menses, subfertility among patients with RPL may, in some cases, reflect recurrent preclinical losses. Menstrual cycle history may provide information about the possibility of oligo-ovulation or other relevant endocrine abnormalities in patients with RPL. An assessment of the timing of intercourse relative to ovulation should be reviewed with couples in an effort to detect dyssynchronous fertilization that could contribute to pregnancy loss (273). A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be discussed specifically. Detailed information about drug and environmental exposure should also be obtained.

Physical Examination

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, DES exposure, and previous
### Table 31.3 Investigative Measures Useful in the Evaluation of Recurrent Early Pregnancy Loss

**History**

1. Pattern, trimester, and characteristics of prior pregnancy losses
2. History of subfertility or infertility
3. Menstrual history
4. Prior or current gynecologic or obstetric infections
5. Signs or symptoms of thyroid, prolactin, glucose tolerance and hyperandrogenic disorders (including PCOS)
6. Personal or familial thrombotic history
7. Features associated with the antiphospholipid syndrome (thrombosis, false positive test for syphilis)
8. Other autoimmune disorders
9. Medications
10. Environmental exposures, illicit and common drug use (particularly caffeine, alcohol, cigarettes, and in utero DES exposure)
11. Genetic relationship between reproductive partners
12. Family history of recurrent spontaneous abortion, obstetric complications, or any syndrome associated with embryonic or fetal losses
13. Previous diagnostic tests and treatments

**Physical Examination**

General physical examination with particular attention to:

1. Obesity
2. Hirsutism/acanthosis
3. Thyroid examination
4. Breast examination/galactorrhea
5. Pelvic examination
   a. Anatomy
   b. Infection
   c. Trauma
   d. Estrogenization
   e. Masculinization

**Laboratory**

1. Parental peripheral blood karyotype
2. Hysterosalpingography or office hysteroscopy, followed by hysteroscopy/laparoscopy, if indicated
3. Thyroid-stimulating hormone level, serum prolactin level if indicated
4. Anticardiolipin antibody level
5. Lupus anticoagulant (activated partial thromboplastin time or Russell Viper Venom)
6. Complete blood count with platelets
8. Protein C activity, antithrombin level if personal or family history of VTE

PCOS, polycystic ovarian syndrome; DES, diethylstilbestrol; VTE, venous thromboembolism.
trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should also be determined.

**Laboratory Assessment**

**Valuable Tests**

Laboratory assessment of couples with RPL should include the following tests:

1. Parental peripheral blood karyotyping with banding techniques

2. Assessment of the intrauterine cavity with either office hysteroscopy, sono-hysterography or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found

3. Thyroid function testing, including serum thyroid-stimulating hormone levels

4. Anticardiolipin antibody and lupus anticoagulant testing (aPTT or Russell Viper Venom testing)

5. Thrombophilia testing:
   a. Factor V Leiden, G20210A prothrombin gene mutation, protein S activity
   b. Serum homocysteine levels
   c. In the presence of a family or personal history of VTE, protein C and antithrombin activity
   d. Possible alterations based on ethnic background: Factor V Leiden and prothrombin are rare in African and Asian populations; Protein C and S are the most common inherited thrombophilias in Chinese populations

6. Platelet levels

**Tests with Unproven Utility**

A number of laboratory assessments are being evaluated for use in patients with a history of RPL. At present, results are either too preliminary to warrant recommendation or the results of studies have been too contradictory to allow final determination of their value. Tests with unproven or unknown utility include:

1. Evaluation of ovarian reserve using day 3 serum follicle-stimulating hormone levels or the clomiphene challenge test is of limited value because decreased ovarian reserve may portend poor outcome in all patients, including those with RPL (274,275).

2. Testing for serologic evidence of PCOS using luteinizing hormone or androgen values may be useful (77–80,276).

3. Testing for peripheral evidence of TH1/TH2 cytokine dysregulation may be of value. Although large studies have failed to demonstrate an association between peripheral cytokine alterations and pregnancy outcome among patients with RPL (180), smaller studies have reported peripheral shifts toward TH1 profiles only in those patients with RPL who subsequently lose their pregnancy (181). One study documented a shift toward TH1 profiles at the time of fetal demise in these patients; however, it is difficult to determine a cause-and-effect relationship (277).
4. Preconceptional testing for the prevalence and activity of peripheral NK cells has been reported in small studies to help determine the prognosis and to assist with patient counseling (278,279). Still, peripheral NK cells may not adequately represent those at the site of implantation, and this testing remains unproven.

5. Testing for antithyroid antibodies, even among women with RPL who are euthyroid, remains controversial. Although some have shown no association between the presence of antithyroid antibodies and recurrent loss (231), others have demonstrated an increased prevalence among patients with a history of RPL (89,232). However, even if the prevalence of antithyroid antibodies is increased among these patients, the significance of their presence is questionable (87).

6. Testing for the presence of a variety of autoantibodies (other than lupus anticoagulant and anticardiolipin antibody) has been hotly debated without consensus (280,281). Testing for some antiphospholipid antibodies, such as antiphosphatidylserine and anti-β2 glycoprotein 1 (anti-β2g), is compelling because their presence has been connected to placental pathology (222–225). One recent, large series has shown anti-β2g to be associated with risk for RPL (282). In patients with known autoimmune diseases and RPL, additional antiphospholipid testing may be warranted (283).

7. Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.

8. The Noyes criteria has low interobserver reproducibility and accuracy and thus cannot reliably be used to diagnose a luteal phase defect on timed endometrial biopsy (284). This tool lacks precision and does not alter clinical management (285).

The following investigations have no place in the care of patients with recurrent spontaneous pregnancy loss:

1. Evaluations that involve extensive testing for serum or site-specific auto- or alloantibodies (including antinuclear antibodies and antipaternal cytotoxic antibodies) are both expensive and unproven. Their use often serves only to verify the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.

2. Testing for parental HLA profiles is never indicated in outbred populations. The association of HLA sharing with poor pregnancy outcomes is applicable only to those populations that have very high and sustained levels of marriage within a limited community (239).

3. Use of mixed lymphocyte cultures has not proven useful. Use of other immunologic tests also is unnecessary unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the couple or their third-party payers.

4. Suppressor cell factor determinations; cytokine, oncogene, and growth factor measurements; and embryotoxic factor assessment are not clinically justified.

Postconception Evaluation

Following conception, patients with histories of RPL should be monitored closely to provide psychological support and to confirm intrauterine pregnancy and its viability.
The incidence of ectopic pregnancy (286,287) and complete molar gestation (287,288) is increased in women with a history of recurrent spontaneous pregnancy loss. Although somewhat controversial (289), some data suggest that the risk of pregnancy complications other than spontaneous abortion are not significantly different between women with and those without a history of recurrent losses (89,290). Two exceptions to this observation are women who have antiphospholipid antibodies and those who have an intrauterine infection.

Determining serum levels of β-human chorionic gonadotropin (hCG) may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, inadequate β-hCG levels do not always occur in pregnancies that ultimately abort (291). Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or abortion occurs (292). The best method for monitoring in early pregnancy is ultrasonography.

Serial ultrasonography and a variety of hormonal and biochemical measurements during early pregnancy have prognostic value in women with histories of recurrent losses (293). If used, serum β-hCG levels should be monitored serially from the time of a missed menstrual period until the level is approximately 1,200 to 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued. Ultrasonographic assessment may then be performed every 2 weeks until the gestational age at which previous pregnancies were aborted. If pregnancy has been confirmed but fetal cardiac activity cannot be documented by approximately 6 to 7 weeks of gestation (by sure menstrual or ultrasonographic dating), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. Nuchal lucency measurement (11–12 weeks) and/or maternal serum analysis (with nuchal lucency and/or at 15–18 weeks) may be used for prenatal assessment. Amniocentesis may be recommended to assess the fetal karyotype after the pregnancy has progressed past the time of prior losses.

The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents. The documentation of aneuploidy may have important prognostic implications and may direct future interventions. Karyotypic analysis is financially prudent among patients with histories of RPL (294). Obtaining karyotypic data from aborted specimens is complicated by difficulties in culturing cells from tissues that may have significant inflammation or necrosis and contamination of specimens with maternal cells. Efforts to develop methods that avoid such difficulties include the application of comparative genomic hybridization technology to RPL (295). This technology has even been used successfully with archived and paraffin-embedded pregnancy tissues (296). In the future, fetal karyotype assessment may also be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood (297).

Therapy

Advances in the treatment of patients with RPL have been regrettably slow. Although there has been a rapid expansion in knowledge of the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of RPL has lagged. In addition to these limitations, progress toward treatment of most causes of RPL has been hampered by a variety of factors. The condition itself has not been defined consistently. The results of clinical trials involving patients with RPL patients are, therefore, often nearly impossible to compare and evaluate. Trial design is frequently substandard, with lack of rationale, lack of appropriate controls, and poor statistical analysis limiting the ability to draw rational conclusions from reported results. Finally, epidemiologic data indicate that most patients with a history of RPL will,
in fact, have a successful pregnancy the next time they conceive (5). For these reasons, with few exceptions, most therapies for RPL must be considered experimental. Until further study is completed, treatment protocols involving these therapies should be undertaken only with informed consent and in the setting of a well-designed, double-blinded, placebo-controlled clinical trial.

Common therapeutic options that currently exist for patients with RPL include the use of donor oocytes or sperm, the use of preimplantation genetic diagnosis, the use of antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the treatment of infections, and a variety of immunologic interventions and drug treatments. Psychological counseling and support is recommended for all patients.

Genetic Abnormalities

No therapies are presently available to treat those parental chromosomal anomalies that potentially contribute to recurrent abortion. Three alternative approaches exist when genetic factors are linked to RPL. Some approaches, such as antithrombotic therapy for patients with inherited thrombophilias, are directed to the effects of the genetic abnormality. Other techniques, such as preimplantation genetic diagnosis, attempt to identify those particular embryos that are affected by chromosomal disorders and select against them. Recent evidence suggests that in women with a history of three or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 58% risk of chromosomal abnormality (298). If the incidence of chromosomal abnormalities among the conceptuses of patients with RPL is this high, it could be argued that the use of assisted reproductive technologies, including preimplantation genetic diagnosis, might be indicated for all patients with unexplained RPL.

Preimplantation genetic diagnosis involves the removal of a single cell from an in vitro–matured embryo. Genetic testing can be performed on this cell to rule out gross chromosomal abnormalities or the presence of specific genetic diseases (e.g., cystic fibrosis). Embryos that are diagnosed with genetic abnormalities are not replaced into the uterine cavity. Those demonstrated to be genetically normal would be considered appropriate for transfer into the uterus. Use of preimplantation genetic diagnosis, therefore, has the potential to dramatically reduce the incidence of pregnancy loss arising from a genetic cause. Use of preimplantation genetic diagnosis in patients with known heritable genetic disorders (e.g., cystic fibrosis, X-linked disorders) is presently in widespread use. Women with a history of RPL have a higher incidence of aneuploid embryos than those without a history of losses (298,299). For this reason, RPL has recently been considered as a reasonable indication for the use of in vitro fertilization with preimplantation genetic diagnosis. The efficacy of this technique in the treatment of patients with RPL continues to be investigated (300,301).

The third approach to patients with genetic factors and RPL is particularly relevant to those with Robertsonian translocations involving homologous chromosomes. In these patients, their genetic anomaly always results in embryonic aneuploidy. Therefore, use of either donor oocyte or donor sperm, depending on the affected partner, is recommended. Use of donor gametes among patients with a history of RPL has been shown to be as effective as its use in matched patients without such a history (302). Synchronization of intercourse with ovulation may benefit some patients with genetic factor RPL (273). In all cases, genetic counseling is warranted.

Anatomic Anomalies

Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. This approach appears to limit
postoperative sequelae while maintaining efficacy in terms of reproductive outcome (67,69). Use may even be safely extended to patients with DES exposure, hypoplastic uteri, and complicating septal anomalies (67,69,303). Attempts to improve on standard hysteroscopic metroplasty, which typically is performed in the operating room using general anesthesia, often with laparoscopic guidance, are presently under investigation. Ultrasonographically guided transcervical metroplasty has been reported to be safe and effective (304). Ambulatory, office-based procedures (305), including septum resection under fluoroscopic guidance (306), also are options.

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This procedure usually is performed early in the second trimester after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with DES-associated uterine anomalies. If endometriosis is encountered during a diagnostic evaluation, it should be resected laparoscopically.

Endocrine Abnormalities

Some investigators have proposed the use of ovulation induction for the treatment of RPL based on the hypothesis that ovulation induction is associated with healthier oocytes (307,308). Healthier oocytes, in turn, may decrease the incidence of luteal phase insufficiency, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Empiric use of empiric ovulation induction for treatment of unexplained RPL should be viewed with caution because recent evidence from small studies indicates such use is not effective (308). In some subsets of patients with RPL, use of ovulation induction could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal phase support with progesterone should be considered for women with luteal phase insufficiency. The efficacy of these therapies, however, has never been substantiated (309). Ovulation induction might also be beneficial for women with hyperandrogen and LH hypersecretion disorders, especially following pituitary desensitization with gonadotropin-releasing hormone agonist therapy (95). This treatment also remains controversial; according to findings from the only large, prospective, randomized controlled trial to date, neither prepregnancy pituitary suppression nor luteal phase progesterone supplementation has therapeutic efficacy (310).

Based on the association between PCOS, hyperandrogenism, hyperinsulinemia, and RPL (77–80), there has been increasing support for the use of insulin-sensitizing agents in the treatment of RPL that occurs in the presence of PCOS (311,312). Prepregnancy glycemic control may be particularly important for women with overt diabetes mellitus (81,82). Thyroid hormone replacement with Synthroid may be helpful in cases of hypothyroidism. There is no place in the medical management of recurrent abortion for either thyroid medication or bromocriptine for women who do not have a thyroid or prolactin disorder.

Infections

Empiric antibiotic treatment has been used for couples with recurrent abortion, despite its unproven efficacy. Elaborate testing for infectious factors and use of therapeutic interventions is not justified unless a patient is immunocompromised or a specific infection has been documented (96). For cases in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment cultures to verify eradication of the infectious agent before attempting conception.
Immunologic Factors

Immune-mediated RPL has received more attention than any other single etiologic classification. Nevertheless, techniques for diagnosis and treatment of most cases remains unclear (154,313–315). Most therapies for proposed immune-related RPL must be considered experimental. As stated earlier, it is known that the developing conceptus contains paternally inherited gene products and tissue-specific differentiation antigens and that maternal recognition of these antigens occurs (184–186). Historically, it has been speculated that both inappropriately weak immune responses to these antigens and unusually strong responses could result in early pregnancy loss. As a consequence, both immunostimulating and immunosuppressive therapies have been proposed.

Immunostimulating Therapies: Leukocyte Immunization

Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immune RPL, and a number of reports support possible mechanisms for potential therapeutic value (316–319). Both individual clinical trials and meta-analyses, however, report conflicting results concerning the efficacy of leukocyte alloimmunization in patients with RPL (320–325). This lack of consensus most certainly reflects the remarkable heterogeneity in study design, patient selection, and therapeutic protocols, as well as the typically small numbers of enrolled subjects in these investigations. One published analysis reports that approximately 11 women with unexplained recurrent abortion would need to be immunized with allogeneic lymphocytes before one additional live birth was achieved (322). Approximately 92% of successful pregnancy outcomes in this study were not attributable to leukocyte immunization. Whether the 8% successful pregnancy rate achieved in leukocyte-immunized women is clinically relevant remains uncertain.

One of the largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained RPL is a part of the Recurrent Miscarriage (REMIS) study (324). This large (more than 90 patients per treatment arm), prospective, placebo-controlled, randomized, double-blinded investigation showed no efficacy for paternal leukocyte immunization in couples with unexplained RPL. A Cochrane review of 19 well-designed trials of immunotherapy for RPL found no evidence that paternal or allogeneic leukocyte immunization altered pregnancy outcome in women with otherwise unexplained RPL (326). Leukocyte immunization also poses significant risk to both the mother and her fetus (296,297). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and autoimmune and isoimmune complications have been reported (321,322,327–330). In addition, alloimmunization to platelets contained in the paternal leukocyte preparation has been associated with cases of potentially fatal fetal thrombocytopenia. The routine use of this therapy for recurrent abortion (that, at best, will only be efficacious in one of 11 women treated) cannot be clinically justified at present. The procedure should be performed only as part of an appropriately controlled trial using informed consent. Other immunostimulating therapies have been proposed and abandoned. Intravenous preparations consisting of syncytiotrophoblast microvillus plasma membrane vesicles have been used to mimic the fetal cell contact with maternal blood that normally occurs in pregnancy (331). The efficacy of this therapy has not been established (326,331). The use of third-party seminal plasma suppositories has also been attempted (332), based on the misconception that TLX was part of an idiotype–anti-idiotype control system (333). Third-party seminal plasma suppositories for recurrent abortion have no scientifically credible rationale and should not be used.

Immunosuppressive Therapies

Immunosuppressive and other immunoregulating therapies have been advocated for cases in which abortion was believed to be due to antiphospholipid antibodies or to inappropriate cellular immunity toward the implanting fetus. Again, study design problems, including small numbers of recruited patients, lack of stratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies, preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.
Intravenous Immunoglobulin

Intravenous immunoglobulins (IVIg) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVIg therapy in the treatment of RPL are based on the theory that some patients have an overzealous immune reactivity to their implanting fetus. Although IVIgs do have immunosuppressive effects, the mechanisms underlying this immune modulation are only partially understood. These mechanisms may include decreased autoantibody production and increased autoantibody clearance, T cell and Fc receptor regulation (334), complement inactivation (335), enhanced T cell suppressor function, decreased T-cell adhesion to the extracellular matrix (336), and downregulation of TH1 cytokine synthesis (337). Based on a large number of relatively small studies using a variety of treatment protocols, there remains no conclusive evidence to suggest that use of IVIg in the treatment of patients with unexplained (and presumed immunologic) RPL has any benefit (338–342). The Cochrane review of immune therapy for RPL also addressed IVIg therapy and reported that its use did not alter pregnancy outcomes in patients with otherwise unexplained RPL (326). Improved posttreatment pregnancy rates may be seen when IVIg is used in those specific patients with autoimmune-mediated pregnancy loss associated with APAS (343,344). Therapy with IVIgs for RPL is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy. Side effects of IVIg therapy include nausea, headache, myalgias, and hypotension. More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) (345).

Progesterone

As mentioned earlier, progesterone also has known immunosuppressive effects (188–191,195,196). A number of studies using in vitro cellular systems relevant to the maternal–fetal interface have now shown that progesterone either inhibits TH1 immunity or causes a shift from TH1 to TH2-type responses (176,194–196,346,347). Progesterone has been administered both intramuscularly and intravaginally for the treatment of RPL. It is thought that vaginal administration may increase local, intruterine concentrations of progesterone better than systemic administration. Vaginal formulations may, therefore, provide a better method of attaining local immunosuppressive levels of progesterone while averting any adverse systemic side effects. Although both vaginal and intramuscular progesterone therapy are associated with few minor side effects, their efficacy in the treatment of either unexplained RPL or RPL associated with TH cell dysregulation has never been investigated appropriately.

Other immunoregulating therapies theoretically useful in treating RPL include the use of cyclosporine, pentoxifylline, and nifedipine, although maternal and fetal risks with these agents preclude their clinical use. Plasmapheresis has also been used to treat women with recurrent abortion and antiphospholipid antibodies (348). Generalized immunosuppression with corticosteroids, such as prednisone, has been advocated during pregnancy for women with recurrent losses and chronic intervillositis (349) and APAS. Although corticosteroids have shown some promise in these patients (349,350), maternal and fetal side effects and the availability of alternative therapies have limited their use. The efficacy and side effects of prednisone plus low-dose aspirin was examined in a recent, large, randomized, placebo-controlled trial treating patients with autoantibodies and RPLs. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk of premature delivery were all increased among those treated with prednisone and aspirin (351).

Antithrombotic Therapy

Therapy for patients with RPLs associated with either APAS or other thrombophilic disorders has focused on the use of antithrombotic medications. Unlike immunosuppressive treatments, this approach mainly treats the effect (hypercoagulability) but not the underlying cause (e.g., genetic, APAS) of RPL. However, there are reports that heparin, a typical anticoagulant, may exert direct immunomodulatory effects by binding to antiphospholipid antibodies (352) and may decrease movement of inflammatory cells.
to sites of alloantigen exposure (353). The combined use of low-dose aspirin (75–80 mg/day) and subcutaneous unfractionated heparin (5,000–10,000 units twice daily) during pregnancy has been best studied among women with APAS and appears to be efficacious (354–356). A typical regimen for women with antiphospholipid antibody syndrome would include use of aspirin (80 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 10,000 IU unfractionated sodium heparin is administered subcutaneously twice daily, throughout gestation. An aPTT should be obtained weekly, and dosages of heparin should be adjusted until anticoagulation is achieved. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risks of preterm labor, premature rupture of the membranes, intrauterine growth restriction, intraparteine fetal demise, and preeclampsia. Other potential risks include gastric bleeding, osteopenia, and abruptio placenta.

The effectiveness of antithrombotic therapy in the treatment of patients with APAS and RPL has led to efforts to expand treatment in new directions. These directions include the use of low-molecular weight heparin (LMWH), the use of antithrombotic therapy in patients with thrombophilia and RPL who do not have APAS, and even the use of such therapy among patients with RPL who do not have thrombophilia (unexplained recurrent losses).

**Low-molecular weight heparin is superior to unfractionated heparin in the treatment of many clotting disorders** (357,358). Low-molecular weight heparin has the advantage of an increased antithrombotic ratio when compared with unfractionated heparin. This characteristic results in improved treatment of inappropriate clotting but fewer bleeding side effects. In addition, LMWH has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. Finally, LMWH has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. Although its safe use in pregnancy is still being evaluated, LMWH has shown promise when combined with low-dose aspirin in the treatment of RPL associated with APAS (355). One study comparing the use of unfractionated heparin and aspirin to LMWH and aspirin in the treatment of women with APAS and adverse pregnancy outcomes showed the therapies had similar effects (359). Efficacy has also been suggested for similar treatment of RPL associated with other thrombophilias, including activated protein C resistance associated with factor V Leiden, mutations in the promoter region of the prothrombin gene, and decreases in protein C and protein S activities (359–363). The use of LMWH for this indication appears to have an excellent safety profile for mother and fetus (364,365).

The prophylactic use of daily low-dose aspirin has become common practice based on its perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of RPL has likewise gained momentum, and many patients with histories of recurrent loss will either self-prescribe this therapy or will inquire about its usefulness. At present, there are no good data supporting its use either in patients with heritable thrombophilias or in the general RPL population. In fact, although studies are small, the use of low-dose aspirin alone has not been shown to be effective in the treatment of RPL associated with APAS (366,367). In these patients, it should be used in combination with unfractionated or low-molecular-weight heparin. One large study evaluating the therapeutic efficacy of empiric use of low-dose aspirin among 805 patients with unexplained RPL concluded that such therapy cannot be justified in patients with early losses but may benefit patients with second trimester losses (367).

Reports of an increased incidence of isolated spontaneous pregnancy loss with the use of aspirin in early pregnancy have raised questions about this practice (368,369). These reports are poorly designed and do not adequately address the level of exposure (81 mg versus 325 mg). At this time, aside from use in combination with heparin for patients with RPL and APAS, and in patients with late losses, aspirin should be avoided during early pregnancy.
More directed antithrombotic therapies have also been described for the treatment of RPL among patients with thrombophilies. For instance, the use of protein C concentrates has been associated with favorable pregnancy outcome in a patient with a history of thrombosis, recurrent fetal losses, and protein C deficiency (370).

As mentioned previously, vitamins B₆, B₁₂, and folate are important in homocysteine metabolism (15,18), and hyperhomocysteinemia is linked to RPL (17,25,62). Women with RPL and isolated fasting hyperhomocysteinemia should be offered supplemental folic acid (0.4–1.0 mg/day), vitamin B₆ (6 mg/day), and possibly vitamin B₁₂ (0.025 mg/day) (371–374). Fasting homocysteine levels should be retested after treatment. If levels are normalized or remain only marginally elevated, no further therapy is necessary. Homocysteine levels will predictably decrease during pregnancy.

Treatment of women with RPL and an identified inherited or acquired thrombophilia should be based on their history:

- If venous thromboembolism occurs during the index pregnancy, posthospitalization management requires therapeutic anticoagulation:
  - *Unfractionated heparin*: 10,000 to 15,000 U subcutaneously every 8 to 12 hours (monitor to keep aPTT 1.5–2.5 times normal), or
  - *LMWH*: enoxaparin 40 to 80 mg subcutaneously twice daily or dalteparin 5,000 to 10,000 U subcutaneously twice daily. Consider monitoring trough factor Xa levels in the third trimester.

- If there is a personal history of venous thromboembolism (particularly in previous pregnancy or with hormonal contraceptive use) or a strong thrombophilic family history, treat with therapeutic anticoagulation.

- If combined thrombophilic defects are detected, treat with therapeutic anticoagulation.

- If an isolated thrombophilic defect is detected and there is no personal or strong family history of thrombotic complications, consider prophylactic anticoagulation:
  - *Unfractionated heparin*: 5,000 U subcutaneously twice daily (first trimester), 7,500 U subcutaneously twice daily (second trimester), and 10,000 U subcutaneously (third trimester)
  - *LMWH*: enoxaparin 40 mg subcutaneously daily or dalteparin 5,000 U subcutaneously daily

- Consider prophylactic anticoagulation in women with RPL and hyperhomocysteinemia refractory to dietary intervention. Therapy should be initiated with documentation of pregnancy. There are no data suggesting initiation preconceptionally improves outcomes.

Thrombotic risk is greatest during the postpartum period. Anticoagulation should be reinitiated after delivery in doses reflecting predelivery treatment regimens. Postpartum anticoagulation should be continued for 6 to 12 weeks postpartum. Women may continue injectable therapy or transition to oral anticoagulants (e.g., coumarin). Use of heparin or of coumarin derivatives does not prohibit breastfeeding.

**Psychological Support**

Experiencing isolated or recurrent losses can be emotionally devastating. The risk of major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women it arises in the first weeks following delivery (375). A caring and empathetic attitude is prerequisite to all healing. The acknowledgment of the pain and suffering couples have experienced as a result of recurrent abortion can be a
cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than their lives into their experience of loss (95). Referrals to support groups and counselors should be offered. Self-help measures, such as meditation, yoga, exercise, and biofeedback may also be useful.

**Prognosis**

The prognosis for successful pregnancy depends both on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses (Table 31.4). As previously discussed, epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, the prognosis for successful pregnancy in couples with a cytogenetic basis for reproductive loss varies from 20% to 80% (376–378). Women with corrected anatomical anomalies may expect a successful pregnancy in 60% to 90% of cases (376, 377, 379, 380). A success rate higher than 90% has been reported for women with corrected endocrinologic abnormalities (376). Between 70% and 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable (381, 382).

Many forms of pre- or postconceptional tests have been proposed to help predict pregnancy outcome (172, 187, 279, 383, 384); none has been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity with ultrasonography may offer prognostic value; however, it appears that predictions may be greatly affected by any underlying diagnosis. In one study, the live birth rate following documentation of fetal cardiac activity between 5 and 6 weeks from the last menstrual period was approximately 77% in women with two or more unexplained spontaneous abortions.

SECTION VII Reproductive Endocrinology

Menopause, the permanent cessation of menstruation, occurs at a mean age of 51 years. Despite a great increase in the life expectancy of women, the age at menopause has remained remarkably constant. A woman in the United States today will live approximately 30 years, or greater than a third of her life, beyond the menopause. After menopause, the ovaries cease to produce significant amounts of estrogen; therefore, symptoms and diseases associated with estrogen deficiency are of increasing importance to women’s health.

The age at menopause appears to be genetically determined and is unaffected by race, socioeconomic status, age at menarche, or number of prior ovulations. Factors that are toxic to the ovary often result in an earlier age of menopause; women who smoke experience an earlier menopause (1), as do many women exposed to chemotherapy or...
pelvic radiation. Women who have had surgery on their ovaries, or have had a hysterectomy, despite retention of their ovaries, also may experience early menopause (2).

Premature ovarian failure, defined as menopause before the age of 40 years, occurs in approximately 1% of women. It may be idiopathic or associated with a toxic exposure, chromosomal abnormality, or autoimmune disorder.

Although menopause is associated with changes in the hypothalamic and pituitary hormones that regulate the menstrual cycle, menopause is not a central event, but rather primary ovarian failure. At the level of the ovary, there is a depletion of ovarian follicles, most likely secondary to apoptosis or programmed cell death. The ovary, therefore, is no longer able to respond to the pituitary hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), and ovarian estrogen and progesterone production cease.

Androgen production from the ovary continues beyond the menopausal transition because of sparing of the stromal compartment. Androgen concentrations are lower in menopausal women than in women of reproductive age. This finding appears to be associated more with aging and decreased functioning of the ovary and adrenal glands over time rather than with menopause per se. Menopausal women continue to have low levels of circulating estrogens, principally from peripheral aromatization of ovarian and adrenal androgens. Adipose tissue is a major site of aromatization, so obesity affects many of the sequelae of menopause. The ovarian–hypothalamic–pituitary axis remains intact during the menopausal transition; thus, FSH levels rise in response to ovarian failure and the absence of negative feedback from the ovary. Atresia of the follicular apparatus, in particular the granulosa cells, results in reduced production of estrogen and inhibit, resulting in reduced inhibit levels and elevated FSH levels, a cardinal sign of menopause.

Several staging systems have been developed to describe the many changes that encompass the transition from reproductive life to postmenopause. The late reproductive years are characterized by regular menses associated with elevated FSH levels. The menopausal transition is characterized by elevated FSH levels associated with variable cycle lengths and missed menses, whereas the postmenopausal period is marked by amenorrhea. The menopausal transition begins with variability in menstrual cycle length accompanied by rising FSH levels and ends with the final menstrual period. Menopause is defined retrospectively as the time of the final menstrual period followed by 12 months of amenorrhea. Postmenopause describes the period following the final menses (3).

The pathophysiologic consequences of menopause may be best understood by considering that the ovary is a women's only source of oocytes, her primary source of estrogen and progesterone, and a major source of androgens. Menopause results in infertility secondary to oocyte depletion. Ovarian cessation of progesterone production appears to have no clinical consequences except for the increased risk of endometrial proliferation, hyperplasia, and cancer associated with continued endogenous estrogen production or administration of unopposed estrogen therapy in menopausal women. The possible effects of declining androgen concentrations that occur with aging are an area of both controversy and active investigation.

The major consequences of menopause are related primarily to estrogen deficiency. It is very difficult to distinguish the consequences of estrogen deficiency from those of aging, as aging and menopause are inextricably linked. Studying the effects of estrogen deficiency and replacement in young women with ovarian failure or of drugs that suppress estrogen synthesis (such as gonadotropin-releasing hormone antagonists) helps to distinguish between the effects of aging and estrogen deficiency. These models are imperfect, though, and differ from natural menopause in many ways.
Principal health concerns of menopausal women include vasomotor symptoms, urogenital atrophy, osteoporosis, cardiovascular disease, cancer, cognitive decline, and sexual problems. Options for caring for menopausal women have increased greatly since hormone therapy (HT) was first introduced in the 1960s. With respect to hormone use, there are many choices of hormone type, dose, and method of administration. Not only have new forms of estrogens and progestins been introduced, but novel ways of combining the two hormones are available. In addition to hormones, selective estrogen receptor modulators (SERMs) and bisphosphonates are available for treatment. Women are requesting more information on complementary and alternative therapies, which are being studied more carefully. The many options now available make caring for postmenopausal women more rewarding as well as more challenging.

Health Concerns After Menopause

Vasomotor Symptoms

Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women, but may continue for up to 10 years or longer in others. Hot flashes are the primary reason women seek care at menopause and request HT. Hot flashes not only disturb women at work and interrupt daily activities but also disrupt sleep (4). Many women report difficulty concentrating and emotional lability during the menopausal transition. Treatment of vasomotor symptoms should improve these cognitive and mood symptoms if they are secondary to sleep disruption and resulting daytime fatigue. The incidence of thyroid disease increases as women age; therefore, thyroid function tests should be performed if vasomotor symptoms are atypical or resistant to therapy.

The physiologic mechanisms underlying hot flashes are incompletely understood. A central event, probably initiated in the hypothalamus, drives an increased core body temperature, metabolic rate, and skin temperature; this reaction results in peripheral vasodilation and sweating in some women. The central event may be triggered by noradrenergic, serotonergic, or dopaminergic activation. Although an LH surge often occurs at the time of a hot flash, it is not causative, because vasomotor symptoms occur in women who have had their pituitary glands removed. Exactly what role estrogen plays in modulating these events is unknown. Vasomotor symptoms are a consequence of estrogen withdrawal, not simply estrogen deficiency. For example, a young woman with primary ovarian failure resulting from Turner syndrome will have a very high FSH level and low estrogen levels, but she will not experience hot flashes until she is treated with estrogens and then therapy is withdrawn.

Systemic estrogen therapy is the most effective treatment available for vasomotor symptoms and associated sleep disturbance. Although standard doses are usually effective, younger women and those with recent oophorectomy may need higher doses. Healthy women in the perimenopausal transition who are experiencing bothersome hot flashes but still menstruating may benefit from oral contraceptives. The high doses of estrogens and progestins in oral contraceptives not only effectively treat vasomotor symptoms but also provide cycle control. Very-low-dose estrogen therapy also effectively treats hot flashes for many women. Low-dose oral esterified and conjugated estrogens (0.3 mg daily) (5,6) or transdermal estradiol (0.025 mg weekly) (7) often is effective and is associated with minimal side effects and endometrial stimulation. Progestin therapy must be given concurrently if a woman has not had a hysterectomy, although with low-dose estrogen therapy, intermittent progestin treatment may be an option.

Given the known risks, described in detail later in this chapter, HT should be used at the lowest effective dose for the shortest amount of time that meets treatment goals. The majority of women with very bothersome hot flashes at the time of the menopausal
transition will benefit from short-term therapy and be able to wean off hormones after several years of use. A major risk of HT, breast cancer, does not appear to increase until after 4 to 5 years of use.

Because vasomotor symptoms appear to be the result of estrogen withdrawal, rather than simply low estrogen levels, if cessation of estrogen therapy is desired, the dose should be reduced slowly over several months. Abruptly stopping treatment may result in a return of disruptive vasomotor symptoms. This recommendation is based on clinical experience, as no controlled trials have been performed to examine the optimal way to cease HT use.

One possible approach to stopping therapy is to reduce the dose and dosing interval slowly, and to let the patient’s symptoms guide the pace at which she discontinues therapy. For example, initially, the patient would be prescribed a reduced dose of HT every day for 2 to 3 months. She would then take the reduced dose every other day for 2 to 3 months, then every third day for 2 to 3 months, and then stop if she is doing well.

When a woman chooses not to take estrogen or when it is contraindicated, other options are available (Table 32.1) (8). Progestin therapy alone is an option for some women. Medroxyprogesterone acetate (MPA) (Provera) (20 mg/day) and megestrol acetate (Megace) (20 mg 2 times daily) effectively treat vasomotor symptoms (9). Several drugs that alter central neurotransmitter pathways also are effective. Agents that decrease central noradrenergic tone, such as clonidine (Catapress), relieve hot flashes, whereas yohimbine, an agent that increases noradrenergic tone, exacerbates symptoms (10). Clonidine has been shown in randomized, placebo-controlled trials to significantly reduce vasomotor symptoms (11). It may be used orally (0.1–0.2 mg/day) or as a weekly transdermal patch (0.1 mg/day). Potential side effects include orthostatic hypotension and drowsiness.

Selective serotonin reuptake inhibitors (SSRIs) also are effective in relieving hot flashes. In a double-blind, randomized, placebo-controlled trial of paroxetine CR (Paxil) (12.5 and 25 mg/day), menopausal women with hot flashes experienced a significant reduction in both the frequency and severity of episodes (12). Hot flash composite scores decreased 62% in the paroxetine group versus 38% in the placebo group. Actual hot flash frequency decreased by 3.3 hot flashes per day with paroxetine versus 1.8 on placebo. The improvement in vasomotor symptoms was independent of any significant change in mood or anxiety symptoms. Both doses were effective, but the lower dose was better tolerated. The most common side effects were headache, nausea, and insomnia. A modest improvement in symptoms also occurred in a randomized, double-blind, placebo-controlled, crossover trial of fluoxetine (Prozac) (20 mg/day) (13). Not all studies show an improvement in vasomotor symptoms with SSRIs. In a 9-month, double-blind, parallel-group trial, there was no significant improvement in hot flashes with either fluoxetine or citalopram (Celexa) (10–30 mg/day) compared with placebo (14).

Modulation of other central neurotransmitters with different antidepressants also may be effective, but have greater potential for adverse effects. Venlafaxine (Effexor) (75 mg/day), a serotonin and norepinephrine reuptake inhibitor, significantly reduced hot flashes in a controlled trial (15). Hot flash scores decreased 61% in the venlafaxine group compared with 27% in the placebo group. The active treatment group experienced significantly more side effects, including dry mouth, nausea, and anorexia. A dopamine antagonist, veralipride (Agreal) (100 mg/day), significantly reduced hot flashes in a controlled trial, but side effects of this class of agent include somnolence, hyperprolactinemia, galactorrhea, and tardive dyskinesia.

Gabapentin (Neurontin), a gamma-aminobutyric acid analogue approved for the treatment of seizures, also reduced hot flash frequency and severity significantly more than placebo in a double-blind, randomized trial (16). Hot flash scores decreased 54% in the women treated with gabapentin (900 mg/day) compared with a 31% reduction in placebo-treated women. The most common adverse events were somnolence, dizziness, and rash.

Bellargal, a combination of ergotamine, phenobarbital, and belladonna alkaloids approved for the treatment of migraines, also reduces hot flashes (17). Its use, though, is limited by anticholinergic side effects, including dry mouth, constipation, and drowsiness.

Many menopausal women are interested in trying nutritional and vitamin supplements for relief of hot flashes. Many of these therapies are claimed to relieve hot flashes but rarely are studied in controlled trials (18). Vasomotor symptoms are particularly sensitive to placebo treatments. Several controlled studies demonstrate a reduction in vasomotor symptoms with soy supplementation, whereas others do not. In one randomized study, soy protein (60 g/day) reduced hot flashes by 45%, a significantly greater reduction than the 30% seen in placebo-treated women (19). In another controlled trial, use of isoflavones (100 mg/day) significantly decreased vasomotor symptoms when compared with placebo, while also reducing total and low-density lipoprotein cholesterol (20). A large controlled trial of soy protein, with and without isoflavones, demonstrated no effect of isoflavones on vasomotor symptoms (21). Soy-related compounds may act as SERMs, with their effects modulated through interactions with the estrogen receptor.

Although often recommended, vitamin E (800 IU/day) only minimally reduced hot flashes in a placebo-controlled, randomized, crossover trial (22). Uncontrolled studies of acupuncture (23), exercise, and paced respiration show an improvement in vasomotor symptoms with the use of these techniques. Women may choose to use alternative and complementary therapies for relief of symptoms, but they should be aware that their safety and efficacy are unproved. Being in a cool environment is associated with fewer subjective
and objective hot flashes (24), so women experiencing symptoms should be encouraged to keep the room temperature low and wear light, layered clothing. Overweight women and those who smoke have more severe vasomotor symptoms than women of normal weight and nonsmokers. These findings provide additional reasons to encourage women to lose weight and stop smoking (25,26).

**Urogenital Atrophy**

Urogenital atrophy results in vaginal dryness and pruritus, dyspareunia, dysuria, and urinary urgency. These common problems in menopausal women respond well to therapy.

**Systemic estrogen therapy is effective for the relief of vaginal dryness, dyspareunia, and urinary symptoms.** For women who should not or choose not to use estrogen therapy, another option is topical application. Because systemic absorption is low, endometrial stimulation is minimal; thus vaginal estrogen therapy may be appropriate even for symptomatic women with breast cancer. Low doses of estrogen cream (Premarin, Estrace) (0.5 g) are effective when used only 1 to 3 times weekly (27). An estradiol vaginal tablet (Vagifem) (25 µg) inserted twice weekly, which may be less messy and easier to use than estrogen cream, is available. An estrogen containing vaginal ring (Estring) (7.5 µg/day), which is placed in the vagina every 3 months and slowly releases a low dose of estradiol, also is available (28).

Studies of the vaginal tablets and ring have confirmed endometrial safety at 1 year, but studies are not available on the long-term effects of low-dose vaginal estrogen therapy on the endometrium. Women using vaginal estrogen therapy should be asked to report any vaginal bleeding, and this bleeding should be evaluated thoroughly. Typically, systemic progestin therapy is not prescribed to women using low-dose vaginal estrogen. In the absence of supportive evidence, it is not unreasonable to recommend the use of progestin for 12 to 14 days, every 6 to 12 months, in women who are long-term users of vaginal estrogens, especially overweight women or those otherwise at increased risk for endometrial hyperplasia. Lubricants (e.g., Replens, KY Jelly) are a nonhormonal alternative for reducing discomfort with intercourse in the presence of urogenital atrophy.

**Vaginal estrogen therapy appears to reduce urinary symptoms, such as frequency and urgency, and has been shown to reduce the likelihood of recurrent urinary tract infections in postmenopausal women** (29). The effect of estrogen therapy on urinary incontinence is unclear. Whereas the results of some studies suggest improvement in incontinence with estrogen therapy, others show a worsening of symptoms (30).

**Osteoporosis**

Osteoporosis, or low bone mass, affects an estimated 30 million women in the United States, or approximately 55% of women older than age 50 years (31). Annual expenditures for medical care of osteoporotic fractures in the United States total $15 billion. Because therapy is most likely to benefit those at highest risk, it is important to review a woman’s risk factors for osteoporosis when making treatment decisions and to consider bone mineral density screening for high-risk women (Table 32.2). Nonmodifiable risk factors include age, Asian or Caucasian race, family history, small body frame, history of a prior fracture, early menopause, and prior oophorectomy. Modifiable risk factors include decreased intake of calcium and vitamin D, smoking, and a sedentary lifestyle. Medical conditions associated with an increased risk of osteoporosis include anovulation during the reproductive years (e.g., secondary to excess exercise or an eating disorder), hyperthyroidism, hyperparathyroidism, chronic renal disease, and diseases requiring systemic corticosteroid use.
Bone mineral density (BMD) measurements may be used to diagnose osteoporosis, determine fracture risk, and identify women who would benefit from therapeutic interventions. Dual x-ray absorptiometry (DXA) of the hip and spine is the primary technique for BMD assessment. BMD is expressed as a T-score, which is the number of standard deviations from the mean for a young, healthy woman. A T-score above –1 is considered normal, a value between –1 and –2.5 denotes osteopenia, and a score below –2.5 indicates osteoporosis.

Although there is a strong association between BMD and fracture risk, a woman’s age, overall health status, and risk for falls also influence her fracture risk. Evaluation of BMD by DXA is recommended for all women aged 65 and older, regardless of risk factors, and for younger postmenopausal women with 1 or more risk factors, other than being white and menopausal (32). Osteoporosis may be assumed in any menopausal woman with a low-impact trauma fracture.

Counseling women to alter modifiable risk factors is important for both the prevention and treatment of osteoporosis. Many women have diets deficient in calcium and vitamin D and will benefit from dietary changes and supplementation. Women should receive 1,000 to 1,500 mg of calcium and 400 to 800 IU of vitamin D daily. This may be achieved through diet or vitamin and mineral supplementation. Reducing the risk of osteoporosis is another of the many health benefits of smoking cessation and regular exercise. Treatment is indicated for all women with osteoporosis as well as for those with osteopenia and additional risk factors. Drug therapies for the prevention and treatment of osteoporosis are principally antiresorptive drugs that reduce bone loss and anabolic agents that stimulate new bone formation (Table 32.3).

Hormone therapy is effective in preventing and treating osteoporosis. In observational studies, estrogen therapy has been shown to reduce osteoporosis-related fractures by
approximately 50% when started soon after menopause and continued long term. It also significantly decreases fracture rates in women with established disease (33). The Women’s Health Initiative (WHI) randomized controlled trial confirmed a significant (34%) reduction in hip fractures in healthy women receiving HT (conjugated equine estrogen 0.625 mg with MPA 5 mg; PremPro) after a mean follow-up of 5 years (34) (Table 32.4). Recent studies demonstrate that even very-low-dose estrogen therapy (estradiol 0.25 mg/day; conjugated equine estrogen 0.3 mg/day with MPA 1.5 mg/day, [PremPro]; transdermal estradiol 0.025 mg/day [Climara, Vivelle, Alora]; and 0.014 mg/day [Menostar]), combined with calcium and vitamin D, produce significant increases in bone mineral density compared with placebo (35–37).

Bisphosphonates, including alendronate (Fosamax, 35–70 mg weekly), risedronate (Actonel, 35 mg weekly), and ibandronate (Boniva, 150 mg monthly) specifically inhibit bone resorption and are very effective for both osteoporosis prevention and
CHAPTER 32 Menopause

Patients should be instructed to take these drugs on an empty stomach with a large glass of water and then to remain upright for at least 30 to 60 minutes. The major side effect is gastrointestinal distress; esophageal ulceration is a rare occurrence. Once-weekly administration of high-dose alendronate or risedronate is therapeutically equivalent to daily dosing and more convenient for patients. Monthly dosing with ibandronate is very convenient and may result in improved long-term continuance with bisphosphonate therapy.

Selective estrogen receptor modulators are compounds that act as both estrogen agonists and antagonists, depending on the tissue. Raloxifene (Evista, 60 mg) is a SERM that has been approved for both the prevention and treatment of osteoporosis (40). Raloxifene exercises estrogenlike actions on bone and lipids without stimulating the breast or endometrium (41). Calcitonin nasal spray (Miacalcin, 200 IU) is another approved treatment for established osteoporosis. Parathyroid hormone (human recombinant PTH 1-34) (teriparatide, Forteo, 20 µg subcutaneously) is a novel therapy for osteoporosis. Unlike most

WHIMS, Women’s Health Initiative Memory Study.

**treatment** (38,39). Patients should be instructed to take these drugs on an empty stomach with a large glass of water and then to remain upright for at least 30 to 60 minutes. The major side effect is gastrointestinal distress; esophageal ulceration is a rare occurrence. Once-weekly administration of high-dose alendronate or risedronate is therapeutically equivalent to daily dosing and more convenient for patients. Monthly dosing with ibandronate is very convenient and may result in improved long-term continuance with bisphosphonate therapy.
treatments for osteoporosis that inhibit bone resorption, parathyroid hormone stimulates new bone formation. Treatment of postmenopausal osteoporotic women with parathyroid hormone by daily subcutaneous injection results in dramatic increases in vertebral, femoral, and total body bone mineral density, and significant reductions in vertebral and nonvertebral fractures (42). Parathyroid hormone is indicated for postmenopausal women with osteoporosis who are at very high risk for fracture.

Cardiovascular Disease

Cardiovascular disease is the leading cause of death for women, accounting for approximately 45% of mortality. Nonmodifiable risk factors include age and family history. Modifiable risk factors include smoking, obesity, and a sedentary lifestyle. Medical conditions associated with an increased risk of heart disease include diabetes, hypertension, and hypercholesterolemia.

Advising women to alter modifiable risk factors and adequately treating diabetes, hypertension, and hypercholesterolemia are important measures in reducing the risk of heart disease. In the past, prevention of heart disease was thought to be a potential benefit of HT. Epidemiologic studies report an approximately 50% decrease in heart disease in woman who use HT (43,44). This observed reduction in coronary heart disease was thought secondary to beneficial effects of HT on lipid levels (45) and direct actions on the vascular wall. Observational studies are prone to bias, though, and woman who choose to use hormones are generally at lower risk for heart disease than those who do not (46).

The WHI randomized controlled trial of combination HT versus placebo showed that not only does HT not prevent heart disease in healthy women, it actually increases the risk of cardiovascular events (34). The WHI is a 15-year study sponsored by the National Institutes of Health that examines ways to prevent heart disease, osteoporosis, and breast and colorectal cancer in women. There are several different studies in WHI involving more than 160,000 healthy postmenopausal women. The WHI randomized controlled trial enrolled approximately 16,000 women nationwide between the ages of 50 and 79 years. The average age of women in the study was 63 years. The major goal of the WHI clinical trial was to determine whether combined estrogen and progestin HT prevented heart disease and fractures, and whether there were risks associated with HT use. After an average of 5 years of follow-up, heart disease and stroke were significantly increased in HT users by 29% and 41%, respectively.

Approximately 11,000 women without a uterus participated in a separate WHI study and were randomized either to estrogen alone or placebo. After an average follow-up of 7 years, there was no increased risk of heart disease in estrogen users (47). Estrogen use did have adverse vascular effects, however, increasing the risk of stroke by 39% and venous thromboembolism by 33%.

There appears to be no role for HT in the prevention of cardiovascular disease, not only in healthy women, but also in women with established heart disease. The Heart and Estrogen/Progestin Replacement Study (HERS), a randomized, placebo-controlled trial of combination estrogen–progestin therapy for secondary prevention of heart disease, also did not demonstrate any reduction in cardiovascular events (48). Overall, there were no significant differences in cardiovascular outcomes between HT and placebo-treated women. There was a significant time factor, however, with more cardiovascular events occurring in women using HT in year 1, and fewer in years 4 and 5.

The WHI trials and the HERS study examined only treatment with conjugated equine estrogens and medroxyprogesterone acetate. The effects of other oral estrogen agents, transdermal estradiol, cyclic HT, or therapy with other progestins may be different. In
addition, the average age of women participating in these trials was more than 15 years beyond the age at which women typically initiate HT for the treatment of vasomotor symptoms. It is possible that early initiation of HT may result in a more favorable risk-benefit profile. In the absence of data from randomized controlled trials, the conservative approach is to assume that the risks of various HT regimens are similar.

Selective estrogen receptor modulators, such as raloxifene, also improve the lipid profile, decreasing total and low-density lipoprotein cholesterol similarly to oral HT, but without increasing high-density lipoprotein cholesterol or triglycerides (49). Whether the beneficial effects of raloxifene on lipid levels will translate into a reduced incidence of heart disease currently is being studied in the Raloxifene Use for the Heart (RUTH) trial, a large randomized, placebo-controlled study examining the effects of raloxifene on cardiovascular disease. In a secondary analysis of results from a randomized, controlled trial of raloxifene versus placebo in more than 7,000 women with osteoporosis, there were no significant differences between groups with regard to coronary and cerebrovascular events. Among a subset of approximately 1,000 women with increased cardiovascular risk at baseline, the women who received raloxifene experienced a significant 40% reduction in cardiovascular events (50).

Breast Cancer

Breast cancer is the most common cancer in women, is the second leading cause of cancer death, and is a major health concern for menopausal women (51). For women in the United States, the lifetime risk of developing invasive breast cancer is 12%; therefore, any therapies that reduce or increase this risk will have a major impact on women’s health. Risk factors for breast cancer include age, early menarche, late menopause, family history, and prior breast disease, including epithelial atypia and cancer. Oophorectomy and term pregnancy before the age of 30 are associated with reduced risk. Many of these risk factors are consistent with the hypothesis that prolonged estrogen exposure increases the risk of breast cancer.

Long-term use of HT is associated with an increased risk of breast cancer (52). Observational studies show a relative risk of approximately 1.3 with long-term HT use, generally defined as greater than 5 years. The results of several studies suggest that the risk of breast cancer associated with the use of estrogen alone may be lower, with a higher risk in users of estrogen plus progestin (53,54). The WHI randomized controlled trial demonstrated a significant (26%) increase in the risk of invasive breast cancer after approximately 5 years of use of HT (34). In women with a prior hysterectomy, there was no increased risk of breast cancer after an average of 7 years of estrogen use alone (47).

The SERM tamoxifen (Nolvadex) is an estrogen antagonist in the breast that is used in the treatment of estrogen-receptor positive breast cancer. Tamoxifen (20 mg) also has been approved for the prevention of breast cancer in high-risk women, resulting in an approximately 50% reduction in the risk of disease (55). Raloxifene also may reduce the risk of breast cancer. Postmenopausal women receiving raloxifene as part of a large osteoporosis treatment trial experienced a 76% reduction in the risk of invasive breast cancer compared with placebo-treated women (56). The Study of Tamoxifen and Raloxifene (STAR) trial is comparing the effectiveness of raloxifene and tamoxifen for the prevention of breast cancer in high-risk women. The Continuing Outcomes Relevant to Evista (CORE) trial is evaluating the effect of raloxifene on breast cancer risk in women with osteoporosis.

The risk of venous thromboembolism (VTE) is increased approximately threefold with the use of tamoxifen and raloxifene. This increase is similar to the increased risk that occurs in HT users. Hot flashes are increased with raloxifene and tamoxifen use, and raloxifene is associated with leg cramps. Tamoxifen acts as an estrogen agonist in the
endometrium, increasing the risk of endometrial polyps, hyperplasia, and cancer, whereas no endometrial stimulation is seen with raloxifene.

Performing a screening mammography examination annually for women older than age 50 years reduces breast cancer mortality. Monthly breast self-examination also is recommended. Women at increased risk for breast cancer are advised not to use HT, or to use it only short term. Women at high risk also may elect to take tamoxifen therapy.

Alzheimer Disease

Alzheimer disease is the most common form of dementia. Women are at greater risk for developing the disease than men, and the number of affected individuals in the United States is expected to double to more than 8 million by 2010. Several small trials and observational studies have suggested that hormone therapy use may decrease the risk of Alzheimer disease (57). A randomized, controlled study in women with mild to moderate Alzheimer disease, however, showed that 1 year of estrogen treatment neither slowed disease progression nor improved cognition (58). The effect of HT on cognitive function in women without dementia was studied in the WHI Memory Study (WHIMS), a randomized, double-blind, placebo-controlled trial of women aged 65 years or older enrolled in the WHI trial. In contrast to the findings of observational studies, women randomized to HT in WHIMS experienced a significant twofold increased risk of dementia, most commonly Alzheimer disease (59). In addition, HT use was associated with an adverse effect on cognition. Compared with placebo-treated women, women in the HT group scored significantly lower on the Modified Mini-Mental State Examination (60). Given the increased incidence of stroke identified in HT users in the WHI trial, it is possible that small, undetected cerebrovascular events were more likely to occur in the HT group, increasing the risk of dementia.

Risks of Hormone Therapy

In addition to an increased risk of heart attack, stroke, breast cancer, and Alzheimer disease, VTEs are increased approximately two- to threefold with HT use. This was confirmed in the WHI clinical trial, in which women assigned to HT experienced twice the incidence of deep venous thrombosis and pulmonary embolism than women randomized to placebo (34). Women taking HT should be advised to stop therapy several days before elective surgery or periods of prolonged immobilization. It is possible that transdermal estrogen therapy may not be associated with an increased risk of VTE. In one case-control study, oral but not transdermal estrogen therapy was associated an increased risk of VTEs (61). There also is a twofold risk of gallbladder disease with HT use. Common side effects include breast tenderness, exacerbation of migraine headaches, and vaginal bleeding.

Contraindications to HT use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, active thromboembolic disorders, and active liver or gallbladder disease. Relative contraindications include heart disease; migraine headaches; and a history of liver or gallbladder disease, endometrial cancer, or thromboembolic events. These situations require a thoughtful assessment of potential risks and benefits and documentation of informed patient consent before treatment.

The use of unopposed estrogen is associated with an increased risk of endometrial hyperplasia and cancer. Therefore, combination estrogen-progestin therapy is recommended for all women with a uterus. Treatment may be provided in a sequential manner, with estrogen daily and progestin for 12 to 14 days of each month, or in a continuous-combined fashion with estrogen and a lower dose of progestin daily.
Sequential regimens result in regular, predictable vaginal bleeding. The benefit of continuous-combined regimens is that approximately 60% to 70% of women will experience amenorrhea by the end of 1 year of therapy; the problem is that the bleeding that does occur is irregular and unpredictable (62). Several new combination therapies have been approved for use that combine norethindrone acetate (NETA) as the progestin, with either ethinyl estradiol (FemHRT) or estradiol (Activella). These products, as well as the low-dose PremPro formulations (0.45/1.5, 0.3/1.5 mg/day), have a lower incidence of breakthrough bleeding than other continuous-combined regimens. In general, older women and women who have been menopausal for several years experience less irregular bleeding with continuous-combined regimens than do younger, recently menopausal women.

For women who note symptoms of depressed mood or bloating with MPA, oral natural micronized progesterone (Prometrium, 100–200 mg/day) is approved for use in HT regimens. It results in a more favorable lipid profile and may have different side effects (45). The major adverse effect of oral progesterone appears to be drowsiness, which may be a benefit for some women if taken at bedtime. Micronized progesterone contains peanut oil and should not be used by women with peanut allergies. Other options for women with intolerance to progestin therapy include using cyclic progestins only 3 to 4 times per year, rather than 12 to 14 days of each month. A progestin-containing intrauterine device or vaginal progesterone cream also may be used. When utilizing an unapproved progestin regimen, increased surveillance of the endometrium with serial ultrasound monitoring and/or endometrial biopsy is indicated (63). Various formulations used for HT are shown in Table 32.5.

Sexual Dysfunction

Many women experience sexual dysfunction, although the exact incidence and etiology are unknown. Sexual dysfunction may involve decreased interest or desire to initiate activity, as well as decreased arousal or ability to achieve an orgasm during sexual relations. The etiology of sexual dysfunction often is multifactorial, including psychological problems such as depression or anxiety disorders, conflict within the relationship, issues relating to prior physical or sexual abuse, medication use, or physical problems that make sexual activity uncomfortable, such as endometriosis or atrophic vaginitis. Analyzing data from the National Health and Social Life Survey, a probability sample of sexual behavior conducted in 1992 with a cohort of adults, the prevalence of sexual dysfunction in the United States was estimated to be as high as 43% in women and 31% in men (64). Although some studies describe decreased levels of sexual desire and activity in older women, sexual concerns are common and not specifically a problem of menopause.

Female sexual dysfunction after menopause is a complex problem with many etiologies. Careful evaluation of physiological, psychological, lifestyle, and relationship variables is required to optimize therapy. Treatment of anxiety and depression, adjustment of antidepressant medication, and relationship counseling may improve sexual function. Specific exercises and activities, often performed under the guidance of a sex therapist, aid many women and couples with sexual dysfunction. Specific treatment of genitourinary atrophy with systemic or local vaginal estrogen therapy or vaginal lubricants effectively reduces dyspareunia and may improve sexual arousal and response. Sildenafil citrate (Viagra) was ineffective in a large randomized, double-blind, placebo-controlled study of women with sexual dysfunction (65). A clitoral therapy device (EROS-CTD™) approved by the U.S. Food and Drug Administration may increase clitoral blood flow and improve arousal in some women (66).

Androgen therapy may have a role in the treatment of sexual dysfunction in menopausal women who have low androgen levels and no other identifiable cause.

(Continued)
for their sexual problem (67). Although ovarian and adrenal androgen levels decline with age, there is not an abrupt decrease in the production of these hormones at menopause as that which occurs with ovarian estradiol (68). Surgical menopause is an exception; testosterone levels decrease by approximately 50% following bilateral oophorectomy.

In a double-blind, crossover study of surgically menopausal women, the administration of supraphysiologic doses of intramuscular testosterone resulted in significantly higher scores of sexual desire, fantasy, and arousal than did treatment with estradiol alone or placebo (69). In a double-blind, randomized study of the effects on libido of oral methyltestosterone (1.25 mg/day) combined with esterified estrogens (0.625 mg/day, Estratest HS), women randomized to treatment with the estrogen-androgen combination reported significantly improved sexual interest and desire compared with women treated with estrogen alone (70). In randomized, double-blind, placebo-controlled studies of estrogen-treated women without ovaries who had sexual dysfunction, physiologic testosterone therapy administered by a transdermal patch resulted in significant increases in sexual activity and pleasure (71,72).

A popular, but untested treatment is the use of a small amount of testosterone ointment or cream (1%), compounded at many pharmacies, applied topically to the vagina, arms, or low abdomen.

Potential risks of androgen therapy include hirsutism, acne, irreversible deepening of the voice, and adverse changes in liver function and lipid levels. As most androgens are aromatized to estrogens, androgen therapy may pose the same risks as estrogen therapy. Women who elect a trial of therapy should be informed of the potential risks, unproven efficacy, and off-label nature of use.

Summary

There are many options available to address the quality of life and health concerns of menopausal women. Currently, the primary indication for HT is the alleviation of hot flashes and associated symptoms. Further details regarding these recommendations have been published by the American College of Obstetricians and Gynecologists and the North American Menopause Society (73,74). Women must be informed of the potential benefits and risks of all therapeutic options, and care should be individualized based on a woman’s medical history, needs, and preferences.

References

CHAPTER 32 Menopause

Most risk factors for the development of endometrial carcinoma are related to prolonged, unopposed estrogen stimulation.

Office endometrial aspiration biopsy is the accepted first step in evaluating a woman with abnormal uterine bleeding or suspected endometrial pathology.

Papillary serous and clear cell endometrial carcinomas make up less than 10% of endometrial cancers, yet account for more than one half of all endometrial cancer deaths.

Most patients with endometrial cancer should undergo surgical staging, including abdominal exploration, peritoneal cytology, hysterectomy, bilateral salpingo-oophorectomy, and selective pelvic and para-aortic lymphadenectomies.

The most important adverse prognostic variables in endometrial cancer are advancing patient age, nonendometrioid or grade 3 histology, deep myometrial invasion, lymph-ovascular space invasion, large tumor size, cervix extension, lymph node metastasis, and intraperitoneal spread.

Postoperative adjuvant radiotherapy in selected patients with endometrial cancer decreases the risk of local vaginal/pelvic recurrence and improves disease-free survival.

Overall 5-year survival rate in endometrial cancer is approximately 75%.

Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread, and management.

Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost one half of all gynecologic cancers in the United States. In 2006, an estimated 41,200 new cases and 7,350 cancer-related deaths are anticipated. Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and bowel cancers, and the eighth leading cause of death from malignancy in women. Overall, about 2% to 3% of women develop endometrial cancer during their lifetime (1).
In recent years, certain factors have led to an increasing awareness of and emphasis on diagnosis and treatment of endometrial cancer. These factors include the declining incidence of cervical cancer and related deaths in the United States, prolonged life expectancy, postmenopausal use of hormone therapy, and earlier diagnosis. The availability of easily applied diagnostic tools and a clearer understanding of premalignant lesions of the endometrium have led to an increase in the number of women diagnosed with endometrial cancer. Although endometrial carcinoma usually presents as early-stage disease and can generally be managed without radical surgery or radiotherapy, deaths from endometrial carcinoma now exceed those from cervical carcinoma in the United States. Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The role of estrogen in the development of most endometrial cancers has clearly been established. Any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.

During the past several decades, the histopathology, spread patterns, and clinicopathologic factors that affect the prognosis of endometrial cancers have been better defined. Management of endometrial cancer has evolved from a program of preoperative intrauterine or external pelvic irradiation followed by hysterectomy based on clinical staging, to an individualized approach using hysterectomy as primary therapy and employing additional postoperative treatment depending on surgical and pathologic findings. Further analysis and investigation are needed to determine whether this initial operative approach to treatment and staging, followed by targeted postoperative therapy, will translate into improved survival rates and lower morbidity.

Epidemiology and Risk Factors

There appear to be two different pathogenetic types of endometrial cancer (2). Type I, accounting for about 75% to 85% of cases, occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous. In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These “estrogen-dependent” tumors tend to be better differentiated and have a more favorable prognosis than tumors that are not associated with hyperestrogenism. Type II endometrial carcinoma occurs in women with no source of estrogen stimulation of the endometrium. These spontaneously occurring cancers are not associated pathologically with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These “estrogen-independent” tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in African-American and Asian women. Over the past decade, molecular genetic studies have shown that these two tumor types evolve via distinct pathogenetic pathways (3). The most frequent early molecular genetic alterations in type I tumors are mutations in the PTEN tumor suppressive gene and K-ras oncogene and microsatellite instability. Type II tumors are more often associated with p53 mutations.

Several risk factors for the development of endometrial cancer have been identified (4–9) (Table 33.1). Most of these risk factors are related to prolonged, unopposed estrogen stimulation of the endometrium. Nulliparous women have 2 to 3 times the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen without sufficient progesterone) increase the risk. Natural menopause occurring after age 52 years increases the risk for endometrial cancer 2.4 times compared with women who experienced menopause before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. The risk of endometrial cancer is increased 3 times in women who are 21 to 50 pounds overweight and 10 times in those more than 50 pounds overweight (resulting from
excess estrone as a result of peripheral conversion of adrenally derived androstenedione by aromatization in fat).

Other factors leading to long-term estrogen exposure, such as polycystic ovary syndrome and functioning ovarian tumors, also are associated with an increased risk for endometrial cancer. Menopausal estrogen therapy without progestins increases the risk of endometrial cancer 4 to 8 times. This risk increases with higher doses and with more prolonged use and can be reduced to essentially baseline levels by the addition of progestin (8). It has been noted that the use of the antiestrogen tamoxifen for treatment of breast cancer is associated with a two- to threefold increased risk for the development of endometrial cancer, although this finding is confounded by the apparent greater risk of endometrial cancer in women who have breast cancer, with or without treatment with tamoxifen (9,10). Diabetes mellitus increases a woman’s risk for endometrial cancer by 1.3 to 2.8 times. Women with hereditary nonpolyposis colorectal cancer syndrome (HNPCC), a cancer susceptibility syndrome with germline mutations in mismatch repair genes MLH1, MSH2, and MSH6, have a 40% to 60% lifetime risk for endometrial as well as colon cancer (11). Other medical conditions, such as hypertension and hypothyroidism, have been associated with endometrial cancer, but a causal relationship has not been confirmed.

### Endometrial Hyperplasia

Endometrial hyperplasia represents a spectrum of morphologic and biologic alterations of the endometrial glands and stroma, ranging from an exaggerated physiologic state to carcinoma in situ. Clinically significant hyperplasias usually evolve within a background of proliferative endometrium as a result of protracted estrogen stimulation in the absence of progestin influence. Endometrial hyperplasias are important clinically because they may cause abnormal bleeding, be associated with estrogen-producing ovarian tumors, result from hormonal therapy, and precede or occur simultaneously with endometrial cancer.

The most recent classification scheme endorsed by the International Society of Gynecological Pathologists is based on architectural and cytologic features as well as long-term studies that reflect the natural history of the lesions (12) (Table 33.2).
Architecturally, hyperplasias are either simple or complex; the major differing features are complexity and crowding of the glandular elements. **Simple hyperplasia** is characterized by dilated or cystic glands with round to slightly irregular shapes, an increased glandular-to-stromal ratio without glandular crowding, and no cytologic atypia. **Complex hyperplasia** has architecturally complex (budding and infolding), crowded glands with less intervening stroma without atypia. **Atypical hyperplasia** refers to cytologic atypia and can be categorized as simple or complex, depending on the corresponding glandular architecture. Criteria for cytologic atypia include large nuclei of variable size and shape that have lost polarity, increased nuclear-to-cytoplasmic ratios, prominent nucleoli, and irregularly clumped chromatin with parachromatin clearing (Fig. 33.1).

The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman and colleagues retrospectively studied endometrial curettings from 170 patients with untreated endometrial hyperplasia followed a mean of 13.4 years (13). They found that progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and 29% of patients with atypical complex hyperplasia. Most of the hyperplasias seemed to remain stable (18%) or regress (74%). The premalignant potential of hyperplasia is influenced by age, underlying ovarian disease, endocrinopathy, obesity, and exogenous hormone exposure (14,15).

As many as 25% to 43% of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen will have an associated, usually well-differentiated, endometrial carcinoma detected during hysterectomy (16). Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.

In a report of 85 menopausal women with endometrial hyperplasia treated with *medroxyprogesterone acetate* (10–20 mg/day), 84% of 65 who did not have cytologic atypia had complete reversal of the lesions, 6% developed recurrent hyperplasia, but none developed cancer at a mean follow-up interval of 7 years (17). By contrast, of 20 patients with cytologic atypia, only 50% responded to progestin, 25% developed recurrent hyperplasia, and 25% developed adenocarcinoma. In another study, hyperplasia resolved in 94% of 32 patients with atypical endometrial hyperplasia who were treated with *megestrol acetate* (20–40 mg/day); however, relapse occurred in all 7 patients who discontinued progestin therapy (18).

Conversely, high-dose progestin therapy (*medroxyprogesterone acetate*, 200 mg/day, or *megestrol acetate*, 160 mg/day) has been reported to have successfully reversed atypical hyperplasia and well-differentiated endometrial adenocarcinoma in 16 (94%) of 17 and 9 (75%) of 12 premenopausal women younger than age 40, respectively. The average treatment course required to achieve disease regression was 9 months (range

Figure 33.1  Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium.  

**A:** The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands.  

**B:** Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nucleoli. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)
3–18 months) (19). Subsequent pregnancies after progestin treatment of endometrial hyperplasia and even well-differentiated cancer have occurred and can apparently be enhanced by the use of assisted reproductive technologies (20).

Progestin therapy is very effective in reversing endometrial hyperplasia without atypia but is less effective for endometrial hyperplasia with atypia. For women with endometrial hyperplasia without atypia, ovulation induction, cyclical progestin therapy (e.g., medroxyprogesterone acetate, 10–20 mg/day for 14 days per month), or continuous progestin therapy (e.g., megestrol acetate, 20–40 mg/day) appear to be effective. Continuous progestin therapy with megestrol acetate (40–160 mg/day) is probably the most reliable treatment for reversing complex or atypical hyperplasia. Therapy should be continued for 2 to 3 months, and endometrial biopsy should be performed 3 to 4 weeks after completion of therapy to assess response.

Periodic endometrial biopsy or transvaginal ultrasonography is advisable in patients being monitored after progestin therapy for atypical hyperplasia because of the presence of undiagnosed cancer in 25% of cases, the 29% progression rate to cancer, and the high recurrence rate after treatment with progestins. For women with atypical complex hyperplasia who no longer desire fertility, hysterectomy is recommended.

Endometrial Cancer Screening

Screening for endometrial cancer should currently not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality (21–23). Routine Papanicolaou’s (Pap) testing is inadequate and endometrial cytologic assessment is too insensitive and nonspecific to be useful in screening for endometrial cancer even in a high-risk population. A progesterone challenge test reveals whether the endometrium has been primed by estrogen, but it does not identify abnormal endometrial pathology. Transvaginal ultrasonographic examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Although many risk factors for endometrial cancer have been identified, screening of high-risk individuals could at best detect only one half of all cases of endometrial cancer. Furthermore, no controlled trials have been carried out to evaluate the effectiveness of screening for endometrial cancer. Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as those receiving postmenopausal estrogen therapy without progestins and members of families with hereditary nonpolyposis colorectal cancer (24). Conversely, women taking tamoxifen receive no benefit from routine screening with transvaginal ultrasonography or endometrial biopsy (25,26).

Fortunately, most patients who have endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding early in the development of the disease, when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis, timely treatment, and a high cure rate.

Endometrial Cancer

Clinical Features

Symptoms

Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of
About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting symptom. Most women recognize the importance of this symptom and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extrauterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (27). Less than 5% of women diagnosed with endometrial cancer are asymptomatic. In the absence of symptoms, endometrial cancer is usually detected as the result of investigation of abnormal Pap test results, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasonography examination or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have a more advanced stage of disease (28).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine (29). Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool.

Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any tumors discovered should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, estrogen therapy, hyperplasia, and cancer or sarcoma (30–33) (Table 33.3). Uterine leiomyomas should never be accepted as a cause of postmenopausal bleeding. Endometrial atrophy is the most common endometrial finding in women with postmenopausal bleeding, accounting for 60% to 80% of such bleeding. Women with endometrial atrophy have usually been menopausal for about 10 years. Endometrial biopsy often yields insufficient tissue or only blood and mucus, and usually bleeding ceases after biopsy. Endometrial polyps account for 2% to 12% of postmenopausal bleeding. Polyps are often difficult to identify with office endometrial biopsy or curettage. Hysteroscopy, transvaginal ultrasonography, or both may be useful adjuncts in identifying endometrial polyps. Unrecognized and untreated polyps may be a source of continued or recurrent bleeding, leading eventually to unnecessary hysterectomy.

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. The risk for endometrial cancer is 4 to 8 times greater in postmenopausal women receiving unopposed estrogen therapy, and the risk increases with time and higher estrogen doses. This risk can be decreased by the addition of a progestin to the estrogen, either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess

</table>
unscheduled bleeding or annually in women not taking a progestin. **Endometrial hyperplasia** occurs in 5% to 10% of patients with postmenopausal uterine bleeding. The source of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. Only about 10% of patients with postmenopausal bleeding have endometrial cancer.

Premenopausal women with endometrial cancer invariably have abnormal uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclical bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women if abnormal bleeding is persistent or recurrent or if obesity or chronic anovulation is present.

**Signs**

Physical examination seldom reveals any evidence of endometrial carcinoma, although obesity and hypertension are commonly associated constitutional factors. Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes and breasts should be assessed carefully. Abdominal examination is usually unremarkable, except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, as well as the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.

**Diagnosis**

Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology (34). The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D & C) or hysterectomy (35–37).

The narrow plastic cannulas are relatively inexpensive, can often be used without a tenaculum, cause less uterine cramping (resulting in increased patient acceptance), and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may also be performed at the time of endometrial biopsy if cervical pathology is suspected. A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results (38).

Hysteroscopy and D & C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D & C alone (39–41).

Transvaginal ultrasonography may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (42–45). Transvaginal ultrasonography, with or without endometrial fluid instillation (sonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is related to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a
collection of fluid within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of 5 mm or less in a postmenopausal woman is consistent with atrophy, more data are needed before ultrasonography findings can be considered to eliminate the need for endometrial biopsy in a patient who has symptoms (46).

Pathology

The histologic classification of carcinoma arising in the endometrium is shown in Table 33.4 (12,47).

Endometrioid Adenocarcinoma

The endometrioid type of adenocarcinoma accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces (Fig. 33.2). As tumors become less differentiated, they contain more solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, glands back-to-back without intervening stoma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding one half of a low-power microscopic field (LPF) (>1 LPF; 4.2 mm in diameter) (48,49).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 33.5). In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades: grade 1, 5% or less of the tumor shows a solid growth pattern; grade 2, 6% to 50% of the tumor shows a solid growth pattern; and grade 3, more than 50% of the tumor shows a solid growth pattern. The presence of notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.
Figure 33.2 Well-differentiated adenocarcinoma of endometrium. The glands and complex papillae are in direct contact with no intervening endometrial stroma, the so-called back-to-back pattern. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Notes on pathologic grading:

Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 (G1) or grade 2 (G2) tumor by one grade.

In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma, nuclear grading takes precedence.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

FIGO, International Federation of Gynecology and Obstetrics.
About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation (Fig. 33.3). In the past, tumors with benign-appearing squamous areas were called adenoacanthomas, and tumors with malignant-looking squamous elements were called adenosquamous carcinomas. It is now recommended that the term endometrial carcinoma with squamous differentiation be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component and the behavior of the tumor is largely dependent on the grade of the glandular component (50,51).

A villoglandular configuration is present in about 2% of endometrioid carcinomas (52,53). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells. The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from papillary serous carcinomas. Secretory carcinoma is a rare variant of endometrioid carcinoma that accounts for about 1% of cases (54,55). It occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors
behave as regular well-differentiated endometrioid carcinomas and generally have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits progesterational changes, but a history of progesterational therapy is rarely elicited. Secretory carcinoma must be differentiated from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure: secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

Mucinous Carcinoma

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than one half of the tumor is composed of cells with intracytoplasmic mucin (56,57). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma. Positive perinuclear immunohistochemical staining with vimentin suggests an endometrial origin (58).

Papillary Serous Carcinoma

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube (59–62). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification (Fig. 33.4). Psammoma bodies frequently are observed.

Uterine papillary serous carcinomas (UPSC) are all considered high-grade lesions. They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Serous carcinomas are often associated with lymph–vascular space and deep myometrial invasion. Even when these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, they behave more aggressively than endometrioid carcinomas and have a propensity to spread intra-abdominally, simulating the behavior of ovarian carcinoma. Of patients with clinical stage I disease, more than one half are found to have deep myometrial invasion, three fourths manifest lymph–vascular space invasion (LVSI), and about one half have extrauterine disease detected at surgery.

The first description of UPSC, in 1982, noted that this entity usually occurred in elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to one half of deaths from endometrial carcinoma (59). Since then, several reports have documented the aggressive nature and poor prognosis of UPSC. Even when the disease was confined to an endometrioid polyp without other evidence of spread, recurrence developed in more than one half of patients (60,61). More recently, in a report on 50 patients surgically staged with UPSC, extrauterine disease was found in 72%. Presence of lymph node metastases, positive peritoneal cytology, and intraperitoneal tumor did not correlate with increasing myometrial invasion (62).

Clear Cell Carcinoma

Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas (54,63,64). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types.

The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks (Fig. 33.5).
Clear cell carcinoma characteristically occurs in older women and is a very aggressive type of endometrial cancer; the prognosis is similar to or worse than that of papillary serous carcinoma. Overall survival rates of 33% to 64% have been reported. Myometrial invasion and LVSI are important prognostic indicators.

Squamous Carcinoma

**Squamous carcinoma of the endometrium** is rare. Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (65).

Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (66–70). Most commonly, both the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis. Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian
Cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. Up to 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity may be helpful in distinguishing between metastatic and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.

**Pretreatment Evaluation** After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly to determine the best and safest approach to management of the disease. A complete history and physical examination is of utmost importance. Patients with endometrial carcinoma are often elderly and obese and have a variety of medical problems, such as diabetes mellitus and hypertension, that affect surgical management. Any abnormal symptoms, such as bladder or intestinal symptoms, should be evaluated.
On physical examination, attention should be directed to enlarged or suspicious-feeling lymph nodes, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach. Stool should be tested for occult blood.

Chest radiography should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, serum chemistries (including renal and liver function tests), blood type and screen, and urinalysis. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. Studies such as cystoscopy, colonoscopy, intravenous pyelography, barium enema, and CT scanning of the abdomen and pelvis are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests (71). Ultrasonography and magnetic resonance imaging (MRI) can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (72). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigenic determinant that is elevated in 80% of patients with advanced epithelial ovarian cancers, also is elevated in most patients with advanced or metastatic endometrial cancer (73). In one study, 23 of 81 patients with apparently localized disease preoperatively had elevated CA125 levels. At surgery, 20 (87%) of these 23 patients with an elevated CA125 were found to have extrauterine disease, whereas only 1 of 58 patients with a normal CA125 had disease spread outside the uterus (74). Another study found that 78% of endometrial cancer patients with lymph node metastases had an elevated preoperative CA125 level (75). Preoperative measurement of serum CA125 may, therefore, help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (76,77).

Clinical Staging

Clinical staging, according to the 1971 FIGO system (Table 33.6), should be performed in patients who are deemed not to be surgical candidates because of their poor medical condition or the spread of their disease (78). With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. One study reported an

FIGO, International Federation of Gynecology and Obstetrics.
operability rate of 87% in a series of 595 consecutive patients with clinical early-stage endometrial cancer (79). A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement, parametrial spread, invasion of the bladder or rectum, or distant metastasis.

Surgical Staging

Most patients with endometrial cancer should undergo surgical staging based on the 1988 FIGO system (80–82) (Table 33.7). At a minimum, the surgical procedure should include sampling of peritoneal fluid for cytologic evaluation, exploration of the abdomen and pelvis with biopsy or excision of any extrauterine lesions suggestive of metastatic cancer, extraperitoneal hysterectomy, and bilateral salpingo-oophorectomy. The uterine specimen should be opened and tumor size (83), depth of myometrial involvement (84–86), and cervical extension assessed. Any suspicious pelvic and para-aortic lymph nodes should be removed for pathologic examination.

Additionally, clinically negative retroperitoneal lymph nodes should be sampled in all patients with one or more of the risk factors noted in Table 33.8. Tumor histology and depth of myometrial invasion appear to be the two most important factors in determining the risk for lymph node metastasis (81,82). The overall incidence of lymph node metastasis in clinical stage I endometrial cancer is about 3% in grade 1, 9% in grade 2, and 18% in grade 3 tumors (Table 33.9). Less than 5% of patients with no myometrial invasion or with superficial (<50%) myometrial invasion have lymph node metastasis, compared with about 20% of patients with deep (>50%) myometrial invasion (Table 33.10). Pelvic
lymph node metastases are present in less than 5% of grade 1 and 2 tumors with superficial myometrial invasion, in about 15% of grade 1 and 2 tumors with deep myometrial invasion or grade 3 tumors with superficial invasion, and in more than 40% of grade 3 tumors with deep myometrial invasion (Fig. 33.6). About one half to two thirds of patients with positive pelvic lymph nodes also have para-aortic lymph node metastases, but the aortic nodes are seldom involved in the absence of pelvic nodal disease. Cervical involvement is associated with about a 15% risk of pelvic or para-aortic node metastasis (82). The incidence of lymph node metastasis also correlates with tumor size (<2 cm, 4%; >2 cm, 15%; entire cavity, 35%) (83). Extraperitoneal spread of disease increases the risk of pelvic and para-aortic nodal metastasis. Adnexal metastasis increases the risk for pelvic and para-aortic nodal metastasis to 32% and 20%, respectively. Of patients with positive peritoneal cytology, 25% have positive pelvic nodes, and 19% have positive para-aortic nodes (82).

Selective pelvic and high common iliac/para-aortic lymph node dissections should, therefore, be performed in the presence of adnexal or cervical involvement, a large (>2 cm) tumor, deep (>50%) myometrial invasion, or a moderate to poorly differentiated endometrioid, papillary serous, or clear cell tumor. Because fewer than 10% of patients with lymphatic metastasis have grossly enlarged nodes, palpation is not an acceptable alternative to biopsy. Conversely, because almost all patients with lymph node metastases have one or more of the aforementioned risk factors, lymph node biopsies are not required in patients assessed intraoperatively to be at very low risk for lymphatic metastasis (ie, patients with small [<2 cm] grade 1 endometrial cancers with only superficial myometrial invasion). In addition, partial omentectomy should be considered in some high-risk patients, especially those with papillary serous and mixed müllerian tumors, which have a propensity for intra-abdominal spread and upper-abdominal recurrence.

Extended surgical staging, including selective pelvic and para-aortic lymphadenectomy, in patients with endometrial cancer does not significantly add to the morbidity from hysterectomy, which is primarily related to other factors, such as patient weight, age, and race; operating time; and surgical technique. The complication rate with this type of surgery is about 20%; about 6% of these complications are serious. The most common complications are wound infection, embolic phenomena, excess blood loss, gastrointestinal injury or obstruction, and lymphocyst formation (87–91).

In addition, selective pelvic and para-aortic lymphadenectomy may have a therapeutic effect (92,93). One study noted that patients who underwent pelvic lymph node sampling had a significant survival advantage overall in both low-risk and high-risk groups (92). Likewise, para-aortic lymphadenectomy has been found to be a significant positive predictor for recurrence-free survival in patients with high-risk endometrial cancer. Among 137 high-risk patients, the 5-year progression-free survival rate was 77% for patients undergoing para-aortic lymph node dissection, compared with 62% for patients not having para-aortic lymphadenectomy (93).

Figure 33.6 The risk for pelvic lymph node metastasis with grade and depth of myometrial penetration in clinical stage I endometrial cancer. Adjuvant pelvic irradiation is recommended for the high-risk group but not for the low-risk group. (From DiSaia PJ, Creasman WT. Management of endometrial adenocarcinoma, stage I with surgical staging followed by tailored adjuvant radiation therapy. Clin Obstet Gynecol 1986;13:751, with permission.)

Extended surgical staging, including selective pelvic and para-aortic lymphadenectomy, in patients with endometrial cancer does not significantly add to the morbidity from hysterectomy, which is primarily related to other factors, such as patient weight, age, and race; operating time; and surgical technique. The complication rate with this type of surgery is about 20%; about 6% of these complications are serious. The most common complications are wound infection, embolic phenomena, excess blood loss, gastrointestinal injury or obstruction, and lymphocyst formation (87–91).

In addition, selective pelvic and para-aortic lymphadenectomy may have a therapeutic effect (92,93). One study noted that patients who underwent pelvic lymph node sampling had a significant survival advantage overall in both low-risk and high-risk groups (92). Likewise, para-aortic lymphadenectomy has been found to be a significant positive predictor for recurrence-free survival in patients with high-risk endometrial cancer. Among 137 high-risk patients, the 5-year progression-free survival rate was 77% for patients undergoing para-aortic lymph node dissection, compared with 62% for patients not having para-aortic lymphadenectomy (93).
Surgical staging is extremely important when one considers the poor correlation of preoperative evaluation and clinical staging with surgical and pathologic findings. In a comparison of preoperative findings with surgical pathology, tumor histology was changed in 27% of patients, tumor grade was changed in 34% of patients, and stage was changed in 51% of patients (94). In the Gynecologic Oncology Group (GOG) series, 22% of 621 patients with clinical stage I endometrial cancer had evidence, discovered at staging laparotomy, of extrauterine spread, including lymph node metastasis, adnexal spread, peritoneal implants, and positive peritoneal cytology (82) (Table 33.11). In two other studies, extrauterine spread was found in clinical stages I (19%) and II (40%), with an overall incidence of 23.4% (95) and in 19 (12.3%) of 154 clinical stage I and II patients (96). In a retrospective comparison of clinical and surgical stage with respect to survival in 156 patients with endometrial cancer, surgery resulted in an increase in the stage in 12.4% and 27.3% of clinical stage I and II patients, respectively (97). Surgical stage was found to be the most important factor affecting prognosis.

All patients with endometrial cancer who are taken to the operating room for primary therapy should, therefore, be prepared to undergo surgical staging. Such staging may include selective pelvic and para-aortic lymph node dissection, in addition to hysterectomy and salpingo-oophorectomy, based on the intraoperative assessment of risk for lymph node metastasis or other extrauterine spread.

Surgical staging identifies most patients with extrauterine disease and has a significant impact on treatment decisions. Surgical staging also identifies patients with uterine risk factors, including deep myometrial invasion, cervical extension, and LVSI. The identification of these factors allows for a more informed approach to the use of postoperative adjuvant radiotherapy, and it is hoped that this approach will improve survival and spare many patients unnecessary exposure to radiation (98–105).

Although stage of disease is the most significant variable affecting survival, a number of other individual prognostic factors for disease recurrence or survival have been identified, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical–pathologic evidence of extrauterine disease spread (Table 33.12). Other factors, such as tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, have also been implicated as having prognostic importance.

### Age

In general, younger women with endometrial cancer have a better prognosis than older women. Two reports observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (98,106). Another series demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 92.1% survival rate for patients younger than 50 years of age (107). Decreased survival was associated with an increased risk for extruterine spread (38% versus 21%) and deep myometrial invasion (57% versus 24%) for these two groups. The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger, 87.3% for patients 51 to 60 years, 78% for patients 61 to 70 years, 70.7% for patients 71 to 80 years, and 53.6% for patients older than 80 years (108).

Increased risk for recurrence in older patients has also been related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent prognostic variable. Increasing patient age has been found to be independently associated with disease recurrence in endometrial cancer. In one study, the mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1-year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years (103).

### Histologic Type

Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (109,110). In a retro-
spective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenosquamous, 14 papillary serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extraterine spread of disease (109).

### Histologic Grade

Histologic grade of the endometrial tumor is strongly associated with prognosis (82,88,100–105). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were more than 5 times more likely to have a recurrence than were patients with grade 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 86%, respectively, compared with 64% for patients with grade 3 tumors (103).

Another study reported similar results, noting recurrences in 9% of patients with grade 1 and 2 tumors compared with 39% of patients with grade 3 lesions (101). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.

### Myometrial Invasion

Because access to the lymphatic system increases as cancer invades into the outer one half of the myometrium, increasing depth of invasion has been associated with increasing likelihood of extraterine spread and recurrence (81,102,105). The association of depth of myometrial invasion with extraterine disease and lymph node metastases has been confirmed (81). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Survival also decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator of the effect of myometrial invasion on survival is distance from the tumor–myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (111,112).

### Lymph–Vascular Space Invasion

Lymph–vascular space invasion appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (94,112–114). The overall incidence of LVSI in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One study reported LVSI in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (113). Another study reported deaths in 26.7% of patients with clinical stage I disease who had LVSI, compared with 9.1% of those without LVSI (93). Likewise, an 83% 5-year survival rate has been reported for patients without demonstrable LVSI, compared with a 64.5% survival rate for those in whom LVSI was present (114). Using multivariate analysis, only depth of myometrial invasion, DNA ploidy, and vascular invasion–associated changes correlated significantly with survival of patients with stage I endometrial adenocarcinomas in another report (115).

### Isthmus and Cervix Extension

The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both is associated with an increased risk for extraterine disease and lymph node metastasis as well as recurrence. One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44%
recurrence rate (100). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extrauterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (88). Patients with cervical involvement also tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.

**Adnexal Involvement**

**Most patients with adnexal spread have other poor prognostic factors that place them at high risk for recurrence.** For the 20% of patients with adnexal spread as their only high-risk factor, however, the survival rate has been reported to be as high as 85% (88).

**Peritoneal Cytology**

The significance of malignant peritoneal cytology in endometrial cancer is a controversial issue (116). Several reports in the literature have noted increased recurrence rates and decreased survival rates and, on this basis, have recommended treatment for positive cytology (117–119). In an early report, positive peritoneal cytology was noted in 26 (16%) of 167 patients with clinical stage I adenocarcinoma of the endometrium (117). Recurrent cancer developed in 10 (38%) of these 26 patients, compared with 14 (10%) of 141 patients with negative cytology. Positive peritoneal cytology was found to be associated with deep myometrial invasion, cervical involvement, adnexal spread, and lymph node metastasis, as well as a propensity for intra-abdominal disease recurrence. Several subsequent reports supported the observation that positive peritoneal cytology was associated with an increased risk for cancer recurrence (118,119). Most of the studies included patients with other evidence of extrauterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG study, however, critically analyzed 1,180 clinical stage I and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed (88). Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted, however, that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, **an equal number of studies have found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in early endometrial cancer** (119–122). In a prospective evaluation of peritoneal cytology in 157 patients with clinical stage I endometrial cancer who underwent primary surgical therapy (120), no treatment was directed specifically to positive cytology. Positive cytology was not significantly associated with disease recurrence. Recurrence developed in 5 (17%) of 30 patients with positive cytology and in 11 (9%) of 127 patients with negative cytology. Of the 5 patients with positive peritoneal cytology who had disease recurrence, only one recurrence arose within the peritoneal cavity. Patients with malignant washings often had other poor prognostic factors: 37%, deep myometrial invasion; 37%, grade 3 tumors; 17%, positive lymph nodes. Disease recurred in none of the patients with positive cytology who had no other poor prognostic factors. A subsequent study confirmed by multivariate analysis that positive peritoneal cytology was not an independent prognostic factor for endometrial cancer recurrence. Only 6 (22%) of the 27 patients with positive cytology as their only evidence of extrauterine disease spread suffered a recurrence despite no therapy directed toward this finding (103). **Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes, not if the disease is otherwise confined to the uterus** (121–123). More grade 3 tumors (41% versus 19%), vascular invasion (18% versus 6%), adnexal spread (18% versus 4%), lymph node metastasis (29% versus 8%), and intraperitoneal spread (18% versus 2%) occurred in patients with positive peritoneal cytology, which contributed to the overall recurrence rate of 47% in these patients (121). The 5-year survival rate for patients with positive peritoneal cytology with disease otherwise confined to the uterus exceeds 90%.
The following conclusions may be reached regarding the prognostic implications of positive peritoneal cytology:

1. Positive peritoneal cytology is associated with other known poor prognostic factors.

2. Positive peritoneal cytology in the absence of other evidence of extrauterine disease or poor prognostic factors probably has no significant effect on recurrence and survival.

3. Positive peritoneal cytology, when associated with other poor prognostic factors or extrauterine disease, increases the likelihood for distant as well as intra-abdominal disease recurrence and has a significant adverse effect on survival.

4. Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% will have para-aortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without lymph node metastases (103). The GOG found that the presence or absence of para-aortic lymph node metastases was of paramount importance in determining prognosis. Of 48 para-aortic node–positive patients, 28 (58%) developed progressive or recurrent cancer, and only 36% of these patients were alive at 5 years, compared with 85% of patients without para-aortic node involvement (87).

Intraperitoneal Tumor

Extrauterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer. Gross intraperitoneal spread has been highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes (82). Extraperitoneal spread other than lymph node metastasis is also significantly associated with tumor recurrence. Another study found that 50% of patients with extrauterine disease developed recurrence, compared with 11% of patients without extrauterine disease, making recurrence almost 5 times more likely in patients with extrauterine disease spread. The 5-year disease-free survival rate for patients with nonlymphatic extrauterine disease was 50%, compared with 88% in other patients (103).

Tumor Size

Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer (83,124). One report determined tumor size in 142 patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity (83). Tumor size better defined an intermediate-risk group for lymph nodes metastasis (ie, patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or
smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm or smaller, 84% for patients with tumors larger than 2 cm, and 64% for patients with tumors involving the whole uterine cavity (124).

Hormone Receptor Status  Estrogen receptor and progesterone receptor levels have been shown to be prognostic indicators for endometrial cancer independent of grade in several studies (125–131). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have improved prognosis with receptor-positive tumors (128). Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

DNA Ploidy and Proliferative Index  About two thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis (115,129,132–140). The proportion of nondiploid tumors increases with stage, lack of tumor differentiation, and depth of myometrial invasion. In several studies, DNA content has been related to clinical course of the disease, with death rates generally reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index also is related to prognosis.

Genetic and Molecular Markers  Mutations in codons 12 or 13 of the K-ras oncogene have been reported in 10% to 20% of endometrial adenocarcinomas (141). The presence of mutations of K-ras appears to be an independent unfavorable prognostic factor (142,143). E-cadherin, an oncogene responsible for cell-to-cell adhesion that seems to play a critical role in initiation and progression of endometrial neoplasia, is found in 5% to 50% of endometrial carcinomas. Reduced expression of e-cadherin is related to advanced stage disease (144,145). Overexpression of the HER-2/neu oncogene, which encodes for a cell surface glycoprotein that is similar to the human epidermal growth factor receptor, has been identified in 10% to 15% of endometrial adenocarcinomas. It is more frequently found in women with metastatic disease, and overexpression has been related to diminished progression-free survival (146–148). Alteration of the tumor suppressor gene p53 has been demonstrated in about 20% of endometrial carcinomas and has been associated with papillary serous cell type, advanced stage, and poor prognosis (139,149–151). Expression of MIB-1 (Ki-67), a proliferation marker, has been associated with extratumor disease spread and decreased survival (152). Analysis of homozygous deletions on chromosome 10q23 in human cancer has led to the discovery of the PTEN tumor-suppressor gene. Mutations and deletions of the PTEN gene occur in 30% to 80% of endometrial cancers, which tend to be endometrioid, well differentiated, and minimally invasive (153–155). Microsatellite instability, present in about 20% of endometrial cancers, appears to be restricted to endometrioid adenocarcinomas and is associated with other molecular features that predict a favorable outcome, including PTEN mutation and absence of p53 overexpression (156,157).

Treatment  An algorithm for the management of patients with clinical stage I and II endometrial cancer is presented in Figure 33.7.

Surgery  

Abdominal Hysterectomy  

Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the primary operative procedures for carcinoma of endometrium. The adnexa should be removed because they may be the site of microscopic metastasis, and patients with
endometrial carcinoma are at increased risk for ovarian cancer occurring either simultaneously or developing later. Removal of a segment of vagina below the cervix is not necessary.

Laparotomy is performed through an abdominal incision that is adequate to allow thorough intra-abdominal exploration and retroperitoneal lymph node dissection, if necessary. A lower-abdominal midline vertical incision is most commonly used, although a lower-abdominal transverse, muscle-dividing incision (e.g., Maylard incision) or muscle-detaching incision (e.g., Cherney incision) usually provides adequate exposure. After opening the abdomen, peritoneal washings are taken from the subdiaphragmatic area, paracolic gutters, and pelvis using 50 mL of saline for each. These washings are sent to the cytology laboratory for examination. Exploration of the abdomen and pelvis is then performed, noting particularly the diaphragm, liver, omentum, and pelvic and aortic lymph nodes. The uterus should be observed for tumor on the serosal surface. Any suspicious-looking lesions or lymph nodes should be excised for biopsy or removed for histologic examination. The uterus is opened in the operating room, and tumor size, depth of myometrial invasion, and cervical extension are assessed. This information, along with the surgical findings and knowledge of the preoperative histology, influences whether pelvic and aortic lymph node dissection is indicated. The uterus is sent to the pathology laboratory, where tissue can be obtained for measurement of steroid hormone receptors and flow cytometry.
For patients in whom lymph node sampling is indicated, lower para-aortic lymph node resection can be accomplished by extending the pelvic peritoneal incisions over the common iliac arteries and lower aorta. Samples of lymph nodes along the upper common iliac vessels are removed from either side and the fat pad overlying the vena cava. Pelvic lymph node samples are obtained by removing nodes overlying the midportion of the external iliac artery and vein and within the obturator fossa above and along the obturator nerve. An omental biopsy or partial omentectomy may also be performed.

**Vaginal Hysterectomy**

Vaginal hysterectomy may be considered for selected patients who are extremely obese and have a poor medical status, or for patients with extensive uterovaginal prolapse. The disadvantages to this approach are that bilateral salpingo-oophorectomy often is technically difficult and abdominal exploration and lymph node sampling cannot be performed. Vaginal hysterectomy is, therefore, particularly suitable for patients who are at low risk for extrauterine spread of disease (i.e., those with clinical stage I, well-differentiated tumors). In one report, a 94% survival rate was found in 56 patients with clinical stage I endometrial carcinoma treated by vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy). Three fourths of these patients had grade 1 lesions (158). Others have reported similar good results (159–161). Vaginal hysterectomy clearly is preferable to radiation therapy alone, but generally should be reserved for specific patients.

**Laparoscopic Management**

Recent advances in endoscopic surgery have allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, there have been several reports that have documented the feasibility of laparoscopically assisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic retroperitoneal lymph node sampling for staging and treatment of patients with endometrial cancer (162–164). In an early study of 59 patients with endometrial cancer managed laparoscopically, 29 had retroperitoneal lymph node sampling (162). In a comparison study of the results of laparoscopic versus traditional laparotomy management of 44 patients with endometrial cancer, 20 patients underwent successful laparoscopic management, 15 had both pelvic and para-aortic lymph node sampling, and 4 had pelvic node sampling only. There was no difference in the number of lymph nodes (19 versus 17) removed in the laparoscopy and laparotomy groups, respectively. Patients undergoing laparoscopic management had shorter hospital stays (2.5 versus 5.0 days) and a lower overall complication rate, although all three patients who had serious complications (one ureteral injury and two small bowel herniations through 12-mm trocar sites) were in the laparoscopy group (163). A subsequent retrospective analysis compared the clinical outcomes and hospital charges for 69 women with early-stage endometrial cancer who underwent laparoscopically assisted vaginal hysterectomy, compared with 251 women who had traditional laparotomy. The patients managed laparoscopically had fewer complications, shorter hospital stays, and lower overall hospital charges than those who underwent laparotomy. Furthermore, there was no difference in recurrence rates between the two groups (164). Several other retrospective studies have evaluated the validity of laparoscopic surgery in endometrial cancer (165–169). In general, these studies demonstrated no differences in number of lymph nodes, estimated blood loss, and disease-free recurrence or survival with laparoscopic versus laparotomy approach to treatment, whereas decreased perioperative morbidity, longer operating times, shorter hospital stays, and earlier return to work were associated with laparoscopy compared with laparotomy. There has been only one randomized trial published comparing laparoscopically assisted vaginal hysterectomy versus abdominal surgery in patients with endometrial cancer (170). Seventy patients with FIGO stages I to III were randomized to laparoscopically assisted simple or
radical hysterectomy versus simple or radical abdominal hysterectomy with or without lymph node dissection. **Blood loss and transfusion rates were lower in the laparoscopy group,** whereas lymph node yield, duration of surgery, and incidence of postoperative complications were similar for both groups. Overall and recurrence-free survival did not differ significantly between the two operative approaches.

Although results of laparoscopic management of endometrial cancer are encouraging, long-term survival analysis is lacking and the risks of port-site metastasis (171), vaginal cuff recurrence (172), and higher incidence of positive peritoneal cytology (173) have been noted. The GOG is currently conducting a large, randomized trial comparing laparoscopically assisted hysterectomy and staging with standard laparotomy approach to evaluate the equivalence of these two approaches with respect to complications and outcomes.

**Radical Hysterectomy**

Radical hysterectomy, with removal of the parametria and upper vagina, as well as bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extrafascial hysterectomy and bilateral salpingo-oophorectomy alone (174–177). Radical hysterectomy also increases both intraoperative and postoperative morbidity and should not, therefore, be performed for treatment of apparent early endometrial cancer.

**Radiation Therapy**

Primary surgery followed by individualized radiation therapy has become the most widely accepted treatment for early-stage endometrial cancers. However, about 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery (79). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series have shown that radiotherapy is effective treatment for patients with inoperable endometrial cancer (178–187) (Table 33.13). One reported on the treatment of 120 patients with clinical stage I and 17 patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary irradiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%, respectively, compared with diseasespecific survival rates of 87% and 85%, respectively. There was no difference in diseasespecific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extraterine pelvic disease recurred in 3%. The authors also treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a 5-year disease-specific survival rate of 49%. Five patients (3%) had serious late complications of radiation therapy (187).

Although it is generally agreed that intracavitary irradiation is necessary to achieve adequate local control, the indications for external-beam radiation therapy in the primary treatment of endometrial cancer are less well defined. Patients with cervical involvement and known or suspected extraterine pelvic spread undoubtedly would benefit from external-beam radiation therapy. Theoretically, external-beam irradiation could also sterilize microscopic nodal disease and possibly increase the radiation dose to deep myometrial or subserosal uterine disease, which may receive an insufficient dose from intracavitary irradiation alone. A correlation between tumor grade and recurrence has been noted in several reports. One found that the 5-year progression-free survival rate for medically inoperable patients with clinical stage I disease treated with radiotherapy alone was 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors (184). Therefore, **patients with grade 3 tumors and a known propensity for deep myometrial invasion and lymph node metastasis also may benefit from external-beam therapy.**
The decision to treat a patient who has endometrial cancer with radiation alone must involve a careful analysis of the relative risks and benefits of surgery. Although radiation alone can produce excellent survival and local control, it should be considered for definitive treatment only if the operative risk is estimated to exceed the 10% to 15% risk for uterine recurrence expected with radiation treatment alone.

Postoperative therapy should be based on prognostic factors determined by surgical and pathologic staging. Patients can generally be classified into three treatment categories (Table 33.14): 

1. **Low Risk** Patients who show a low incidence of recurrence and a high rate of cure without any postoperative therapy

2. **Intermediate Risk** Patients who have a reduced rate of surgical cure but may or may not benefit from additional therapy

3. **High Risk** Patients who have a high rate of recurrence and a low survival rate without postoperative therapy

Options for postoperative management in these patients include observation, vaginal vault irradiation, external pelvic irradiation, extended-field (pelvic and para-aortic) irradiation, whole-abdomen irradiation, progestins, or systemic chemotherapy (see Fig. 33.7).

**Postoperative Adjuvant Therapy**

Patients with grade 1 and 2 lesions without myometrial invasion (stage Ia, grades 1 and 2) have an excellent prognosis and require no postoperative therapy. In a GOG
study, there were no recurrences and a 100% disease-free 5-year survival rate in the 91 patients in this category, 72 of whom had received no additional treatment after hysterectomy (88). Other investigators have reported equally favorable results with only surgical therapy in similar patients (188, 189).

Vaginal Vault Irradiation Numerous studies have shown that the incidence of vaginal recurrence in patients with tumors apparently confined to the uterus can be reduced from as high as 15% to 1% or 2% by the administration of vaginal irradiation. This finding is important because vaginal vault recurrence carries a poor prognosis (190, 191). Preoperative or postoperative vaginal vault irradiation use has been found to decrease the incidence of vaginal recurrence from 14% to 1.7% and to improve 5-year survival rates from 75% to over 90% (99, 192). In a 10-year follow-up of a randomized trial comparing surgery alone (total abdominal hysterectomy and bilateral salpingo-oophorectomy) with preoperative and postoperative radium treatment in patients with clinical stage I endometrial adenocarcinoma, the incidence of vaginal recurrence was 7.5% with hysterectomy alone, 4.5% with preoperative intracavitary radium followed by hysterectomy, and 0% with hysterectomy followed by postoperative vaginal radium (193). In a subsequent study of 92 patients with surgical stage I disease who had grade 1 or 2 tumors with less than 50% myometrial invasion treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy and postoperative vaginal cesium or radium, there were no recurrences, and the 5-year estimated disease-free survival rate was 99%. There was only one minor complication, proctitis, which responded to conservative treatment (194).
In a GOG study of surgical and pathologic risk factors and outcomes, none of the three recurrences in the vaginal radiation implant group was vaginal or pelvic, whereas 7.4% of recurrences in the pelvic radiation therapy group were vaginal, and 18.2% of recurrences were vaginal in the group that did not receive adjuvant radiation. The investigators concluded that postoperative vaginal cuff irradiation reduced local recurrence and had a therapeutic ratio superior to whole-pelvis irradiation in patients at risk for isolated vaginal cuff recurrence (88).

In the past, postoperative vaginal irradiation was most commonly administered using low-dose-rate radium or cesium sources via colpostats to deliver a surface dose of 6,000 to 7,000 cGy to the upper vagina. More recently, afterloading outpatient techniques using high-dose-rate iridium sources have been employed (195–199). Morbidity is low, although vaginal stenosis and dyspareunia may be a problem for postmenopausal patients in the absence of regular vaginal dilation.

Patients most likely to benefit from vaginal irradiation are those who have surgical stage I grade 1 and 2 tumors with superficial (less than 50%) myometrial invasion (stage Ib G1,2) or grade 3 tumors with no invasion (stage Ia G3) and patients with stage IIa G1,2 disease with superficial myometrial invasion.

**External Pelvic Irradiation**

External pelvic irradiation decreases the risk of pelvic recurrence after hysterectomy in certain high-risk groups. Patients found to benefit most from adjuvant postoperative whole-pelvis irradiation are those with cervical involvement, pelvic lymph node metastases, or pelvic disease outside the uterus (adnexa, parametria), and patients with clinical stage I disease who are at significant risk for nodal metastasis (grade 3 tumors with any degree of myometrial invasion, grade 1 and 2 tumors with more than 50% myometrial invasion, large [>2 cm] grade 2 and 3 tumors with superficial myometrial invasion, and any grade tumor with LVSI) (200).

In a study of 41 endometrial cancer patients treated with postoperative pelvic irradiation (5,000–5,040 cGy) who had grade 3 tumors or deep myometrial invasion and histologically negative para-aortic lymph nodes (pelvic lymph nodes not sampled), 4 patients (9.7%) developed recurrences. Only one of the recurrences (2.4%) was within the treatment field, however, and the 5-year estimated disease-free survival rate was 88% (194). In the GOG study, the pelvic recurrence rate was higher in the surgery-only group of patients (31.8%) than in the patients who received postoperative external beam radiation therapy (16.8%) (88).

In 1980, the first randomized study was performed to evaluate the possible benefit of postoperative pelvic irradiation in clinical stage I endometrial cancer (105). After total abdominal hysterectomy and bilateral salpingo-oophorectomy, all 540 patients received vaginal vault radium and were then randomized to receive either 4,000 cGy of whole-pelvis irradiation or no further therapy. The addition of pelvic irradiation did not affect the overall 5-year survival rate. Patients receiving pelvic irradiation had a lower pelvic failure rate but a higher distant failure rate. Of note, patients with grade 3 tumors and more than 50% myometrial invasion had a lower rate of death from cancer if they received postoperative pelvic irradiation (18.2% versus 27.5%). This study has been criticized for a lack of complete surgical staging (no lymph node biopsies were performed) and the relatively low dose of external-beam irradiation (4,000 cGy) used.

The GOG recently published a prospective, randomized study of surgery alone versus surgery plus adjuvant pelvic irradiation in intermediate-risk endometrial cancer (stages Ib to IIb occult). Of 392 patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grade 1–2, 82% <50% myometrial invasion). Disease recurrence was reduced by 58% (p = 0.007) with the use of postoperative pelvic irradiation. After 2 years, the cumulative recurrence rate was 12% in the group with no postoperative treatment compared with 3% in the group that received pelvic irradiation. The pelvic failure rate was 8.9% in the surgery-alone group compared with 1.6% in the postoperative pelvic irradiation group. Overall survival rates also were improved,
although not significantly, in patients receiving postoperative pelvic irradiation compared with those treated only with surgery (92% versus 86%, respectively) (201).

Another randomized trial of surgery and postoperative pelvic radiotherapy versus surgery alone for 714 patients with stage I endometrial carcinoma was carried out by the Netherlands PORTEC Study Group. Eligibility criteria were stage IC, grade 1 to 2, and stage IB, grade 2 to 3; patients with stage IB, grade 3, made up only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. Local-regional recurrences developed in 14% of the surgery group, compared with 4% of the postoperative pelvic irradiation group. Overall, the 5-year survival rate was no different between the two groups (85% versus 81%, respectively) (202).

Postoperative whole-pelvis external-beam irradiation usually involves the delivery of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper one half of the vagina inferiorly, the lower border of the L4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation at the surface of the vaginal apex usually is boosted to 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea, although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may also be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; however, the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

Patients at high risk for recurrence may benefit from pelvic irradiation. The pelvic failure rate is reduced and, at least in patients with grade 3 tumors and deep myometrial invasion, survival rates also appear to be improved. Patients with cervical extension and extraperitoneal pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, also should benefit from postoperative pelvic irradiation.

Extended-field Irradiation

Patients with histologically proven para-aortic node metastases who have no other evidence of disease spread outside the pelvis should be treated with extended-field irradiation. The entire pelvis, common iliac lymph nodes, and para-aortic lymph nodes are included within the radiation field. The para-aortic radiation dose is limited to 4,500 to 5,000 cGy. Extended-field radiotherapy appears to improve survival in patients with endometrial cancer who have positive para-aortic lymph nodes (88,203–206).

Five-year survival rates of 47% and 43% have been reported for patients with surgically confirmed para-aortic lymph node metastases only and for those with para-aortic as well as pelvic lymph node metastases, respectively, using postoperative extended-field irradiation. Only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (203). In a GOG study, 37 of 48 patients with positive para-aortic nodes received postoperative para-aortic irradiation, 36% of whom remained tumor free at 5 years (88). A comparison of patients with positive para-aortic nodes treated with megestrol acetate alone versus megestrol acetate and extended-field irradiation showed that the survival rate in the patients receiving extended-field irradiation was significantly better: 53% versus 12.5%, respectively (204). In another study of 18 patients with positive para-aortic nodes, 5-year survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (205).

Whole-abdomen Irradiation

Whole-abdomen irradiation therapy usually is reserved for patients with stage III and IV endometrial cancer. It may also be considered for patients who have papillary serous or mixed müllerian tumors, which have a propensity for upper-abdominal
The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy, with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the para-aortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients to discontinue treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdomen irradiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, generally is low (5% to 10%).

In a series of 27 patients treated with surgical stage III endometrial cancer with whole-abdomen irradiation, patients with spread to the adnexa, positive peritoneal cytology, or both had a 5-year, relapse-free survival of 90%, whereas all patients with macroscopic disease beyond the adnexa had recurrence (207). Similar results were reported by others (208,209). Some have advocated the use of adjuvant whole-abdomen radiotherapy for patients with high-risk stage I and II endometrial carcinoma, including those with deep myometrial invasion, high-grade tumors, and papillary serous histology, because of the high proportion of recurrences in the upper abdomen. A 5-year recurrence-free survival rate of 85% has been reported (210,211). With whole-abdomen irradiation in patients at increased risk for intra-abdominal metastatic disease, such as those with nonnodal extrauterine disease and papillary serous histology, an actuarial 5-year relapse-free survival rate of 70% has been reported, with no significant toxicity (212). Similarly, others have noted a 3-year disease-free survival rate of 79% in patients with stage III and IV endometrial adenocarcinoma treated with whole-abdomen irradiation (213). Still other reports of using adjuvant postoperative whole-abdomen irradiation in early-stage uterine papillary serous carcinoma suggest a reduction in recurrence rates (214–216). Unfortunately, most recurrences are in the upper abdomen in all of these patients, despite this type of radiotherapy. It is reasonable to use whole-abdomen irradiation postoperatively to treat patients with adnexal or upper-abdominal disease, such as in the omentum, that has been completely excised and in patients who are at very high risk for intra-abdominal recurrence, such as those with papillary serous tumors. It should not be used in patients with gross residual intraperitoneal disease.

**Progestins**

Because most endometrial cancers have both estrogen and progesterone receptors and progestins have been successfully used to treat metastatic endometrial cancer, postoperative adjuvant progestin therapy has been attempted to reduce the risk of recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, several large randomized, placebo-controlled studies have failed to identify a benefit for adjuvant progestin therapy (217–222).

Conversely, in a series of 25 patients with positive peritoneal cytology as their only evidence of disease spread outside the uterus who were treated with adjuvant progestin for 1 year postoperatively (223), 22 patients had a second-look laparoscopy, and only one patient was found to have persistent intraperitoneal malignant cells. No patient had evidence of recurrent cancer. Therefore, progestins may have a role in treating positive peritoneal cytology in this setting (224).

**Chemotherapy**

Adjuvant cytotoxic chemotherapy has been studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative irradiation and then randomly assigned patients to receive no further therapy or doxorubicin (Adriamycin) chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups (225). Researchers at the M. D. Anderson Cancer Center treated 62 high-risk patients with postoperative adjuvant cisplatin, doxorubicin, and cyclophosphamide (PAC) chemotherapy. The presence of extrauterine disease was the only significant risk factor for recurrence, and no benefit to adjuvant chemotherapy could be found (226,227).
More recently, use of adjuvant postoperative chemotherapy has been studied in patients with surgical stage III/IV disease. The GOG compared whole-abdomen irradiation versus doxorubicin/cisplatin chemotherapy in 388 patients with advanced endometrial cancer who had undergone maximal surgical resection of disease to less than 2 cm. Patients who received chemotherapy had a 13% improvement in 2-year progression-free survival (50% versus 46%) and an 11% improvement in overall 2-year survival (70% versus 59%) compared with patients treated with whole-abdomen irradiation. Although this study was the first to suggest an improvement in outcome for use of adjuvant chemotherapy compared with radiation, toxicity was more prevalent with chemotherapy; patients with gross residual disease were assigned to the radiation arm, almost guaranteeing failure; and overall, 55% of patients experienced a recurrence or progression during the study period (228).

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus (229–247). Preoperative assessment of cervical involvement is difficult. Endocervical curettage has relatively high false-positive (50%–80%) and false-negative rates. Histologic proof of cancer infiltration of the cervix or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasonography, hysteroscopy, or MRI may show cervical invasion.

The relatively small number of true stage II cases in reported series and the lack of randomized, prospective studies preclude formulation of a definitive treatment plan. Three areas must be addressed in any treatment plan:

1. For optimal results, the uterus should be removed in all patients.
2. Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.
3. Because the incidence of disease spread outside the pelvis to the para-aortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.

Two approaches have usually been used in the treatment of clinical stage II disease:

1. Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy
2. Combined radiation and surgery (external pelvic irradiation and intracavitary radium or cesium followed in 6 weeks by total abdominal hysterectomy and bilateral salpingo-oophorectomy)

An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of allowing accurate surgical–pathologic information to be obtained. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. In addition, reported results are no better than those with combined radiation and less radical surgical therapy (247). The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, traditional approach to the management of clinical stage II endometrial cancer has been to use external and intracavitary irradiation followed by
**extrafascial hysterectomy**. This combined approach has resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients (230–238). Patients who have medically inoperable disease are usually treated with external-beam irradiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors (187) (see Table 33.13).

Another method of management of clinical stage II endometrial cancer that is gaining favor is an initial surgical approach followed by irradiation. This method is based on the difficulty in establishing the preoperative diagnosis of cervical involvement in the absence of a gross cervical tumor, the evidence that radiation is equally effective when given after hysterectomy, and the high incidence of extrapelvic disease when the cervix is involved. Exploratory laparotomy with an extrafascial or modified radical hysterectomy, bilateral salpingo-oophorectomy, peritoneal washings for cytology, resection of grossly enlarged pelvic nodes, and selective high common iliac and lower paraaortic lymphadenectomy are performed. These procedures are followed by appropriate pelvic or extended-field external and intravaginal irradiation, depending on the results of surgical staging. Excellent results have been reported using this treatment scheme (241–244).

**Clinical Stages III and IV**

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas (248–255). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. **Treatment for stage III endometrial carcinoma must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intraperitoneal spread when disease is known to extend outside of the uterus into the pelvis.** In the presence of an adnexal mass, surgery should be performed initially to determine the nature of the mass. Surgery should also be performed to determine the extent of disease and to remove the bulk of the disease if possible. This procedure should include peritoneal washings for cytologic examination, selective para-aortic and pelvic lymphadenectomy, removal of any enlarged lymph nodes, biopsy or excision of any suspicious areas within the peritoneal cavity, and partial omentectomy and peritoneal biopsies. Except in patients with bulky parametral disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. **The goal of surgery is eradication of all macroscopic disease because this finding is of major prognostic importance in the management of patients with clinical stage III disease.** Postoperative therapy can then be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% has been reported for all patients with stage III disease; however, the survival was 80% when only adnexal metastases were present, compared with 15% when other extrauterine pelvic structures were involved (248). Patients with surgical–pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) (237). Patients who are treated with combined surgery and irradiation fare better than patients who receive radiation therapy alone (255).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases (255–259). **Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal therapy or chemotherapy.** One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. In one report, control of pelvic disease was achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, progestins, or both (256). **Several reports have noted a positive impact of cytoreductive surgery on survival, the median**
survival being about 3 times greater with optimal cytoreduction (18–34 months versus 8–11 months, respectively) (257–259). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both (260,261).

**Recurrent Disease**

About one fourth of patients treated for early endometrial cancer develop recurrent disease. More than one half of the recurrences develop within 2 years, and about three fourths occur within 3 years of initial treatment. The distribution of recurrences is dependent in large part on the type of primary therapy: surgery alone versus surgery plus local or regional radiotherapy. In a GOG study of 390 patients with surgical stage I disease, vaginal and pelvic recurrences were noted to make up 53% of all recurrences in the group treated with surgery alone, whereas only 30% of recurrences were vaginal or pelvic in the group treated with combined surgery and radiotherapy (88). Therefore, after combined surgery and radiotherapy (vaginal or external beam), 70% or more of patients with treatment failures have distant metastases, and most of these patients do not have evidence of local or pelvic recurrence. The most common sites of extrapelvic metastases are the lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone. In general, patients with isolated vaginal recurrences fare better than those with pelvic recurrences, who in turn have a better chance of cure than those with distant metastases. Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy also tend to have an improved prognosis.

In a 1984 report on 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital from 1960 to 1976 (262), site of recurrence was local or regional in 190 patients (50%), distant in 108 patients (28%), and local and distant in 81 patients (21%). The median time of recurrence was 14 months for patients with local recurrences and 19 months for patients with distant metastases. Of all recurrences, 34% were detected within 1 year, and 76% were detected within 3 years of primary treatment. At the time of diagnosis of recurrence, 32% of patients had no symptoms. Vaginal bleeding was the most common symptom associated with local recurrence, and pelvic pain was most often present with pelvic recurrence. Hemoptysis was the initial symptom in 32% of patients with lung metastases, but 45% of cases of lung metastases were asymptomatic and picked up on routine chest x-ray. Only 9% of patients with metastases at other sites did not have symptoms; most had pain (37%) or other symptoms such as anorexia, nausea and vomiting, or ascites related to intra-abdominal carcinomatosis, neurologic symptoms such as seizures from brain metastases, or jaundice caused by liver metastases.

Overall, only 29 (7.7%) of the 379 patients were alive without evidence of disease from 3 to 19 years. This included 22 patients (12%) with local or pelvic recurrence, 5 patients (5%) with distant metastases, and 2 patients (2%) with both local and distant recurrences. The best results were obtained in the 42 patients with vaginal vault recurrences who were treated with radiotherapy, resulting in a 24% survival rate. None of the 78 patients with pelvic soft tissue recurrence survived. Three patients (7%) with only lung metastases treated with progestins, two patients with lymph node metastases treated with combined radiotherapy and progestins, and two patients with local recurrence and lung metastases treated with radiotherapy, surgery, and progestins survived.

**Surgery**

A small subset of patients who develop recurrent endometrial cancer may benefit from surgical intervention. Pelvic or vaginal recurrence in patients who have not received prior pelvic irradiation is best treated with external irradiation plus some type of brachytherapy. Surgical resection of a metastatic nodule greater than 2 cm in diameter before irradiation, however, may improve local control. Pretherapy investigation for extrapelvic metastasis in these patients may include surgical evaluation of the peritoneal cavity and retroperitoneal lymph nodes for evidence of subclinical metastases.
In one small series, upper-abdominal disease was found at laparotomy in 3 (37.5%) of 8 patients with presumed localized pelvic recurrence. Presence of subclinical extrapelvic metastases was associated with larger pelvic tumor size (>2 cm) and elevated serum CA125 levels (263). A few patients with intraperitoneal recurrence may benefit from laparotomy to relieve intestinal obstruction. Tumor-reductive surgery may be performed before administration of whole-abdomen radiation therapy or systemic hormonal therapy or chemotherapy.

Isolated central pelvic recurrence after irradiation is rare. In patients with this type of recurrence, exploratory laparotomy may be performed with the plan to proceed with pelvic exenteration if there is no evidence of disease outside the pelvis and no lymph node metastases. Exenterative surgery for recurrent endometrial cancer in the pelvis is of value in selected patients because of the high incidence of associated occult extrapelvic metastases. Of 36 patients who underwent pelvic exenteration for recurrent endometrial carcinoma at Memorial Sloan-Kettering Cancer Center, 75% died of their cancer within 1 year of operation, and only 14% were alive after 5 years (261).

Radiation Therapy
Patients with isolated local or regional recurrences after initial surgical treatment of endometrial cancer should be treated with radiotherapy (191,264–271). The best local control and subsequent cure are usually achieved by a combination of external-beam radiation therapy followed by a brachytherapy boost to deliver a total tumor dose of at least 6,000 cGy. Women with low-volume disease limited to the pelvis have the best outcome. For patients with isolated vaginal recurrence treated with irradiation, reported survival rates range from 24% to 45%. Conversely, for those patients who undergo irradiation of the pelvic extension of their disease, lower survival rates (0%–24%) have been reported. Significant factors that determine control of pelvic disease and survival in patients with locally recurrent endometrial cancer include initial endometrial cancer grade 1, younger age at recurrence, recurrent tumor size 2 cm or less, time from initial treatment to recurrence of more than 1 year, vaginal versus pelvic disease, and radiation therapy that included brachytherapy vaginal boost.

Hormone Therapy
The use of progestational agents for treatment of metastatic endometrial cancer was first described in 1961, when researchers observed an objective response rate of 29% in 21 patients (272). In a report from 1974, a beneficial response was observed in 35% of 308 patients (273). Subsequent reports have noted somewhat less optimistic response rates, probably as a result of more strictly applied criteria for objective responses (274–277) (Table 33.15). Reports from Roswell Park Cancer Center and the Mayo Clinic observed objective response rates of 16% and 11%, respectively, with an additional 15% to 40% of patients exhibiting stable disease for at least 3 months (274,275). In 1986, the GOG

HPC, hydroxyprogesterone caproate (Delalutin); MPA, medroxyprogesterone acetate (Provera, Depo-Provera); MA, megestrol acetate (Megace); IM, intramuscular; PO, oral.
initially reported on the use of oral medroxyprogesterone acetate for treatment of patients with advanced or recurrent endometrial cancer (276). Of 219 patients with measurable disease, 8% had a complete response, 6% had a partial response, 52% had stable disease, and 34% developed progressive disease within 1 month. The mean survival time for the entire group was 10.4 months. In a follow-up study comparing two different doses of oral medroxyprogesterone acetate, similar response rates were achieved (26% for 200 mg/day and 18% for 1,000 mg/day) (277). The type, dose, and route of administration of the progestin seemed to have no effect on response in these studies.

The response of metastatic endometrial carcinoma to progestin therapy is related to several clinical and pathologic factors. Higher response rates are observed in well-differentiated tumors. A 20.5% response in low-grade tumors and only 1.4% response in high-grade tumors have been noted (275). Likewise, the probability of an objective response to progestin therapy is about 70% for tumors that are estrogen- and progesterone-receptor positive, compared with about 5% to 15% for tumors that are negative for both receptors. A longer disease-free interval is associated with higher response rates to progestins. The response rate to progestins has been found to range from 6% in patients with an interval from primary treatment to recurrence of less than 6 months to 65% in patients in whom disease recurred more than 5 years after initial treatment (274). Other observed but less well-documented factors that may have an adverse effect on response to progestins are disease recurrence within a prior radiation field, large tumor burden, and advanced primary versus recurrent disease (274,275).

Tamoxifen, a nonsteroidal antiestrogen with some estrogenic properties, has been evaluated for treatment of metastatic endometrial carcinoma based on experience in using this agent in breast cancer treatment. Its use as either a single agent or in combination with a progestin is related to its ability to inhibit the binding of estradiol to the estrogen receptor and to increase progesterone receptors. In a review of eight studies using tamoxifen, 20 to 40 mg/day, in patients with metastatic endometrial carcinoma, the overall response rate was 22%, with a range of 0% to 53% (278). Responses to tamoxifen were more likely to be observed in patients with low-grade, hormone receptor–positive tumors who had a prior response to progestin therapy. In an attempt to reverse the hormone receptor downregulation seen with progestin therapy, tamoxifen has been given along with progestins, but the overall responses to combined tamoxifen and progestin therapy have been similar to those noted for single-agent progestin therapy.

Progestins are currently recommended as initial treatment for all patients with recurrent endometrioid tumors with hormone receptor-positive tumors. Radiation therapy, surgery, or both should be used whenever feasible for treatment of localized recurrent cancer such as vaginal, pelvic, bone, and peripheral lymph node disease; however, these patients should also be given long-term progestin therapy unless they are known to have a progesterone-receptor–negative tumor. Patients with nonlocalized recurrent tumors, especially if progesterone receptors are known to be positive, are candidates for progestin therapy, either megestrol acetate, 80 mg twice daily, or medroxyprogesterone acetate, 50 to 100 mg three times daily. Progestin therapy should be continued for at least 2 to 3 months before assessing response. If a response is obtained, the progestin should be continued for as long as the disease is static or in remission. In the presence of a relative contraindication to high-dose progestin therapy (e.g., prior or current thromboembolic disease, severe heart disease, or inability of the patient to tolerate progestin therapy), tamoxifen, 20 mg twice daily, is recommended. Failure to respond to hormonal therapy is an indication for initiating chemotherapy.

Chemotherapy Although several chemotherapeutic agents or combinations of agents are capable of inducing objective responses and even remissions in patients with metastatic endometrial carcinoma, response and survival times are short, and all cytotoxic therapy should be
considered palliative (278–280). The most active chemotherapeutic agents are doxorubicin, the platinum compounds cisplatin and carboplatin, and paclitaxel (Taxol). Doxorubicin, 50 to 60 mg/m² every 3 weeks (281–283); cisplatin, 60 to 75 mg/m² every 3 weeks (284,285); and carboplatin, 350 to 400 mg/m² every 4 weeks (286,287) have been associated with response rates of 21% to 29%. Paclitaxel, 250 mg/m² as a 24-hour infusion with granulocyte colony-stimulating factor support (287), or 175 mg/m² as a 3-hour infusion every 3 weeks (288–290), has produced response rates of about 36%. Alkylating agents such as cyclophosphamide and melphalan, 5-fluorouracil, altretamine (hexamethylmelamine) (291), liposomal doxorubicin (292), and topotecan (293,294) have shown activity against endometrial cancer. Most responses obtained with use of these agents have been partial, generally averaging only 3 to 6 months, with the median survival time ranging from 4 to 8 months.

Combination chemotherapy regimens employing doxorubicin and cisplatin (283,295); cyclophosphamide, doxorubicin, and cisplatin (296,297); paclitaxel and cisplatin with or without doxorubicin (298,299); and carboplatin and paclitaxel (300) have resulted in response rates ranging from 38% to 76%. Despite these fairly impressive response rates, most responses have been partial, with durations of 4 to 8 months, and the median survival time has generally been less than 12 months.

Response to chemotherapy in patients with metastatic endometrial cancer does not appear to be affected by prior or concurrent progestin therapy. Metastatic site, age, disease-free interval, histology, and tumor grade also appear to have no effect on chemotherapy response. However, patients with long disease-free intervals and better performance status may live longer.

Treatment Results

Comprehensive survival data for endometrial cancer are provided by FIGO (301). Survival in relation to clinical and surgical stage is shown in Table 33.16 and in relation to surgical stage and grade in Table 33.17. The overall 5-year survival rate was 76%. Patients who underwent surgical staging had much better 5-year survival rates than those staged clinically across all stages (respectively): stage I, 87% versus 54%; stage II, 76% versus

Follow-up after Treatment

History and physical examination remain the most effective methods of follow-up in patients treated for endometrial cancer (302–305). Patients should be examined every 3 to 4 months during the first 2 years and every 6 months thereafter. About one half of patients discovered to have recurrent cancer have symptoms, and 75% to 80% of recurrences are detected initially on physical examination. Particular attention should be given to peripheral lymph nodes, the abdomen, and the pelvis. Very few asymptomatic recurrences are detected by vaginal cytology.

Chest x-ray every 12 months is an important method of posttreatment surveillance. Almost one half of all asymptomatic recurrences are detected by chest x-ray. Other radiologic studies, such as intravenous pyelography and CT scans, are not indicated for routine follow-up of patients who do not have symptoms.

Serum CA125 measurement has been suggested for posttreatment surveillance of endometrial cancer (305–307). Elevated CA125 levels have been documented in patients with recurrent tumor, and these levels have correlated with the clinical course of disease. However, CA125 levels may be normal in the presence of small recurrences, making the utility of CA125 measurements for follow-up of patients after treatment of early-stage disease suspect. Determinations of CA125 should be obtained in patients with elevated levels at the time of diagnosis or with known extraterine disease.

Estrogen Therapy after Treatment of Endometrial Cancer

A history of endometrial cancer has long been considered a contraindication to estrogen therapy because of the concern that occult metastatic disease might be activated by estrogen. Although this is a reasonable concern, the magnitude of this risk has never been quantified.
and, in fact, there is no evidence that estrogen therapy after apparently successful treatment of endometrial cancer increases the risk for cancer recurrence.

In a nonrandomized, retrospective follow-up study of 221 patients with clinical stage I endometrial cancer, 47 patients who had received estrogen after treatment were compared with 174 who had not been treated with estrogen. There were no significant differences between the two groups with respect to known risk factors for cancer recurrence. There were 26 (14.9%) recurrences in the patients not treated with estrogen, compared with only 1 (2.1%) recurrence in the patients treated with estrogen. Moreover, in the group not receiving estrogen, there were 26 deaths (16 from cancer and 10 from intercurrent disease), compared with only 1 death among those taking estrogen (308). Similarly in another report, no recurrent cancers and no intercurrent deaths were found in 44 women who took estrogen after treatment for endometrial cancer, compared with eight recurrences and eight intercurrent deaths (five from myocardial infarction) in 99 women who did not take estrogen (309). In a subsequent study of 123 surgical stage I and II endometrial cancer patients, 62 (50.5%) who received estrogen therapy postoperatively were identified. After controlling for risk factors for recurrence, there was no detectable difference in recurrence rate or time to recurrence between those patients who had received estrogen therapy and those who had not (310). More recently, a retrospective cohort study of matched treatment-control pairs found two recurrences (1%) among the 75 women using estrogen, compared with 11 recurrences (14%) in the 75 women not using estrogen after primary therapy for endometrial cancer (311). In all of these studies, however, most patients did not commence estrogen therapy immediately after surgery.

Many women who have been successfully treated for endometrial cancer suffer side effects of estrogen deficiency, such as vasomotor instability, vaginal dryness, and dyspareunia, as well as the long-term risk of osteoporosis. Because of the risk of hormone therapy for all women, its use in women previously treated for endometrial cancer should be considered carefully after the patient has been counseled about risks, benefits, and options. A compromise between immediate postoperative estrogen therapy and no hormone therapy might be to withhold estrogen for 1 to 3 years after treatment, the time in which most recurrences develop, thereby minimizing the chances of administering estrogen to patients with residual cancer. Alternatively, topical estrogen alone can be used judiciously to treat vaginal symptoms. Symptomatic relief of hot flashes can be achieved by prescribing progestins such a medroxyprogesterone acetate, 10 mg orally daily or 150 mg intramuscularly every 3 months, or nonhormonal agents such as Belleragl, clonidine, and venlafaxine.

**Uterine Sarcoma**

Uterine sarcomas are relatively rare tumors of mesodermal origin. They constitute 2% to 6% of uterine malignancies (312–314). There is an increased incidence of uterine sarcomas after radiation therapy to the pelvis for either carcinoma of the cervix or a benign condition. The relative risk of uterine sarcoma after pelvic radiotherapy has been estimated to be 5.38, with an interval of usually 10 to 20 years (315). Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread, and management.

**Classification**

The three most common histologic variants of uterine sarcoma are endometrial stromal sarcoma (ESS), leiomyosarcoma, and malignant mixed müllerian tumor (MMMT) of both homologous and heterologous type (316) (Table 33.18). Variations in the relative incidences of uterine sarcomas occur in different published series, probably...
related to the strictness of criteria used to classify smooth muscle and endometrial stromal tumors as sarcomas. In general, leiomyosarcoma and MMMT each make up about 40% of tumors, followed by ESS (15%) and other sarcomas (5%), although MMMT predominates in more recent reports. Staging of uterine sarcomas is based on the FIGO system for endometrial carcinoma (see Table 33.6 and 33.7).

Endometrial Stromal Tumors

Stromal tumors occur primarily in perimenopausal women between ages 45 and 50 years; about one third occur in postmenopausal women. There is no relationship to parity, associated diseases, or prior pelvic radiotherapy. These tumors are rare in African-American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain and pressure caused by an enlarging pelvic mass occur less often, and some patients do not have symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma. At surgery, the diagnosis is suggested by the presence of an enlarged uterus filled with soft, gray-white to yellow necrotic and hemorrhagic tumors with bulging surfaces associated with wormlike elastic extensions into the pelvic veins.
Endometrial stromal tumors are composed purely of cells resembling normal endometrial stroma. They are divided into three types on the basis of mitotic activity, vascular invasion, and observed differences in prognosis: (i) endometrial stromal nodule, (ii) endometrial stromal sarcoma, and (iii) high-grade or undifferentiated sarcoma.

**Endometrial stromal nodule** is an expansive, noninfiltrating, solitary lesion confined to the uterus with pushing margins, no lymphatic or vascular invasion, and usually less than 5 mitotic figures per 10 high-power microscopic fields (5 MF/10 HPF). These tumors should be considered benign because there have been no recurrences or tumor-associated deaths reported after surgery (317,318).

**Endometrial stromal sarcoma** (formerly termed low-grade ESS or endolymphatic stromal myosis) is distinguished from high-grade ESS or undifferentiated endometrial sarcoma microscopically by a mitotic rate of less than 10 MF/10 HPF as well as clinically by a more protracted course. Recurrences typically occur late, and local recurrence is more common than distant metastases (319–323). Although endometrial stromal sarcoma often behaves in a histologically aggressive fashion, it lacks the aneuploid DNA content and high proliferative index associated with high-grade stromal sarcoma. Flow cytometric analysis can be used to differentiate the two conditions and predict response to therapy.

Endometrial stromal sarcoma has extended beyond the uterus in 40% of cases at the time of diagnosis, but the extraterine spread is confined to the pelvis in two thirds of the cases. Upper-abdominal, pulmonary, and lymph node metastases are uncommon. Recurrence occurs in almost one half of cases at an average interval of about 5 years after initial therapy. Prolonged survival and even cure are not uncommon even after the development of recurrent or metastatic disease.

**Optimum initial therapy for patients with endometrial stromal sarcoma consists of surgical excision of all grossly detectable tumor.** Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. The adnexa should always be removed because of the propensity for tumor extension into the parametria, broad ligaments, and adnexal structures as well as the possible stimulating effect of estrogen from retained ovaries on the tumor cells. A beneficial effect of radiation therapy has been reported, and pelvic irradiation is recommended for inadequately excised or locally recurrent pelvic disease (319). There is also evidence that endometrial stromal sarcoma is hormone dependent or responsive. Objective responses to progestin therapy have been reported in 48% of patients in one series (323). Recurrent or metastatic lesions may also be amenable to surgical excision. Long-term survival and apparent cures have been noted in patients with pulmonary metastases (324).

**High-grade ESS or undifferentiated endometrial sarcoma** is a highly malignant neoplasm. Histologically, it exhibits greater than 10 MF/10 HPF and often completely lacks recognizable stromal differentiation. This tumor has a much more aggressive clinical course and poorer prognosis than endometrial stromal sarcoma (316,319,325–327). The 5-year disease-free survival is about 25%. Treatment of undifferentiated endometrial sarcoma should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy. The poor therapeutic results obtained to date suggest that radiation therapy, chemotherapy, or both should be used in combination with surgery. These tumors, unlike endometrial stromal sarcoma, are not responsive to progestin therapy.

**Uterine tumor resembling ovarian sex-cord tumor (UTROSCT)** is a rare variant of endometrial stromal sarcoma in which benign glands and epithelial cells are found. Immunohistochemically, these tumors express cytokeratin, epithelial membrane antigen, vimentin, and smooth muscle actin. Although some of these tumors have infiltrative margins, almost all of them behave benignly. The so-called mixed UTROSCT have a significant endometrial stromal sarcoma component and tend to behave more aggressively (328,329).
Leiomyosarcoma

The median age for women with leiomyosarcoma (43 to 53 years) is somewhat lower than that for other uterine sarcomas, and premenopausal patients have a better chance of survival. This malignancy has no relationship with parity, and the incidence of associated diseases is not as high as in MMMT or endometrial adenocarcinoma. African-American women have a higher incidence and a poorer prognosis than women of other races. A history of prior pelvic radiation therapy can be elicited in about 4% of patients with leiomyosarcoma. The incidence of sarcomatous change in benign uterine leiomyomas is reported to be between 0.13% and 0.81% (330–340).

Presenting symptoms, which usually are of short duration (mean, 6 months) and not specific to the disease, include vaginal bleeding, pelvic pain or pressure, and awareness of an abdominopelvic mass. The principal physical finding is the presence of a pelvic mass. The diagnosis should be suspected if severe pelvic pain accompanies a pelvic tumor, especially in a postmenopausal woman. Endometrial biopsy, although not as useful as in other sarcomas, may establish the diagnosis in as many as one third of cases when the lesion is submucosal.

Survival rates for patients with uterine leiomyosarcoma range from 20% to 63% (mean, 47%). The pattern of tumor spread is to the myometrium, pelvic blood vessels and lymphatics, contiguous pelvic structures, abdomen, and then distantly, most often to the lungs. The number of mitoses in the tumor has traditionally been the most reliable microscopic indicator of malignant behavior (Fig. 33.8).

Generally, tumors with less than 5 MF/10 HPF behave in a benign fashion, and tumors with more than 10 MF/10 HPF are frankly malignant with a poor prognosis. Tumors with 5 to 10 MF/10 HPF, termed cellular leiomyomas or smooth muscle tumors of uncertain malignant potential, are less predictable. Therefore, in addition to mitotic index greater than 10, other histologic indicators used to classify uterine smooth muscle tumors as malignant are severe cytologic atypia and coagulative tumor cell necrosis (341). Uterine smooth muscle tumors with any two of these three features are associated with a poor prognosis. Gross presentation of the tumor at the time of surgery is also an important prognostic indicator. Tumors with infiltrating tumor margins or extension beyond the uterus are associated with poor prognosis, whereas tumors less than 5 cm, originating within myomas, or with pushing margins are associated with prolonged survival.

Five other clinical pathologic variants of uterine smooth muscle tumors deserve special comment: (i) myxoid leiomyosarcoma, (ii) leiomyoblastoma, (iii) intravenous leiomyomatosis, (iv) benign metastasizing uterine leiomyoma, and (v) disseminated peritoneal leiomyomatosis.

Myxoid leiomyosarcoma is characterized grossly by a gelatinous appearance and apparent circumscribed border. Microscopically, the tumors have a myxomatous stroma and extensively invade adjacent tissue and blood vessels (342). The mitotic rate is low (0–2 MF/10 HPF), which belies their aggressive behavior and poor prognosis. Surgical excision by hysterectomy is the mainstay of treatment. The low mitotic rate and abundance of intra-cellular myxomatous tissue suggest that these tumors would not be responsive to radiation therapy or chemotherapy.

Leiomyoblastoma includes smooth muscle tumors designated as epithelioid leiomyomas, clear cell leiomyomas, and plexiform tumorlets (343,344). This group of atypical smooth muscle tumors is distinguished by the predominance of rounded rather than spindle-shaped cells and by a clustered or cordlike pattern. These lesions should be regarded as specialized low-grade leiomyosarcomas with fewer than 5 MF/10 HPF. Leiomyoblastoma is treated with hysterectomy, and the prognosis is excellent.
Intravenous leiomyomatosis is characterized by the growth of histologically benign smooth muscle into venous channels within the broad ligament and then into uterine and iliac veins (345–348). The intravascular growth takes the form of visible, wormlike projections that extend out from a myomatous uterus into the parametria toward the pelvic sidewalls. It may be confused with low-grade stromal sarcoma. Symptoms are related to the associated uterine myomas. Most patients are in the late fifth and early sixth decades of life. The prognosis is excellent, even when tumor is left in pelvic vessels. Late local recurrences can occur, and deaths from extension into the inferior vena cava or metastases to the heart have been reported. Estrogen may stimulate the proliferation of these intravascular tumors. Treatment should be total abdominal hysterectomy and bilateral salpingo-oophorectomy with removal of as much of the tumor as possible.

Benign metastasizing uterine leiomyoma is a rare condition in which a histologically benign uterine smooth muscle tumor acts in a somewhat malignant fashion and produces benign metastases, usually to the lungs or lymph nodes (349). In most instances, intravenous leiomyomatosis is not apparent. The metastasizing myomas are capable of growth at distant sites, whereas the intravenous tumors spread only by direct extension within blood vessels. Both experimental and clinical evidence suggests that...
these tumors are stimulated by estrogen. Therefore, removing the source of estrogen, by
castration or withdrawal of exogenous estrogen, or by treatment with progestins, tamox-
ifen, or a gonadotropin agonist, has an ameliorating effect (350). Surgical treatment should
consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy as well as
resection of pulmonary metastases, if possible.

**Disseminated peritoneal leiomyomatosis** is a rare clinical entity characterized by
benign smooth muscle nodules scattered throughout the peritoneal cavity (351). This
condition probably arises as a result of metaplasia of subperitoneal mesenchymal stem
cells to smooth muscle, fibroblasts, myofibroblasts, and decidual cells under the influence
of estrogen and progesterone. Most reported cases have occurred in 30- to 40-year-old
women who are or who have recently been pregnant or who have a long history of oral
contraceptive use. Intriguing features of this disease are its grossly malignant appearance,
benign histology, and favorable clinical outcome. Intraoperative diagnosis requires frozen-
section examination. Exirpative surgery, including total abdominal hysterectomy, bilateral
salpingo-oophorectomy, omentectomy, and excision of as much gross disease as possible
may be indicated in menopausal women. Removal of the source of excess estrogen, treat-
ment with progestins, or both has resulted in regression of unresected tumor masses.
Almost all patients have a good prognosis.

**Malignant Mixed Müllerian Tumors**

Malignant mixed müllerian tumors are composed histologically of a mixture of
sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the
sarcomatous element may resemble the normal endometrial stroma (homologous or the so-
called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as
cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived
from totipotential endometrial stromal cells (352–355).

Almost all of these tumors occur after menopause, at a median age of 62 years. The
incidence is higher in African-American women. These tumors are often found in association with other medical conditions, such as obesity, diabetes mellitus, and hypertension.
A history of previous pelvic irradiation can be obtained in 7% to 37% of patients.

The most frequent presenting symptom is postmenopausal bleeding, which occurs in
80% to 90% of cases. Other less common symptoms are vaginal discharge, abdominal or pelvic pain, weight loss, and passage of tissue from the vagina. The duration of symptoms
usually is only a few months. On physical examination, uterine enlargement is present in
50% to 95% of patients, and a polypoid mass may be seen within or protruding from the
docervical canal in up to 50% of patients. Diagnosis can usually be determined by
biopsy of an endocervical mass or endometrial curettage.

The tumor grows as a large, soft, polypoid mass filling and distending the uterine cavity;
necrosis and hemorrhage are prominent features. The myometrium is invaded to various
degrees in almost all cases. The most frequent areas of spread are the pelvis, lymph nodes,
peritoneal cavity, lungs, and liver. This metastatic pattern suggests that these neoplasms
spread by local extension and regional lymph node metastasis in a manner similar to that
of endometrial adenocarcinoma, although they behave more aggressively.

The most important single factor affecting prognosis in patients with MMMT is the
extent of tumor at the time of treatment. One study noted that in patients with tumor
apparently confined to the uterine corpus (stage I), the 2-year survival rate was 53%,
whereas the survival rate dropped to 8.5% when disease had extended to the cervix,
vagina, or parametria (stage II and III); no patients with disease outside the pelvis (stage IV) survived (356). In another study, 5-year survival for patients with disease confined to
the corpus (74%) was significantly greater than for those with more advanced disease
(24%) (357).
Unfortunately, disease has extended outside the uterus in 40% to 60% of cases at the time of diagnosis, indicating the highly malignant nature of this lesion. Even when disease is believed to be confined to the uterus preoperatively and potentially is still curable, surgical and pathologic staging identifies extrauterine spread of disease in a significant number of cases. In one study, 55% of women with clinical stage I MMMT had a higher surgical–pathologic stage. Only 28% of tumors were actually confined to the uterine corpus, 16% had extension to the cervix, and 56% showed extrauterine spread (358). In a significant number of patients, lymph node metastases and positive peritoneal cytology has been found with early-stage MMMT (357,359,360). Deep myometrial invasion, which is present in about one half of stage I cases, is associated with poor prognosis. Almost all patients in whom tumor involves the outer one half of the myometrium die from the disease. Patients who die from MMMT tend to have larger tumors and a higher incidence of LVSI. Patients with a history of prior pelvic irradiation generally have a poorer prognosis. Overall, the 5-year survival rate for patients with MMMT is about 20% to 30%.

*Adenosarcoma* is an uncommon variant of MMMT (361,362). It consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. Most patients present with postmenopausal vaginal bleeding, and the disease is diagnosed or suspected based on endometrial curettage. Most adenosarcomas are well circumscribed and limited to the endometrium or superficial myometrium. The treatment is hysterectomy and bilateral salpingo-oophorectomy, with or without adjuvant radiotherapy. Because recurrences, mostly in the form of local pelvic or vaginal disease, have been reported in 40% to 50% of cases, adjuvant postoperative intravaginal or pelvic irradiation has been recommended.

### Treatment

Recurrences develop in more than one half of cases of uterine sarcoma, even when disease is apparently localized at the time of treatment (363–365). At least one half of recurrences occur outside the pelvis, with isolated pelvic failures accounting for less than 10% of recurrences. The most common sites of recurrence are the abdomen and lungs. These data emphasize that the major limitation to cure of uterine sarcomas is distant spread.

Based on this type of evidence, treatment of most stage I and II uterine sarcomas should include hysterectomy, bilateral salpingo-oophorectomy, and treatment of the pelvic lymphatics by irradiation or surgery. Strong consideration should also be given to the use of adjuvant chemotherapy to decrease the incidence of distant metastases. Stage III uterine sarcomas are probably best treated by an aggressive combined approach of surgery, radiation therapy, and chemotherapy. Stage IV disease must be treated with combination chemotherapy.

### Surgery

The first step in the treatment of early uterine sarcoma should be exploratory laparotomy. Because extirpative survey is the most important aspect of treatment, and knowledge of the extent and spread of the disease is important for further management, one should not forego or delay surgery by using radiation therapy or chemotherapy first. At the time of surgery, the peritoneal cavity should be carefully explored and peritoneal washings obtained. Special attention should be given to the pelvic and para-aortic lymph nodes; selected lymphadenectomies should be performed with ESS and MMMT, but are not necessary in leiomyosarcoma, in which the risk of lymph node metastases is low. Total abdominal hysterectomy is the standard procedure, and bilateral salpingo-oophorectomy should also be performed in all patients except premenopausal women with leiomyosarcoma. Based on the surgical and pathologic findings, additional therapy with radiation therapy or chemotherapy can then be planned. Rarely, a patient may be cured by excision of an isolated pulmonary metastasis (366,367).
Radiation Therapy

Most studies have found adjuvant preoperative or postoperative radiation therapy to be of value in decreasing pelvic recurrences and thereby increasing quality of life in patients with localized ESS and MMMT, but not with leiomyosarcoma (368–376). Radiation therapy thus appears to have a role used in combination with surgery in the treatment of MMMT and ESS confined to the pelvis. By increasing the disease-free progression interval and pelvic control, radiation therapy probably increases the overall survival to some degree.

Chemotherapy

Several chemotherapeutic agents have been found to have activity in sarcomas, including vincristine, actinomycin D, cyclophosphamide, doxorubicin, dimethyl triazeno imidazole carboxamide (dacarbazine, DTIC), cisplatin, ifosfamide paclitaxel, gemcitabine, and liposomal doxorubicin (377). Doxorubicin appears to be the most active single agent in the treatment of leiomyosarcoma, producing a 25% response rate (378). Ifosfamide also has some activity to a lesser degree (379). On the other hand, cisplatin and ifosfamide have demonstrated clear activity in MMMT, with responses rates of 18% to 42% and 32%, respectively (380–382). Doxorubicin has demonstrated less than a 10% response rate in MMMT (378). Paclitaxel yielded an 18% response rate with MMMT (383), but had limited activity in leiomyosarcomas (384). Gemcitabine (385) and liposomal doxorubicin (386) have shown activity in leiomyosarcomas.

Combination chemotherapy with doxorubicin and DTIC, or these two drugs plus vincristine and cyclophosphamide, has been reported to yield somewhat higher response rates (387–389). Similarly, ifosfamide has been combined with mesna uroprotection, doxorubicin, and DTIC to treat metastatic pure sarcomas (390). More recently, gemcitabine has been combined with docetaxel for treatment of metastatic leiomyosarcoma, yielding an overall response rate of 53%, including patients previously treated with doxorubicin (391). Combined ifosfamide and cisplatin chemotherapy has resulted in a higher response rate (54% versus 36%) and a longer progression-free survival than ifosfamide chemotherapy alone for treatment of advanced MMMT (392). A combination of paclitaxel and carboplatin for treatment of advanced uterine MMMT was recently reported to result in a complete response rate of 80% (four fifths) and a median progression-free interval of 18 months (393).

Adjuvant Treatment

Because of the relatively low survival rate in localized uterine sarcomas and the high incidence of failure resulting from subsequent distant metastasis, adjuvant treatment programs employing chemotherapy have been tested (394–397). Unfortunately, most reports have been unable to show a clear improvement in survival by the addition of postoperative adjuvant chemotherapy in early uterine sarcoma. The GOG conducted a trial of postoperative adjuvant doxorubicin in stage I and II uterine sarcoma patients. Of the 75 patients randomized to receive doxorubicin, 41% developed a recurrence, compared with 53% of 81 patients receiving no adjuvant chemotherapy, but these differences were not significant (394). Other smaller, nonrandomized adjuvant chemotherapy studies employing cyclophosphamide, cisplatin plus doxorubicin, and ifosfamide plus cisplatin reported recurrence rates of 33%, 24%, and 31%, respectively (395–397).

Human papillomavirus (HPV) infection is the causal agent of cervical cancer. Screening programs are effective at decreasing the incidence of cervical cancer. Although the most common histologic type of cervical cancer is squamous, the relative and absolute incidence of adenocarcinoma is increasing. Cervical cancer is clinically staged, although modern radiographic modalities such as computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, or positron emission tomography (PET) may be beneficial for individual treatment planning. Treatment of cervical cancer is based on stage of disease. In general, early stage disease (I–IIa) can be treated with either radical surgery or radiation therapy. Advanced stage disease (IIb–IV) is best treated with chemoradiation. Vaginal cancer is a rare disease with many similarities to cervical cancer. Radiation therapy is the mainstay of treatment for most patients; however, select patients may be treated with radical surgery.

Cervical cancer ranks as the third most common gynecologic neoplasm in the United States, behind cancer of the corpus and ovary, mainly as a result of the effectiveness of screening programs. Worldwide, cervical carcinoma continues to be a significant health care problem. In third world countries, where limited health care resources exist, cervical carcinoma remains a significant cause of mortality. Because cervical cancer is preventable, it is imperative that gynecologists and other primary care providers who administer health care to women be familiar with screening techniques, diagnostic procedures, and risk factors for cervical cancer as well as management of preinvasive disease. Vaginal cancer is a rare tumor that shares a similar epidemiology and risk factor profile as cervical cancer.
Cervical Cancer

Epidemiology and Risk Factors

Invasive cancer of the cervix is considered a preventable disease because it has a long preinvasive state, cervical cytology screening programs are currently available, and the treatment of preinvasive lesions is effective. In spite of the preventable nature of this disease, however, 9710 new cases of invasive cervical cancer resulting in 3700 deaths were anticipated in the United States in 2006 (1). Nationally, the lifetime probability of developing cervical cancer is 1:128. Although screening programs in the United States are well established, it is estimated that 30% of cervical cancer cases will occur in women who have never had a Pap test. In developing countries, this percentage approaches 60% (2). In spite of these statistics, the worldwide incidence of invasive disease is decreasing, and cervical cancer is being diagnosed earlier, leading to better survival rates (1,3). The mean age for cervical cancer in the United States is 47 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age (1).

There are numerous risk factors for cervical cancer: young age at first intercourse (<16 years), multiple sexual partners, cigarette smoking, race, high parity, and lower socioeconomic status. The relationship to oral contraceptive use has been debated. Some investigators have proposed that use of oral contraceptives may increase the incidence of cervical glandular abnormalities (4,5); however, this hypothesis has not been consistently supported. Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with the herpes virus was previously thought to be the initiating event in cervical cancer; however, infection with human papillomavirus (HPV) has now been determined to be the causal agent in the development of cervical cancer, with herpes virus and Chlamydia trachomatis likely acting as cofactors. The role of human immunodeficiency virus (HIV) in cervical cancer is thought to be mediated through immune suppression. The Centers for Disease Control and Prevention have described cervical cancer as an acquired immune deficiency syndrome (AIDS)–defining illness in patients infected with HIV (6).

The initiating event in cervical dysplasia and carcinogenesis is infection with HPV. HPV infection has been detected in up to 99% of women with squamous cervical carcinoma (7). There are more than 100 different types of HPV, and more than 30 of which can affect the lower genital tract. There are 14 high-risk HPV subtypes; two of the high-risk subtypes, 16 and 18, are found in up to 62% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is through the interaction of viral E6 and E7 proteins with tumor suppressor genes p53 and Rb, respectively. Inhibition of p53 prevents cell cycle arrest and cellular apoptosis, which normally occurs when damaged DNA is present, whereas inhibition of Rb disrupts transcription factor E2F, resulting in unregulated cellular proliferation (8). Both steps are essential for the malignant transformation of cervical epithelial cells.

Evaluation

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding as well. Patients with advanced disease may present with a malodorous vaginal discharge, weight loss, or obstructive uropathy. In asymptomatic women, cervical cancer is most commonly identified through evaluation of abnormal cytologic screening tests.

Initially, all women suspected of having cervical cancer should have a general physical examination performed to include evaluation of the supraclavicular, axillary, and inguinal-femoral lymph nodes to exclude the presence of metastatic disease. On pelvic
examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas (Fig. 34.1). The vaginal fornices should also be closely inspected. With invasive cancer, the cervix is usually firm and expanded, and these features should be confirmed by digital examination. Rectal examination is also important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. Additionally, rectal examination is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination.

When obvious tumor growth is present, a cervical biopsy is usually sufficient for diagnosis. If gross disease is not present, a colposcopic examination with cervical biopsies and endocervical curettage is warranted. If the diagnosis cannot be established conclusively with colposcopy and directed biopsies, cervical conization may be necessary.

**Colposcopic Findings of Invasion**

Colposcopic examination is mandatory for patients with suspected early invasive cancer based on cervical cytology and a grossly normal-appearing cervix. Colposcopic findings that suggest invasion are (i) abnormal blood vessels, (ii) irregular surface contour with loss of surface epithelium, and (iii) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage Ia2 or Ib1, the patient should undergo a conization. In the presence of a large cervical biopsy specimen showing invasion greater than 3 mm or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma, therapy should proceed without delay, and the patient could undergo radical surgery or radiation therapy.
Abnormal Blood Vessels  Abnormal vessels may be looped, branched, or reticular. Abnormal looped vessels are the most common colposcopic finding and arise from the punctated and mosaic vessels present in cervical intraepithelial neoplasia (CIN). As the neoplastic growth process proceeds and the need for oxygen and nutrition increases, angiogenesis occurs as a result of tumor and local tissue production of VEGF, PDGF, EGF, and other cytokines, resulting in the proliferation of blood vessels and neovascularization. Punctate vessels push out over the surface of the epithelium in an erratic fashion, producing the looped, corkscrew, or J-shaped pattern of abnormal vessels characteristic of invasive disease. Abnormal blood vessels also arise from the cervical stroma and are pushed to the surface as the underlying cancer invades. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or right angles, with the caliber sometimes enlarging after branching. Sharp turns, dilations, and luminal narrowing also characterize these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in postmenopausal women with atrophic epithelium. When cancer involves this epithelium, the surface is eroded, and the capillary network is exposed. These vessels are very fine and short, and appear as small comma-shaped vessels without an organized pattern. They are not specific to invasive cancer; atrophic cervicitis may also have this appearance.

Irregular Surface Contour  Abnormal surface patterns are observed as tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to loss of desmosomes. Irregular contour also may occur as a result of papillary characteristics of the lesion. This finding can be confused with a benign HPV papillary growth on the cervix. For that reason, biopsies should be performed on all papillary cervical growths to avoid missing invasive disease.

Color Tone  Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

Adenocarcinoma  Adenocarcinoma of the cervix does not have a specific colposcopic appearance. All of the aforementioned blood vessels may be seen in these lesions as well. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination.

Histologic Appearance of Invasion  Cervical conization is required to assess correctly the depth and the linear extent of involvement when microinvasion is suspected. Early invasion is characterized by a protrusion of malignant cells from the stromal–epithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and small- to medium-sized nucleoli (9). These early invasive lesions form tonguelike processes without measurable volume and are classified as International Federation of Gynecology and Obstetrics (FIGO) stage Ia1. With further progression, more tonguelike processes and isolated malignant cells appear in the stroma, followed by a proliferation of fibroblasts (desmoplasia) and a bandlike infiltration of chronic inflammatory cells (Fig. 34.2). With increasing depth of invasion, lesions occur at multiple sites, and the growth becomes measurable by depth and linear extent. Lesions that are smaller than 3 mm are classified as FIGO stage Ia1. Lesions that are 3 to 5 mm or more in depth and up to 7 mm in linear
As the depth of stromal invasion increases, the risk of capillary lymphatic space involvement is increased. Dilated capillaries, lymphatic spaces, and foreign-body multinucleated giant cells containing keratin debris are often seen in the stroma.

The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. Depth of invasion is a significant predictor for the development of pelvic lymph node metastasis and tumor recurrence. Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade between 3 to 5 mm have positive pelvic lymph nodes in 3% to 8% of cases. Although the significance of the cutoff at 3 mm has not been identified completely, it has been postulated that small capillary–lymphatic spaces at this level are incapable of facilitating the transport of malignant cells. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, simulating vascular lymphatic invasion (see Fig. 34.2). Therefore, suspected vascular–lymphatic involvement with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is a fixation artifact rather than true vascular invasion.

**Staging**

Cervical cancer is a clinically staged disease. The FIGO staging system is the current standard and is applicable to all histologic types of cervical cancer. The current FIGO staging system is presented in Table 34.1 and Figure 34.3. The staging procedures allowed by FIGO are listed in Table 34.2. **When there is doubt concerning the stage to which a**

---

*a* The diagnosis of both stages Ia1 and Ia2 should be based on microscopic examination of removed tissue, preferably a cone, which must include the entire lesion. The depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. The second dimension, the horizontal spread, must not exceed 7 mm. Vascular space involvement, either venous or lymphatic, should not alter the staging but should be specifically recorded because it may affect treatment decisions in the future. Lesions of greater size should be staged as Ib. As a rule, it is impossible to estimate clinically whether a cancer of the cervix has extended to the corpus. Extension to the corpus should therefore be disregarded.

*b* A patient with a growth fixed to the pelvic wall by a short and indurated, but not nodular, parametrium should be allotted to stage IIb. At clinical examination, it is impossible to decide whether a smooth, indurated parametrium is truly cancerous or only inflammatory. Therefore, the case should be assigned to stage III only if the parametrium is nodular to the pelvic wall or the growth itself extends to the pelvic wall.

*c* The presence of hydronephrosis or nonfunctioning kidney due to stenosis of the ureter by cancer permits a case to be allotted to stage III even if, according to other findings, it should be allotted to stage I or II.

*d* The presence of the bullous edema, as such, should not permit a case to be allotted to stage IV. Ridges and furrows into the bladder wall should be interpreted as signs of submucous involvement of the bladder if they remain fixed to the growth at palpation (ie, examination from the vagina or the rectum during cystoscopy). A cytologic finding of malignant cells in washings from the urinary bladder requires further examination and a biopsy specimen from the wall of the bladder.

FIGO, International Federation of Gynecology and Obstetrics.

cancer should be allocated, the earlier stage should be selected. After a clinical stage is assigned and treatment has been initiated, the stage must not be changed because of subsequent findings by either extended clinical staging or surgical staging. The “upstaging” of patients during treatment will produce an erroneous perception of improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by stage at diagnosis: 38%, stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (3,10,12).

Additional Staging Modalities

Various investigators have used lymphangiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET) in an attempt to improve the accuracy of clinical staging (12–17).
Unfortunately, these modalities in general suffer from poor sensitivity and high false-negative rates. Evaluation of the para-aortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% (12–14). Overall, lymphangiography has a sensitivity of 79% and specificity of 73% (18). Computed tomography has poor sensitivity (34%) but excellent specificity (97%) (18). The accuracy of CT scanning is 80% to 85%; the false-negative rate is 10% to 15%, and the false-positive rate is 20% to 25% (15–17). Ultrasound has a high false-negative rate (30%), low sensitivity (19%), but high specificity (99%) (18). Early MRI data showed that MRI results were comparable to those of CT scanning (19), a finding confirmed on meta-analysis (20). However, a recent systematic review comparing CT scan with MRI has shown that MRI is significantly more sensitive with equivalent specificity. Additionally, MRI has excellent sensitivity on T2-weighted images for the detection of parametrial disease (21). As a result, MRI has become the preferred study to evaluate tumor size, lymph node metastasis, and local tumor extension.

Position emission tomography scans are increasingly being utilized either alone or in conjunction with CT or MRI to detect metastatic disease; however, large prospective data series are limited. Early studies suggest that PET may be more useful than other techniques for the detection of abdominal and extrapelvic disease, with comparable or better sensitivity (76%–100%) and specificity (94%) (22,23). In addition, PET scans may be a better predictor of treatment outcome. Although early studies show promise for the use of PET.
scans in evaluating cervical cancer, the sensitivity for detecting metastatic disease less than 1 cm in size appears to be limited (24).

When abnormalities are noted on CT, MRI, or PET, radiographic guided fine-needle aspirations (FNA) can be performed to confirm metastatic disease and individualize treatment planning. Because these tests are not generally available throughout the world and the interpretation of results can be variable, these studies are not currently used for staging. They may, however, be useful in individual treatment planning.

The clinical staging system developed by FIGO is based on the belief that cervical cancer is a local disease until rather late in its course. Unfortunately, the accuracy of clinical staging is limited, and surgical evaluation, although not practical or feasible in all patients, can more accurately identify metastatic disease. Surgical staging has been advocated by providers who believe that surgical information details the extent of disease, allowing the treatment to be tailored to the individual (25). However, other providers believe that surgical staging should be limited to patients who are enrolled in clinical trials. These beliefs are based on the lack of randomized controlled studies demonstrating a survival benefit in patients who have had surgical staging.

**Pathology**

**Squamous Cell Carcinoma**  
Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix. Histologically, variants of squamous cell carcinoma include large cell keratinizing, large cell nonkeratinizing, and small cell types (26). Large cell keratinizing tumors consist of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls (Fig. 34.4). The category of small cell carcinoma

![Image of squamous cell carcinoma](image-url)
includes poorly differentiated squamous cell carcinoma and small cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small- to medium-sized nuclei and more abundant cytoplasm than those of the latter. The designation of small cell anaplastic carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. Small cell anaplastic carcinoma infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. Immunohistochemistry or electron microscopy can differentiate the small cell neuroendocrine tumors. Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small cell variant. Furthermore, small cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Other less common variants of squamous carcinoma include verrucous carcinoma and papillary (transitional) carcinoma. Verrucous carcinomas may resemble giant condyloma acuminatum, are locally invasive, and rarely metastasize. Papillary carcinomas histologically resemble transitional cells of the bladder and may have more typical squamous cell invasion at the base of the lesion. Papillary carcinomas behave and are treated in a manner similar to traditional squamous cell cancers, except that late recurrences have been noted.

Adenocarcinoma

In recent years, there has been an increasing number of cervical adenocarcinomas reported in women in their 20s and 30s. Although the total number of cases of adenocarcinoma has been relatively stable, this disease is being seen with increasing frequency in young women, especially as the number of cases of invasive squamous cell carcinoma decreases. Older reports indicated that 5% of all cervical cancers were adenocarcinomas (27), whereas newer reports show a proportion as high as 18.5% to 27% (28,29).

Adenocarcinoma in situ (AIS) is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist (30). In addition to AIS, intraepithelial or invasive squamous neoplasia occurs in 30% to 50% of cervical adenocarcinomas (31). A squamous intraepithelial lesion may be observed colposcopically on the ectocervix and the coexistent adenocarcinoma often is higher in the cervical canal.

Patients with AIS who are treated with conization should undergo close clinical follow-up. Endocervical curettage, often used in surveillance, may miss residual or invasive disease, and false-negative rates as high as 50% have been reported (32). In addition, skip lesions not resected at the time of conization may be present. For these reasons, hysterectomy should be considered the standard therapy for patients who have completed their childbearing. In two reports, however, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures (33,34). Because cervical AIS tends to affect women during their reproductive years, a thorough discussion of risks and benefits should take place, and treatment should be individualized.

Adenocarcinoma of the cervix is managed in the same a manner to that used for squamous cell carcinoma. Previously, it was believed that adenocarcinoma was associated with a worse prognosis and outcome when compared with squamous cell carcinoma. A study of 203 women with adenocarcinoma and 756 women with squamous carcinoma supported this assertion (29). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some have attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present. When adjusted for stage, however, it now appears that
there is no difference in prognosis between the two histologic subtypes. Adenocarcinoma may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis may require cervical conization.

The clinical features of stage I adenocarcinomas have been well studied (28,35–37). These studies have identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same (36,37). Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers (36).

The choice of treatment for bulky stage I and II tumors is controversial. Treatment with radiation alone has been advocated by some (38), whereas others support radiation plus extrafascial hysterectomy (39,40). In 1975, Rutledge et al. (39) reported an 85.2% 5-year survival rate for all patients with stage I disease treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery. The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage II disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus surgery. A subsequent report revealed no significant difference in survival among patients treated with radiation alone or radiation plus extrafascial hysterectomy (41).

Invasive adenocarcinoma may be pure (Fig. 34.5A and B) or mixed with squamous cell carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous (26), with a wide range of cell types, growth patterns, and differentiation. About 80% of cervical adenocarcinomas are made up predominantly of cells of the endocervical type with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary. Within each cell type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid–Schiff (PAS) staining to confirm their glandular differentiation.

There are several special variants of adenocarcinoma. Minimal deviation adenocarcinoma (adenoma malignum) is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. In addition, the lining cells have abundant mucinous cytoplasm and uniform nuclei (42,43). Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis. Special immunohistochemical staining may be required to establish the diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but more recent studies have found a favorable prognosis if the disease is detected early (44). Although rare, similar tumors have also been reported in association with endometrioid, clear, and mesonephric cell types (45).

An entity described as villoglandular papillary adenocarcinoma also deserves special attention (46). It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, are well differentiated, and are either in situ or superficially invasive. Follow-up information is encouraging. None of these tumors has recurred after cervical conization or hysterectomy, and no metastasis has been detected among women undergoing pelvic nodal dissection. This tumor appears to have limited risk for spread beyond the uterus.
Invasive adenocarcinoma of the cervix, well-differentiated. Irregular glands are lined with tall columnar cells with vacuolated mucinous cytoplasm resembling endocervical cells. Nuclear stratification, mild nuclear atypism, and mitotic figures are evident.
Adenosquamous Carcinoma

Carcinomas with a mixture of malignant glandular and squamous components are known as adenosquamous carcinomas. Patients with adenosquamous carcinoma of the cervix have been reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma (47). Whether this is true when corrected for size of lesion is controversial (35,36).

In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. In poorly differentiated or immature adenosquamous carcinomas, however, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS. In one study (45), 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine. These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than do squamous cell carcinomas without mucin secretion (45), and they are similar to the signet-ring variant of adenosquamous carcinoma (48).

Glassy cell carcinoma has been recognized as a poorly differentiated form of adenosquamous carcinoma (48). Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. Approximately half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include adenoid basal carcinoma and adenoid cystic carcinoma. Adenoid basal carcinoma simulates the basal cell carcinoma of the skin (49). Nests of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a distinct parallel nuclear arrangement, so-called peripheral palisading. An “adenoid” pattern occasionally develops, with “hollowed-out” nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor has been removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved (49). Mitoses may be seen but are not numerous.

Sarcoma

The most important sarcoma of the cervix is embryonal rhabdomyosarcoma, which occurs in children and young adults. The tumor has grapelike polypoid nodules, known as botryoid sarcoma, and the diagnosis depends on the recognition of rhabdomyoblasts (50). Leiomyosarcomas and mixed mesodermal tumors involving the cervix may be primary but are more likely to be secondary to uterine tumors. Cervical adenosarcoma has been described as a low-grade tumor with a good prognosis (50). If recurrence develops, it is generally a central recurrence that may be treated with resection and hormonal therapy.

Malignant Melanoma

On rare occasions, melanosis has been seen in the cervix. Thus, malignant melanoma may arise de novo in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: (i) small cell, (ii) large cell, (iii) classical carcinoid, and (iv) atypical carcinoid (51).
Neuroendocrine tumors of the cervix are rare, and treatment regimens have been based on small case series of patients.

Small cell (neuroendocrine type) carcinoma of the cervix is aggressive in nature and is similar to cancer arising from the bronchus (52). The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize. At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study of 11 patients with disease apparently confined to the cervix, a high rate of lymph node metastasis was noted (53). Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy as well as by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotropic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver, and brain scanning as well as bone marrow aspiration and biopsy to evaluate the possibility of metastatic disease. Therapy generally consists of surgery, chemotherapy, and radiation. Because patients with early-stage disease have distant metastases, multimodal therapy is recommended. The main active chemotherapeutic agent is etoposide.

Local therapy alone gives almost no chance of cure of small cell carcinoma. Regimens of combination chemotherapy have improved the median survival rates in small cell bronchogenic carcinoma, and these regimens are now being used for treatment of small cell carcinoma of the cervix. Combination chemotherapy may consist of vincristine, doxorubicin, and cyclophosphamide (VAC) or VP-16 (etoposide) and cisplatin (EP) (54). Patients must be monitored carefully because they are at high risk for developing recurrent metastatic disease (55).

Patterns of Spread

Cancer of the cervix spreads by (i) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (ii) lymphatic metastasis; (iii) blood-borne metastasis; and (iv) intraperitoneal implantation. The incidence of pelvic and para-aortic nodal metastasis is shown in Table 34.3.

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated cervical primaries. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph

vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic pattern of spread for these malignancies. Isolated metastasis to the cervix in such cases may be the first sign of a primary tumor elsewhere in the body.

### Treatment Options

The treatment of cervical cancer is similar to the treatment of any other type of malignancy in that both the primary lesion and potential sites of spread should be evaluated and treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, chemotherapy, or chemoradiation. Whereas radiation therapy can be used in all stages of disease, surgery is limited to patients with stage I to IIA disease. The 5-year survival rate for stage I cancer of the cervix is approximately 85% with either radiation therapy or radical hysterectomy. A recent study using the National Cancer Institute’s Surveillance Epidemiology and End Results data showed by an intent-to-treat analysis that patients in the surgery arm had an improved survival when compared with patients in the radiation arm (56). In general, optimal therapy consists of radiation or surgery alone to limit the increased morbidity that occurs when the two treatment modalities are combined. There have recently been great strides in the treatment of cervical carcinoma, including adjuvant chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma.

### Surgery

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important. Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of patients undergoing radiation therapy (57). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which in general are easily repaired and without long-term complications. Sexual dysfunction is less likely to occur after surgical therapy than radiation because of vaginal shortening, fibrosis, and atrophy of the epithelium associated with radiation. Surgical therapy shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to endogenous estrogen or to exogenous estrogens if the patient is postmenopausal.

In general, radical hysterectomy is reserved for women who are in good physical condition. Advanced chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts (58). Generally, it is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy. When selected in this manner, the urinary fistula rate is less than 2% (59), and the operative mortality rate is less than 1% (60). A summary of the management of cervical cancer is presented in Table 34.4.

If radiation therapy is needed, ovarian function may be preserved by transposing the ovaries out of the planned radiation field. While transposition may provide some protection, some studies suggest that normal ovarian function is preserved in fewer than 50% of patients (61,62). Additionally, metastasis to the ovaries occurs in 0.5% of cases of squamous cell cancer and 1.7% of cases of adenocarcinomas of the cervix, so ovarian preservation at the time of surgery may incur a small risk (63).
Cone biopsy of the Cervix

Cone biopsy of the cervix serves both a diagnostic and therapeutic role in cervical cancer. The procedure is indicated to confirm the diagnosis of cancer, as well as to definitively treat stage Ia1 disease when preservation of fertility is desired. For effective treatment, there must be no evidence of lymph–vascular space invasion, and both endocervical margins and curettage findings must be negative for cancer or dysplasia. Because stage Ia1 cancers have less than a 1% risk of lymph node metastasis, lymphadenectomy is not necessary. If the endocervical margin or curettage is positive for dysplasia or malignancy, further treatment is necessary as these findings are strong predictors of residual disease. For squamous cell carcinoma, the risk of residual disease is 4% if both the endocervical margin and curettage are negative for dysplasia or malignancy, 22% if the endocervical margin alone is positive, and 33% if both are positive (64). In cases of adenocarcinoma in situ, the status of the cone margins is particularly important, with residual preinvasive and invasive disease noted in up to 25% and 3%, respectively, of cases with negative margins, and up to 80% and 7%, respectively, in cases with positive margins (65, 66).

Simple (Extrafascial) Hysterectomy

Type I hysterectomy is an appropriate therapy for patients with stage Ia1 tumors without lymph–vascular space invasion who are not desirous of future fertility. In such cases, lymphadenectomy is not recommended. If lymph–vascular space invasion is found, a modified radical hysterectomy with pelvic lymphadenectomy is appropriate and effective therapy.

Radical Trachelectomy

Radical trachelectomy is a procedure that is gaining popularity as a surgical management option for women with stage Ia2 and Ib1 disease who desire uterine preservation and fertility. This procedure may be performed vaginally or abdominally (Fig. 34.6), and it usually is accompanied by pelvic lymphadenectomy and cervical cerclage placement. The risk of positive pelvic lymph nodes with stage Ia2 cancer may be as high as 8%, indicating the need for lymphadenectomy. Lymphadenectomy may be performed either laparoscopically or by the open laparotomy technique. Experience with this therapeutic modality is limited, and it is uncertain if long-term outcome is similar to that of...
traditionally therapy, although early results are promising. Patients who are ideal candidates for this procedure have tumors less than 2 cm in diameter, negative lymph nodes, and no lymph–vascular space involvement. There are limited data on subsequent pregnancy outcomes after radical trachelectomy; however, successful outcomes have been reported. In one study, there were 102 pregnancies and 65 live births in 92 women who had radical tracheelectomy. Increased rates of preterm birth, preterm premature rupture of membranes, and miscarriages have been noted. (67,68).

Although radical trachelectomy and lymphadenectomy are performed with curative intent, it should be remembered that the risk of recurrence after such procedures depends on risk factors being well-defined. If recurrence develops, definitive therapy with surgery or radiation is necessary.

**Radical Hysterectomy**

The radical hysterectomy (Fig. 34.7A and B) performed most often in the United States is that described by Meigs in 1944 (69). The operation includes pelvic lymph node dissection along with removal of most of the uterosacral and cardinal ligaments and the upper one third of the vagina. This operation has been referred to as the type III radical hysterectomy (70).

The hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments (70). This procedure is often referred to as the modified radical or type II hysterectomy. Wertheim’s original operation did not include pelvic lymph node dissection but instead included selective removal of enlarged lymph nodes. The modified radical hysterectomy (type II) differs from the radical hysterectomy (type III) in the following ways:

1. The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.
Figure 34.7A  **Radical hysterectomy.** An intraoperative photograph showing the lateral dissection during a radical hysterectomy. Note the ureter running beneath the uterine artery (tissue in the clamp).

Figure 34.7B  **Radical hysterectomy specimen.**
2. The cardinal ligament is not divided near the sidewall but instead is divided at about its midportion near the ureteral dissection.

3. The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.

4. A smaller margin of vagina is removed.

Radical hysterectomies can be further classified as extended radical hysterectomy (type IV and type V). In the type IV operation, the periureteral tissue, superior vesicle artery, and as much as three fourths of the vagina are removed (70). In the type V operation, portions of the distal ureter and bladder are resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered (70).

The abdomen is opened through either a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic node dissection and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The para-aortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. In premenopausal patients, the ovaries are generally conserved. The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is then palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

**Lymphadenectomy** After inspection of the abdomen and pelvis, the pelvic and para-aortic lymph nodes should be inspected and palpated. Lymph nodes suspicious for gross disease should be excised and evaluated by frozen section. If metastatic disease is identified, consideration should be given to abandoning radical surgery in favor of primary chemoradiation therapy. If the patient has no gross evidence of metastatic disease, the pelvic lymphadenectomy is begun.

**Pelvic Lymphadenectomy** The pelvic lymph node dissection is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemoclips is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is then dissected. The obturator lymph nodes are dissected next; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. Although in most patients both the obturator artery and vein are dorsal to the obturator nerve, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and clipped caudally. Dissection continues cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and
medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. In general, drainage of the pelvic and para-aortic lymph node beds is not performed because of the increase in complications in patients in whom drains have been used (71).

**Patients who have bulky cervical tumors or grossly positive pelvic nodes, or for whom frozen section evaluation will be performed, should then undergo para-aortic lymph node evaluation to determine the full extent of disease and to guide adjuvant therapy.**

**Para-aortic Lymph Node Evaluation** The bowel is packed to expose the peritoneum overlying the bifurcation of the aorta. The peritoneum is incised medial to the ureter and over the right common iliac artery. A retractor is placed retroperitoneally to expose the aorta and the vena cava. Any enlarged para-aortic lymph nodes are removed, hemaclips are applied for hemostasis, and specimens are sent for analysis by frozen section. If the lymph nodes are positive for metastatic cancer, an option is to discontinue the operation and treat the patient with radiation therapy (69). If the lymph nodes are negative for disease, the left side of the aorta is palpated through the peritoneal incision with a finger passed under the inferior mesenteric artery. The lymph nodes on this side of the aorta are more lateral and nearly behind the aorta and the common iliac artery. If the left para-aortic lymph nodes appear healthy and the cervical tumor is small with no suspicious pelvic lymph nodes, these additional lymph nodes are not submitted for frozen-section analysis. If they are removed, they may be dissected through the incision made for the right para-aortic nodes, or they may be dissected after reflection of the sigmoid colon medially.

**Development of Pelvic Spaces** The pelvic spaces are developed by sharp and blunt dissection (Fig. 34.8).

---

**Figure 34.8** The pelvic ligaments and spaces. (From Berek JS, Hacker F. *Practical gynecologic oncology*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, with permission.)
The paravesical space is bordered by the following structures:

1. The obliterated umbilical artery running along the bladder medially
2. The obturator internus muscle along the pelvic sidewall laterally
3. The cardinal ligament posteriorly
4. The pubic symphysis anteriorly

The attachments of the vagina to the tendinous arch form the floor of the paravesical space.

The pararectal space is bordered by the following structures:

1. The rectum medially
2. The cardinal ligament anteriorly
3. The hypogastric artery laterally
4. The sacrum posteriorly

The coccygeus (levator ani) muscle forms the floor of the pararectal space.

The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes as well as dissection of the ureter as it passes into the vesicouterine ligament tunnel.

**Dissection of the Bladder** The dissection of the bladder from the anterior part of the cervix and vagina is a critical step. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure. The bladder should be mobilized off of the upper third of the vagina to remove the tumor safely and with adequate margins.

**Dissection of the Uterine Artery** The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, preserving the superior vesicle arteries. The uterine vessels are then brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

**Dissection of the Ureter** The ureter is dissected free from the medial peritoneal flap at the level of the uterosacral ligament. As the ureter passes near the uterine artery, there is a consistent arterial branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) may now be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. The posterior ligament is also divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy.

**Posterior Dissection** The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. The rectum is rolled free from the uterosacral ligaments, which
are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to develop the cardinal ligament separate from the rectum. A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp then is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and a suitable margin of proximal vagina is removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

Complications of Radical Hysterectomy

Acute Complications

The acute complications of radical hysterectomy include (72):

- Blood loss (average, 0.8 liters)
- Ureterovaginal fistula (1%–2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1%–2%)
- Small bowel obstruction (1%)
- Febrile morbidity (25%–50%)

Febrile morbidity is most often caused by pulmonary infection (10%) and is seen frequently with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (73).

Subacute Complications

The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation. For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistention. Bladder drainage is usually accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish voiding trials at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 to 100 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients (73), and the cause is uncertain. Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains has not been shown to reduce this morbidity (71). Ureteral obstruction, partial venous obstruction, and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion
of the lymphocyst wall and placement of either large bowel or omentum into the lympho-
cyst should be performed.

**Chronic Complications**  The most common chronic effect of radical hysterectomy is
bladder hypotonia or, in extreme instances, atony. This condition occurs in about 3% of
patients, regardless of the method of bladder drainage used (74,75). It may be a result
of bladder denervation and not simply a problem associated with bladder overdistention
(76). Voiding every 4 to 6 hours, increasing intra-abdominal pressure with Credé’s maneu-
ver, and intermittent self-catheterization may be used to manage bladder hypotonia.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy,
recurrent cancer, or lymphocyst formation (59). If the stricture is associated with lympho-
cyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that
occur after radiation therapy should be managed with ureteral stenting. If a ureteral stric-
ture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma
is the most common cause. A CT scan of the area of obstruction should be obtained and
cytologic assessment by FNA should be performed if there is a target lesion to exclude
carcinoma. If the results of these tests are negative, a ureteral stent may be placed to relieve
the stricture. Close observation for recurrent carcinoma is necessary, and the diagnosis of
recurrence may ultimately require laparotomy.

**Nerve-Sparing Radical Hysterectomy**

Nerve-sparing radical hysterectomies have been described in recent years in an
attempt to diminish the bladder dysfunction, sexual dysfunction, and colorectal
motility disorders commonly encountered after traditional radical hysterectomy.
Multiple techniques have been described involving the identification of the pelvic auto-
nomic nerves at the sacral promontory followed by various surgical methods of nerve
preservation as the nerves transit the cardinal ligaments. These techniques are promising
and have been shown in small series to reduce postoperative bladder dysfunction (77,78).

**Laparoscopic Radical Hysterectomy**

Laparoscopic-assisted radical vaginal hysterectomy is being performed with increasing
frequency in highly selected patients. In one large series of 200 women with stage
Ia1–Ib cervical cancer treated with laparoscopic lymphadenectomy followed by radical
vaginal hysterectomy, the authors found a 5-year survival rate comparable to patients
treated with a similar abdominal approach and a comparable rate of intraoperative compli-
cations (79).

The use of laparoscopy in cervical cancer patients is appealing because it may lead to less
blood loss, improved cosmetic results, shorter duration of hospitalization, and faster
recovery.

**Sentinel Lymph Node Evaluation**

Sentinel lymph node detection has become an integral part of the management strategy for
breast cancer and melanoma and is currently being investigated as a diagnostic tool in
multiple human malignancies, including carcinoma of the cervix. The sentinel node is a
specific lymph node (or nodes) that is the first to receive drainage from a malignancy and
is a primary site of nodal metastasis. In theory, the presence or absence of metastatic
disease in the sentinel node should reflect the status of the nodal basin as a whole. Thus, a
negative sentinel lymph node would allow omission of lymphadenectomy of the involved
nodal basin. Sentinel lymph nodes are detected through perilesional injection of radiola-
beled technicium-99 or blue dye followed by intraoperative identification of the sentinel
lymph nodes utilizing handheld gamma probes or visual identification of blue-stained
nodes. These techniques are primarily applicable in patients with early-stage disease and
clinically negative lymph nodes, in whom lymph node status may influence the extent of the procedure or the use of adjuvant treatment.

Although data utilizing sentinel lymph node detection techniques in cervical cancer are limited, several interesting conclusions can be drawn from completed studies. Sentinel nodes can be detected in 80% to 100% of cervical cancer patients and have been detected by both laparotomy and laparoscopic techniques with equivalent detection rates. A combination of dye and radiolabeled techniques appears to be superior for the detection of sentinel lymph nodes over either technique used alone. Test sensitivity of 65% to 87% can be expected with a 90% to 97% negative predictive value. The likelihood of detecting sentinel nodes may depend on the tumor volume, the time from injection to retrieval of the sentinel nodes, and the volume of dye or radiolabeled tracer injected. Sentinel node detection rates do not appear to be influenced by prior cold knife cone biopsy. False-negative results have been reported. **The role of sentinel node detection in cervix cancer is purely investigational at this time; although the technique is promising, complete lymphadenectomy, when indicated, remains the standard of care** (80).

**Postoperative Management**

**Prognostic Variables for Early-Stage Cervical Cancer (Ia2–IIa)**

The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on the presence or absence of several intermediate and high-risk pathologic factors (72,81–95).

Intermediate-risk factors for recurrent disease:

1. Large tumor size
2. Cervical stromal invasion to the middle or deep one third
3. Lymph-vascular space invasion

High-risk factors for recurrent disease:

1. Positive or close margins
2. Positive lymph nodes
3. Microscopic parametrial involvement

Patients treated with radical hysterectomy that have intermediate- or high-risk factors have a 30% and 40% risk, respectively, of recurrence within 3 years (96–98).

**Lesion Size**  Lesion size is an independent predictor of survival. Patients with lesions smaller than 2 cm have a survival rate of approximately 90%, and patients with lesions larger than 2 cm have a 60% survival rate (84). When the primary tumor is larger than 4 cm, the survival rate drops to 40% (82,93). An analysis of a Gynecologic Oncology Group prospective study of 645 patients showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm (94).

**Depth of Invasion**  Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of approximately 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm (72,94,98).
**Parametrial Spread**  Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative. When the parametrium is involved and pelvic lymph nodes are also positive, the 5-year survival rate falls to 39% to 42% (85,95).

**Lymph–Vascular Space Involvement**  The significance of the finding of lymph–vascular space involvement is somewhat controversial. Several reports have shown a 50% to 70% 5-year survival rate when lymph–vascular space invasion is present and a 90% 5-year survival rate when invasion is absent (72,84,88,99–103). Others have found no significant difference in survival if the study is controlled for other risk factors (93,94,104–106). Lymph–vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

**Lymph Nodes**  The most dependent variable associated with survival is the status of the lymph nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate (94,107), whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases (90–92,98,107–109).

Data on lymph node status can be summarized as follows:

1. When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved (99,110,111).

2. Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22%–40% survival rate) than unilateral positive pelvic nodes (59%–70%) (110,111).

3. The presence of more than three positive pelvic lymph nodes is accompanied by a 68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive (90,108).

4. Patients in whom tumor emboli are the only findings in the pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate is 62.1% and 54% with microscopic invasion and macroscopic disease, respectively (81).

Given the high risk of recurrent disease in surgically treated patients with early-stage cervical cancer who exhibit intermediate- or high-risk pathologic factors, adjuvant radiation or chemoradiation therapy should be considered.

---

**Primary Radiation Therapy**  Radiotherapy can be used to treat all stages of cervical cancer, with cure rates of about 70% for stage I, 60% for stage II, 45% for stage III, and 18% for stage IV (3). A comparison of surgery and radiation for treatment of low-stage disease is shown in Table 34.5. Primary radiation treatment plans generally consist of a combination of external teletherapy to treat the regional lymph nodes and to decrease the tumor volume, and brachytherapy delivered by intracavitary applicators or interstitial implants to provide a treatment boost to the central tumor. Intracavitary therapy alone may be used in patients with early disease when the incidence of lymph node metastasis is negligible.

The treatment sequence depends on tumor volume. Stage Ib lesions smaller than 2 cm may be treated first with an intracavitary source to treat the primary lesion, followed by external therapy to treat the pelvic lymph nodes. Larger lesions require external radiotherapy first to shrink the tumor and to reduce the anatomic distortion caused by the cancer. Such
a treatment strategy enables the therapist to achieve better intracavitary dosimetry. The usual doses delivered are 7,000 to 8,000 cGy to point A (defined as 2 cm superior to the external cervical os and 2 cm lateral to the internal uterine canal) and 6,000 cGy to point B (defined as 3 cm lateral to point A), limiting the bladder and rectal dosage to less than 6,000 cGy. To achieve this level, it is necessary to adequately pack the bladder and bowel away from the intracavitary source. Localization films and careful calculation of dosimetry are mandatory to optimize the dose of radiation and to reduce the incidence of bowel and bladder complications. Local control depends on delivering an adequate dose to the tumor from the intracavitary source.

Although brachytherapy has traditionally been prescribed using a low-dose rate technique, high-dose rate techniques are becoming more popular, and controversy currently exists over which technique is superior. Low-dose rates typically use Cs-137 as the source, whereas high-dose rates use Ir-192. Proponents of high-dose rate techniques argue that the exposure of radiation to medical personnel is less, ambulatory therapy is possible, and total treatment time is less. Advocates of low-dose rate techniques cite literature suggesting that complication rates are higher with higher-dose rate therapy. Several published trials have shown that although there may be slight stage-related differences in survival between patients treated with low- and high-dose rate regimens, overall the techniques have comparable survival and complication rates (112–114).

As noted, clinical staging is imprecise and fails to accurately predict disease extension to the para-aortic nodes in 7% of patients with stage Ib, 18% with stage IIb, and 28% with stage III disease (115). Such patients will have “geographic” treatment failures if standard pelvic radiotherapy ports are used. As a result, treatment plans for these patients are individualized based on CT scans and biopsies of the para-aortic lymph nodes for consideration of extended-field radiotherapy. The routine use of extended-field radiation for “prophylactic para-aortic radiation” without documentation of distant metastasis to the para-aortic nodes has been evaluated and is typically not practiced because of the increased enteric morbidity associated with this treatment modality.

### Intensity Modulated Radiation Therapy

A relatively new method of providing external beam therapy, known as intensity modulated radiation therapy (IMRT), may be a significant therapeutic development. This technique uses computer-generated algorithms that accurately distinguish between target treatment volumes and normal tissue. The radiation beam intensity is then modulated to optimize the delivery of radiation to the specified treatment volume while sparing adjacent normal tissue. The result appears to be much more accurate treatment of...
the tumor with minimal toxicity. Emphasizing this point is a recent study in 40 gynecologic cancer patients in which IMRT was used. Excellent coverage of the planned treatment volume was obtained, with no patient suffering grade 3 toxicity, and only 60% of patients suffering grade 2 toxicity compared with a historical rate of 90% toxicity with conventional techniques (116). This technique is especially promising for treating cervical cancer because it allows higher doses to be delivered much more precisely, allowing patients who are unable to undergo brachytherapy because of pelvic anatomy and tumor geometry a chance for curative therapy. Studies utilizing IMRT in treating patients with cervical cancer are limited, but experience with this technique is increasing.

**Adjuvant Radiation**

In an effort to improve survival rates, postoperative radiotherapy has been recommended for patients with high- and intermediate-risk factors such as metastasis to pelvic lymph nodes (72,82,99,107), invasion of paracervical tissue (85,86), deep cervical invasion (117), or positive surgical margins (108,118). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high-risk factors is controversial. Increasing evidence supports the use of adjuvant radiation, however. Particularly controversial but best studied is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that pelvic lymphadenectomy does not remove all of the nodal and lymphatic tissue and subsequent radiotherapy can sterilize remaining cancer. The hesitancy to recommend postoperative radiotherapy relates to the significant rate of postradiation bowel and urinary tract complications (119). Most of the data currently available are retrospective. However, a randomized study by the Gynecologic Oncology Group comparing radiation with no further treatment for patients at high risk for recurrence with negative pelvic nodes revealed a 30% serious complication rate, 16% reoperation rate, and a 2% mortality rate as a result of treatment-related complications (120).

**Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-year actuarial survival rates.** One multi-institutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% versus 60%) (98). However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, number, and location of positive nodes after radical hysterectomy (121), no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation ($p = 0.03$). In a Cox regression analysis of 320 women who underwent radical hysterectomy, 72 of whom received postoperative radiotherapy (91), there was a significant decrease in pelvic recurrence but no survival benefit. A multi-institutional retrospective study was performed of 185 women with positive pelvic nodes after radical hysterectomy, 103 of who received postoperative radiotherapy (93). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes were found to influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant recurrence, the addition of chemotherapy to postoperative radiotherapy has been proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given cisplatin, vinblastine, and bleomycin after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment (122). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients with positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated postoperatively with radiation therapy plus cisplatin and bleomycin (123).
The location of lymph node metastases is apparently relevant to postirradiation recurrence rates. When common iliac lymph nodes are involved, the survival rate drops to 20% (100). As the number of positive pelvic nodes increases, the percentage of positive common iliac and low para-aortic nodes increases (ie, 0.6% when pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes) (100). This information has been used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease (100). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes, and a survival rate of 51% occurred in patients with positive common iliac nodes; these rates are better than the survival rates of 50% and 23%, respectively, for historical control groups receiving radiotherapy to the pelvis alone.

The Gynecologic Oncology Group reported the results of a randomized controlled trial on patients with cervical cancer treated by radical hysterectomy and found to have at least two of the following risk factors: capillary lymphatic space invasion, more than one third stromal invasion, and large tumor burden (121). A total of 277 patients were entered into the study, with 140 patients randomized to no further therapy and 137 patients randomized to adjuvant pelvic radiotherapy. Patients with these risk factors who were treated postoperatively with radiation therapy had a statistically significant (47%) decrease in recurrent disease. The study results have not had adequate follow-up to show a statistically significant decrease in mortality. The data, however, demonstrate improved survival rates. The morbidity with combination therapy was acceptable, with a low rate of enteric and urinary complications. A second Gynecologic Oncology Group study of patients with high-risk cervical cancer randomized patients to concurrent chemoradiation therapy or radiation therapy alone (96), as discussed below.

**Concurrent Chemoradiation**

Radiation therapy fails to achieve tumor control in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its relative lack of success in treating patients with cervical cancer, has been studied as neoadjuvant treatment in combination with surgery. Concomitant use of chemotherapy and radiation has been studied extensively by the Gynecologic Oncology Group, and results of five randomized studies have been reported. The concept of chemoradiation encompasses the benefits of systemic chemotherapy with the benefits of regional radiation therapy. Additionally, the use of chemotherapy to sensitize cells to radiation therapy has been shown to improve local–regional control. These new results have changed the way cervical cancer is treated in many medical centers.

An intergroup trial involving the Gynecologic Oncology Group, the Southwestern Oncology Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage Ia2, Ib, or IIa cervical cancer who were found to have positive pelvic lymph nodes, positive parametrial extension, or positive vaginal margins at the completion of radical hysterectomy (123). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (cisplatin, 5-FU, radiation therapy) and 116 receiving radiation. The results of this trial showed a statistically significant improvement in progression-free survival and overall survival at 43 months for the patients receiving concurrent chemoradiation. The 4-year survival rates for the patients receiving chemoradiation versus radiation alone were 81% and 71%, respectively. The toxicity levels in the two groups were acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm. This study showed that in patients with these high-risk factors after radical hysterectomy for stage Ia2, Ib, and IIa disease, chemoradiation is the postoperative treatment of choice.

Concurrent chemoradiation was also evaluated in patients with advanced cervical carcinoma. Gynecologic Oncology Group protocol 85 was a prospective study that enrolled
patients with stage IIb to IVa cervical cancer and compared concurrent chemoradiation (124). There were 177 patients treated with cisplatin, 5-FU, and radiation. These patients were compared with 191 patients treated with hydroxyurea and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation and were treated with cisplatin and 5-FU had a statistically significant improvement in progression-free interval and overall survival (122). Hematologic toxicity levels in the two groups were similar. **This study showed that cisplatin-based concurrent chemoradiation was a superior treatment when compared with hydroxyurea and concurrent radiation.**

Gynecologic Oncology Group protocol 120 was initiated to evaluate patients with negative para-aortic nodes and cervical carcinoma stage IIb to IVa treated with concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly cisplatin; or cisplatin, 5-FU, and hydroxyurea; or hydroxyurea. There were 176 patients in the weekly cisplatin arm; 173 patients in the cisplatin, 5-FU, and hydroxyurea arm; and 177 patients in the hydroxyurea arm (125). The two treatment arms with cisplatin-based chemotherapy and radiation showed an improvement in progression-free interval and overall survival at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with cisplatin-based chemotherapy and radiation, compared with the patients treated with hydroxyurea and radiation (126). **This study confirmed the findings of GOG 85 and again suggested that cisplatin-based concurrent chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.**

A third Gynecologic Oncology Group trial evaluated patients with stage Ib to IVa cervical cancer. Of the patients enrolled in this study, 70% had stage Ib or IIa disease (127). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and progression-free intervals for patients receiving concurrent chemoradiation were significantly improved (127). **The results of this study suggested that chemoradiation is the treatment of choice for stage IIb to IVa disease and that those patients with stage Ib2 and IIa disease may also benefit from chemoradiation.**

A Gynecologic Oncology Group study of chemoradiation comparing concurrent cisplatin and radiation with radiation alone in patients with bulky Ib cervical cancer also included adjuvant hysterectomy after completion of the radiation (127). There were 183 patients assigned to the concurrent chemotherapy and radiation arm, and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with 21% who were treated with concurrent chemoradiation (126). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group that received radiation alone (126). The study also included adjuvant hysterectomy after completion of radiation treatment. However, because the results did not show an improvement in survival by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. **This study supported the results of previous studies and showed that patients with bulky stage Ib and IIa cervical cancer treated with concurrent chemoradiation had survival rates superior to those treated with radiation alone. These two studies suggest that patients with bulky stage Ib and IIa disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly cisplatin.**

**Surgical Staging Before Radiation**

Surgical staging procedures designed to discover positive lymph nodes have been devised. Transperitoneal exploration was initially used, but was associated with a
16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (128,129). When transperitoneal exploration was routinely employed, the subsequent radiotherapy dose to the para-aortic chain was 5,500 to 6,000 cGy, which is now known to be excessive. Intestinal morbidity was predominately a result of postsurgical adhesions entrapping the intestine in the radiotherapy field, resulting in bowel exposure to the full dose of radiation. In the absence of postsurgical adhesions, the small bowel would move in and out of the radiotherapy field and receive a lesser dose. To avoid these complications, extraperitoneal dissection of the para-aortic nodes is now recommended, and the radiation dose should be reduced to 5,000 cGy or less (130,131). When such an approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients (132,133), and the 5-year survival rate is 15% to 26% in patients with positive para-aortic nodes (17,133). Survival appears to be related to the amount of disease in the para-aortic nodes and to the size of the primary tumor. In patients whose metastases to the para-aortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (134,135). Surgical staging techniques have improved to include laparoscopic assessment of the para-aortic and pelvic lymph nodes. Studies have demonstrated benefit from surgical staging with improved survival and changes in treatment plans in 40% of patients (131,132).

Management of Grossly Positive Para-aortic Lymph Nodes

The management of patients with macroscopic or grossly positive para-aortic lymph nodes discovered at the time of surgery or by imaging studies is controversial. It is likely that grossly positive nodes are beyond the ability of radiation therapy alone to sterilize. Therefore, to improve survival, additional therapy is required. In a representative study of the multiple reports in the literature (25), lymph node metastases were noted in 133 of 266 patients. Pelvic and para-aortic nodes were positive in 44 patients and positive para-aortic nodes were noted in only 2 patients. Five- and ten-year survival rates were similar for patients with macroscopically positive resectable nodes and microscopically positive nodes. Patients with unresectable nodal disease had a worse survival rate than those with resectable disease. All patients underwent extraperitoneal lymph node resections and subsequent radiotherapy. There was a 10% incidence of severe morbidity related to radiation use. Consistent with other reports in the literature, this study showed that extraperitoneal debulking lymphadenectomy confers a survival advantage similar to that enjoyed by patients with micrometastatic disease without additional morbidity (25).

Prophylactic Para-aortic Radiation Therapy

Prophylactic extended-field radiation therapy is an alternative to surgical staging of the para-aortic lymph node chain in women with advanced cervical cancer judged to be at high risk but without radiological or clinical evidence of para-aortic lymph node involvement. This treatment strategy was evaluated in 441 patients with stage I–III disease (136). High rates of gastrointestinal toxicity were noted in the treatment group. There was no difference in disease-free survival or overall survival between the control and treated groups, although treated patients had fewer para-aortic failures. A lack of difference in survival rates in this study may be related to high local and regional failure rates, suggesting that ideal patients for prophylactic radiotherapy would be those in whom there is a high likelihood of achieving pelvic control. A survival benefit was noted in a study by the Radiation Therapy Oncology Group (137), in which 367 patients with stage Ib–IIB disease were randomized to pelvic radiotherapy versus pelvic and extended field radiotherapy. The extended field treatment arm suffered more grade 4 and 5 toxicity, confirming previous studies. Complicating the issue is another study from the Radiation Therapy Oncology Group that revealed that in locally advanced cervical cancer, pelvic radiation therapy with concurrent cisplatin chemotherapy was superior to extended-field radiation therapy (138).
The appropriate role of prophylactic para-aortic radiation therapy is still under investigation.

**Supraclavicular Lymph Node Biopsy**

Although not standard practice, the performance of a supraclavicular lymph node biopsy has been advocated in patients with positive para-aortic lymph nodes before the initiation of extended-field irradiation as well as in patients with a central recurrence before exploration for possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive para-aortic lymph nodes is 5% to 30% (139). Cytologic assessment by FNA can obviate the need for an excisional biopsy and thus should be performed if any enlarged nodes are present. If the scalene lymph nodes are found to be positive, the disease is incurable, and treatment is palliative.

**Complications of Radiation Therapy**

Perforation of the uterus may occur at the time of insertion of the uterine tandem. This is a problem particularly for elderly patients and those who have had a previous diagnostic conization procedure. When perforation is recognized, the tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have had uterine perforation (140), possibly because these patients have more extensive uterine disease. Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after insertion of the intracavitary system. If uterine perforation has been excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a cephalosporin, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a *Bacteroides* species–specific antibiotic should be administered. If fever persists or if the patient shows signs of septic shock or peritonitis, the intracavitary system must be removed. Antibiotics are continued until the patient has recovered, and the intracavitary application is delayed for 1 to 2 weeks.

**Acute Morbidity** The acute effects of radiotherapy are caused by ionizing radiation on the epithelium of the intestine and bladder and occur after administration of 2,000 to 3,000 cGy. Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasionally bleeding from the bladder or bowel mucosa. Bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents may also help. Bladder symptoms may be treated with antispasmodic medication. Severe symptoms may require a week of rest from radiotherapy.

**Chronic Morbidity** The chronic effects of radiotherapy result from radiation-induced vasculitis and fibrosis and are more serious than the acute effects. These complications occur several months to years after radiotherapy has been completed. The bowel and bladder fistula rate after pelvic radiation therapy for cervical cancer is 1.4% to 5.3% (57,59). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients (57,59).

**Proctosigmoiditis** Bleeding from proctosigmoiditis should be treated with a low-residue diet, antidiarrheal medications, and steroid enemas. In extreme cases, a colostomy may be required to rest the bowel completely. Occasionally resection of the rectosigmoid must be performed.

**Rectovaginal Fistula** Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients. The successful closure of fistulas with bulbocavernosus flaps (141) or sigmoid colon transposition (142) has been reported. Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of an anastomotic leak or breakdown from prior repairs.
Small Bowel Complications  Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may be particularly susceptible to chronic damage because of its relatively fixed position at the cecum. Patients with small bowel complications typically have a long history of crampy abdominal pain, intestinal rushes, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms. Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early surgical intervention after the anemia has resolved and good nutritional status has been attained. The type of procedure performed depends on individual circumstances (143). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left in situ. In the latter case, the fistula will act as its own mucous fistula.

Urinary Tract  Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supravesicular urinary diversion. Occasionally, a small fistula can be repaired with either a bulbocavernous flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and a cytologic sample should be obtained at the site of the obstruction using FNA guided by a CT scan. If the findings are negative, the patient should undergo exploratory surgery to evaluate the presence of recurrent disease. If radiation fibrosis is the cause, ureterolysis may be possible or indwelling ureteral stents may be passed through the open urinary bladder to relieve obstruction.

Chemotherapy

Neoadjuvant Chemotherapy  Randomized trials have been initiated by the Gynecologic Oncology Group and other large centers to determine the efficacy of neoadjuvant chemotherapy. In the era of effective chemoradiation therapy, there is no evidence that neoadjuvant chemotherapy offers superior results or a survival advantage over standard therapy.

Chemotherapy for Advanced Disease  Chemotherapy has been studied in advanced cervical cancer with mixed results. Single-agent chemotherapy has been the standard for advanced or recurrent disease. Active agents include cisplatin, carboplatin, paclitaxol, and ifosfamide, but response rates are only 10% to 20% with a median duration of only 4 to 6 months. More recently, a number of trials have been performed to determine whether multiagent chemotherapy is superior. The Gynecologic Oncology Group 149 studied patients with histologically confirmed, advanced stage (IVb), recurrent or persistent squamous cell cancer of the cervix and randomized these patients to one of two combination chemotherapy treatment arms. Of the 287 patients, 146 patients were randomized to the cisplatin and ifosfamide arm, and 141 patients received cisplatin, ifosfamide, and bleomycin. There were no differences in overall survival, progression-free survival, response rates, or overall toxicity between the two combination chemotherapy regimens (144). In another trial sponsored by the Gynecologic Oncology Group, single-agent cisplatin was compared to cisplatin plus either dibromodulcitol or ifosfamide plus mesna. In this trial, the combination of cisplatin plus ifosfamide had a better response rate (31% versus 18%) and median time to progression (4.6 months versus 3.2 months) compared with single agent cisplatin. Toxicity was notably higher in the combination regimen, and there was no overall survival advantage demonstrated (145). Recently, the Gynecologic
Oncology Group published the results of a study comparing single-agent cisplatin to cisplatin plus paclitaxel in women with stage IVb squamous cell cancer of the cervix. Although the response rate (36% versus 19%) and progression-free survival (4.8 months versus 2.8 months) were greater for the combination regimen, there was only a 1-month increase in overall survival (146). Finally, the regimen of methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC), which had received considerable attention because of preliminary studies suggesting high response rates, was evaluated in Gynecologic Oncology Group protocol 179. In this study, MVAC was compared to cisplatin alone, and cisplatin combined with topotecan. The MVAC arm was prematurely closed because of excessive toxicity, and the remaining cisplatin arms were compared. Although the response rate (16% versus 14%) was not statistically significant, the combination arm had a slightly higher overall survival rate. Based on these results, the GOG has initiated a trial comparing topotecan, paclitaxel, vinorelbine, and gemcitabine each in combination with cisplatin. Overall, it appears that multiagent regimens offer an improved response rate and slightly higher overall survival but with increased toxicity.

Treatment of Cervical Cancer by Stage

**Stage Ia**

Lesions with invasion less than or equal to 3 mm have a less than 1% incidence of pelvic node metastases. Patients with these lesions, along with those with definitive evidence for nodal metastases or central pelvic recurrence, may be treated with endocervical curettage. Surgical staging may be indicated for lesions with evidence of lymphatic space invasion. The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

**Stage Ia2**

Lesions with invasion greater than 3 mm but less than or equal to 5 mm have a 5% incidence of pelvic node metastases. These patients may be considered for surgical staging with endocervical curettage. If central pelvic recurrence is not demonstrated, these patients may be treated with external beam radiation therapy. If central pelvic recurrence is demonstrated, these patients may be treated with a combination of external beam radiation therapy and pelvic node dissection.

**Stage Ib**

Lesions with invasion greater than 5 mm but less than or equal to 7 mm have a greater than 10% incidence of pelvic node metastases. These patients may be considered for surgical staging with endocervical curettage. If central pelvic recurrence is not demonstrated, these patients may be treated with external beam radiation therapy. If central pelvic recurrence is demonstrated, these patients may be treated with a combination of external beam radiation therapy and pelvic node dissection.

**Stage Ic**

Lesions with invasion greater than 7 mm have a greater than 25% incidence of pelvic node metastases. These patients may be considered for surgical staging with endocervical curettage. If central pelvic recurrence is not demonstrated, these patients may be treated with external beam radiation therapy. If central pelvic recurrence is demonstrated, these patients may be treated with a combination of external beam radiation therapy and pelvic node dissection.
Cervical adenocarcinoma may be treated in a fashion similar to patients with this stage and a squamous lesion. Some providers disagree with this interpretation because of the difficulty of establishing a pathologic diagnosis of microinvasion from a glandular lesion. Patients diagnosed with microinvasive cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy or conization.

**Stage Ia2 >3–5 mm Invasion** Lesions with invasion of >3 to 5 mm have a 3% to 8% incidence of pelvic node metastases (147–149); thus, pelvic node dissection is necessary for these lesions. The primary tumor may be treated with a modified radical hysterectomy (type II) or a radical trachelectomy if preservation of fertility is desired. If intermediate- or high-risk pathologic factors are identified in the surgical specimen, adjuvant radiation or chemoradiation therapy is recommended, respectively.

**Stage Ib1 and Ib2 Invasive Cancer** Stage Ib lesions are subdivided into stage Ib1, which denotes lesions that are 4 cm or smaller in maximum diameter, and stage Ib2, which denotes lesions that are larger than 4 cm. These patients may be managed with either radical trachelectomy or a type III radical hysterectomy, with pelvic lymphadenectomy. Radical trachelectomy should be restricted to candidates with low-risk disease, an absence of lymph-vascular space invasion, and tumor size less than 2 cm. The para-aortic lymph node chain must be evaluated, especially if pelvic nodal disease is encountered. Adjuvant radiation therapy is recommended if intermediate-risk factors are identified postoperatively. Adjuvant chemoradiation is indicated if high-risk features are found.

Alternatively, primary chemoradiation therapy with curative intent is appropriate. A comparison of radical hysterectomy with radiation has resulted in similar survival rates for the two treatment modalities. Several studies comparing patients treated by either radical hysterectomy or radiation therapy showed similar survival rates and outcomes for both groups (81,150). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity compared with patients treated with either modality alone. Therefore, some clinicians advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation.

**Bulky Stage Ib2 and IIa Invasive Cancer** Patients with bulky Ib2 and IIa disease may be treated with either primary chemoradiation or radical surgery. Because many of these patients will be found to have intermediate- or high-risk factors postoperatively, strong consideration should be given to primary chemoradiation. If surgical therapy is desired, a type III radical hysterectomy with pelvic and para-aortic lymphadenectomy, followed by adjuvant chemoradiation if intermediate- or high-risk factors are present, is appropriate therapy. This option has benefits of complete surgical staging and ovarian preservation, if desired. Disadvantages of primary surgery include increased morbidity if multimodality therapy is utilized (150).

**Stage IIb to IIIb Invasive Cancer** Therapy for patients with stage IIb or greater cervical cancer has traditionally been radiation therapy. Primary pelvic radiotherapy fails to control disease progression in 30% to 82% of patients with advanced cervical carcinoma (3). Two thirds of these failures occur in the pelvis (151). A variety of agents have been used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. Because chemoradiation has been shown to be superior to radiation therapy alone, chemoradiation is now the preferred treatment strategy for these patients, with cisplatin the chemotherapy agent of choice. Nodal involvement, particularly the para-aortic lymph nodes, is the most important factor related to survival (see section on Concurrent Chemoradiation.)
Stage IVa and IVb Cancer  Although primary exenteration may be considered for patients with direct extension to the rectum or bladder, it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3.8% (152). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to brachytherapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before chemoradiation to avoid septic episodes from fecal contamination. In certain clinical situations, such as with patients who have stage IVa disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion may be performed, followed by chemoradiation. Patients with stage IVb cervical carcinoma are candidates for chemotherapy and palliative pelvic radiation therapy. Control of symptoms with the least morbidity is of primary concern in this patient population.

Patient Evaluation and Follow-up after Therapy  Patients who receive radiotherapy should be closely monitored to assess treatment response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina is expected and should be noted. During rectovaginal examination, careful palpation of the uterosacral and cardinal ligaments for nodularity is important. Cytologic assessment by FNA of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic examination, the supraclavicular and inguinal lymph nodes should be carefully examined, and cervical or vaginal assessment should be performed every 3 months for 2 years and then every 6 months for the next 3 years. Endocervical curettage may be performed in patients with large central tumors.

Radiography of the chest may be performed yearly in patients who have advanced disease. Metastasis to the lung has been reported in 1.5% of cases. Solitary nodules are present in 25% of cases with metastasis. Resection of a solitary nodule in the absence of other persistent disease may yield some long-term survivors (153). Although intravenous pyelography (IVP) is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if urinary symptoms warrant evaluation. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment (154).

Patients who have had radical hysterectomy and who are at high risk for recurrence may benefit from early recognition of recurrence because they might be saved with radiation therapy. In these patients, a routine CT urogram 6 to 12 months after surgery may be beneficial. After radical hysterectomy, about 80% of recurrences are detected within 2 years (155). In general, the larger the primary lesion, the shorter the median time is to recurrence (156).

Special Considerations

Cervical Cancer during Pregnancy  The incidence of invasive cervical cancer associated with pregnancy is 1.2 in 10,000 (157). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be biopsied. Diagnosis is often delayed during pregnancy because bleeding is attributed to pregnancy-related complications. If the result of the Pap test is positive for malignant cells, and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary.
Conization in the first trimester of pregnancy is associated with an abortion rate as high as 33% (158,159), as well as hemorrhagic and infectious complications. Because conization subjects the mother and fetus to complications, it should be performed only in the second trimester and only in patients with colposcopy findings consistent with cancer, biopsy-proven microinvasive cervical cancer, or strong cytologic evidence of invasive cancer. Inadequate colposcopic examination may be encountered during pregnancy in patients who have had prior ablative therapy. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Patients with obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment until fetal maturity is achieved in patients with stage Ia cervical cancer (158,160,161). Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term. Historically, these patients were allowed to deliver vaginally, and a hysterectomy was performed 6 weeks postpartum if further childbearing was not desired. However, in a multivariate analysis of 56 women with cervical cancer diagnosed during pregnancy and 27 women with cervical cancer diagnosed within 6 months of delivery, vaginal delivery was the most significant predictor of recurrence (162). In addition, most recurrences after vaginal delivery involved distant sites. The ideal delivery method for these patients is not known definitively; however, strong consideration should be given to performing a cesarean birth in women with cervical cancer of any stage (162). If vaginal delivery is chosen, close inspection of the episiotomy site is required during follow-up because of rare reports of metastatic cervical cancer at these locations (163).

Patients with 3 to 5 mm of invasion and those with lymph–vascular space invasion may also be followed to term or delivered early after establishment of fetal pulmonary maturity (158,161). They may be delivered by cesarean birth, followed immediately by modified radical hysterectomy and pelvic lymphadenectomy. Patients with more than 5 mm invasion should be treated as having frankly invasive carcinoma of the cervix. Treatment depends on the gestational age of the pregnancy and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably unwise to delay therapy for longer than 4 weeks (160,161). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymph node dissection. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stage II–IV cervical cancer should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation that spontaneous abortion will occur before the delivery of 4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken.

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. Overall survival is slightly better because an increased proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis (158,161). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival (162).
Cancer of the Cervical Stump

Cancer of the cervical stump was more common many decades ago when supracervical hysterectomy was popular; however, as this operation has gained new popularity, this situation may again become more common. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact (164). Radical parametrectomy with upper vaginectomy and pelvic lymphadenectomy is the standard procedure. Advanced-stage disease may present a therapeutic problem for the radiotherapist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or with an external treatment plan in which lateral ports are used to augment the standard anterior and posterior ports. Such a technique will reduce the dosage to the bowel and bladder and thus reduce the incidence of complications.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. A CT urogram can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and generally do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilation of the cervical canal and will not interfere with treatment. The pyometra also should be drained, and the patient should be given antibiotics to cover Bacteroides species, anaerobic Staphylococcus and Streptococcus species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix has been advocated, but the catheter itself may become obstructed, leading to further occlusion of the drainage. Repeated dilation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic lymphadenectomy may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin when the pyometra has healed. Patients often have a significant amount of pus in the uterus or a tubo-ovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma after Extrrafascial Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, further treatment is predicated on the extent of disease. Microinvasive disease in patients at low risk for lymph node metastasis does not require further treatment. Invasive disease may be treated with radiotherapy or reoperation involving a pelvic node dissection and radical excision of parametrical tissue, cardinal ligaments, and the vaginal stump (165).

Reoperation Reoperation is indicated particularly for a young patient who has a small lesion and in whom preservation of ovarian function is desirable. It is not indicated for patients who have positive margins or obvious residual disease (165). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Radiation Therapy Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy.
Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer (166–168). A delay in treatment of more than 6 months is associated with a 20% survival rate (168).

**Acute Hemorrhage**

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel’s solution (ferric subsulfate) should be packed tightly against the cervix. After proper evaluation, external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy/day. Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation. Occasionally, vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy. However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor, compromising the effectiveness of subsequent radiotherapy.

**Ureteral Obstruction**

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy. With aggressive management, a median survival rate of 17 months may be achieved for these patients (169).

**Barrel-shaped Cervix**

The expansion of the upper endocervix and lower uterine segment by tumor has been referred to as a barrel-shaped cervix. Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose (170). Attempts have been made to overcome this problem radiotherapeutically by means of interstitial implants into the tumor with a perineal template, but high central failure rates have also been reported with this technique (171).

One approach is to use a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix. An extrafascial hysterectomy is performed 2 to 3 months after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrafascial hysterectomy (172,173). This method appears to result in a lower rate of central failure (2%), although it is not clear that the overall survival rate is improved. There is disagreement concerning the need for extrafascial hysterectomy, and the Gynecologic Oncology Group is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the para-aortic nodes (see Stage Ib and IIa discussion).

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. Such patients must receive their entire course of therapy from external sources, leading to a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic
lymphadenectomy is preferable if the patient’s medical condition allows such an approach. There may be a role for IMRT in the management of such tumors.

**Recurrent Cervical Cancer**

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who have been treated initially with surgery should be considered for radiation therapy, and those who have had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by either surgery or radiation therapy.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids also may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (155).

**Radiation Retreatment**

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who have had suboptimal or incomplete primary therapy. This may allow the radiotherapist to deliver curative doses of radiation to the tumor. The proximity of the bladder and rectum to the cancer and the relative sensitivity of these organs to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into locally recurrent cancer through a perineal template may help overcome these dosimetric considerations (165,174). The fistula rates are high, however, and the consequences must be considered seriously before interstitial therapy is initiated. In general, for patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice. Palliative radiotherapy can be given to patients with localized metastatic lesions that are deemed incurable. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

**Surgical Therapy**

Surgical therapy for postirradiation recurrence is limited to patients with central pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extrafascial or radical hysterectomy. However, the difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as a last chance for cure (175,176).

**Exenteration**

There are three types of exenterative procedures: (i) an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), (ii) a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), and (iii) a total exenteration (removal of both bladder and rectum with the vagina, cervix, and uterus [Fig. 34.9]). A total exenteration that includes a large perineal phase includes the entire rectum and leaves the patient with a permanent colostomy as well as a urinary conduit (infralevator). In selected patients, a total exenteration may take place above the levator muscle (supralevator), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

**Preoperative Evaluation and Patient Selection**

It is imperative to search for metastatic disease before undergoing an exenteration. The presence of metastatic disease in this setting is considered a contraindication to exenterative procedures. Physical examination includes careful palpation of the peripheral lymph nodes with FNA.
cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes has been advocated by some clinicians but is not routinely practiced (139,177). A CT scan of the lung can detect disease missed on routine radiographic examination of the chest. Abdominal and pelvic CT scans are helpful in the detection of liver metastases and enlarged para-aortic nodes. Cytologic study of any abnormality should be undertaken with CT-guided FNA. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies should be offered (178–181). The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall. Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotic administration, and prophylaxis for deep venous thrombosis with low-dose heparin or pneumatic calf compression should be undertaken (182). Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years. Other medical illnesses should be taken into account. When life expectancy is limited, exenterative surgery is unwise.

Anterior Exenteration Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina. Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal muscularis, and findings at laparotomy still must be considered. Generally, the presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.
**Posterior Exenteration**  A posterior exenteration is rarely performed for recurrent cervical cancer. It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissection of the ureters through the cardinal ligaments will not be necessary.

**Total Exenteration**  Total exenteration with a large perineal phase is indicated when the disease extends to the lower part of the vagina (see Fig. 34.9). Because distal vaginal lymphatics may empty into the nodal basins of the inguinal region, these nodes should be carefully evaluated preoperatively. A suprapelevator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (183,184). Samples from margins of the rectal edge should be obtained for frozen-section evaluation because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion has helped improve a woman's physical appearance after exenteration (185–187). When both a rectal anastomosis and a continent diversion are performed, the patient will not have a permanent external appliance. Associated psychological trauma in such cases may be avoided. Every effort should be made to create a neovagina simultaneously with the exenteration (188). This procedure helps in the reconstruction of the pelvic floor after extirpation of the pelvic viscera. Regardless whether a neovagina is constructed, it is desirable to mobilize the omentum on the left gastroepiploic artery to create a new pelvic floor.

Surgical mortality from exenterative procedures has steadily decreased to an acceptable level of less than 10%. Common causes of postoperative death are sepsis, pulmonary thromboembolism, and hemorrhage. Fistulas of the gastrointestinal and genitourinary tract are serious surgical complications, with a 30% to 40% mortality rate despite attempts at surgical repair. The risk for fistula formation has decreased because nonirradiated segments of bowel have been used for formation of the urinary conduit (182). The 5-year survival rate is 33% to 60% for patients undergoing anterior exenteration and 20% to 46% for those undergoing total exenteration (178–188). Survival rates are worse for patients with recurrent disease (larger than 3 cm), invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (181). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%; thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted. Discontinuation of the procedure is advisable if any nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

**Laterally Extended Endopelvic Resection**  Locally recurrent cervical cancer in a previously irradiated field is associated with a dismal prognosis. Exenterative therapy has traditionally been reserved for the highly select patient with centrally recurrent disease, a selection criteria that excludes most patients with recurrence. Recently, a new technique called laterally extended endopelvic resection (LEER) procedure has been described, which offers a new surgical treatment option for patients with recurrent disease involving the pelvic sidewall. The LEER procedure involves extending the lateral resection plane of the traditional pelvic exenteration to include resection of the internal iliac vessels; the endopelvic portion of the obturator internus muscle; and the coccygeus, iliococcygeus, and pubococcygeus muscles. Extension of the surgical plane allows for resection of lateral tumors with a negative margin. Experience with it is limited (189).

**Chemotherapy for Recurrent Cervical Cancer**  Recurrent cervical cancer is not considered curable with chemotherapy. The delivery of chemotherapy to recurrent tumor in a prior radiated field may be compromised because of altered blood supply caused by radiation. Topotecan and cisplatin has been reported to have response rates of 15% to 20%, with a median duration of 6 to 9 months (190).
Many other agents have shown activity against cervical cancer and may be used in attempt to help control symptoms. Several clinical trials with various drugs (e.g., paclitaxel, topotecan, cisplatin, and carboplatin) have shown response rates of up to 45%. Most responses are partial (191), and complete responses are unusual and are generally limited to patients with chest metastases, in whom the dose of drug delivered to the disease is stronger than that delivered to the fibrotic postirradiated pelvis (192).

Palliative Therapy

Palliative therapy for patients with incurable disease consists of radiation or chemotherapy or both. Palliative radiation therapy is intended to relieve symptoms of pain or bleeding associated with advanced disease and may be administered as either external beam therapy (teletherapy) or brachytherapy. Special care should be given to previously irradiated sites because additional radiation therapy may be associated with unacceptable morbidity. Single or multiagent palliative chemotherapy may also be used with variable response rates. Symptomatic recurrent disease within previously irradiated fields may not respond well to palliative chemotherapy.

Vaginal Carcinoma

Primary vaginal cancer is a relatively uncommon tumor, representing only 1% to 2% of malignant neoplasms of the female genital tract (193,194). The incidence of invasive vaginal cancer is 0.42 per 100,000 women, and it has remained relatively unchanged since the 1980s (195). Primary vaginal cancer should be differentiated from cancers metastatic to the vagina, which constitute the majority of vaginal cancers (80% to 90%) (196).

Staging

The FIGO staging of vaginal cancer dictates that a tumor extending to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor involving both the vulva and the vagina should be classified as a cancer of the vulva.

The FIGO staging for vaginal carcinoma is shown in Table 34.6. Staging is performed by clinical examination and, if indicated, cystoscopy, proctoscopy, and chest and skeletal radiography. Information derived from lymphangiography, CT, MRI, or PET cannot be used to change the FIGO stage; however, it can be used for planning treatment. Unfortunately, 75% of patients present with stage II–IV disease, complicating the treatment and subsequent cure rates (197–199).

FIGO, International Federation of Gynecology and Obstetrics.
Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare, and treatment is generally by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph–vascular space invasion, and size of the lesion.

Etiology

The cause of squamous cell carcinoma of the vagina is unknown. The association of cervical cancer with HPV suggests that vaginal cancer may have a similar association (200). Human papillomavirus has been recovered from 80% of precursor lesions and 60% of squamous cell cancers of the vagina (53,54). In addition, as many as 30% of women with vaginal cancer have a history of cervical cancer treated within the previous 5 years (201–203). As with cervical cancer, there appears to be a premalignant phase called vaginal intraepithelial neoplasia (VAIN) (see Chapter 17). The exact incidence of progression to invasive vaginal cancer from VAIN is not known; however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (204,205).

By convention, any new vaginal carcinoma developing at least 5 years after cervical cancer should be considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

1. Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
2. New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis (the role of HPV in this setting is suspected)
3. Increased susceptibility to carcinogenesis caused by radiation therapy

Screening

Routine screening of all patients for vaginal cancer is inappropriate. For women who have had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit, as these patients are at an increased lifetime risk for developing vaginal cancer. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. For women who have had a hysterectomy for benign disease and have no antecedent history of CIN 2–3, performance of Pap testing is unnecessary. If the patient has a history of cervical dysplasia or cervical cancer, yearly screening is recommended. When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who have had hysterectomy for benign disease (206). Because primary vaginal tumors tend to be multicentric, the entire vaginal mucosa should be considered at risk. Therefore, in addition to screening cytology, careful bimanual examinations of the entire vagina and vulva is recommended for women at high risk.

Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.

Diagnosis

The diagnostic workup includes a complete history and physical examination, careful speculum examination and palpation of the vagina, and bimanual pelvic and rectal
examinations. It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be overlooked.

In early squamous cell lesions, the diagnosis is often suggested by an abnormal Pap test result; however, this is not true for clear cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is suggested by cytologic findings in only 33% of cases. Visually suspicious areas in the vagina should be evaluated with a targeted biopsy using the same instruments as those used for cervical biopsies. Careful palpation of the vagina may be helpful in detecting submucosal irregularities. The most common site of vaginal cancer is in the upper one third of the vagina on the posterior wall. The developing tumor may be missed during initial inspection because of obscured visualization caused by the blades of the speculum (207). Colposcopy is valuable in evaluating patients with abnormal Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy may be necessary to determine invasion. Occult invasive carcinoma may be detected by such an excision, particularly in patients who have a history of prior hysterectomy in whom the vaginal vault closure may bury some of the vaginal epithelium at risk for cancer (208).

Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and para-aortic lymph nodes may occur in advanced disease. Lesions in the lower one third of the vagina may spread directly to the inguinal femoral lymph nodes as well as the pelvic nodes (209). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of cases. These tumors most commonly occur in the upper one third, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years (210,211). Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (212–214). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. The most common adenocarcinoma of the vagina is metastatic, originating from the colon, endometrium, ovary, or, rarely, pancreas and stomach. In general, adenocarcinomas affect a younger population of women, regardless of whether they were exposed to diethylstilbestrol (DES) in utero (215). Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (216). In women exposed to DES in utero, adenocarcinoma may develop in vaginal adenosis.

Diethylstilbestrol was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, seven young women were reported with clear cell adenocarcinoma of the vagina (Fig. 34.10); later, an association between this cancer and maternal ingestion of DES during pregnancy was identified (217). Subsequently, more than 500 cases of clear cell cancer of the vagina and cervix have been reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

The estimated risk for developing clear cell adenocarcinoma for an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (218). Clear cell adenocarcinoma in women with a history of in utero exposure to DES typically presents in the exocervix or anterior, upper one third of the vagina. These tumors vary greatly in size and are most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant factors include a tubulocystic growth pattern,
size less than 3 cm^2, and less than 3 mm of stromal invasion. Because the use of DES in pregnant women was discontinued in 1971, most of these tumors probably have been discovered. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

Ninety-seven percent of cases of vaginal clear cell adenocarcinoma are associated with adenosis. Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to DES in utero, adenosis can also be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

Malignant melanoma of the vagina is rare and extremely lethal, occurring most often in white women. The average age of these patients is 58 years (219). Most lesions are deeply invasive, corresponding to a Clark level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower one third of the vagina (220). Melanomas have a wide variety of size, color, and growth patterns (218,221). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) has been the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (219,220). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. There is no difference in overall survival of patients with local as opposed to radical excision (219). The survival rate is approximately 10% at 5 years.

The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (222). Vaginal sarcomas are usually fibrosarcomas or
leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 34.11). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus uteri during postmenopausal years. Preoperative chemotherapy with vincristine, actinomycin D, and cyclophosphamide, followed by conservative surgery or radiation, has led to improved survival.

**Figure 34.11 Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma).** This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross striations may become evident.

Treatment selection is based on the clinical examination, CT scan results, chest radiography results, age, and condition of the patient. Most tumors are treated by radiation therapy. Surgery is limited to highly selective cases.

Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy. If the uterus is in situ, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary. Patients with stage IV disease with either rectovaginal or vesicovaginal fistula may be candidates for primary pelvic exenteration with pelvic and para-aortic node dissection (218). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who receive prior radiation therapy (188).

Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that used for cervical cancer. Surgical staging with
resection of enlarged lymph nodes followed by radiation therapy may improve the control of pelvic disease.

Radiation therapy is the treatment of choice for all patients except those described previously. Small superficial lesions may be treated with intracavitary radiation alone (218). Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitary and interstitial therapy to deliver a high dose to the primary tumor (211,219). If the uterus is intact and the lesion involves the upper vagina, an intruterine tandem and ovoids can be used. If the uterus has been previously removed, a vaginal cylinder may be used for superficial irradiation. When brachytherapy is used, high- and low-dose rate techniques have been described. If the lesion is more than 0.5 cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel. Extended-field radiation may be used for vaginal cancer in a manner similar to its use for cervical carcinoma, although there is no experience reported with the use of this technique in the treatment of vaginal cancer. Likewise, there is no reported experience with combination chemoradiation treatment. However, concurrent use of 5-FU and cisplatin has been highly successful in anal and cervical cancer and thus should be considered for treatment of vaginal cancer.

Sequelae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for both surgery and radiation treatment. For large tumors, the risk of bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring débridement, and often leads to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical estrogen to maintain adequate vaginal function.

Survival

The overall 5-year survival rate for patients with vaginal cancer is 42% (Table 34.7). Even for patients with stage I disease, the 5-year survival rate is less than 70%, which is 15% lower than that for comparable stages of cervical or vulvar cancer (220–224). Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors. Radiation techniques, including interstitial implants with Syed applicator and combination chemoradiation, are the mainstay of therapy. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some

SECTION VIII Gynecologic Oncology

The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age. About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant. The average age of patients with borderline tumors is approximately 46 years.

Ovarian cancer has been associated with low parity and infertility. Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective of the disease, with a risk reduction of 0.3 to 0.4.

Oral contraceptive use reduces the risk of epithelial ovarian cancer. Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).

Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, these tests are not cost-effective and should not be used routinely to screen for ovarian cancer.

Most epithelial ovarian cancer is sporadic, with familial or hereditary patterns accounting for 5% to 10% of all malignancies. Hereditary ovarian cancers in general occur in women approximately 10 years younger than those with nonhereditary tumors.

Most hereditary ovarian cancer is associated with germline mutations in the BRCA1 gene; a small proportion of inherited disease is associated with mutations in the gene BRCA2. The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated. The value of prophylactic salpingo-oophorectomy in these patients has been documented.
The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. Patients with advanced-stage disease should undergo “debulking” or cytoreductive surgery to remove as much of the tumor and its metastases as possible, if the patient is medically stable. The performance of a debulking operation as early as possible in the course of the patient’s treatment should be considered the standard of care.

Combination chemotherapy with carboplatin and paclitaxel is the treatment of choice for patients with high-risk, low-stage disease. For advanced-stage epithelial ovarian cancer, the choice of intravenous versus intraperitoneal platinum and taxane chemotherapy should be individualized.

In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one third of these are malignant. In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly.

The most common types of malignant germ cell tumors are dysgerminomas, immature teratomas, and endodermal sinus tumors. Preservation of fertility should be standard in most patients. The most effective chemotherapy is bleomycin, etoposide, and cisplatin (BEP) combination.

Stromal tumors include granulosa cell tumors, which are low-grade malignancies. In premenopausal women, they can be treated conservatively. Adjuvant chemotherapy is of unproven value.

Metastatic tumors to the ovaries are most frequently from the breast and gastrointestinal tract.

Fallopian tube carcinomas are treated the same as ovarian cancer, with staging, cytoreductive surgery, and platinum and taxane chemotherapy.

Of all the gynecologic cancers, ovarian malignancies represent the greatest clinical challenge. Epithelial cancers are the most common ovarian malignancies, and because they are usually asymptomatic until they have metastasized, patients have advanced disease at diagnosis in more than two thirds of the cases. Ovarian cancer represents a major surgical challenge, requires intensive and often complex therapies, and is extremely demanding of the patient’s psychological and physical energy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are more than 20,000 new cases annually in the United States, and more than 15,000 women can be expected to succumb to their illness (1). Ovarian cancer is the seventh most common cancer in women in the United States, accounting for 3% of all malignancies and 6% of deaths from cancer in women, and almost one third of invasive malignancies of the female genital organs. Ovarian cancer is the fifth most common cause of death from malignancy in women. A woman’s risk at birth of having ovarian cancer sometime in her life is 1% to 1.5%, and that of dying from ovarian cancer almost 0.5% (2).

**Epithelial Ovarian Cancer**

Approximately 90% of ovarian cancers are derived from tissues that come from the coelomic epithelium or mesothelium (2). The cells are a product of the primitive mesoderm, which can undergo metaplasia. A classification of the histologic types of epithelial tumors of the ovary is presented in Table 35.1. Neoplastic transformation can occur when the cells are genetically predisposed to oncogenesis or exposed to an oncogenic agent or both (3).

### Pathology

#### Invasive Cancer

Seventy-five percent of epithelial cancers are of the serous histologic type. Less common types are mucinous (20%), endometrioid (2%), clear cell, Brenner, and undifferentiated carcinomas; each of the last three types represents less than 1% of epithelial lesions (2). Each tumor type has a histologic pattern that reproduces the mucosal features of a section of the lower genital tract (3). For example, the serous or papillary pattern has an appearance similar to that of the glandular epithelial lining and fallopian...
tube. Mucinous tumors contain cells that resemble the endocervical glands, and the endometrioid tumors resemble the endometrium.

**Borderline Tumors**

An important group of tumors to distinguish is the **tumor of low malignant potential**, also called the **borderline tumor**. Borderline tumors are lesions that tend to remain confined to the ovary for long periods, occur predominantly in premenopausal women, and are associated with a very good prognosis (2–8). They are encountered most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, metastatic implants may occur with borderline tumors. Such implants have been divided into **noninvasive and invasive forms**. The latter group has a higher likelihood of developing into progressive, proliferative disease in the peritoneal cavity, which can lead to intestinal obstruction and death (2,6).

The criteria for the diagnosis of borderline tumors (Fig. 35.1) are as follows (7):

1. Epithelial hyperplasia in the form of pseudostratification, tufting, cribiform, and micropapillary architecture
2. Nuclear atypia and increased mitotic activity
3. Detached cell clusters
4. Absence of destructive stromal invasion (i.e., without tissue destruction)

![Figure 35.1](image_url) **Figure 35.1** Borderline malignant serous tumor of the ovary. Complex papillary fronds are lined with pseudostratified columnar cells. The epithelium and the stroma are clearly separated by a basement membrane, indicating no stromal invasion.
It should be emphasized that about 20% to 25% of borderline tumors spread beyond the ovary. The diagnosis of borderline tumor versus malignant ovarian tumor must be based on the histologic features of the primary tumor (7).

**Classification of Epithelial Ovarian Tumors**

**Serous Tumors**

Serous tumors develop by invagination of the surface ovarian epithelium and are so classified because they secrete serous fluid (as do tubal secretory cells). *Psammoma bodies*, more correctly foci of foreign material, frequently are associated with these invaginations and may be a response to irritative agents that produce adhesion formation and the entrapment of the surface epithelium. In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrescences are present, often resulting from local irritants (2).

**Borderline Serous Tumors**

Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor, and 50% occur before the age of 40 years. As many as 10% of women with ovarian serous borderline tumors have extraovarian implants, and some will eventually die of the disease (9). Although multiple foci of disease have been documented in the abdominal cavity with secondary deposits in the pelvis, omentum, and adjacent tissues, including lymph nodes, metastases outside the abdominal cavity are rare. Death can occur as the result of intestinal obstruction (10–12).

The implants are divided histologically into invasive and noninvasive implants (6,10). In the noninvasive implants, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (6). The invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Bell et al. (6) have reported that only three of 30 women with noninvasive implants died, whereas four of six women with invasive implants died. In the series of McCaughey et al., two of 13 patients with noninvasive implants and all five patients with invasive implants died (9). Others have noted no differences in prognosis (10,11).

Rare examples of borderline malignant serous tumors with foci of microinvasion have been reported by Bell and Scully (12). Most patients are young, International Federation of Gynecology and Obstetrics (FIGO) stage I, and sometimes pregnant. Only one of 30 such patients died of disease, and she had stage III disease.

**Malignant Serous Carcinomas**

In malignant serous tumors, stromal invasion is present (2). The grade of tumor should be identified. In well-differentiated serous adenocarcinomas, papillary and glandular structures predominate (Fig. 35.2); poorly differentiated neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity; and moderately differentiated carcinomas are intermediate between these two lesions. Laminated, calcified psammoma bodies are found in 80% of serous carcinomas. *Serous psammocarcinoma* is a rare variant of serous carcinoma characterized by massive psammoma body formation and low-grade cytological features. At least 75% of the epithelial nests are associated with psammoma body formation. Patients with serous psammocarcinoma have a protracted clinical course and a relatively favorable prognosis; their clinical course more closely resembles that of serous borderline tumor than serous carcinoma.
Mucinous Tumors

These cystic ovarian tumors have loculi lined with mucin-secreting epithelium. The lining epithelial cells contain intracytoplasmic mucin and resemble those of endocervix, gastric pylorus, or intestina. They represent about 8% to 10% of epithelial ovarian tumors. They may reach enormous size, filling the entire abdominal cavity (2).

Borderline Mucinous Tumors

The mucinous tumor of low malignant potential is often a diagnosis difficult to make. Although it is common to find a rather uniform pattern from section to section in the serous borderline tumor, this is not true in the mucinous tumors. Frequently, well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. Therefore, it is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration.

Malignant Mucinous Carcinomas

Bilateral tumors occur in 8% to 10% of cases. The mucinous lesions are intraovarian in 95% to 98% of cases (Fig. 35.3). Because most ovarian mucinous carcinomas contain intestinal-type cells, they cannot be distinguished from metastatic carcinoma of the gastrointestinal tract on the basis of histology alone. Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension of vascular lymphatic spread.

Pseudomyxoma Peritonei

*Pseudomyxoma peritonei* is a clinical term used to describe the finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity surrounded by fibrous tissue. It is most commonly secondary to a well-differentiated...
appendiceal carcinoma or other gastrointestinal primary, and less commonly, a mucocele of the appendix.

**Endometrioid Tumors**

Endometrioid lesions constitute 6% to 8% of epithelial tumors. Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1925, Sampson (13) suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis. The adenocarcinomas are similar to those seen in the uterine corpus. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated (Fig. 35.4).

**Borderline Endometrioid Tumors** The endometrioid tumor of low malignant potential has a wide morphologic spectrum. Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with glandular crowding. When there are back-to-back glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline endometrioid tumors have a prominent fibromatous component. In such cases, the word adenofibroma is used.

**Malignant Endometrioid Carcinomas** Endometrioid tumors are characterized by an adenomatous pattern with all the potential variations of epithelia found in the uterus.

**Multifocal Disease** The endometrial or endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. Endometrioid carcinoma of the ovary is associated in 15% to 20% of the cases with carcinoma of the endometrium. Identification of multifocal disease is important, because patients with disease metastatic from the
uterus to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival (14). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

**Clear Cell Carcinomas**

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e., tubulocystic, papillary, recticular, and solid). The tumors are made up of clear and hobnail cells that project their nuclei to the apical cytoplasm. The tall clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes (Fig. 35.5). Focal areas of endometriosis and endometrioid carcinoma sometimes occur. The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to diethylstilbestrol (DES) in utero. Nuclei of clear cell carcinoma range from grade 1 to grade 3, but pure grade 1 tumors are extremely rare. Almost invariably high-grade (grade 3) nuclei are identified. Hence, clear cell carcinoma is not graded.

**Brenner Tumors**

**Borderline Brenner Tumors** Borderline, or proliferating, Brenner tumors have been described. In such cases, the epithelium does not invade the stroma. Some investigators subclassify those tumors that resemble low-grade papillary transitional cell carcinoma of the urinary bladder as proliferating tumors and those with a higher grade of transitional cell carcinoma in situ as borderline malignant Brenner tumors (15). Complete surgical removal usually results in cure.
Malignant Brenner Tumors  These are rare and are defined as benign Brenner tumors coexisting with invasive transitional cells or another type of carcinoma. In malignant Brenner tumors there is stromal invasion associated with a benign or borderline Brenner tumor component.

Transitional Cell Tumors  The designation transitional cell tumor refers to a primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor. An important finding is that those ovarian carcinomas that contain more than 50% of transitional cell carcinoma are more sensitive to chemotherapy and have a more favorable prognosis than other poorly differentiated ovarian carcinomas of comparable stage (16,17). Transitional cell tumors differ from malignant Brenner tumors in that they are more frequently diagnosed in an advanced stage and, therefore, are associated with a poorer survival rate (18).

Small cell carcinoma occurs mainly in young women, who may have symptoms of hypercalcemia. Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

Peritoneal Carcinomas  Primary peritoneal tumors are histologically indistinguishable from primary ovarian serous tumors. In the case of borderline serous peritoneal tumors and serous peritoneal carcinomas, the ovaries are normal or minimally involved, and the tumors affect predominantly the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (19–21). In the review of 38 cases of peritoneal borderline serous
tumors from the literature, 32 women had no persistent disease, four were well after resection of recurrence, one developed an invasive serous carcinoma, and one died from the effects of the tumor (19).

Peritoneal serous carcinomas have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Primary peritoneal endometrioid carcinoma is less common.

The primary malignant transformation of the peritoneum has been called primary peritoneal carcinoma or primary peritoneal papillary serous carcinoma. Peritoneal carcinoma simulates ovarian cancer clinically. In patients for whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the omentum. This phenomenon can thus produce a condition in which so-called ovarian cancer can arise in a patient whose ovaries were surgically removed many years earlier (22).

Mesotheliomas

Peritoneal malignant mesotheliomas fall into the following four categories (2,23): (i) fibrosarcomatous, (ii) tubulopapillary (papillary-alveolar), (iii) carcinomatous, and (iv) mixed. These lesions appear as multiple intraperitoneal masses and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease. Malignant mesotheliomas should be distinguished from ovarian tumor implants and primary peritoneal müllerian neoplasms.

Clinical Features

More than 80% of epithelial ovarian cancers are found in postmenopausal women (Fig. 35.6). The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age (2,3,24). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines (24). These cancers are relatively uncommon in women younger than age 45. Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two thirds of ovarian malignancies in such patients being germ cell tumors (2,24,25). About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant (2,3).

The average age of patients with borderline tumors is approximately 46 years (2,3,5). Eighty to ninety percent of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to one in three (2,3). Fewer than 1% of epithelial ovarian cancers occur before the age of 20 years, with two thirds of ovarian malignancies in such patients being germ cell tumors.

Etiology

Ovarian cancer has been associated with low parity and infertility (26). Although there have been a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation (see Chapter 4), none has been so strongly correlated as prior reproductive history and duration of the reproductive career (26,27). Early menarche and late menopause increase the risk of ovarian cancer (27). These factors and the relationship of parity and infertility to the risk of ovarian cancer have led to the hypothesis that suppression of ovulation may be an important factor. Theoretically, the surface epithelium undergoes repetitive disruption and repair. It is thought that this process might lead to a higher probability of spontaneous mutations that can unmask germline mutations or otherwise lead to the oncogenic phenotype (see Chapter 6).
Prevention Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective of the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer (26). Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer). Women who have had two children and have used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction (28). Therefore, the oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is also important for women with a strong family history of ovarian cancer (see discussion below).

Fenretinide (4-hydroxyretinoic acid), a vitamin A derivative, has been given to women with unilateral breast cancer in an effort to reduce the risk of contralateral breast cancer. In a prospective, randomized, placebo-controlled trial conducted in Italy (29), women with unilateral breast cancer were given for 6 months either fenretinide orally or a placebo. In the treatment group, no ovarian cancers developed, whereas there were six cases of ovarian cancer in the control group. A larger trial is ongoing in an attempt to verify these data.

The performance of a prophylactic salpingo-oophorectomy reduces, but does not eliminate, the risk of ovarian and fallopian tube cancers (19,22). Because the entire peritoneum is at risk, peritoneal carcinomas can occur even after prophylactic
oophorectomy. In premenopausal women at low risk for ovarian cancer, a thorough discussion of the risks and benefits of oophorectomy should be undertaken. The ovaries may provide protection from cardiovascular and orthopedic diseases, and long-term mortality may not be decreased by the performance of prophylactic oophorectomy (30).

Screening

The value of tumor markers and ultrasonography to screen for epithelial ovarian cancer has not been clearly established by prospective studies. Screening results with transabdominal ultrasonography have been encouraging (31–33), but specificity has been limited. However, advances in transvaginal ultrasonography have been shown to have a very high (>95%) sensitivity for the detection of early-stage ovarian cancer, although this test alone might require as many as 10 to 15 laparotomy procedures be performed for each case of ovarian cancer detected (31,32). Routine annual pelvic examinations have had disappointing results in the early detection of ovarian cancer (34). Transvaginal color-flow Doppler to assess the vascularity of the ovarian vessels has been shown to be a useful adjunct to ultrasonography (35,36), but it has not been shown to be useful in screening.

CA125 has been shown to contribute to the early diagnosis of epithelial ovarian cancer (37–43). Regarding the sensitivity of the test, CA125 can detect 50% of patients with stage I disease (37,42). Data suggest that the specificity of CA125 is improved when the test is combined with transvaginal ultrasonography (44) or when the CA125 levels are followed over time (43,44). These data have encouraged the development of prospective screening studies in Sweden and the United Kingdom (39,40). In these studies, patients with elevated CA125 levels (>30 U/mL) have undergone abdominal ultrasonography, and 14 ovarian cancers have been discovered among 27,000 women screened. About four laparotomies were performed for each case of cancer detected.

A randomized trial of nearly 22,000 women aged 45 years or older was performed in the United Kingdom (44). The patients were assigned to either a control group of routine pelvic examination (n = 10,977) or to a screening group (n = 10,958). The screening consisted of three annual screens that involved measurement of serum CA125 levels, pelvic ultrasonography if the CA125 was 30 U/mL or higher, and referral for gynecologic examination if the ovarian volume was 8.8 mL or greater on the ultrasonography. Of the 468 women in the screened group with an elevated CA125, 29 were referred for surgery, six cancers were discovered, and 23 had false-positive screening results, yielding a positive predictive value of 20.7%. During a 7-year follow-up period, cancer developed in 10 additional women in the screened group, as it did in 20 women in the control group. Although the median survival of women in whom cancer developed in the screened group was 72.9 months, compared with 41.8 months in the control group (p = 0.0112), the number of deaths did not differ significantly between the control and screened groups (18/10,977 versus 9/10,958; relative risk 2.0 [0.78 to 5.13]). Therefore, these data show that a multimodal approach to ovarian cancer screening is feasible, but a larger trial is necessary to determine whether this approach affects mortality. Such a three-arm randomized trial is ongoing in the United Kingdom, and the anticipated accrual is approximately 50,000 women per study arm and 100,000 women in the control arm. Based on the risk of ovarian cancer (ROC) algorithm, patients in the third group will be referred for transvaginal ultrasonography and/or surgery (45). Women will be screened for 3 years and studied for 7 years. This trial may demonstrate more definitively the feasibility of screening for ovarian cancer as well as the impact of early detection on survival.

A new approach is the use of proteomic patterns to identify ovarian cancer using surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) technology
In a study using this technology, the sensitivity for predicting ovarian cancer was 100% with a specificity of 95% and a positive predictive value of 94%. The assay correctly identified all 18 women with stage I tumors. This technology is in the early phases of development and validation, and its efficacy has yet to be demonstrated in large population-based studies.

Another new approach is the measurement of plasma DNA levels and allelic imbalance by a technique known as digital single nucleotide polymorphism (SNP) analysis. In a study by Chang et al. (47), this analysis had a 87% (13 of 15) positive correlation in stages I and II patients, and a 95% (37 of 39) correlation in patients with stages III and IV disease.

Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, these tests are not cost-effective and should not be used routinely to screen for ovarian cancer (48). In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof of this will require a large, prospective study (41,42). Screening in women who have a familial risk may have a better yield, but additional study is necessary (48,49).

<table>
<thead>
<tr>
<th>Genetic Risk for Epithelial Ovarian Cancer</th>
<th>The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% (1–3). The risk of ovarian cancer is higher than that in the general population in women with certain family histories (50–59). Most epithelial ovarian cancer is sporadic, with familial or hereditary patterns accounting for 5% to 10% of all malignancies (51).</th>
</tr>
</thead>
</table>

**Hereditary Ovarian Cancer**

**BRCA1 and BRCA2**

Most hereditary ovarian cancer is associated with mutations in the **BRCA1 gene**, located on chromosome 17 (50). A small proportion of inherited disease is associated with germline mutations in another gene, **BRCA2**, located on chromosome 13 (52). Discovered through linkage analyses, these two genes are associated with the genetic predisposition to both ovarian and breast cancer. There may be other yet undiscovered genes that predispose to ovarian and breast cancer (59).

In the past, it had been thought that there were two distinct syndromes associated with a genetic risk, site-specific hereditary ovarian cancer and hereditary breast-ovarian cancer syndrome. However, it is now believed that these groups essentially represent a continuum of mutations with different degrees of penetrance within a given family (54,59). In addition, there is a higher-than-expected risk of ovarian and endometrial cancer in the Lynch II syndrome, known also as the **hereditary nonpolyposis colorectal cancer syndrome (HNPCC syndrome)** (60).

The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated (54). There are numerous distinct mutations that have been identified on each of these genes, and the mutations have different degrees of penetrance that may account for the preponderance of either breast cancer, ovarian cancer, or both, in any given family. Based on analysis of women who have a mutation in the **BRCA1 gene** and are from high-risk families, the lifetime risk of ovarian cancer may be as high as 28% to 44%, and the risk has been calculated to be as high as 27% for those women with a **BRCA2 mutation** (51,52,58). The risk of breast cancer in women with a **BRCA1 or BRCA2 mutation** may be as high as 56% to 87%.
Hereditary ovarian cancers in general occur in women approximately 10 years younger than those with nonhereditary tumors (51). Because the median age of epithelial ovarian cancer is in the mid- to late 50s, a woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of carrying an affected gene.

Breast and ovarian cancer may exist in a family in which there is a combination of epithelial ovarian and breast cancers, affecting a mixture of first- and second-degree relatives. Women with this syndrome tend to have these tumors at a young age, and the breast cancers may be bilateral. If two first-degree relatives are affected, this pedigree is consistent with an autosomal dominant mode of inheritance (44,50).

**Founder Effect**

There is a higher carrier rate of BRCA1 and BRCA2 mutations in women of Ashkenazi Jewish descent and in Icelandic women (56,57,59). There have been three specific mutations carried by the Ashkenazi population, 185delAG and 5382insC on BRCA1, and 6174delT on BRCA2. The total carrier rate for a patient of Ashkenazi Jewish descent to have at least one of these three mutations is 1 in 40, or 2.5%, and thus there is a substantial risk in this population. The increased risk is a result of the *founder effect*, in which a higher rate of mutations occurs in a defined geographic area.

**Pedigree Analysis**

The risk of carrying a germline mutation that predisposes to ovarian cancer depends on the number of first- and/or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both), and on the number of malignancies that occur at an earlier age. The degree of risk is difficult to determine precisely unless a full pedigree analysis is performed.

1. In families with two first-degree relatives (i.e., mother, sister, or daughter) with documented premenopausal epithelial ovarian cancer, the risk that a female first-degree relative has an affected gene could be as high as 35% to 40% (52).

2. In families with a single first-degree relative and a single second-degree relative (i.e., grandmother, aunt, first cousin, or granddaughter) with epithelial ovarian cancer, the risk that a woman has an affected gene also may be increased. The risk may be two- to 10-fold higher than in those without a familial history of the disease (52).

3. In families with a single postmenopausal first-degree relative with epithelial ovarian carcinoma, a woman may not have an increased risk of having an affected gene because the case is most likely to be sporadic. However, if the ovarian cancer occurs in a premenopausal relative, this could be significant, and a full pedigree analysis should be undertaken.

4. Women with a primary history of breast cancer have twice the expected incidence of subsequent ovarian cancer (51).

**Hereditary Nonpolyposis Colon Cancer, or Lynch II Syndrome**

HNPCC syndrome, which includes multiple adenocarcinomas, involves a combination of familial colon cancer (known as the Lynch I syndrome); a high rate of ovarian, endometrial, and breast cancers; and other malignancies of the gastrointestinal and genitourinary systems (60). The mutations that have been associated with this syndrome
are MSH2, MLH1, PMS1, and PMS2. The risk that a woman who is a member of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least 3 times the relative risk of the general population. A full pedigree analysis of such families should be performed by a geneticist to determine the risk more accurately.

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and depends on her age, her reproductive plans, and the extent of risk. In all of these syndromes, women at risk benefit from a thorough pedigree analysis. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members’ ovarian cancer.

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in BRCA1 or BRCA2 is comparable to that of sporadic tumors (53). Women with breast cancer who carry these mutations, however, are at a greatly increased risk of ovarian cancer as well as a second breast cancer: the lifetime risk of ovarian cancer is 54% for women who have a BRCA1 mutation and 23% for those with a BRCA2 mutation, and for the two groups together, there is an 82% lifetime risk of breast cancer (62).

Although recommended by the National Institutes of Health Consensus Conference on Ovarian Cancer (63), the value of screening with transvaginal ultrasonography, CA125 levels, or other procedures has not been clearly established in women at high risk. Bourne and co-workers (49) have shown that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and thus they recommend screening in high-risk women.

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for development of ovarian cancer in women who have a mutation in either BRCA1 or BRCA2 (64). The risk reduction is significant: in women who have taken oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease.

Prophylactic Oophorectomy in High-risk Women

The value of prophylactic salpingo-oophorectomy in these patients has been documented (65–71). Women at high risk for ovarian cancer who undergo prophylactic oophorectomy have a risk of harboring occult neoplasia: in one series of 98 such operations, 3 (3.1%) patients had a low-stage ovarian malignancy (67). The protection against ovarian cancer is excellent: the performance of a prophylactic salpingo-oophorectomy reduced the risk of BRCA-related gynecologic cancer by 96% (68). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma, a tumor for which women who have mutations in BRCA1 and BRCA2 may have a higher predisposition. In these series, the subsequent development of peritoneal...
carcinoma was 0.8% and 1%, respectively (66,67). In addition, the risk of developing subsequent breast cancer was reduced by 50% to 80%. Women at high risk for ovarian cancer who undergo prophylactic oophorectomy have a risk of harboring occult neoplasia. In one series of 42 such operations, four patients (9.5%) had a malignancy, one of which was noted at surgery and three that were microscopic; all were smaller than 5 mm (66).

The role of hysterectomy is more controversial. Although most studies show no increase in the rate of uterine and cervical tumors, there are some reports of an increase of papillary serous tumors of the endometrium (71). Women on tamoxifen are at higher risk for benign endometrial lesions (e.g., polyps) and endometrial cancer. Therefore, it is reasonable to consider the performance of a prophylactic hysterectomy in conjunction with salpingo-oophorectomy, and this decision should be individualized.

The survival of women who have a BRCA1 or BRCA2 mutation and develop ovarian cancer is longer than that for those who do not have a mutation. In one study, the median survival for mutation carriers was 53.4 months compared with 37.8 months for those with sporadic ovarian cancer from the same institution (72).

**Recommendations**

Current recommendations for management of women at high risk for ovarian cancer are summarized as follows (61,63,70):

1. **Women who appear to be at high risk for ovarian or breast cancer should undergo genetic counseling and, if the risk appears to be substantial, may be offered genetic testing for BRCA1 and BRCA2.**

2. **Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months, although the efficacy of this approach is not clearly established.**

3. **Oral contraceptives should be recommended** to young women before they embark on an attempt to have a family.

4. **Women who do not wish to maintain their fertility or who have completed their families should be recommended to undergo prophylactic bilateral salpingo-oophorectomy.** The risk should be clearly documented, preferably established by BRCA1 and BRCA2 testing, before oophorectomy is performed. These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas occasionally can occur after bilateral oophorectomy (19,22,71).

5. **In women who also have a strong family history of breast or ovarian cancer, annual mammographic screening should be performed beginning at age 30 years.**

6. **Women with a documented HNPCC syndrome should be treated as above, but in addition, they should undergo periodic screening mammography, colonoscopy, and endometrial biopsy (60,68).**

**Symptoms**

The majority of women with epithelial ovarian cancer have vague and nonspecific symptoms (3,73–75). In early-stage disease, the patient may experience irregular menses if she is premenopausal. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation (73–75). Occasionally, she may perceive lower
abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, are unusual.

In advanced-stage disease, patients most often have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may report irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women (72). In one survey of 1,725 with ovarian cancer, 95% recalled symptoms before diagnosis, including 89% with stage I and II disease and 97% with stages III and IV disease (74). Some 70% had abdominal or gastrointestinal symptoms, 58% pain, 34% urinary symptoms, and 26% pelvic discomfort.

**Signs**

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If, in addition, an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually reports abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should have become atrophic and not palpable. It has been proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that has been referred to as the postmenopausal palpable ovary syndrome (76). This concept has been challenged, because subsequent authors have reported that only about 3% of palpable masses measuring <5 cm in postmenopausal women are malignant (49).

**Diagnosis**

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory (e.g., diverticular) disease or neoplastic colonic mass, must be excluded (3). A pelvic kidney can simulate ovarian cancer.

Serum CA125 levels have been shown to be useful in distinguishing malignant from benign pelvic masses (77). For a postmenopausal patient with an adnexal mass and a very high serum CA125 level (>200 U/mL), there is a 96% positive predictive value for malignancy. For premenopausal patients, however, the specificity of the test is low because the CA125 level tends to be elevated in common benign conditions.

For the premenopausal patient, a period of observation is reasonable provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). Generally, an interval of no more than 2 months is allowed, during which hormonal suppression with the oral contraceptive may be used. If the lesion is not neoplastic it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is >8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient has been taking clomiphene citrate or other agents to induce ovulation (31–34). Patients whose lesions are suggestive of malignancy (i.e., predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with adnexal masses.
Ultrasonographic signs of malignancy include an adnexal pelvic mass with areas of complexity, such as irregular borders, multiple echogenic patterns within the mass, and dense multiple irregular septae. Bilateral tumors are more likely to be malignant, although the individual characteristics of the lesions are of greater significance. Transvaginal ultrasonography may have a somewhat better resolution than transabdominal ultrasonography for adnexal neoplasms (78–81). Doppler color flow imaging may enhance the specificity of ultrasonography for demonstrating findings consistent with malignancy (82–84).

In the premenopausal patient, a period of observation is reasonable, provided the adnexal mass is not clinically suspicious (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). Generally, an interval of 2 months is allowed for observation. The size of the lesion is of importance. If a complex cystic mass is more than 8 to 10 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient has been taking clomiphene citrate or other agents to induce ovulation (85–87). If the lesion is not neoplastic, it should remain stable or regress, as measured by pelvic examination and pelvic ultrasonography. If a mass does not regress, or if it increases in size or complexity, it must be presumed to be neoplastic and removed surgically.

In postmenopausal women with unilocular cysts measuring 8 to 10 cm or less and normal serial CA125 levels, expectant management is acceptable, and this approach may decrease the number of surgical interventions (85–87).

Premenopausal patients whose lesions are clinically suspicious (i.e., large, predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with complex adnexal masses of any size.

The diagnosis of an ovarian cancer requires an exploratory laparotomy. The preoperative evaluation of the patient with an adnexal mass is outlined in Figure 14.20 (see Chapter 14).

Before the planned exploration, the patient should undergo routine hematologic and biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest. Abdominal and pelvic computed tomography (CT) or magnetic resonance imaging (MRI) are of limited value for a patient with a definite pelvic mass (88–90). A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy (88). The value of PET scanning is still being evaluated (91,92). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver-spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites.

The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in selected patients with symptoms and signs suspicious for colon cancer. This study should be performed for any patient who has evidence of occult blood in the stool or of intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if there are upper gastrointestinal symptoms such as nausea, vomiting, or hematemesis (3,93). Bilateral mammography is indicated if there is any breast mass, because occasionally breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

A Pap test should be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.
Differential Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries (85–87). A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomata, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory or neoplastic colonic mass, must be excluded (94). A pelvic kidney can simulate ovarian cancer.

Patterns of Spread

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, by lymphatic dissemination, and by hematogenous spread.

Transcoelomic  The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity. The cells tend to follow the circulatory path of the peritoneal fluid. The fluid tends to move with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Therefore, metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule, the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus (3).

Lymphatic  Lymphatic dissemination to the pelvic and para-aortic lymph nodes is common, particularly in advanced-stage disease (95–97). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes (95). Burghardt et al. (97) reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes. In another series (95), the rate of para-aortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV.

Hematogenous  Hematogenous dissemination at the time of diagnosis is uncommon. Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion (3). Systemic metastases are seen more frequently in patients who have survived for some years. Dauplat et al. (98) reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally intraperitoneal.

Prognostic Factors

The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (99).

Pathologic Factors

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (3). Histologic type has not generally been believed to be of prognostic significance, but several papers recently have contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (99,100).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (101–104). However, studies of the reproducibility of grading ovarian cancers
have shown a high degree of intraobserver and interobserver variation (105,106). Because there is significant heterogeneity of tumors and observational bias, the value of histologic grade as an independent prognostic factor has not been clearly established. Baak et al. (107) have presented a standard grading system based on morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to distinguish low-grade or borderline patterns from other tumors.

**Biologic Factors**

Several biologic factors have been correlated with prognosis in epithelial ovarian cancer. Using flow cytometry, Friedlander et al. (108) showed that ovarian cancers were commonly aneuploid. Furthermore, they and others showed that there was a high correlation between FIGO stage and ploidy; low-stage cancers tend to be diploid and high-stage tumors tend to be aneuploid (108–112). **Patients with diploid tumors have a significantly longer median survival than those with aneuploid tumors**: 5 years versus 1 year, respectively (108). Multivariate analyses have demonstrated that **ploidy is an independent prognostic variable** and one of the most significant predictors of survival (108). Flow cytometric analysis also provides data on the cell cycle, and the proliferation fraction (S phase) determined by this technique has correlated with prognosis in some studies (108–112).

More than 100 proto-oncogenes have been identified, and studies have focused on the amplification or expression of these genetic loci and their relationship to the development and progression of ovarian cancer (113,114). For example, Slamon et al. (115) reported that 30% of epithelial ovarian tumors expressed HER-2/neu oncogene and that this group had a poorer prognosis, especially patients with more than five copies of the gene. Berchuck et al. (116) reported a similar incidence (32%) of HER-2/neu expression. In their series, patients whose tumors expressed the gene had a poorer median survival (15.7 months versus 32.8 months). Others have not substantiated this finding (117–122), and a review of the literature by Leary et al. (118) revealed an overall incidence of HER-2/neu expression of only 11%. Thus, the **prognostic value of HER-2/neu expression in ovarian cancer is unclear, and further study is required.**

The most commonly expressed tumor suppressor gene in ovarian cancer is **p53** (123–125). Indeed, as many as one half of all epithelial ovarian cancers have evidence of mutated **p53** in the tumor. Other tumor suppressor genes that are being evaluated are **ras** and **PTEN** (126–128).

The **in vitro** clonogenic assay has been studied in relation to ovarian cancer. A significant inverse correlation has been reported between clonogenic growth **in vitro** and survival (129–131). Multivariate analysis has found that clonogenic growth in a semisolid culture medium is a significant independent prognostic variable (131). The use of an “**extreme drug resistance assay**” has been suggested as a possible means of directing therapy by defining platinum-sensitive and resistant tumors **in vitro** (132). **Further study will be needed to evaluate the clinical usefulness of these assays.**

**Clinical Factors**

In addition to stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (133–141). Among patients with stage I disease, Dembo et al. (138) showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not. Sjövall et al. (139) confirmed that **ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis, whereas tumors found to have already ruptured preoperatively do have a poorer prognosis.** A multivariate analysis of these and several other studies was performed by Vergote et al. (141), who found that for early-stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture.
Initial Surgery for Ovarian Cancer

Staging

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 35.2 (24). The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. For patients in whom exploratory laparotomy does not reveal any macroscopic evidence of disease on inspection and palpation of the entire intra-abdominal space, a careful search for microscopic spread must be undertaken. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (142). Since then, survival rates of 90% to 100% have been reported for patients who were properly staged and were found to have stage Ia or Ib disease (143–144).

Table 35.2 FIGO Staging for Primary Carcinoma of the Ovary

<table>
<thead>
<tr>
<th>Stage</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>Growth limited to the ovaries.</td>

<tr>
<td>IIIa</td>
<td>Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces.</td>
</tr>
<tr>
<td>IIIb</td>
<td>Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Nodes negative.</td>
</tr>
<tr>
<td>IIIc</td>
<td>Abdominal implants &gt;2 cm in diameter or positive retroperitoneal or inguinal nodes or both.</td>
</tr>
<tr>
<td>IV</td>
<td>Growth involving one or both ovaries with distant metastasis. If pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV. Parenchymal liver metastasis equals stage IV.</td>
</tr>
</tbody>
</table>

These categories are based on findings at clinical examination or surgical exploration or both. The histologic characteristics are to be considered in the staging, as are results of cytologic testing as far as effusions are concerned. It is desirable that a biopsy be performed on suspicious areas outside the pelvis.

FIGO, International Federation of Obstetrics and Gynecology.

*To evaluate the impact on prognosis of the different criteria for allotting cases to stage Ic or IIc, it would be of value to know if rupture of the capsule was (i) spontaneous or (ii) caused by the surgeon and if the source of malignant cells detected was (i) peritoneal washings or (ii) ascites.
Technique for Surgical Staging

In patients whose preoperative evaluation suggests a probable malignancy, a midline or paramedian abdominal incision is recommended to allow adequate access to the upper abdomen (3,142). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a “J” incision (3).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. If ovarian malignancy is present and the tumor is apparently confined to the ovaries or the pelvis, thorough surgical staging should be performed. Staging involves the following steps (3,142):

1. Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.

2. If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 mL of saline from the pelvic cul-de-sac, each paracolic gutter, and beneath each hemidiaphragm. Obtaining the specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.

3. A systematic exploration of all the intra-abdominal surfaces and viscera is performed, proceeding in a clockwise fashion from the cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the para-aortic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.

4. Any suspicious areas or adhesions on the peritoneal surfaces should be biopsied. If there is no evidence of disease, multiple intraperitoneal biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.

5. The diaphragm should be sampled either by biopsy or by scraping with a tongue depressor and obtaining a sample for cytologic assessment. Biopsies of any irregularities on the surface of the diaphragm can be facilitated by use of the laparoscope and the associated biopsy instrument.

6. The omentum should be resected from the transverse colon, a procedure called an infracolic omentectomy. The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised just a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum. If the gastrocolic ligament is palpably normal, it does not need to be resected.

7. The retroperitoneal spaces should be explored to evaluate the pelvic and para-aortic lymph nodes. The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. This may be performed on the ipsilateral side only for unilateral tumors. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed. The para-aortic area should be explored.
Results

Metastases in apparent stage I and II epithelial ovarian cancer occur in as many as 3 in 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (96,143–152). In a review of the literature (142), occult metastases were found in biopsies of the diaphragm in 7.3% of such patients, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings.

The importance of careful initial surgical staging is emphasized by the findings of a cooperative national study (143) in which 100 patients with apparent stage I and II disease who were referred for subsequent therapy underwent additional surgical staging. In this series, 28% of the patients initially believed to have stage I disease were “upstaged” and 43% of those believed to have stage II disease had more advanced lesions. A total of 31% of the patients were upstaged as a result of additional surgery, and 77% were reclassified as having stage III disease. Histologic grade was a significant predictor of occult metastasis. Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Borderline Tumors

The principal treatment of borderline (low malignant potential) ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. After a frozen section has determined that the histology is borderline, premenopausal patients who desire preservation of ovarian function may undergo a conservative operation, a unilateral oophorectomy (3,153,154). In a study of patients who underwent unilateral ovarian cystectomy only for apparent stage I borderline serous tumors, Lim-Tan et al. (154) found that this conservative operation was also safe; only 8% of the patients had recurrences 2 to 18 years later, all with curable disease confined to the ovaries. Recurrence was associated with positive margins of the removed ovarian cyst (154). Thus, hormonal function and fertility can be maintained (3,153,154). For patients in whom an oophorectomy or cystectomy has been performed and a borderline tumor is later documented in the permanent pathology, no additional immediate surgery is necessary.

Stage I

After a comprehensive staging laparotomy, only a minority of women will have local disease (FIGO stage I). There are over 20,000 women diagnosed yearly with epithelial ovarian cancer in the United States, and nearly 4,000 of these have disease confined to the ovaries (1,155). The prognosis for these patients depends on the clinical–pathologic features, as outlined below. Because of this emphasis on the importance of surgical staging, the rate of lymph node sampling has increased in the United States, with a study showing that for women with stage I and II disease, the percentage having lymph nodes sampled increased from 38% to 59% from 1991 to 1996 (156).

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging (142,143). In certain circumstances, a unilateral salpingo-oophorectomy may be performed. Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 35.3).

Stage I Low-risk

Fertility Preservation in Early-stage Ovarian Cancer For patients who have undergone a thorough staging laparotomy and for whom there is no evidence of spread.
beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage Ia, grade 1 to 2 disease who desire to preserve fertility. The conditions of the women should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA125 levels. Generally, the other ovary and the uterus are removed at the completion of childbearing.

Guthrie et al. (152) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No untreated patients who had stage Ia, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. Furthermore, the Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus melphalan for patients with stage Ia and Ib, grade 1–2 disease (100). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

Stage I High-risk

For patients whose disease is more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings, complete surgical staging must be performed (3). The surgery should include the performance of a hysterectomy and bilateral salpingo-oophorectomy in addition to the staging laparotomy. Additional therapy is indicated, and although the optimal therapy for these patients is not known, most patients are treated with chemotherapy, as outlined below.

### Advanced-Stage Ovarian Cancer

The surgical management of all patients with advanced-stage disease is approached in a similar manner, with modifications made for the overall status and general health of the patient, as well as the extent of residual disease present at the time treatment is initiated. A treatment scheme is outlined in Figure 35.7. Most patients subsequently receive combination chemotherapy for an empiric number of cycles.

### Cytoreductive Surgery for Advanced-stage Disease

If the patient is medically stable, she should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible (157–184) (see Fig 35.7). The operation to remove the primary tumor as well as the associated metastatic disease is...
referred to as “debulking” or cytoreductive surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum (Fig. 35.8). In a minority of
patients, most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged progression-free survival.

The removal of bulky tumor masses may reduce the volume of ascites present. Often, ascites will completely disappear after removal of the primary tumor and a large omental “cake.” Also, removal of the omental cake often alleviates the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and lead to an improvement in the overall nutritional status of the patient, thereby facilitating the patient’s ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and such areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Thus, surgical removal of these bulky tumors may eliminate areas that are most likely to be relatively resistant to treatment.

In addition, larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the “resting” phase (i.e., G0 cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

Figure 35.8 Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area. (From Heintz APM, Berek JS. Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian malignancies. Edinburgh, UK: Churchill Livingstone, 1987:134, with permission.)
Goals of Cytoreductive Surgery  The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. Griffiths (157) initially proposed that all metastatic nodules should be reduced to $<1.5$ cm in maximal diameter and showed that survival was significantly longer in patients for whom this was achieved.

Subsequently, Hacker and Berek (158–160) showed that patients whose largest residual lesions were $<5$ mm had a superior survival rate, which was substantiated by Van Lindert et al. (161). The median survival of patients in this category was 40 months, compared with 18 months for patients whose lesions were $<1.5$ cm and 6 months for patients with nodules $>1.5$ cm. Patients whose disease has been completely resected to no macroscopic (microscopic only) residual disease have the best overall survival (162) (Fig. 35.9). Approximately 60% of patients in this category will be free of disease at 5 years.

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small-bowel mesentery, in the lesser omentum, or in the porta hepatis.

The ability of cytoreductive surgery to influence survival is limited by the extent of metastases before cytoreduction, presumably because of the presence of phenotypically resistant clones of cells in large metastatic masses. A patient whose metastatic tumor is very large (i.e., $>10$ cm before cytoreductive surgery) has a shorter survival than those with smaller areas of disease (160,162). Extensive carcinomatosis, the presence of ascites, and poor tumor grade, even with lesions that measure $<5$ mm, may also shorten the survival (163–166).

![Figure 35.9](image-url) Survival of patients with stage IIIc epithelial ovarian cancer based on the maximal size of residual tumor after exploratory laparotomy and tumor resection. (From Pecorelli S, Odicino F, Maisonneuve P, et al. Carcinoma of the ovary. Annual Report of the Results of Treatment of Gynaecological Cancer. J Epidemiol Biostat 1998;3:75–102, with permission.)
Exploration  The supine position on the operating table may be sufficient for surgical exploration of most patients. However, for those with extensive pelvic disease for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen as well as to the pelvis.

After the peritoneal cavity is opened, ascitic fluid, if present, should be evacuated. In some centers, fluid is submitted for in vitro research studies, such as molecular analyses. In cases of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is metastatic, particularly from the stomach, colon, or pancreas. If optimal status is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. However, removal of the primary tumor and omental cake is usually both feasible and desirable.

Pelvic Tumor Resection  The essential principle of removal of the pelvic tumor is to use the retroperitoneal approach. To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. The procedure is initiated by division of the round ligaments bilaterally if the uterus is present. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesicular spaces are identified and developed as described in Chapter 34.

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

Hysterectomy, which is often not a simple operation, is then performed. The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. The hysterectomy and resection of the contiguous tumor are completed by ligation of the uterine vessels and the remainder of the tissues within the cardinal ligaments.

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract (167,168). Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease (168).

Intestinal Resection  The disease may involve focal areas of the small or large intestine, and resection should be performed if it would permit the removal of all or most of the abdominal metastases and the patient will be left with optimal disease at the end of the cytoreduction. Apart from the rectosigmoid colon, the most frequent sites of intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection of one or more of these segments of bowel may be necessary (167, 169).

If the disease surrounds the rectosigmoid colon and its mesentery, it may be necessary to remove that portion of the colon to clear the pelvic disease (Fig. 35.10) (167). After the pararectal space is identified in such patients, the proximal site of colonic involvement is
identified, the colon and its mesentery are divided, and the rectosigmoid is removed along with the uterus en bloc. A reanastomosis of the colon is performed.

**Omentectomy** Advanced epithelial ovarian cancer often completely replaces the omentum, forming an “omental cake.” This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is then lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the transverse colon. The peritoneum is incised to open the appropriate plane, which is developed by sharp dissection along the serosa of the transverse colon. Small vessels are ligated with hemoclips. The omentum is then separated from the greater curvature of the stomach by ligation of the right and left gastroepiploic arteries and ligation of the short gastric arteries (Fig. 35.11).

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the left and to the capsule of the liver and the hepatic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. However, it will occasionally be necessary to perform splenectomy to remove all the omental disease (170).
Resection of Other Metastases

Other large masses of tumor that are located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction. Resection of extensive disease from the surfaces of the diaphragm is generally neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days (170,171). The use of the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may help facilitate resection of small tumor nodules, especially those on flat surfaces (172,173).

Feasibility and Outcome

Although no randomized prospective study has ever been performed to define the value of primary cytoreductive surgery, all retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to progression-free survival in patients with advanced ovarian cancer (176). In addition, quality of life is likely to be significantly enhanced by removal of bulky tumor masses from the pelvis and upper abdomen (179).

An analysis of the retrospective data available suggests that these operations are feasible for 70% to 90% of patients when performed by gynecologic oncologists (165,166). Major morbidity is in the range of 5% and operative mortality is in the range of 1% (169, 174, 175). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation (169).

In a meta-analysis of 81 studies of women who underwent cytoreductive surgery for advanced ovarian cancer, Bristow et al. documented that the extent of debulking correlated with incremental benefits in survival, i.e., the greater the percentage of
tumor reduction, the longer the survival: Each 10% increase in cytoreduction equaled a 5.5% increase in median survival (176). Women whose cytoreduction was greater than 75% of their tumor burden had a median survival of 33.9 months compared with 22.7 months for women whose tumors were cytoreduced to less than 75% (p < 0.001). The performance of a pelvic and para-aortic lymphadenectomy in patients with stage III disease does not prolong survival based on the results of a large prospective, randomized trial (177).

A prospective randomized study of “interval” cytoreductive surgery was carried out by the European Organization for the Research and Treatment of Cancer (EORTC). Interval surgery was performed after three cycles of platinum-combination chemotherapy in patients whose primary attempt at cytoreduction was suboptimal. Patients in the surgical arm of the study demonstrated a survival benefit when compared with those who did not undergo interval debulking (178). Most of these patients had not had an aggressive attempt to debulk their tumor at their initial surgery. The risk of mortality was reduced by more than 40% in the group that was randomized to the debulking arm of the study. Based on these data, the performance of a debulking operation as early as possible in the course of the patient’s treatment should be considered the standard of care (179).

A prospective phase III study of interval cytoreductive surgery was conducted by the GOG (180), but the study design was different because the patients entered on the trial had already undergone a maximal attempt at tumor resection at their initial surgery. The randomized findings showed no difference between the group who had an additional attempt at debulking after three cycles of chemotherapy compared with those who did not. The median survival of the 216 women who underwent interval cytoreduction was 32 months compared with 33 months for the 209 women who did not undergo surgical cytoreduction.

There is evidence that the survival of women with advanced ovarian cancer is improved when the surgeon is specifically trained to perform cytoreductive surgery (181–184) and when there is centralization of care (182). Therefore, whenever feasible, patients with advanced ovarian malignancy should be referred to a subspecialty unit for primary surgery, and every effort should be made to attain as complete a cytoreduction as possible.

Chemotherapy

Stage I Epithelial Ovarian Cancer

Early-stage, Low-risk

Guthrie et al. (152) studied the outcome of 656 patients with early-stage epithelial ovarian cancer. No patients who had stage Ia, grade 1 cancer who did not receive radiation or chemotherapy died of their disease; thus, adjuvant therapy is unnecessary. Furthermore, the GOG carried out a prospective, randomized trial of observation versus melphalan for patients with stage Ia and Ib, grades 1 and 2 disease (100). Five-year survival for each group was 94% and 96%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.

Early-stage, High-risk

In patients whose disease is high-risk, e.g., more poorly differentiated or in whom there are malignant cells either in ascitic fluid or in peritoneal washings, additional therapy is indicated. Most investigators recommend chemotherapy for these patients.
Chemotherapy for patients with early-stage high-risk epithelial ovarian cancer can be either single agent or multiagent. Some researchers have questioned the wisdom of overly aggressive chemotherapy in women with early-stage disease, suggesting that the evidence for a durable impact on survival is marginal (187,188,194). Furthermore, the risk of leukemia with alkylating agents and platinum make the administration of adjuvant therapy risky unless there is a significant benefit (199,200).

Because cisplatin, carboplatin, cyclophosphamide, and paclitaxel (Taxol) are active single agents against epithelial ovarian cancer, these drugs have been administered in various combinations. There are some series in which cisplatin or cyclophosphamide (PC) or both have been used to treat patients with stage I disease (189–191). In a GOG trial of three cycles of cisplatin and cyclophosphamide versus intraperitoneal chromic phosphate ($^{32}$P) in patients with stage Ib and Ic disease, the progression-free survival of women receiving the platinum-based chemotherapy was 31% higher than those receiving the radiocolloid (191). Similar results were also reported by a multicenter trial performed in Italy by the Gruppo Italiano Collaborativo Oncologica Ginecologica (GICOG) for progression-free survival, although there was no overall survival advantage. Carboplatin can be substituted for cisplatin in the therapy of these patients (197), although it is unclear if there is a survival benefit.

Two large parallel randomized phase III clinical trials were conducted on women with early-stage disease: the International Collaborative Ovarian Neoplasm Trial 1 (ICON1) and the Adjuvant Chemotherapy Trial in Ovarian Neoplasia (ACTION) (201,202).

In the ICON1 trial, 477 patients from 84 centers in Europe were entered. Patients of all stages were eligible for the trial if, in the opinion of the investigator, it was unclear whether adjuvant therapy would be of benefit. Most patients were said to have stages I and IIa disease but optimal surgical staging was not required, so it is likely an unquantified number of these women had stage III disease. Adjuvant platinum-based chemotherapy was given to 241 patients, and no adjuvant chemotherapy was given to 236 patients. The 5-year survival was 73% in the group who received adjuvant chemotherapy compared with 62% in the control group (HR = 0.65, $p = 0.01$) (202).

In the ACTION trial, 440 patients from 40 European centers were randomized; 224 patients received adjuvant platinum-based chemotherapy, and 224 patients did not (201). Patients with stages I and IIa, grades 2 and 3 were eligible. Only about one third of the total group was optimally staged (151 patients). In the observation arm, optimal staging was associated with a better survival [hazard ratio (HR) = 2.31, $p = 0.03$], and in the nonoptimally staged patients, adjuvant chemotherapy was associated with an improvement in survival (HR = 1.78, $p = 0.009$). In optimally staged patients, no benefit of adjuvant chemotherapy was seen. Therefore, in the ACTION trial, the benefit from adjuvant chemotherapy was limited to the patients with nonoptimal staging, suggesting that patients might only benefit if they had a higher likelihood of occult microscopic dissemination.

When the data from the two trials were combined and analyzed (203), a total of 465 patients were randomized to receive platinum-based adjuvant chemotherapy and 460 to observation until disease progression. After a median follow-up of more than 4 years, the overall survival was 82% in the chemotherapy arm and 74% in the observation arm (HR = 0.67, $p = 0.001$). Recurrence-free survival was also better in the chemotherapy arm: 76% versus 65% (HR = 0.64, $p = 0.001$). The results of this analysis must be interpreted with caution, because most of the patients did not undergo thorough surgical staging, but the findings suggest that platinum-based chemotherapy should be given to patients who have not been optimally staged.

The current GOG trial includes patients with high-risk stage I and stage II disease, and consists of three cycles of carboplatin and paclitaxel followed by a randomization to either
observation versus 26 weeks of weekly low-dose (40 mg/m²) paclitaxel. High-risk stage I is defined as stages Ia or Ib, grade 3, stage Ic, or clear cell carcinomas.

The recommendations for therapy follow:

- Patients with high-grade, high-risk stage I epithelial ovarian cancer should be given adjuvant chemotherapy. The type depends on the patient's overall health and status.
- Treatment with carboplatin and paclitaxel chemotherapy for three to six cycles seems desirable in these patients, whereas a short course of a single agent, either carboplatin or paclitaxel, may be preferable for older women.

## Advanced-stage Epithelial Ovarian Cancer

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer (204–222). After the introduction of cisplatin in the latter half of the 1970s, platinum-based combination chemotherapy became the most frequently used treatment regimen in the United States. Paclitaxel became available in the 1980s, and this drug was incorporated into the combination chemotherapy in the 1990s (204–209). Comparative trials of paclitaxel, cisplatin, and carboplatin are summarized below.

In a meta-analysis performed on studies of patients with advanced-stage disease, those patients given cisplatin-containing combination chemotherapy were compared with those treated with regimens that did not include cisplatin (213). Survival differences between the groups were seen from 2 to 5 years, with the cisplatin group having a slight survival advantage, but this difference disappeared by 8 years.

The major advance in the treatment of advanced-stage disease was the incorporation of paclitaxel into the chemotherapeutic regimens. A series of randomized, prospective clinical trials with paclitaxel-containing arms have defined the current recommended treatment protocol in advanced epithelial ovarian cancer (207,208,217,218).

Reporting the GOG data (Protocol 111), McGuire et al. showed that the combination of cisplatin (75 mg/m²) and paclitaxel (135 mg/m²) was superior to cisplatin (75 mg/m²) and cyclophosphamide (600 mg/m²), each given for six cycles (207). In suboptimally resected patients, the paclitaxel-containing arm produced a 36% reduction in mortality. These data were verified in a trial conducted jointly by the European Organization for the Research and Treatment of Cancer (EORTC), the Nordic Ovarian Cancer Study Group (NOCOVA), and the National Cancer Institute of Canada (NCIC), in which patients with both optimal and suboptimal disease were treated (208). In this study, the paclitaxel-containing arm produced a significant improvement in both progression-free interval and overall survival in both optimal and suboptimal groups. Based on these two studies, paclitaxel should be included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless precluded by toxicity.

A three-arm comparison of paclitaxel (T) versus cisplatin (P) versus PT in suboptimal stage III and IV patients (Protocol 132) showed equivalency in the three groups, but crossover from one drug to the other was permitted (209). The study essentially showed that the combination regimen was better tolerated than the sequential administration of the agents in suboptimally resected patients.

There is no evidence that increasing the dose of cisplatin >50 mg/m² improves survival (221–223).

The second-generation platinum analogue, carboplatin, was introduced and developed to have less toxicity than its parent compound, cisplatin. In early trials, carboplatin was shown to have lower overall toxicity (211). Fewer gastrointestinal side effects, especially
nausea and vomiting, were observed than with cisplatin, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. Carboplatin is, however, associated with a higher degree of myelosuppression.

The initial studies showed that carboplatin and cisplatin had approximately a 4:1 equivalency ratio. Thus, a standard single-agent dose of about 400 mg/m² has been used in most phase II trials (217–219). The dose is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the Calvert formula (223). The target AUC is 5 to 6 for untreated patients with ovarian cancer. Alternatively, a dose of approximately 350 to 450 mg/m² carboplatin can be used initially in patients with a normal serum creatinine and adjusted to toxicity. A platelet nadir of approximately 50,000/mL is a suitable target (211).

**Carboplatin and Paclitaxel**

Two randomized, prospective clinical studies have compared the combination of paclitaxel and carboplatin to paclitaxel and cisplatin (217,218). In both studies, the efficacy and survival rates were similar, but the toxicity was more acceptable with the carboplatin-containing regimen. In the first trial, GOG Protocol 158, the randomization was carboplatin AUC = 7.5 and paclitaxel 175 mg/m² over 3 hours versus cisplatin 75 mg/m² and paclitaxel 135 mg/m² over 24 hours (Fig. 35.12). The disease progression–free survival of the carboplatin-containing arm was 22 months versus 21.7 months for the control arm (217). The gastrointestinal and neurotoxicity of the carboplatin arm were appreciably lower than that of the cisplatin arm. A similar result was obtained in a large randomized trial in Germany (218), in which the dose of carboplatin was AUC = 6 and paclitaxel was 185 mg/m² over 3 hours compared with the same dose of paclitaxel and cisplatin 75 mg/m². Based on these data, the preferred regimen in patients with advanced-stage disease has been the paclitaxel plus carboplatin combination (219).

The International Collaborative Ovarian Neoplasm (ICON) 3 trial was a study of 2,074 women with all stages of ovarian cancer, including 20% who had stage I or II disease (224). Carboplatin plus paclitaxel was compared with two non-paclitaxel regimens, carboplatin (70%), or CAP (30%). The regimens were chosen before randomization and based on the clinical preference of the treating physician. One third of patients who received carboplatin or CAP subsequently received second-line paclitaxel, and this additional chemotherapy was often given before clinical progression. With a median follow-up of 51 months, the carboplatin plus paclitaxel and the control groups had a similar progression-free survival (0.93) and overall survival (0.98). The median survival for the paclitaxel plus carboplatin and control groups was 36.1 and 35.4 months, respectively. The median duration of progression-free survival was 17.3 and 16.1 months, respectively. The researchers concluded that single agent carboplatin and CAP were as effective as paclitaxel and carboplatin for first-line chemotherapy. Because carboplatin as a single agent had a lower toxicity than the other regimens and the median survival (33 months) was similar in the prior trial (ICON 2) that had compared carboplatin and CAP as first-line treatment (225), the researchers suggested that carboplatin alone was the preferred therapy. However, the design of the study limits the validity of the results, because patients with FIGO stage I to IV disease were included, the extent of primary surgery was variable, and the study was not audited by an independent data monitoring committee. Also, the majority (85%) of patients who relapsed after single-agent carboplatin or paclitaxel subsequently received the other drug. Therefore, the study is not conclusive.

**Carboplatin and Docetaxel**

Docetaxel has a different toxicity profile from paclitaxel. The SCOT-ROC (Scottish Gyneacological Cancer Trials Group) study randomly assigned 1,077 women with stage Ic
to IV epithelial ovarian cancer to carboplatin with either paclitaxel or docetaxel (226). The efficacy of docetaxel appeared to be similar to paclitaxel: The median progression-free survival was 15.1 months versus 15.4 months, and the docetaxel group had fewer neurologic effects, arthralgias, myalgias, and extremity weakness than the paclitaxel group. However, the docetaxel plus carboplatin regimen was associated with significantly more myelosuppression and its consequences, i.e., serious infections and prolonged grade 3 to 4 neutropenia. Therefore, additional study will be necessary to determine whether docetaxel should supplant paclitaxel in the primary treatment of epithelial ovarian cancer.

**Five-Arm Trial**

An intergroup, international trial (GOG 182/SWOG 182/ICON 5) compared the standard combination of carboplatin and paclitaxel with these drugs in combination with gemcitabine, topotecan, or liposomal doxorubicin in sequential doublets or triplets (227,228). The study shows that the addition of any three drugs to the standard chemotherapy does not enhance outcome or survival (228).

**Intraperitoneal Chemotherapy**

A randomized, prospective GOG study (Protocol 104) of intraperitoneal cisplatin versus intravenous cisplatin (100 mg/m²), each given with 750 mg/m² cyclophosphamide, has been performed jointly by the Southwest Oncology Group (SWOG) and the GOG in patients with minimal residual disease (229). The intraperitoneal cisplatin arm had a somewhat longer overall median survival than the intravenous arm, 49 versus 41 months ($p = 0.03$). In the patients with minimal residual disease (<0.5 cm maximal residual), however, there was no difference between the two treatments, 51 versus 46 months ($p = 0.08$).

In a follow-up GOG study (Protocol 114), the dose-intense arm was initiated by giving a moderately high dose of carboplatin (dose AUC = 9) for two induction cycles, followed by intraperitoneal cisplatin 100 mg/m² and intravenous paclitaxel 135 mg/m² over 24 hours, versus intravenous cisplatin 75 mg/m² and intravenous paclitaxel 135 mg/m² (230). The dose-intense arm results were slightly better—the disease progression–free median survival was 27.6 months compared with 22.5 months for the control arm ($p = 0.02$). However, there was no difference in overall survival (52.9 months versus 47.6 months, $p = 0.056$). Thus, based on this study, it was unclear if dose intensification with intraperitoneal cisplatin would have a sustained long-term impact on the survival of these patients.

A third randomized prospective GOG study (Protocol 172) compared intraperitoneal cisplatin and paclitaxel versus intravenous cisplatin and paclitaxel (231). The combination of cisplatin 75 mg/m² and paclitaxel 135 mg/m² given intravenously every 3 weeks was compared with paclitaxel 135 mg/m² intravenous day 1, followed by cisplatin 100 mg/m² intraperitoneal day 2, and paclitaxel 60 mg/m² intraperitoneal day 8 every 3 weeks, each given for 6 cycles. While 83% of the patients randomized to intravenous chemotherapy completed all 6 cycles of therapy, only 42% of those treated with intraperitoneal chemotherapy completed the 6 cycles, principally because of catheter-related complications. For patients in either group who could not complete the therapy because of cisplatin-related toxicity, the chemotherapy was switched to intravenous carboplatin. Comparing the intravenous and intraperitoneal arms, the median duration of progression-free survival was 18.3 and 23.8 months, respectively ($p = 0.05$). The median duration of overall survival in the intravenous-therapy and intraperitoneal-therapy groups was 49.7 and 65.6 months, respectively ($p = 0.03$) (231). Quality of life was significantly worse in the intraperitoneal-therapy group before cycle 4 and 3-6 weeks after treatment but not one year after treatment. A summary of the intraperitoneal catheter related issues in this trial has been presented (232).

Based on these randomized trials, the intraperitoneal route of administration for cisplatin and paclitaxel chemotherapy in the primary treatment of optimally resected
Stage III ovarian cancer is an acceptable therapeutic alternative to intravenous chemotherapy with carboplatin and paclitaxel (233). However, thus far there has been no randomized direct comparison of this intraperitoneal regimen to intravenous carboplatin and paclitaxel or to intrapertitoneal carboplatin and paclitaxel. Intraperitoneal therapy can be used in patients with optimally resected tumors who have a good performance status and are in overall good health. Because intraperitoneal chemotherapy is more cumbersome and has a higher morbidity than intravenous therapy, the use of this technique of drug delivery should be individualized after thorough discussion with the patient.

**Neoadjuvant Chemotherapy**

Some authors have suggested that, for patients with suboptimal stage III and stage IV disease, chemotherapy may be given in lieu of debulking surgery. A series performed by Schwartz et al. (234) suggested that the survival of these patients treated with neoadjuvant or cytoreductive chemotherapy was comparable to those patients historically treated in the same institution with debulking surgery followed by conventional chemotherapy. As other authors have shown a benefit to debulking patients before chemotherapy (235,236), the issue would need to be resolved by a prospective clinical trial. However, two or three cycles of chemotherapy before cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may dry up the effusions, improve the patient’s performance status, and decrease postoperative morbidity, particularly chest morbidity.

**Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer**

For the treatment of advanced-stage epithelial ovarian cancer, the following is recommended (Table 35.4):

- Combination chemotherapy with intraperitoneal cisplatin and paclitaxel or intravenous carboplatin and paclitaxel are the treatments of choice for patients with advanced disease. The advantages and disadvantages of the intraperitoneal versus intravenous routes of administration of these drugs should be discussed with the patient.

- The recommended doses and schedule for intraperitoneal chemotherapy are paclitaxel 135 mg/m² intravenous on day 1, followed by cisplatin 50-100 mg/m² intraperitoneal on day 2, followed by paclitaxel 60 mg/m² intraperitoneal on day 8, every 3 weeks for 6 cycles, as tolerated.

- The recommended doses and schedule for intravenous chemotherapy are: carboplatin (starting dose AUC = 5–6), and paclitaxel (175 mg/m²), every 3 weeks for 6-8 cycles.

- In patients who cannot tolerate combination chemotherapy, single-agent, intravenously administered carboplatin (AUC = 5–6) or paclitaxel 175 mg/m² can be given.

- In patients who have a hypersensitivity to paclitaxel or carboplatin, either desensitization can be performed, or an alternative active drug can be substituted (e.g., docetaxel, liposomal doxorubicin, topotecan, etoposide). Etoposide can be given orally.

The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of the patient, as well as the extent of residual disease present at the time treatment is initiated.
Immunotherapy

There is currently a great deal of interest in the use of immunotherapies in ovarian cancer. Cytokines have been used extensively in second-line therapy, and the activity of interferon-α, interferon-γ, and interleukin-2 has been demonstrated, as discussed below (3). In a recent trial of interferon-γ plus cisplatin combination chemotherapy versus chemotherapy alone, patients who received the interferon had a longer disease progression–free survival (237). A randomized, multicenter trial of first-line carboplatin and paclitaxel with or without interferon-γ has been conducted, and there is no survival advantage in the patients who received interferon-γ.

Hormonal Therapy

There is no evidence that hormonal therapy alone is appropriate primary therapy for advanced ovarian cancer. The use of progestational agents in the treatment of recurrent well-differentiated endometrioid carcinomas is supported by the current data. In one study, 30 evaluable patients with recurrent epithelial cancers were treated; 17 (57%) had an objective response, and three (10%) of these patients achieved a complete response (238). All responding patients had well-differentiated, estrogen receptor–positive tumors. A trial of tamoxifen in combination with multiagent chemotherapy is being conducted.

**Drugs that can be substituted for paclitaxel if hypersensitivity to that drug occurs; the number of treatments administered as tolerated.
Consolidation and Maintenance of Complete Clinical Response to First-line Chemotherapy

Because as many as 80% of women with advanced-stage disease who completely respond to their first-line chemotherapy will ultimately relapse, several trials have been conducted that administer a drug to these patients immediately following their primary treatment in an effort to decrease the relapse rate.

**Paclitaxel** In a study conducted by the GOG and SWOG, 277 women with advanced ovarian cancer who had a complete clinical remission to first-line chemotherapy were randomized to receive 3 or 12 cycles of additional single-agent paclitaxel (175 or 135 mg/m² every 28 days) (239). Patients were excluded if they had developed grade 2 or 3 neurotoxicity during their initial chemotherapy. Because of cumulative toxicity, the mean number of actual cycles of paclitaxel received by the group assigned to receive 12 cycles was 9. The treatment-related grade 2 to 3 neuropathy was more common with longer treatment, 24% versus 14% of patients, respectively. The study was closed after a median follow-up of only 8.5 months, and an interim analysis showed a significant 7-month prolongation in median progression-free survival (28 versus 21 months) with 9 versus 3 months of consolidation paclitaxel. However, there was no difference in median overall survival. The rate of disease progression increased significantly after maintenance therapy was discontinued, which suggested that long-term survival would not be likely to be improved. Furthermore, it is unlikely that a survival benefit will be seen with longer follow-up, because patients assigned to three cycles were given the option of receiving an additional nine courses of paclitaxel after the study was discontinued (240). Another placebo-controlled, randomized trial using two formulations of paclitaxel is being conducted by the GOG.

**Topotecan** Four additional treatment courses of topotecan were administered to patients following six cycles of carboplatin and paclitaxel in two randomized trials, one conducted in Italy (241) and the other in Germany (242). In the larger trial conducted in Germany, 1,059 evaluable patients were randomly assigned to six cycles of paclitaxel (175 mg/m² over 3 hours) and carboplatin (AUC 5) with (537 patients) or without (522 patients) four additional cycles of topotecan (1.25 mg/m² IV days 1 to 5 every 3 weeks) (242). In the Italian trial, 273 women were randomly assigned to receive four additional cycles (137 patients) of topotecan at a dose of 1 mg/m² on days 1 to 5 every 3 weeks or no further chemotherapy (136 patients) (241). Preliminary reports suggest no significant differences in either progression-free or overall survival in patients who received four to six cycles of consolidation topotecan.

**Cisplatin** In a randomized clinical trial of intraperitoneal cisplatin for consolidation versus observation, there was no difference in survival between the treatment arms (243).

**Immunotherapy** Trials of monoclonal antibodies directed toward ovarian cancer–associated antigens are being conducted. Monoclonal antibodies (MonAb) directed toward CA125 (OvaRex) (244) and toward the HMFG (human milk fat globulin) (245) tumor–associated antigens have been conducted. In a randomized, placebo-controlled trial of intravenous OvaRex (ant-CA125 MonAb) as consolidation/maintenance, Berek et al. reported that a subset of patients with optimal ovarian cancer who had achieved a prompt clinical remission after three cycles of chemotherapy (as indicated by a rapid decline in CA125) had a longer time to disease relapse (24 months) compared with those who received placebo (10.8 months) \((p = 0.06)\) (244). A randomized trial of an intraperitoneally administered yttrium-labeled antimucin (HMFG) MonAb versus placebo was not associated with an improved overall survival after a negative second-look laparoscopy (245). However, the time to intraperitoneal relapse was effectively delayed by the IP MonAb, suggesting regional activity for the drug.
Summary

The clinical benefit of consolidation and maintenance chemotherapy and immunotherapy remains unclear. Patients and their physicians may consider prolonged single-agent paclitaxel an option, but it should not be considered the standard of care at this time.

Treatment Assessment

Many patients who undergo optimal cytoreductive surgery and subsequent chemotherapy for epithelial ovarian cancer will have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments have proven to be too insensitive to exclude the presence of subclinical disease. Therefore, a second-look surgery has been performed to evaluate these patients (142,246–255). Most often, patients have undergone formal reassessment laparotomy, although the laparoscope has also been used in this circumstance (253–255). However, there is a 35% false-negative rate if laparoscopy is used for a second-look procedure (142,254).

Tumor Markers

Tumor markers are not reliable enough to predict accurately which patients with epithelial tumors will experience complete eradication of disease with a particular therapy. Carcinoembryonic antigen (CEA) levels are often elevated in patients with ovarian cancer, but the test is too nonspecific and insensitive to have much use in the management of these patients (42). The level of CA125, a surface glycoprotein associated with müllerian epithelial tissues, is elevated in about 80% of patients with epithelial ovarian cancers, particularly those with nonmucinous tumors. The levels frequently become undetectable after the initial surgical resection and one or two cycles of chemotherapy.

Levels of CA125 have been correlated with findings at second-look operations. Positive levels are useful in predicting the presence of disease, but negative levels are an insensitive determinant of the absence of disease. In a prospective study (256), the predictive value of a positive test was shown to be 100%; if the level of CA125 was positive (>35 U/mL), disease was always detectable in patients at the second-look procedure. The predictive value of a negative test was only 56%; if the level was <35 U/mL, disease was present in 44% of the patients at the time of the second-look surgery. A review of the literature suggests that an elevated CA125 level predicts persistent disease at second-look surgery in 97% of the cases (257), but the CA125 level is not sensitive enough to exclude subclinical disease in many patients.

Serum CA125 levels can be used during chemotherapy to follow those patients whose levels were positive at the initiation of therapy (3,257). The change in level generally correlates with response. Those patients with persistently elevated levels after three cycles of treatment most likely have persistent disease. When levels rise after treatment, almost invariably treatment has failed, and continuation of the current regimen is futile. A retrospective study has determined that a doubling of the CA125 level from its nadir in those patients with a persistently elevated level accurately predicts disease progression (258).

Radiologic Assessment

For patients with stage I to III epithelial ovarian cancer, radiologic tests generally have been of limited value in assessing the response to therapy for subclinical disease. Ascites can be readily detected, but even quite large omental metastases can be missed on CT scan (259). If liver enzyme levels are abnormal, the liver can be evaluated with a CT scan or ultrasonography. A positive CT scan and fine-needle aspiration (FNA) cytology indicating tumor persistence could document persistent or recurrent disease, but the false-negative rate of a CT scan is about 45% (260). Positron-emission tomography (PET) alone or with CT imaging may help in the detection of relapse, although the relative value of adding PET has not been established. There appears to be a higher false-positive rate with PET compared
with CT (90–92). MRI can be used as an alternative to CT in patients with allergies to the contrast medium (90).

**Second-look Operations**

A second-look operation is one performed on a patient who has no clinical evidence of disease after a prescribed course of chemotherapy to determine the response to therapy.

**Second-look Laparotomy** The technique of the second-look laparotomy is essentially identical to that for the staging laparotomy (142). The operation should be performed through a vertical abdominal incision. The incision should be initiated below the level of the umbilicus, so that if pelvic disease is detected in the absence of any palpable upper abdominal disease, a smaller incision might suffice. The incision can be extended cranially as needed. After multiple cytologic specimens have been obtained, samples of the peritoneal surfaces should be collected for biopsy, particularly in any areas of previously documented tumor. These are the most important areas to sample for biopsy because they are most likely to give a positive result. Any adhesions or surface irregularities should be sampled. In addition, biopsy specimens should be taken from the pelvic side walls, the pelvic cul-de-sac, the bladder, the paracolic gutters, the residual omentum, and the diaphragm. A pelvic and para-aortic lymph node dissection should be performed for those patients whose nodal tissues have not been previously removed.

About 30% of patients with no evidence of macroscopic disease will have microscopic metastases (246–249). Also, for many patients with microscopic disease, it will be detected in only the occasional biopsy or cytologic specimen. Therefore, a large number of specimens (at least 20 to 30) should be obtained to minimize possibility of false-negative results of the operation. In selected patients in whom gross residual tumor is discovered at second-look surgery, resection of isolated masses may be performed. The removal of all macroscopic areas of disease might facilitate response to salvage therapies (261–268).

Second-look laparotomies have not been shown to influence patient survival (250,251). Therefore, they should be performed selectively, e.g., in patients receiving therapy in a setting where second-line therapies are undergoing clinical trials.

The findings at second-look correlate with subsequent outcome and survival (142,246–252). Patients who have no histologic evidence of disease have a significantly longer survival than those in whom microscopic or macroscopic disease is documented at laparotomy (251,252). The attainment of negative findings with second-look surgery is not tantamount to a cure (252). Indeed, the reported probability that a patient will have a recurrence after a negative second-look laparotomy ranges from 30% to 50% at 5 years (142,246–252). Clearly, it is not possible to sample every potential site of disease. In addition, disease can become clinically apparent in sites that are occult, such as the liver parenchyma (98). Most recurrences after a negative second-look laparotomy occur in patients with poorly differentiated cancers (252).

Variables associated with the outcome of the second-look laparotomy are (i) initial stage, (ii) tumor grade, (iii) the size of the residual tumor and the size of the largest metastatic tumor before treatment, and (iv) the type of chemotherapy. No single variable or combination of variables is sufficiently predictive of the findings of a second-look laparotomy (3,142).

**Second-look Laparoscopy** The laparoscope in epithelial ovarian cancer patients may be used to stage disease in patients who have undergone a prior laparotomy for a tumor that was incompletely staged. Second-look laparoscopy may also be useful for patients on experimental treatment protocols, especially second-line treatments that require some evaluation of
Second-line Therapy

Secondary Cytoreduction

Secondary cytoreduction may be defined as an attempt at cytoreductive surgery at some stage following completion of first-line chemotherapy (261). Patients with progressive disease on chemotherapy are not suitable candidates for secondary cytoreduction, but patients who are clinically free of disease and undergo second-look laparotomy may benefit if all macroscopic residual disease can be resected (262–264). Patients with recurrent disease are occasionally candidates for surgical excision of their disease. Tumor resection under these circumstances should be restricted to those who have a disease-free interval of at least 12, but preferably 24, months or those in whom all macroscopic disease can be resected, regardless of the disease free interval (261–268).

Second-line Chemotherapy

If disease persists at the time of second-look laparotomy, or if clinically progressive disease develops during primary therapy, patients usually have been switched to an alternative treatment, often a second-line chemotherapy. The response rates for second-line chemotherapies have been 15% to 35% for most drugs tested by the oral or intravenous route (269–292). Active drugs that have been used as single agents include cisplatin, carboplatin, paclitaxel, docetaxel (Taxotere), topotecan, gemcitabine, etoposide (VP-16), doxorubicin (Doxil), vinorelbine (Navelbine), ifosfamide, 5-fluorouracil with leucovorin, and hexamethylmelamine. Single-agent drugs are sometimes used for second-line chemotherapy because of their relative ease of administration and low toxicity.

Platinum-sensitive Disease

Second-line therapies have been categorized by whether the patients responded to their initial platinum-based chemotherapy. Although this concept has been variously defined, platinum sensitivity has been related to a disease progression–free interval of at least 6 months. Response rates after retreatment with cisplatin have been shown to be higher in patients whose time to clinical relapse after prior response to cisplatin is longer than 6 months, especially when it is 12 to 24 months (271–273). Thus, the concept of platinum sensitivity is a continuum: The longer the interval, the higher the probability of a secondary response to secondary platinum-based chemotherapy. Carboplatin is active as a second-line agent in patients who have responded to prior cisplatin treatment, and response rates in these patients have been 20% to 30% (271). The concept of platinum sensitivity and paclitaxel sensitivity should influence the choice of second-line chemotherapy.

In patients who have platinum- or paclitaxel-sensitive tumors, retreatment with a platinum drug or paclitaxel is appropriate. Second-line responses to paclitaxel, carboplatin, and cisplatin in those patients who have responded previously to cisplatin have been observed in 20% to 25% of patients. Furthermore, the length of a prior response to platinum-based chemotherapy is highly predictive of the upper limit of the duration of response to a subsequent platinum treatment using the same or similar drugs (274).

There are studies that suggest that a platinum plus paclitaxel may be better for second-line therapy than platinum alone (293,294). In a series of 25 women who relapsed 6 months or longer after first-line carboplatin and paclitaxel, retreatment with the same combination of drugs resulted in a response rate of 91% and a median progression-free interval of more
than 9 months (294). Others suggest that single-agent therapy (cisplatin or carboplatin) should be considered the standard of care for platinum-sensitive relapsing disease (295,296). In most studies, there is a lack of survival advantage and greater toxicity with multiagent compared with single-agent regimens, although the combination of carboplatin and paclitaxel is well tolerated (297).

The use of combination platinum plus paclitaxel chemotherapy versus a single-agent platinum was tested in two multinational randomized phase III trials (298) and a randomized phase II study (299). In a report of the ICON4 (298) and AGO-OVAR-2.2 (299) trials, 802 women with platinum-sensitive ovarian cancer who relapsed after being treatment-free for at least 6 to 12 months were randomized to platinum-based chemotherapy (72% carboplatin or cisplatin alone; 17% CAP; 4% carboplatin plus cisplatin; and 3% cisplatin plus doxorubicin) or paclitaxel plus platinum-based chemotherapy (80% paclitaxel plus carboplatin; 10% paclitaxel plus cisplatin; 5% paclitaxel plus both carboplatin and cisplatin; and 4% paclitaxel alone). The AGO-OVAR-2.2 trial did not accrue its planned number of patients. In both trials, a significant proportion of the patients had not received paclitaxel as part of their initial chemotherapeutic regimen. Combining the trials for analysis, there was a significant survival advantage for the paclitaxel-containing therapy (HR = 0.82) with a median follow up of 42 months. The absolute 2-year survival advantage was 7% (57% vs. 50%), and there was a 5-month improvement in median survival (29 vs. 24 months). Progression-free survival was better with the paclitaxel regimen (HR = 0.76); there was a 10% difference in 1-year progression-free survival (50% vs. 40%) and a 3-month prolongation in median progression-free survival (13 vs. 10 months). The toxicities were comparable, except there was a significantly higher incidence of grade 2 to 4 neurologic effects (20% vs. 1%) and alopecia (86% vs. 25%) in the paclitaxel group. Conversely, myelosuppression was significantly greater with the non-paclitaxel-containing regimens. These data support the slight advantage of a second-line regimen containing both paclitaxel and a platinum agent compared with platinum-based therapy alone, especially in patients who have not received paclitaxel in their primary chemotherapeutic regimen.

Platinum-resistant and Refractory Disease In cisplatin-refractory patients, response rates to second-line carboplatin are less than 10% (270,272). The management of women who have platinum-resistant disease requires the use of non–cross-resistant agents. Single-agent therapy is typically used, because combination regimens are associated with more toxicity without additional benefit. There are a variety of active drugs; paclitaxel, docetaxel, topotecan, liposomal doxorubicin, gemcitabine, oral etoposide, and tamoxifen are the most frequently used. Other active agents include vinorelbine, ifosfamide, and leucovorin-modulated 5-fluorouracil. These agents have resulted in second-line response rates of about 8% to 28% in patients with platinum-resistant disease (275–292).

Some researchers have used these drugs to prolong the “platinum-free interval,” hoping that their use will allow the tumor to become platinum sensitive during the interval use of non–cross-resistant agents. The rationale for this method is that the platinum-free interval is equivalent to the treatment-free interval, and before the availability of other active drugs, these two terms were synonymous. However, there are no data to support the hypothesis that the interposition of another drug can produce an increased platinum sensitivity as a result of a longer interval since the last platinum treatment.

Single-agent paclitaxel shows objective responses in 24% to 30% in phase II trials of women with platinum-resistant ovarian cancer (300–306). Weekly paclitaxel is active, and the toxicity, especially myelosuppression, is less than with the every-3-weeks regimens. Docetaxel also has some activity in these patients (307–309).

Topotecan is an active second-line treatment for patients with platinum-sensitive and platinum-resistant disease (310–325). Weekly topotecan administered at a dose of
4 mg/m²/week for 3 weeks with a week off every month produced a response rate similar to the 5-day regimen with considerably less toxicity; therefore, this is now considered the regimen of choice for this agent (325). Liposomal doxorubicin (Doxil in the United States and Caelyx in Europe) has activity in platinum- and taxane-refractory disease (326–328). The predominant severe toxicity of liposomal doxorubicin is the hand-foot syndrome, also known as palmar-plantar erythrodysesthesia or acral erythema. This morbidity is observed in 20% of patients who receive 50 mg/m² every 4 weeks (326). There have been two randomized trials comparing liposomal doxorubicin with topotecan. In a study of 237 women who relapsed after receiving one platinum-containing regimen, 117 of whom (49.4%) had platinum-refractory disease (328), liposomal doxorubicin 50 mg/m² over 1 hour every 4 weeks was compared with topotecan 1.5 mg/m²/day for 5 days every 3 weeks. The two treatments had a similar overall response rate (20% vs. 17%), time to progression (22 vs. 20 weeks), and median overall survival (66 vs. 56 weeks). The myelotoxicity was significantly lower in the liposomal doxorubicin–treated patients than with those receiving topotecan with grade 3 or 4 neutropenia (12% vs. 71%) and grade 3 or 4 thrombocytopenia (1% vs. 35%). However, with more long term follow-up of these patients (329), the median survival was 62.7 weeks for those treated with liposomal doxorubicin and 59.7 weeks for topotecan–treated patients ($p = 0.05$). In the subset of patients with platinum-sensitive disease, the median survival was 107.9 weeks for those treated with liposomal doxorubicin versus 70.1 weeks for topotecan–treated patients ($p = 0.017$), suggesting a slight advantage of the liposomal doxorubicin in this second-line setting.

Gemcitabine has been associated with response rates of 20% to 50%, with 15% to 30% in patients who are platinum resistant (330–334). Oral etoposide should be considered one of the principal drugs to be used in patients with paclitaxel- and platinum-resistant disease (335,336). Other active agents include hexamethylmelamine (337,338), capecitabine (339), 5-fluorouracil and leukovorin (340), and ifosfamide with mesna (341).

**Hormonal Therapy**

Tamoxifen has been associated with response rates of 15% to 20% in well-differentiated carcinomas of the ovary (342–346). The gonadotropin-agonist leuprolide acetate (Lupron) has been shown to produce a response rate of 10% in one series (347). Trials combining tamoxifen and leuprolide acetate, and tamoxifen and combination chemotherapy are being conducted (348). Aromatase inhibitors, e.g., letrozole, anastrozole, and exemestane, which have been shown to have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer (349). One of the principal advantages of this class of agents is the very low toxicity (350).

**Immunotherapy**

Herceptin, an antibody directed toward the extracellular protein produced when the HER-2neu oncogene is overexpressed, has been used extensively in breast cancer, where it has been shown to improve the response rate to chemotherapy in selected patients. Trials of this antibody in patients whose ovarian cancers overexpress erbB2 was conducted by the GOG, but only 11% of the tumors overexpressed the protein, and the response rate was only about 4% (351).

In addition to its use as a maintenance therapy (245), the OvaRex anti-CA125 monoclonal antibody is being used alone and in combination with a variety of cytotoxic agents in the treatment of patients with recurrent disease (352,353).

**Intraperitoneal Therapy**

For patients with minimal residual (<5 mm) or microscopic disease confined to the peritoneal cavity, consideration can be given to intraperitoneal chemotherapy or immunotherapy. The failure of second-line intravenous chemotherapy to control residual disease has led to the use of intraperitoneal therapies for small, persistent disease.
Intraperitoneal Chemotherapy

Cytotoxic chemotherapeutic agents, such as cisplatin, 5-fluorouracil, cytosine arabinoside (Ara-C), etoposide (VP-16), and mitoxantrone, have been used for patients with persistent epithelial ovarian cancer (354–363), and complete responses have been seen in patients who begin treatment with minimal residual disease. The surgically documented response rates reported with this approach are about 20% to 40% for carefully selected patients, and the complete response rate is about 10% to 20%. Cisplatin seems to be the best drug, although various combinations of agents (e.g., cisplatin plus etoposide) have been shown to have significant activity (356,357). Although it has been suggested that this approach produces a significant subsequent improvement in survival (359), there are no prospective phase III data, and the patients so treated tend to be those with a more favorable prognosis regardless of subsequent therapy.

Intraperitoneal Immunotherapy

Another approach is the use of intraperitoneal immunotherapy such as interferon (364–370). Interferon has been found to have some activity for patients with minimal residual disease (364,365). Intraperitoneal administration interferon-α, interferon-γ, tumor necrosis factor, and interleukin-2 has been performed. The response rate for the intraperitoneal cytokines, interferon-α and interferon-γ, is the same as that for the cytotoxic agents (i.e., 28% to 50%) (364–370). The intraperitoneal administration of interferon-α has produced a 32% (9 of 28) surgically documented complete response rate, and a 50% (14 of 28) total response rate for patients with minimal residual disease after primary combination chemotherapy with cisplatin (364,369). This experience was replicated in a multi-institutional trial in which the surgically documented complete response rate was 28% in platinum-sensitive patients (365).

The interferons have been combined with cytotoxic agents in an effort to increase the overall response rates. In several trials, the combination of cisplatin and interferon-α seemed to produce a 50% complete response rate, which was greater than that produced by either single agent (367–369). Surgically documented responses to intraperitoneal therapy have been generally limited to patients with minimal residual disease (i.e., <5 mm maximal tumor dimension) and patients whose tumors have been responsive to cisplatin chemotherapy.

Candidates for Intraperitoneal Therapy

Intraperitoneal treatment is not suitable for all patients because it can be cumbersome, requiring catheters that remain functional. Neither patients with extensive intraperitoneal adhesions nor patients with extraperitoneal disease are appropriate candidates. On the basis of these issues and the failure to achieve responses in most patients with bulky, platinum-refractory disease, second-line intraperitoneal chemotherapy and immunotherapy should still be considered experimental (371).

High-dose Chemotherapy and Autologous Bone Marrow Transplantation

The use of high-dose chemotherapy and either autologous bone marrow transplantation (ABMT) or peripheral stem cell protection has been tested in patients with advanced ovarian cancer (372–375). A phase III randomized trial of 57 patients treated with high-dose chemotherapy (cyclophosphamide 6,000 mg/m² and carboplatin 1,600 mg/m²) with peripheral blood stem cell support as consolidation versus 53 patients treated with conventional dose maintenance (cyclophosphamide 600 mg/m² and carboplatin 300 mg/m²) has been reported (374). Only 43 of the 57 (75%) women completed the high-dose therapy, whereas 48 of 53 (92%) completed the standard dose regimen, and there was no statistically significant difference in progression-free and overall survival between the two groups of patients. A nonrandomized trial of ABMT for consolidation in 96 patients conducted at the MD Anderson Cancer Center showed a 6-year survival of 37%, but it is unclear if this would be survival advantage (375).
Radiation Therapy

Whole-abdominal radiation therapy given as a salvage treatment has been shown to be associated with a relatively high morbidity. The principal problem associated with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of patients treated with this approach develop intestinal obstruction, which necessitated exploratory surgery with potential morbidity (376).

Intestinal Obstruction

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or, more frequently, in association with recurrent disease (142,377–393). Obstruction may be related to a mechanical blockage or to carcinomatous ileus.

The intestinal blockage can be corrected in most patients whose obstruction appears at the time of initial diagnosis. However, the decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., <2 months), surgical relief of the obstruction is not indicated (377). In those whose projected life span is longer, features that predict a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites (378).

For most patients with recurrent ovarian cancer who have intestinal obstruction, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer. More than one half of the patients have small-bowel obstruction, one third have colonic obstruction, and one sixth have both (379–383). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can either be resected or bypassed, depending on what is easier to accomplish safely. Intestinal bypass is generally less morbid than resection, and in patients with progressive cancer, the survival time after these two operations is the same (384–390).

If multiple obstructions are present, resection of several segments of intestine is usually not indicated, and intestinal bypass and/or colostomy should be performed. A gastrostomy may occasionally be useful in this circumstance (389), and this can usually be placed percutaneously (392).

Surgery for bowel obstruction in patients with ovarian cancer carries an operative mortality of about 10% and a major complications rate of about 30% (377–390). The need for multiple reanastomoses and prior radiation therapy increase the morbidity, which consists primarily of sepsis and enterocutaneous fistulae. The median survival ranges from 3 to 12 months, although about 20% of such patients survive longer than 12 months (391–393).

Survival

The prognosis for patients with epithelial ovarian cancer is related to several clinical variables. Survival analyses based on the most commonly used prognostic variables are presented (1,3,24,133–137). Including patients at all stages, patients younger than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients
older than 50 years. The 5-year survival rate for carefully and properly staged patients with stage I disease is 76% to 93%, depending on the tumor grade. The 5-year survival for stage II is 60% to 74%. The 5-year survival rate for stage IIIa is 41%, for stage IIIb about 25%, for stage IIIc 23%, and for stage IV disease 11% (Fig 35.13).

An analysis of the National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States during the last period of analysis (1988 to 1994). In this cohort, the survival for stage I was 93%, for stage II 70%, for stage III 37%, and for stage IV 25% (394). Compared with the interval 1983 to 1987, there was a statistically significant improvement in survival for stages I, III, and IV disease.

Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival (24). When all stages of borderline tumors are included, the 5-year survival rate is about 86% to 90%.

Regarding patients with invasive cancer, the 5-year survival rate for grade I epithelial ovarian cancers is about 91%, compared with about 74% for grade 2 and 75% for grade 3 (24,394). For stage II disease, the survivals are 69%, 60%, and 51%, respectively, for grades 1, 2, and 3. Examining stage III to IV patients, the 5-year survivals for grades 1, 2, and 3, respectively, are 38%, 25%, and 19%. Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease and only 5% for those with nonoptimal disease (136,137,162). Patients whose Karnofsky’s index (KI) is low (<70) have a significantly shorter survival than those with a KI >70 (24).
Nonepithelial Ovarian Cancers

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. Nonepithelial malignancies of the ovary account for about 10% of all ovarian cancers (2,3,395). Nonepithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas, lipid cell tumors). Although there are many similarities in the presentation, evaluation, and management of these patients, these tumors also have many unique qualities that require a special approach (2,395–398).

Germ Cell Malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is only about one tenth the incidence of malignant germ cell tumors of the testis, so most of the advances in the management of these tumors have been extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads (2,3,395).

Classification

A histologic classification of ovarian germ cell tumors is presented in Table 32.5 (3,395). Both α-fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies; therefore, the presence of circulating hormones can be

clinically useful in the diagnosis of a pelvic mass and in monitoring the course of a patient after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are produced by up to 95% of dysgerminomas, and serial measurements of LDH may be useful for monitoring the disease.

\[1\text{-}\text{Antitrypsin (AAT) can rarely be detected in association with germ cell tumors. When the histologic and immunohistologic identification of these substances in tumors is correlated, a classification of germ cell tumors emerges (Fig. 35.14) (399).}

In this scheme, embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP, and this lesion is the progenitor of several other germ cell tumors (399). More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure germinomas do not secrete these markers.

\[\text{Epidemiology}\]

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,3). Germ cell malignancies account for fewer than 5% of all ovarian cancers in western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African-American societies, where epithelial ovarian cancers are much less common.
In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one third of these are malignant (2,3,395). Germ cell tumors account for two thirds of the ovarian malignancies in this age group. Germ cell cancers also are seen in the third decade, but thereafter they become quite rare.

Clinical Features

Symptoms

In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and often are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities also may occur in menarcheal patients. Some young patients may misinterpret the early symptoms of a neoplasm as those of pregnancy, and this can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (397).

Signs

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible (see Fig. 14.8 and Chapter 14). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum hCG and AFP titers, a complete blood count, and liver function tests. A radiograph of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. A karyotype should be obtained preoperatively for all premenarcheal girls because of the propensity of these tumors to arise in dysgenetic gonads (396,400). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these patients require surgical exploration, such extensive and time-consuming evaluation is unnecessary. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles (401).

Dysgerminoma

Dysgerminoma is the most common malignant germ cell tumor, accounting for about 30% to 40% of all ovarian cancers of germ cell origin (2,3,399). The tumors represent only 1% to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, and they rarely occur after 50 years of age (2,3,397). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Dysgerminomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter include the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic
germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is conceivable that the germ cell could free itself of its normal control and multiply indiscriminately. The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,3). The capsule is slightly bosselated, and the consistency of the cut surface is spongy and gray-brown in color (Fig. 35.15).

The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale–staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 35.16). Mitotic figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelioid cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Occasional dysgerminomas may contain syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter the behavior of the tumor (2,3).

Because the dysgerminoma is a germ cell tumor and parthenogenesis (stimulation of the basic germ cell to atypical division) is the most commonly accepted genesis for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma,
endodermal sinus tumor, and other extraembryonal lesions are also commonly associated with the dysgerminoma.

Approximately 5% of dysgerminomas are discovered in phenotypic women with abnormal gonads. This malignancy can be associated with patients who have pure gonadal dysgenesis (46,XY, bilateral streak gonads), mixed gonadal dysgenesis (45,X/46,XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46,XY, testicular feminization). Therefore, for premenarcheal patients with a pelvic mass, the karyotype should be determined (see Chapter 26).

For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas, which are benign ovarian tumors that are composed of germ cells and sex cord stroma. If gonadoblastomas are left in situ in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies.

About 65% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis. About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. In fact, dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.

For patients whose contralateral ovary has been preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years. This figure includes those not given additional therapy, as well as patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor most commonly spreads via the lymphatic system. It can also spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination...
of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are seen principally in the lower vertebrae. Metastases to the lungs, liver, and brain are seen most often in patients with long-standing or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease (403,404).

**Treatment**

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and proper surgical staging. Chemotherapy or radiation is administered to patients with metastatic disease. Because the disease principally affects girls and young women, special consideration must be given to the preservation of fertility and use of chemotherapy as needed whenever possible. An algorithm for the management of ovarian dysgerminoma is presented in Fig. 35.17.

**Surgery** The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy (405). If there is a desire to preserve fertility, the contralateral ovary, fallopian tube, and uterus should be left in situ, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy. If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with advanced disease (407,408). For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left in situ for possible future embryo transfer (402). Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

In patients in whom the neoplasm appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of any occult metastatic disease. All peritoneal surfaces should be inspected and palpated, and any suspicious lesions should be sampled for biopsy. Unilateral pelvic lymphadenectomy and at least careful palpation and biopsy of enlarged para-aortic nodes are particularly important parts of the staging. These tumors often metastasize to the para-aortic nodes around the renal vessels. Dysgerminoma is the only germ cell tumor that tends to be bilateral, and not all of the bilateral lesions are associated with obvious ovarian enlargement. Therefore, bisection of the contralateral ovary and excisional biopsy of any suspicious lesion are desirable (405–408). If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are (i) repeat laparotomy for surgical staging, (ii) regular pelvic and abdominal CT scans, or (iii) adjuvant chemotherapy. As these are rapidly growing tumors, our preference is to perform regular surveillance. Tumor markers (LDH, AFP, and \( \beta \)-hCG) should also be monitored in case occult mixed germ cell elements are present.

**Radiation Therapy** Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, however, so radiation should rarely be used as first-line treatment (407).

**Chemotherapy** There have been numerous reports of successful control of metastatic dysgerminomas with systemic chemotherapy, and this technique should now be regarded as the treatment of choice (407–419). The obvious advantage is the preservation of fertility (420–423).
Dysgerminoma

**Apparently confined to ovary(s)**
- Unilateral oophorectomy
- Inspect contralateral ovary

**Metastatic disease**
- Unilateral salpingo-oophorectomy
- Remove readily resectable metastases

**Surgical staging performed**

**No metastatic disease**

**Documented occult metastatic disease**
- CT scan or ultrasound of pelvis and abdomen
  - q 2 mos × first 6 mos
  - q 3 mos × next 6 mos
  - q 6 mos × second yr

**Small focus in contralateral ovary**
- Resect focus with ovarian preservation

**CT scan of ultrasound of pelvis and abdomen**
- BEP × 4–6 cycles

**If cytologic or histologic evidence of relapse**
- Observation
- Physical examination every 2 months for first 12 months
- CT scan at 6 and 12 months

**Resect focus with ovarian preservation**
- BEP × 4 cycles

**If cytologic or histologic evidence of relapse**
- BEP × 4 cycles
- ?Second-look

**Figure 35.17 Management of dysgerminoma of the ovary.** (From Berek JS, Hacker NF. Practical gynecologic oncology, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005:518, with permission.)
The most frequently used chemotherapeutic regimens for germ cell tumors are BEP (bleomycin, etoposide, and cisplatin), VBP (vinblastine, bleomycin, and cisplatin), and VAC (vincristine, actinomycin, and cyclophosphamide) (407–425) (Table 35.6).

The GOG studied three cycles of the EC regimen, consisting of etoposide (120 mg/m² intravenously on days 1, 2, and 3 every 4 weeks) and carboplatin (400 mg/m² intravenously on day 1 every 4 weeks) for patients with completely resected ovarian dysgerminoma, stages Ib, Ic, II, or III (416). The results showed a sustained disease-free remission rate of 100%.

For patients with advanced, incompletely resected germ cell tumors, the GOG studied cisplatin-based chemotherapy in two consecutive protocols (409, 410). In the first study, patients received four cycles of vinblastine (12 mg/m² every 3 weeks), bleomycin (20 units/m² intravenously every week for 12 weeks), and cisplatin (20 mg/m² per day intravenously for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look laparotomy were treated with six cycles of VAC. In the second trial, patients received three cycles of BEP initially, followed by consolidation with VAC, which was later discontinued in patients with dysgerminomas (410). The VAC consolidation after BEP in patients with tumors other than dysgerminoma is still being investigated, but VAC does not appear to improve the outcome of the BEP regimen. A total of 20 evaluable patients with stage III and IV dysgerminoma were treated in these two protocols, and 19 are alive and free of disease after 6 to 68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. Another study at MD Anderson Cancer Center (413) used BEP in 14 patients with residual disease, and all patients were free of disease during long-term follow-up. These results suggest that patients with advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with cisplatin-based combination chemotherapy. The best regimen is four cycles of BEP based on the data from testicular cancers (424, 425).

There appears to be no need to perform a second-look laparotomy in patients with dysgerminoma whose macroscopic disease was all resected during the primary operation (426–428). In patients with macroscopic residual disease at the start of chemotherapy, we

a All doses given intravenously.
prefer to perform a second-look operation, because second-line therapy is available and the earlier persistent disease is identified, the better the prognosis should be.

**Recurrent Disease**

About 75% of recurrences occur within the first year after initial treatment (2,395–397), the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes. These patients should be treated with either radiation or chemotherapy, depending on their primary treatment. Patients with recurrent disease who have had no therapy other than surgery should be treated with chemotherapy. If prior chemotherapy with BEP has been given, POMB-ACE (vincristine, bleomycin, cisplatin, etoposide, actinomycin D, and cyclophosphamide) may be used (Table 35.7), and consideration should be given to the use of high-dose chemotherapy (e.g., with carboplatin and etoposide). Alternatively, radiation therapy is effective for this disease, with the major disadvantage being loss of fertility if pelvic and abdominal irradiation is required.

**Pregnancy**

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage Ia cancer is found, the tumor can be removed intact and the pregnancy continued. For patients with more advanced disease, continuation of the pregnancy...
depends on the gestational age of the fetus. Chemotherapy can be given in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus (420).

**Prognosis**

For patients whose initial disease is stage Ia (i.e., a unilateral encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% (406,407). The features that have been associated with a higher tendency to recur include lesions larger than 10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern (2,399).

Although in the past, surgery for advanced disease followed by pelvic and abdominal irradiation resulted in a 5-year survival rate of 63% to 83%, cure rates of 85% to 90% for this same group of patients are now being reported with the use of VBP, BEP, or EC combination chemotherapy (407–424).

**Immature Teratomas**

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy. This lesion represents 10% to 20% of all ovarian malignancies seen in women younger than 20 years and 30% of the deaths from ovarian cancer in this age group (2). About 50% of pure immature teratomas of the ovary occur in women between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

**Pathology and Grading**

Of fundamental importance in the understanding of the teratoma is a recognition of the maturation of the various elements. If maturation continues along normal lines, the mature or adult teratoma results, and the prognosis is excellent. Conversely, abnormal maturation of these elements produces undisciplined growth that can be fatal. Teratomas containing immature elements, although relatively rare, have been recognized more commonly during the past two decades (Fig. 35.18). Among the tumors with embryonal elements, those containing neural tissues demonstrate most clearly the importance of the ability to mature. Gliomatosis peritonei is the most dramatic demonstration of the significance of maturation, because most patients with these tumors have survived, even with this disseminated disease (3).

Immature teratomas are classified according to a grading system (grades 1 to 3) that is based on the degree of differentiation and the quantity of immature tissue (429). A determination of the amount of undifferentiated neural tissue is of prognostic importance. A grade 1 tumor is one in which less than one low-power microscopic field (LPF) contains immature neural elements, a grade 2 tumor has one to three LPFs with immature elements, and a grade 3 tumor has more than three LPFs with these elements. The prognosis can be correlated with the grade determined by the quantity of these immature neural elements; with a higher grade, there is a poorer prognosis (2,3).

Previously, most malignant teratomas were classified as secondary neoplasms developing in a primarily benign teratoma. During the last decade, lesions composed primarily of immature embryonal or extraembryonal elements have become more prevalent, and the basic demonstration of malignancy is the inability of the tissue to mature rather than the presence of individual cell anaplasia (i.e., the mitotic activity may be low). This unique aspect is demonstrated by an absence of aneuploidy in the few cases that have been studied (3).
Malignant change in benign cystic teratomas has been recorded as occurring in 0.5% to 2% of cases, usually in patients older than 40 years of age (429). The most common malignancy developing in the initially benign teratoma is squamous cell carcinoma. Other neoplasms have been reported (e.g., melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) (2). Carcinomas may arise from any of the epithelial elements.

**Diagnosis**

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these lesions will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely, they are associated with the production of steroid hormones and can be accompanied by sexual pseudoprecocity (395–397). Tumor markers are negative unless a mixed germ cell tumor is present.

**Treatment**

*Surgery* In a premenopausal patient whose lesion appears to be confined to a single ovary, unilateral oophorectomy and surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary (3,429). Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Bloodborne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).
It is unclear whether debulking of metastatic implants enhances the response to combination chemotherapy (430–437). Unlike epithelial lesions, immature teratomas are much more chemosensitive. Because cure ultimately depends on the ability to deliver chemotherapy promptly, any surgical resection that may be potentially morbid and therefore delay chemotherapy should be resisted.

**Chemotherapy**

Patients with stage Ia, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage Ia, grades 2 or 3, adjuvant chemotherapy should be used (411–413,426–444). Chemotherapy is also indicated for patients who have ascites, regardless of tumor grade. The most frequently used combination chemotherapeutic regimen in the past has been VAC (438–440). However, in a GOG study, the relapse-free survival rate in patients with incompletely resected disease was only 75% (440). The newer approach has been to incorporate cisplatin into the primary treatment of these tumors, and most of the experience has been with the VBP and BEP regimens (411,412,444). No direct comparison of these regimens with VAC has been reported, but the BEP combination can save some patients who have persistent or recurrent disease after VAC (434,435,444).

The GOG has been prospectively studying three courses of BEP therapy for patients with completely resected stage I, II, and III ovarian germ cell tumors (411,412,444). Overall, the toxicity has been acceptable, and 91 of 93 patients whose nondysgerminomatous tumors were treated are clinically free of disease. Thus, the BEP regimen, which is used more extensively for testicular cancer, seems to be superior to the VAC regimen in the treatment of completely resected nondysgerminomatous germ cells tumors of the ovary. Because some tumors can progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days (445).

The switch from VBP to BEP has been prompted by the experience in patients with testicular cancer, in which the replacement of vinblastine with etoposide has been associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. Furthermore, the use of bleomycin seems to be important for this group of patients. In a randomized study of three cycles of etoposide plus cisplatin with or without bleomycin (EP versus BEP) in 166 patients with germ cell tumors of the testes, the BEP regimen had a relapse-free survival rate of 84% compared with 69% for the EP regimen \( p = 0.03 \) (424). In addition, cisplatin may be slightly better than carboplatin in the setting of metastatic germ cell tumors. One hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of etoposide plus cisplatin (EP) versus four cycles of etoposide plus carboplatin (EC). There have been three relapses with the EP regimen versus seven with the EC regimen, although the overall survival of the two groups is identical thus far (425). In view of these results, **BEP is the preferred treatment regimen for patients with Gross residual disease and has replaced the VAC regimen for patients with completely resected disease.**

The necessity of adjuvant chemotherapy for all patients with resected immature teratomas is uncertain. Several reports support the successful management of these patients with surgery alone (436,437,446). In the largest series, an intergroup study from the Pediatric Oncology Group and the Children’s Cancer Group, 73 children with immature teratoma (44 of ovarian origin) underwent surgery followed by surveillance. With a median follow-up of 35 months, the overall 3-year event-free survival rates for all patients and those with ovarian teratomas were 93% and 100%, respectively. Thirteen of the 44 girls with an immature ovarian teratoma had microscopic foci of yolk sac tumor in the teratoma; one developed recurrent disease and was successfully salvaged with cisplatin-based chemotherapy. Of note, 82% of the tumors were grade 1 or 2; however, 92% of those with foci of yolk sac tumor were grade 2 or 3.
Patients who have immature teratomas with malignant squamous elements seem to have a poorer prognosis than those whose tumors are without these elements (415,446,447). The treatment in these patients is also the BEP regimen.

**Radiation Therapy**  
Radiation therapy is generally not used in the primary treatment of patients with immature teratomas. Furthermore, there is no evidence that the combination of chemotherapy and radiation has a higher rate of disease control than chemotherapy alone. Radiation therapy should be reserved for patients with localized persistent disease after chemotherapy (407,426).

**Second-look Laparotomy**  
The need for a second-look operation has been questioned (427,428). It seems not to be justified in patients who have received chemotherapy in an adjuvant setting (i.e., stage Ia, grades 2 and 3), because chemotherapy in these patients is so effective. Second-look laparotomy in patients with macroscopic residual disease at the start of chemotherapy may be of value in selected patients, because there are no reliable tumor markers for this disease and such patients are at higher risk of failure.

If a second-look operation is performed, sampling of any peritoneal lesions should be performed and the retroperitoneal lymph nodes should be evaluated carefully. If only mature elements are found during the second-look procedure, chemotherapy should be discontinued. If the presence of persistent immature elements is documented, alternative chemotherapy should be employed. An enlarged contralateral ovary may contain a benign cyst or a mature cystic teratoma, which may be managed with an ovarian cystectomy (395,397).

**Prognosis**  
The most important prognostic feature of the immature teratoma is the grade of the lesion (2,429). In addition, the stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Patients whose tumors have been incompletely resected before treatment have a significantly lower probability of 5-year survival than those whose lesions have been completely resected (i.e., 94% versus 50%) (397). Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically determined stage I lesions (426,429,432).

The degree or grade of immaturity generally correlates with the metastatic potential and curability. The 5-year survival rates for all stages combined have been reported to be 82%, 62%, and 30% for patients with grades 1, 2, and 3, respectively (429). Occasionally, these tumors are associated with mature or low-grade glial elements that have implanted throughout the peritoneum, and such patients usually have a favorable long-term survival (2,3).

**Endodermal Sinus Tumors**  
Endodermal sinus tumors (EST) have also been referred to as yolk sac carcinomas because they are derived from the primitive yolk sac (2,3). These lesions are the third most frequent malignant germ cell tumors of the ovary. ESTs occur in patients with a median age of 16 to 18 years (2,3,448). About one third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients (396).

**Pathology**  
The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration are present in these rapidly growing lesions. The capsule is intact in most cases.
The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary in such young patients is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients (3).

Microscopically, the characteristic feature is the endodermal sinus, or Schiller-Duval body (Fig. 35.19). The cystic space is lined with a layer of flattened or irregular endothelium into which projects a glomeruloid tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements represent undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. The association of EST with dysgerminoma must be emphasized if diagnosis and therapy are to be optimal (2,3).

Most EST lesions secrete AFP and, rarely, they may elaborate detectable AAT. AFP can be demonstrated in the tumor by means of the immunoperoxidase technique. There is a good correlation between the extent of disease and the level of AFP, although discordance also has been observed. The serum level of these markers, particularly AFP, is useful in monitoring the patient’s response to treatment (448–452).

Treatment

Surgery  The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter outcome (397,450). Any gross metastases should be removed, if possible, but thorough surgical staging is not indicated because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series (397,444).
Bilaterality is not seen in these lesions, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III (452).

**Chemotherapy**  
All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy. Before the routine use of combination chemotherapy for this disease, the 2-year survival rate was only about 25%. After the introduction of the VAC regimen, this rate improved to 60% to 70%, indicating the chemosensitivity of most of these tumors (439,440). Furthermore, with conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

VPB is a more effective regimen than VAC in the treatment of EST, particularly in the treatment of measurable or incompletely resected tumors (444). In the GOG series, only about 20% of patients with residual metastatic disease responded completely to the VAC regimen, whereas about 60% of those treated with VPB had a complete response (412). In addition, this regimen may save some patients in whom VAC therapy has failed.

Workers at the Charing Cross Hospital in London have developed the POMB-ACE regimen for high-risk germ cell tumors of any histologic type (453) (see Table 35.7). This protocol introduces seven drugs into the initial management, which is intended to minimize the chances of developing drug resistance. Drug resistance is particularly relevant for patients with massive metastatic disease, and the POMB-ACE regimen may be used as primary therapy for such patients as well as for those with liver or brain metastases. The POMB schedule is only moderately myelosuppressive, so the intervals between each course can be kept to a maximum of 14 days (usually 9 to 11 days), thereby minimizing the time for tumor regrowth between courses. When bleomycin is given by a 48-hour infusion, pulmonary toxicity is reduced. With a maximum of 9 years of follow-up, the Charing Cross group has seen no long-term side effects for patients treated with POMB-ACE. Children have developed normally, menstruation has been physiologic, and several have completed normal pregnancies.

Cisplatin-containing combination chemotherapy, preferably BEP or POMB-ACE, should be used as primary chemotherapy for ESTs. The optimal number of treatment cycles has not been established. The GOG protocols have used three to four treatment cycles given every 4 weeks (444,453). Alternatively, three cycles can be given to patients with stage I and completely resected disease, and two further cycles can be given after negative tumor marker status is achieved by patients with macroscopic residual disease before chemotherapy.

**Second-look Laparotomy**

The value of a second-look operation has yet to be established in patients with an EST. It seems reasonable to omit the operation for patients with pure low-stage lesions and for patients whose AFP values return to normal and remain normal for the balance of their treatment (451,452). There have been reported cases in which the AFP has returned to normal despite persistent measurable disease; some of these cases have been mixed germ cell tumors (452). For patients whose AFP levels do not return to normal, persistent disease can be assumed and alternative chemotherapy (e.g., POMB-ACE) can be offered.

---

**Rare Germ Cell Tumors of the Ovary**

**Embryonal Carcinoma**

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and
c ytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series (454). Older patients have been reported (455). Embryonal carcinomas may secrete estrogens, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding (2). The clinical picture is otherwise similar to that of the EST. The primary lesions tend to be large, and about two thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy (451).

The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with BEP) (412,444). Radiation does not seem to be useful for primary treatment.

Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries (456). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient’s response to treatment. In the presence of high hCG levels, isosexual precocity has been seen to occur in about 50% of patients whose lesions appear before menarche (456,457).

There are only a few limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses have been reported with the MAC (methotrexate, actinomycin D, and cyclophosphamide) regimen used in a manner described for gestational trophoblastic disease (458) (see Chapter 37). Alternatively, the BEP regimen can be used. The prognosis of ovarian choriocarcinomas has been poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of “embryoid bodies.” This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm) (2,399). The lesion tends to occur in very young, premenarcheal girls with signs of pseudopuberty and elevated AFP and hCG titers. Anecdotally, the VAC chemotherapeutic regimen has been reported to be effective (399,459).

Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series (458), the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16%. The most frequent combination was a dysgerminoma and an EST. The mixed lesions may secrete either AFP, hCG, or both or neither of these markers, depending on the components.

These lesions should be managed with combination chemotherapy, preferably BEP. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion. Therefore, for these patients, a second-look laparotomy may be indicated to determine the precise response to therapy if macroscopic disease was present at initiation of chemotherapy.

The most important prognostic features are the size of the primary tumor and the relative size of its most malignant component (458). For stage Ia lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one third EST, choriocarcinoma, or grade 3 immature teratoma also have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.
Late Effects of Treatment of Malignant Germ Cell Tumors of the Ovary

Although there are substantial data regarding late effects of cisplatin-based therapy in men with testicular cancer, sparse information is available for women with ovarian germ cell tumors. Among the adverse events from chemotherapy reported in men are renal and gonadal dysfunction, neurotoxicity, cardiovascular toxicity, and secondary malignancies.

Gonadal Function

An important cause of infertility in patients with ovarian germ cell tumors is unnecessary bilateral salpingo-oophorectomy and hysterectomy. Although temporary ovarian dysfunction or failure is common with platinum-based chemotherapy, most women will resume normal ovarian function, and childbearing is usually preserved (400,406,408, 460–464). In one representative series of 47 patients treated with combination chemotherapy for germ cell malignancies, 91.5% resumed normal menstrual function, and there were 14 healthy live births and no birth defects (422). Factors such as older age at initiation of chemotherapy, greater cumulative drug dose, and longer duration of therapy all have an adverse effect on future gonadal function (461).

Secondary Malignancies

An important cause of late morbidity and mortality in patients receiving chemotherapy for germ cell tumors is the development of secondary tumors. Etoposide in particular has been implicated in the development of treatment-related leukemias (465,466). The chance of developing treatment-related leukemia following etoposide is dose related. The incidence of leukemia is approximately 0.4% to 0.5% (representing a 30-fold increased likelihood) in patients receiving a cumulative etoposide dose of less than 2,000 mg/m² (465), compared with as much as 5% (representing a 336-fold increased likelihood) in those receiving more than 2,000 mg/m² (465). In a typical three- or four-cycle course of BEP, patients receive a cumulative etoposide dose of 1,500 or 2,000 mg/m², respectively. Despite the risk of secondary leukemia, risk-benefit analyses have concluded that etoposide-containing chemotherapy regimens are beneficial in advanced germ cell tumors; one case of treatment-induced leukemia would be expected for every 20 additionally cured patients who receive BEP as compared with PVB. The risk-benefit balance for low-risk disease, or for high-dose etoposide in the salvage setting, is less clear (466).

Sex Cord–stromal Tumors

Sex cord–stromal tumors of the ovary account for about 5% to 8% of all ovarian malignancies (2,3,395,396,467–473). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the “female” cells (i.e., granulosa and theca cells) and “male” cells (i.e., Sertoli and Leydig cells), as well as morphologically indifferent cells. A classification of this group of tumors is presented in Table 35.8.

Granulosa-stromal Cell Tumors

Granulosa-stromal cell tumors include granulosa cell tumors, thecomas, and fibromas. The granulosa cell tumor is a low-grade malignancy; rarely, thecomas and fibromas have morphologic features of malignancy and then may be referred to as fibrosarcomas.

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder are found in women throughout their reproductive and postmenopausal years (470). Granulosa cell tumors are bilateral in only 2% of patients.
Granulosa cell tumors range from a few millimeters to 20 centimeters or more in diameter. The tumors are rarely bilateral, and they have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and are commonly yellow or gray-yellow in color. The granulosa-theca cell tumor is probably the most inaccurately diagnosed lesion of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. Lesions misdiagnosed as granulosa cell tumors included metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (467).

The classic granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular cytoplasm suggesting hyperchromatism (3). “Coffee bean” grooved nuclei are common, as are mitoses, thus simulating the corresponding elements in the normal, mature follicle. Conversely, if the epithelial elements are bizarre with atypical mitoses, the lesion should not be categorized as a poorly differentiated granulosa cell tumor but instead as an undifferentiated mesothelial neoplasm. In the most common variety, the granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there is a resemblance to primordial follicles (i.e., Call-Exner bodies) (Fig. 35.20). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granular cell tumors are often cystic, contain luteinized cells, and can be associated with precocious puberty.

Pathology

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder is distributed throughout the reproductive and postmenopausal years (470–473). They are bilateral in only 2% of patients.

</table>

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion (470). For women of reproductive age, most patients have menstrual irregularities or secondary amenorrhea, and cystic hyperplasia of the endometrium is frequently present. For postmenopausal women, abnormal uterine bleeding is frequently the initial symptom. Indeed, the estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer.

Endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia (2,456,467–470,472).

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and rarely a pleural effusion is present (467–470). Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Granulosa cell tumors are usually stage I at diagnosis but may recur 5 to 30 years after initial diagnosis (469). The tumors may also spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. When granulosa cell tumors do recur, they can progress quite rapidly. Malignant thecomas are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (467). Inhibin is secreted by some granulosa cell tumors and is a useful marker for the disease (474–478). An elevated serum inhibin level in a premenopausal woman presenting with amenorrhea and infertility is suggestive of a granulosa cell tumor (479).

Treatment

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and
Chemotherapy are reserved for the treatment of recurrent or metastatic disease (470–476, 480–483).

**Surgery** Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage Ia tumors in children or in women of reproductive age (468). At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. For premenopausal patients in whom the uterus is left in situ, an endometrial biopsy should be performed because of the possibility of a coexistent adenocarcinoma of the endometrium (470).

**Radiation Therapy** There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (470, 481).

**Chemotherapy** There is no evidence that adjuvant chemotherapy will prevent recurrence of disease (483–486). Metastatic lesions and recurrences have been treated with a variety of antineoplastic drugs. Although the data are inconclusive, four to six cycles of BEP in selected patients with stage III/IV disease is an acceptable regimen (480). In a GOG study, 37% (14 of 30) patients treated with BEP had a negative second-look laparotomy, and completely responding patients had a median time to progression of 24.4 months (487). The use of hormonal agents, such as progestins, antiestrogens, and aromatase inhibitors, have been suggested, but there are limited data available to suggest effectiveness (480).

**Prognosis**

Granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. As such, 10-year survival rates of about 90% have been reported, with 20-year survival rates dropping to 75% (468–470, 479, 480). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (467).

The DNA ploidy of the tumors has recently been correlated with survival. Holland and colleagues (484) reported DNA aneuploidy in 13 of 37 patients (35%) with primary granulosa cell tumors. The presence of residual disease was found to be the most important predictor of progression-free survival, but DNA ploidy was an independent prognostic factor. Patients with residual-negative DNA diploid tumors had a 10-year progression-free survival of 96%.

Juvenile granulosa cell tumors of the ovary are rare and make up less than 5% of ovarian tumors in childhood and adolescence (488). About 90% are diagnosed in stage I, and they have a favorable prognosis. The juvenile subtype behaves less aggressively than the adult type. Advanced-stage tumors have been successfully treated with platinum-based combination chemotherapy, e.g., BEP (480, 487).

**Sertoli-Leydig Tumors**

Sertoli-Leydig tumors occur most frequently in the third and fourth decades of life; 75% of the lesions are seen in women younger than 40 years. These lesions are extremely rare and account for less than 0.2% of ovarian cancers (2). Sertoli-Leydig cell tumors are most frequently low-grade malignancies, although occasionally a poorly differentiated variety may behave more aggressively (489).
The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (489). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulphate (2,492). Rarely, the Sertoli-Leydig tumor can be associated with manifestations of estrogrenization (i.e., isosexual precocity, irregular, or postmenopausal bleeding).

**Treatment**

Because these low-grade lesions are only rarely bilateral (<1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (3,470). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate (490,491).

There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease have been reported with pelvic irradiation and the VAC chemotherapy regimen (3,397).

**Prognosis**

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (3,492). Most fatalities occur in the presence of poorly differentiated lesions.

---

**Uncommon Ovarian Cancers**

There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipoid (or lipid) cell tumors and the primary ovarian sarcomas.

---

**Lipoid Cell Tumors**

Lipoid cell tumors are believed to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases have been reported, and bilateral disease has been noted in only a few (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance reflecting corticosteroid secretion. Rare cases of estrogen secretion and isosexual precocity have been reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, are associated with metastatic lesions. Metastases are usually in the peritoneal cavity but rarely occur at distant sites. The primary treatment is surgical extirpation of the primary lesion. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

---

**Sarcomas**

Malignant mixed mesodermal sarcomas of the ovary are extremely rare; only about 100 cases have been reported. Most lesions are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian malignancies. These lesions are biologically aggressive, and most patients have evidence of metastases.

There is no effective treatment for ovarian sarcomas, and most patients die within 2 years. Doxorubicin, with or without cyclophosphamide, has produced an occasional partial response, and cisplatin is currently undergoing clinical trials (493–497). For patients in whom all macroscopic disease can be resected, we have observed disease-free survival of more than 3 years in two patients treated with six cycles of cisplatin and epirubicin.
Small Cell Carcinomas

This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (498). The tumors are all bilateral. Approximately two thirds of the tumors are accompanied by paraendocrine hypercalcemia. This tumor accounts for one half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (498).

The management of these malignancies consists of surgery followed by platinum-based chemotherapy or radiation therapy or both. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or calcitonin. The prognosis tends to be poor, with most patients dying within 2 years of diagnosis in spite of treatment.

Metastatic Tumors

About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (499–515). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous or lymphatic spread, or by transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic

Nonovarian cancers of the genital tract can spread by direct extension or they may metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases (2,3), usually by direct extension. Under some circumstances, it is difficult to know whether the tumor originated in the tube or in the ovary when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Although adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in as many as 5% of cases, two synchronous primary tumors probably occur with greater frequency (514). In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.

Nongynecologic

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 35.21). In autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral (499–504). Similarly, when ovaries are removed to palliate advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, either ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.

Krukenberg Tumor

The Krukenberg tumor, which can account for 30% to 40% of metastatic cancers to the ovaries, arises in the ovarian stroma and has characteristic mucin-filled, signet-ring cells (505–507) (Fig. 35.22). The primary tumor is most frequently located in the stomach and less commonly in the colon, breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers at some institutions, and they are usually bilateral. The lesions are usually not discovered until the primary disease is advanced and, therefore, most
Figure 35.21  Metastatic carcinoma in the ovary. Note the “Indian file” pattern found in this metastatic breast carcinoma.

Figure 35.22  Krukenberg tumor of the ovary metastatic from a gastric carcinoma. Malignant cells have discrete vacuoles that push nuclei eccentrically, giving a signet-ring appearance. Mucicarmine stain demonstrates the cytoplasmic vacuoles to be mucin.
patients die of their disease within 1 year. In some cases, a primary tumor is never found.

**Other Gastrointestinal Tumors**

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the small intestine. As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease (501). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema is indicated to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, particularly if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically (500,501), and the histological distinction between the two can be difficult (508–512). Lesions that arise in the appendix may be associated with ovarian metastasis and have frequently been confused with primary ovarian malignancies, especially when associated with pseudomyxoma peritonei (508,512). Therefore, it is reasonable to consider the performance of prophylactic bilateral salpingo-oophorectomy at the time of surgery for women with colon cancer (513).

**Melanoma**

Rare cases of malignant melanoma metastatic to the ovaries have been reported (515). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion. Malignant melanoma can arise rarely in a mature cystic teratoma (516).

**Carcinoid Tumors**

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (517). Conversely, only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the time of discovery of the metastatic carcinoid. However, in perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. Furthermore, the discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion (518).

**Lymphoma and Leukemia**

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (519–521). About 5% of patients with Hodgkin disease will have lymphomatous involvement of the ovaries, but this involvement occurs typically with advanced-stage disease. With Burkitt’s lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries much less frequently, and leukemic infiltration of the ovaries is uncommon (521). Sometimes the ovaries can be the only apparent site of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist-oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. In general, most lymphomas no longer require extensive surgical staging, although biopsy of enlarged lymph nodes should generally be performed. In some cases of Hodgkin disease, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia in general. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.

**Fallopian Tube Cancer**

Carcinoma of the fallopian tube accounts for 0.3% of all cancers of the female genital tract (2,3,522–528). In histologic features and behavior, fallopian tube carcinoma is
similar to ovarian cancer; thus, the evaluation and treatment are also essentially the same (Fig. 35.23). The fallopian tubes are frequently involved secondarily from other primary sites, most often the ovaries, endometrium, gastrointestinal tract, or breast. They may also be involved in primary peritoneal carcinomatosis. Almost all cancers are of epithelial origin, most frequently of serous histology. Rarely, sarcomas have also been reported.

Clinical Features

Tubal cancers are seen most frequently in the fifth and sixth decades, with a mean age of 55 to 60 years (522). Women who have germline mutations in BRCA1 and BRCA2 are at substantially higher risk for developing fallopian tube carcinoma; therefore, prophylactic surgery in these women should include a complete removal of both tubes along with the ovaries (66,529).

Symptoms and Signs

The classic triad of symptoms and signs associated with fallopian tube cancer is (i) a prominent watery vaginal discharge (i.e., hydrops tubae profluens), (ii) pelvic pain, and (iii) a pelvic mass. However, this triad is noted in fewer than 15% of patients (3).

Vaginal discharge or bleeding is the most common symptom reported by patients with tubal carcinoma and is documented in more than 50% of patients (3,523). Lower abdominal or pelvic pressure and pain also are noted in many patients. However, the symptoms may be rather vague and nonspecific. For perimenopausal and postmenopausal women with unusual, unexplained, or persistent vaginal discharge, even in the absence of bleeding, the clinician should be concerned about the possibility of occult tubal cancer.
Fallopian tube cancer is often found incidentally in asymptomatic women at the time of abdominal hysterectomy and bilateral salpingo-oophorectomy.

On examination, a pelvic mass is present in about 60% of patients, and ascites may be present if advanced disease exists. For patients with tubal carcinoma, the results of dilation and curettage will be negative, although abnormal or adenocarcinomatous cells may be seen in cytologic specimens obtained from the cervix in 10% of patients.

Spread Pattern
Tubal cancers spread in much the same manner as epithelial ovarian malignancies, principally by the transcoelomic exfoliation of cells that implant throughout the peritoneal cavity. In about 80% of the patients with advanced disease, metastases are confined to the peritoneal cavity at the time of diagnosis.

The fallopian tube is richly permeated with lymphatic channels, and spread to the para-aortic and pelvic lymph nodes is common. Metastases to the para-aortic lymph nodes have been documented in at least 33% of the patients with all stages of disease.

Staging
Fallopian tube cancer is staged according to FIGO. The staging is based on the surgical findings at laparotomy (Table 35.9). According to this system, about 20% to 25% of patients have stage I disease, 20% to 25% have stage II disease, 40% to 50% have stage III disease, and 5% to 10% have stage IV disease. A somewhat lower incidence of advanced disease is seen in these patients than in patients with epithelial ovarian carcinomas, presumably because of the earlier occurrence of symptoms, particularly vaginal bleeding or unusual vaginal discharge. Findings on transvaginal ultrasonography and CT scan may be suspicious for tubal carcinomas.

Treatment
The treatment of this disease is the same as that of epithelial ovarian cancer. Exploratory laparotomy is necessary to remove the primary tumor, to stage the disease, and to resect metastases. After surgery, the most frequently employed treatment is carboplatin and paclitaxel chemotherapy.

Surgery
Patients with tubal carcinoma should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy. If there is no evidence of gross tumor spread, a staging operation is performed. The retroperitoneal lymph nodes should be adequately evaluated, and peritoneal cytologic studies and biopsies should be performed, along with an infracolic omentectomy.

In patients with metastatic disease, an effort should be made to remove as much tumor bulk as possible. The role of cytoreductive surgery in this disease is unclear, but extrapolation from the experience with epithelial ovarian cancer indicates that significant benefit might be expected, particularly if all macroscopic disease can be resected.

Chemotherapy
As with epithelial ovarian cancer, the most active agents are platinum and the taxanes. Experience with cisplatin and paclitaxel indicates that complete responses can be obtained. Therefore, the recommended treatment for fallopian tube cancer is the same as that for epithelial ovarian cancer, i.e., platinum and taxane-based chemotherapy. A variety of other chemotherapeutic agents that are effective against recurrent ovarian cancer appear to be active in recurrent or persistent fallopian tube carcinomas. These agents include docetaxel, etoposide, topotecan, gemcitabine and liposomally...
### Radiation Therapy

Although most patients with tubal cancers have been treated with radiation therapy in the past, its role in the management of the disease is limited because of the more recent data with chemotherapy (532–537). An alternative is whole-abdominal irradiation, which has been used in patients with no evidence of gross disease in the abdomen (i.e., completely resected disease or microscopic metastases only) (3,522). Pelvic irradiation alone was once popular, but this approach should be abandoned because this disease tends to spread to the upper abdomen (523).

### Prognosis

The overall 5-year survival for patients with epithelial tubal carcinomas is about 40%. This number is higher than for patients with ovarian cancer and reflects the

</tbody>
</table>

*The staging system does not distinguish between microscopic foci or replacement of tubal epithelium by malignant epithelium and grossly evident masses in the tubal lumen that do not penetrate the wall beyond the epithelium. The former have not been reported to spread beyond the tube, whereas the latter can extend beyond the tube, recur, and be fatal.

*The mucosa presumably refers to the epithelium because involvement of the lamina propria component of the mucosa requires staging of the tumor as la.

*Because the fallopian tube has no submucosa, this designation presumably refers to the lamina propria.

*encapsulated doxorubicin* (533–537). As data on well-staged lesions are scarce, it is unclear whether patients with disease confined to the fallopian tube (i.e., a stage Ia, grade 1 or 2 carcinoma) benefit from additional therapy.
somewhat higher proportion of patients diagnosed with early-stage disease. The outlook is clearly related to the stage of disease, but the available data relate to patients who have not been surgically staged. Thus, the reported 5-year survival rate for patients with stage I disease is only about 65%. The 5-year survival rate for patients with stage II disease is 50% to 60%, but it is only 10% to 20% for patients with stages III and IV disease (522,527).

Tubal Sarcomas

Tubal sarcomas, particularly malignant mixed mesodermal tumors, have been described but are rare. They occur mainly in the sixth decade and are typically advanced at the time of diagnosis. If all gross disease can be resected, platinum-based combination chemotherapy should be tried. However, survival is generally poor, and most patients die of their disease within 2 years (2,492).

CHAPTER 35  Ovarian and Fallopian Tube Cancer

Vulvar Cancer

Christine H. Holschneider
Jonathan S. Berek

- Vulvar lesions require biopsy to avoid delay in diagnosis.
- The modern approach to patients with vulvar cancer is individualized.
- Management of the primary lesion and groin nodes is determined separately.
- Most T1, T2, and early T3 lesions can be managed with radical local excision.
- Large T3 and T4 primary tumors are best treated with chemoradiation followed by more limited surgical resection.
- If groin dissection is indicated, it should be a thorough inguinofemoral lymphadenectomy.
- The single most important prognostic factor is lymph node status: 5-year survival with no groin node metastases is greater than 90%; with groin node metastases, it is 50%.
- Recurrence in the groin is almost universally fatal.

With 3,740 new cases and 880 deaths annually in the United States (1), vulvar cancer is uncommon, representing 3% to 5% of malignancies of the female genital tract. Squamous cell carcinomas account for about 90% of all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell carcinomas, and sarcomas are much less common. The incidence of \textit{in situ} vulvar cancer nearly doubled between the mid-1970s and the mid-1990s, whereas the overall rate of invasive squamous cell carcinoma has remained relatively stable (2,3). However, in women younger than 50 years, there has been a striking increase in the incidence of not only \textit{in situ} but also invasive squamous cell carcinoma of the vulva (4).

Following the reports of Taussig (5) in the United States and Way (6) in Great Britain, radical vulvectomy and \textit{en bloc} groin dissection, with or without pelvic lymphadenectomy, has been considered standard treatment for all patients who have operable disease. Postoperative morbidity was high and prolonged hospitalization common. During the
past 20 years, a number of significant advances have been made in the management of vulvar cancer, reflecting a paradigm shift toward a more conservative surgical approach without compromised survival and with markedly decreased physical and psychological morbidity:

1. Individualization of treatment for all patients with invasive disease (7,8)

2. Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva (7–11)

3. Omission of the groin dissection for patients with T1 tumors and <1 mm of stromal invasion (7,8)

4. Elimination of routine pelvic lymphadenectomy (12–16)

5. The use of separate incisions for the groin dissection to improve wound healing (17,18)

6. Omission of the contralateral groin dissection in patients with lateral T1 lesions and negative ipsilateral nodes (8,19)

7. The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease (20,21)

8. The use of postoperative radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes (16)

**Etiology**

The etiology of vulvar cancer has been only partially elucidated and is likely to be multifactorial. Based on histopathologic and environmental factors, there appear to be at least two distinct etiologic entities of squamous cell carcinoma of the vulva.

1. **Basaloid or warty types,** which tend to be multifocal, occur generally in younger patients and are related to human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), and cigarette smoking.

2. **Keratinizing types,** which tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus and squamous hyperplasia.

High-grade vulvar intraepithelial neoplasia (VIN 3) has been most closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but a recent review of 3,322 published patients with VIN 3, reports a 9% progression rate to cancer for untreated cases (22). Ten percent to 20% of vulvar carcinoma in situ lesions harbor an occult invasive component (23,24), and VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases. DNA of HPV has been documented in 89% of patients with VIN 3 and in up to 86% of warty or basaloid type carcinomas of the vulva, but it occurs in less than 10% of the keratinizing type of carcinomas of the vulva (25). **Epidemiologic risk factors for the basaloid or warty type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking** (25,26). Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch–scratch cycle associated with lichen sclerosus and squamous hyperplasia,
with atypical changes occurring in the repaired epithelium. In keratinizing carcinoma, associated lichen sclerosus or squamous hyperplasia is found in more than 80% of patients (27,28), yet their causative role remains controversial. Supportive evidence that some of these lesions could be precancerous comes from molecular studies that demonstrate aneuploid DNA content, p53 overexpression, and monoclonal expansion of keratinocytes in lichen sclerosus and associated squamous hyperplasia (29,30). In the past, some studies have reported vulvar cancer to be more common in patients who are obese, have hypertension and diabetes mellitus, or are nulliparous (31,32), but a more recent case-control study of vulvar cancer was unable to confirm any of these as risk factors (26).

Types of Invasive Vulvar Cancer

The varieties of invasive vulvar cancer are shown in Table 36.1.

</table>

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. As discussed previously, squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as basaloid carcinoma, warty carcinoma, and keratinizing squamous carcinoma (27). Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer (33). Most vulvar squamous carcinomas reveal keratinization (Fig. 36.1). Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph–vascular space invasion, tumor thickness, depth of stromal invasion, histologic pattern of invasion (spray and stellate versus broad and pushing), and increased amount of keratin (34–37).

Microinvasive squamous carcinoma of the vulva has been defined as a lesion ≤2 cm in diameter with ≤1 mm stromal invasion (38). Depth of stromal invasion is measured vertically from the epithelial–stromal junction (basement membrane) of the most superficial dermal papilla to the deepest point of tumor invasion (Fig. 36.2). When the tumor invades ≤1 mm, metastasis to the inguinal lymph nodes is extremely rare among reported series. However, when invasion is >1 mm, there is a significant risk of inguinal lymph node metastasis.

Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women; the mean age at diagnosis is about 65 years. However, 15% of patients who
Figure 36.1  **Squamous cell carcinoma of the vulva, keratinizing type.** The multiple pearl formations consist of laminated keratin.

Figure 36.2  **Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia.** An irregular nest of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells.
develop vulvar cancer do so before age 40. There may be a long-standing history of an associated vulvar intraepithelial disorder, such as lichen sclerosus, squamous hyperplasia, or VIN. As many as 27% of patients with vulvar cancer are reported to have a second primary malignancy (39–41). Based on data from the National Cancer Institute’s Surveillance Epidemiology and End Results (SEER) program, patients with invasive vulvar cancer have an increased risk of 1.3 for developing a subsequent cancer. **Most of the excess second cancers were smoking related** (e.g., cancers of the lung, buccal cavity and pharynx, esophagus, nasal cavity, and larynx) or related to infection with human papillomavirus (e.g., cervix, vulva, vagina, and anus) (42).

**Most patients are asymptomatic at the time of diagnosis.** If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin may be the initial symptom.

A **careful inspection of the vulva should be part of every gynecologic examination.** On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, leukoplakic, or warty in appearance. It may be pigmented, red or white, and tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN or vulvar dystrophies (24). Thus, any lesion of the vulva warrants a biopsy.

**Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) also may be primary sites.** Approximately 10% of the cases are too extensive to determine a site of origin, and about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it is unifocal or multifocal, should be performed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix, and **colposcopy of the cervix and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.**

**Diagnosis**

Diagnosis requires a wedge biopsy specimen, which usually can be obtained in the office using local anesthesia. If the lesion is only about 1 cm in diameter, excisional biopsy is preferable. The biopsy should include sufficient underlying dermis to assess for microinvasion.

Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any confluent warty lesion requires biopsy before medical or ablative therapy is initiated.

**Routes of Spread**

Vulvar cancer spreads by the following routes:

1. **Direct extension** to involve adjacent structures such as the vagina, urethra, and anus
2. **Lymphatic embolization** to the regional inguinal and femoral lymph nodes
3. **Hematogenous spread** to distant sites, including the lungs, liver, and bone

Lymphatic metastases may occur early in the disease. Twelve percent of T1 tumors **have regional metastases** (39,43). Initially, spread is usually to the inguinal lymph nodes, which are located between Camper’s fascia and the fascia lata (9). From these superficial groin nodes, the disease will spread to the deep femoral nodes, which are located medially...
along the femoral vessels (Fig. 36.3). Cloquet’s or Rosenmüller’s node, situated beneath the inguinal ligament, is the most cephalad of the femoral node group. Metastases to the femoral nodes without involvement of the inguinal nodes have been reported (44–47). A recent study from the MD Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer who at initial surgery had negative nodes on superficial inguinal lymphadenectomy (48), and intraoperative lymphatic mapping studies have found the sentinel node to be deep to the cribriform fascia in 5% of cases (49).

From the inguinal-femoral nodes, the cancer spreads to the pelvic nodes, particularly the external iliac group. Although direct lymphatic pathways from the clitoris and Bartholin gland to the pelvic nodes have been described, these channels seem to be of minimal clinical significance (12,50,51). The lymphatics of the vulva from either side form a rich network of anastomoses along the midline. Lymphatic drainage from the clitoris, anterior labia minora, and perineum is bilateral. For lateral vulvar tumors, metastases to contralateral lymph nodes in the absence of ipsilateral nodal involvement is rare (0.4% for T1 tumors) (43).

The overall incidence of inguinal-femoral lymph node metastases is reported to be about 30% (10,11,47,49,50–54) (Table 36.2). Metastases to pelvic nodes occur in about 12% of cases. Pelvic nodal metastases are rare (0.6%) in the absence of groin node involvement, but they occur on average in about 16% of cases with positive groin nodes (see Table 36.2). The risk increases to 33% in the presence of clinically suspicious groin nodes (13) and to about 50% if there are three or more pathologically positive inguinal-femoral nodes (13,16,40). The incidence of lymph node metastases in relation to depth of invasion is shown in Table 36.3. Hematogenous spread usually occurs late in the course of vulvar cancer and is rare in the absence of lymph node metastases.

**Staging**

Previously, vulvar carcinoma was staged clinically based on tumor size and location, palpable regional lymph node status, and a limited search for distant metastases. The prognostic
importance of the lymph node status is significant, yet the accuracy of the clinical assessment of the lymph nodes is limited. Microscopic metastases may be present in nodes that are not clinically suspicious, and suspicious nodes may be enlarged because of inflammation only. When compared with surgical staging, the percentage of error in clinical staging increases from 18% for stage I disease to 44% for stage IV disease (40).

These factors led the Cancer Committee of the International Federation of Gynecology and Obstetrics (FIGO) in 1988 to introduce a surgical staging system for vulvar cancer, which was revised in 1995 to separate T1 lesions invasive to 1 mm or less as stage Ia (Table 36.4). This surgical staging system offers much improvement over the previous clinical staging system, but there remains need for further refinements. One major problem is that stage III represents a very heterogeneous group of patients. It includes patients ranging from those

multiple positive groin nodes, who have a very poor prognosis.

**Prognosis and Survival**

Survival of patients with vulvar cancer correlates with FIGO stage. The prognosis for patients
with early-stage disease is generally very good (Table 36.5). The single most important prognostic factor is lymph node status (55–60). A recent report from the Mayo Clinic on 330 patients with primary squamous cell carcinoma of the vulva demonstrated a significant correlation between lymph node status and risk of treatment failure, especially in the first 2 years after initial therapy: 44.2% overall recurrence rate with positive versus 17.5% with negative lymph nodes. Interestingly, more than one third of relapses presented 5 years or more after initial therapy (61). Patients with negative lymph nodes have a 5-year survival rate of approximately 90%, which falls to approximately 50% for patients with positive nodes (62). The number of positive nodes is of critical importance: Patients with one microscopically positive lymph node have a prognosis similar to those with negative lymph nodes, whereas patients with three or more positive nodes have a poor prognosis with a two-year survival rate of 20% (63). The survival

<sup>a</sup>TNM Classification:

**T**: Primary tumor

- Tx: Primary tumor cannot be assessed
- Tis: Carcinoma in situ (preinvasive carcinoma)
- T<sub>1</sub>: Tumor confined to the vulva and/or perineum, ≤2 cm in greatest dimension
- T<sub>2</sub>: Tumor confined to the vulva and/or perineum, >2 cm in greatest dimension
- T<sub>3</sub>: Tumor invades any of the following: lower urethra, vagina, anus, bladder mucosa, rectal mucosa, pelvic bone

**N**: Regional lymph nodes

- N<sub>0</sub>: No lymph node metastases
- N<sub>1</sub>: Unilateral regional lymph node metastases
- N<sub>2</sub>: Bilateral regional lymph node metastases

**M**: Distant metastases

- Mx: Presence of distant metastases cannot be assessed
- M<sub>0</sub>: No distant metastases
- M<sub>1</sub>: Distant metastases (including pelvic lymph node metastases)

---

<sup>b</sup>The depth of stromal invasion is measured from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

rate for patients with positive pelvic nodes is about 11% (64). Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (63). Tumor ploidy is another important prognostic factor. Data from the Norwegian Radium Hospital (65) demonstrate a 5-year crude survival rate of 62% for diploid and 23% for the aneuploid tumors (\(p < 0.001\)). In a multivariate Cox regression analysis, tumor ploidy was the second most important prognostic factor after lymph node status.

### Treatment

After the pioneering work of Taussig (5) in the United States and Way (6) in Great Britain, en bloc radical vulvectomy and bilateral dissection of the groin and pelvic nodes became the standard treatment for most patients with operable vulvar cancer. If the disease involved the anus, rectovaginal septum, or proximal urethra, some type of pelvic exenteration was combined with the dissection.

Although the survival rate improved markedly with this aggressive surgical approach, several factors have led to modifications of this treatment plan during the past 30 years. These factors are summarized as follows:

1. An increasing proportion of patients with early-stage disease—up to 50% of patients in many centers—have T1 tumors.
2. There were concerns about the postoperative morbidity and associated long-term hospitalization common with the en bloc radical dissection.
3. Increasing awareness has emerged of the psychosexual consequences of radical vulvectomy.

To individualize the patient’s care and determine the appropriate therapy, it is necessary to determine independently the primary lesion as well as groin lymph nodes. Before initiation of therapy, all patients should undergo colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract.

### Management of the Primary Lesion

**Early Vulvar Cancer (T1)** The modern approach to the management of patients with T1 carcinoma of the vulva should be individualized (7,8). There is no standard approach applicable to every patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease. Radical vulvectomy has in
the past been considered the standard treatment for primary vulvar lesions, but this operation is associated with significant surgical morbidity and disturbances of sexual function and body image. Psychosexual sequelae are a major long-term morbidity associated with the treatment of vulvar cancer (9). One study reported that sexual arousal was reduced to the eighth percentile and body image was reduced to the fourth percentile for women who had undergone vulvectomy when compared with healthy adult women (66).

Traditionally, there has been concern that without an en bloc resection, intervening tissue left between the primary tumor and the regional lymph nodes may contain microscopic tumor foci in draining lymphatics. However, experience with a separate incision technique for node dissection has confirmed that metastases rarely occur in the skin bridge in patients without clinically suspicious nodes in the groin (18).

During the past 20 years, several investigators have advocated a radical local excision rather than a radical vulvectomy for the primary lesion for patients with T1 tumors (7–10). Regardless of whether a radical vulvectomy or a radical local excision is performed, the surgical margins adjacent to the tumor will be the same. An analysis of the available literature indicates that the incidence of local invasive recurrence after radical local excision is not higher than that after radical vulvectomy (10,43,64,67). This finding suggests that in the presence of an otherwise normal-appearing vulva, radical local excision is a safe surgical option, regardless of the depth of invasion.

A review of 135 patients with all stages of disease assessed the surgical margin that must be obtained to prevent local disease recurrence. In this study, a 1-cm tumor-free surgical margin on the vulvar specimen (0.8-cm on pathologic specimen) resulted in a very high rate of local control (68). Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by about 25%. Thus, at the time of radical local excision, at least a 1-cm grossly negative margin, which should extend down to the level of the inferior fascia of the urogenital diaphragm, should be obtained. For stage Ia lesions, lesser forms of vulvar excision, such as wide local excision, are as effective as radical surgery for the prevention of vulvar recurrences (69).

When vulvar cancer arises in the presence of VIN or some nonneoplastic epithelial disorder, treatment will be influenced by the patient’s age. Elderly patients who often have had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it will be desirable to conserve as much of the vulva as possible. Thus, radical local excision should be performed for the invasive disease, and the associated intraepithelial disease should be treated in the manner most appropriate to the patient. For example, topical steroids may be required for lichen sclerosus or squamous hyperplasia, whereas VIN may require superficial local excision and primary closure.

Radical local excision is most appropriate for lesions on the lateral or posterior aspects of the vulva (Fig. 36.4). Midline lesions pose special challenges because of their proximity to clitoris, urethra, or anus. For anterior lesions, conservative clitoris-sparing surgery allows for excellent local control as long as pathological margins are at least 8 mm (70). For tumors that involve the clitoris or that are in close proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with periclitoral lesions, the primary lesion can be treated with a small field of radiation therapy, possibly with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be performed after therapy to confirm the absence of any residual disease (62).
In recent years, the indications for vulvar conservation have been extended to selected patients with T2 and early T3 tumors. Although the reported experience is limited (10,11,71), a recent study suggests that the local recurrence rate for patients with conservatively treated T2 tumors is identical to that for patients with T1 tumors (72) as long as surgical margins of at least 1 cm are obtained. The tumor-free margin should be the same, whether or not a radical vulvectomy or a radical local excision is performed, so it would seem to be both feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. Tumors that are most suitable to a more conservative resection are those involving the posterior half of the vulva, where preservation of the clitoris and mons pubis is feasible.

For patients with more advanced T2 and T3 lesions, management consists of radical vulvectomy and bilateral inguinal-femoral lymphadenectomy or chemoradiation therapy, as discussed below. If the disease involves the distal urethra, vagina, or anus, partial resection...
of these organs would be required. Alternatively, it is often preferable to give preoperative
radiation therapy with chemosensitization to allow for a less radical resection (see below).

**Closure of Large Defects**

After radical local excision, primary closure without tension often can be accomplished for smaller defects. However, if a more extensive dissection has been required to treat a large primary lesion, a number of options are available to repair the defect.

1. An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (73).

2. Full-thickness skin flaps may be devised (74–77). The rhomboid flap is best suited to covering large defects of the posterior vulva (77), whereas for lateral defects, a mons pubis pedicle flap has been advocated (74).

3. Myocutaneous flaps may be developed to cover the defect. Unilateral or bilateral gracilis myocutaneous grafts are most useful when an extensive area from the mons pubis to the perianal area has been resected. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (78).

4. If extensive defects exist in the groin and vulva, the tensor fascia lata myocutaneous graft may be the most applicable (79).

---

**Advanced Disease:**

Large T₃ and T₄ Primary Tumors

To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration would be needed in addition to radical vulvectomy and inguinal-femoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (66,80). Reported 5-year survival rates are about 50% (81–84). For many of these patients, a combined approach of surgery and radiation therapy offers improved survival and reduced morbidity and thus becomes the preferred treatment approach. Numerous small prospective and retrospective series report on the use of external beam radiation, often with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation approximate 90% (85–88).

It is important that this chemoradiation is followed by a more limited resection of the tumor bed and lymphadenectomy on an individualized basis. About one half of the specimens will contain residual tumor (21,89), and local relapse rates are as high as 50% to 79% with external radiation alone (with or without concomitant chemotherapy) (90,91), emphasizing the need for a combined approach that involves radiation and surgery.

As experience with this combination therapy has evolved, it appears that external beam therapy is generally appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery has also been significantly modified. A more limited vulvar resection is now advocated, and bulky N₂ and N₃ nodes are resected without full groin lymphadenectomy to avoid the leg edema associated with groin lymphadenectomy and radiation. With this combined radiation-surgical approach, 5-year survival rates as high as 76% have been reported (89). With the experience now accrued, preoperative radiation, with or without concurrent chemotherapy, should be regarded as the treatment of first choice for patients with advanced vulvar cancer who would otherwise require some type of pelvic exenteration.

**Management of the Lymph Nodes**

Groin dissection is associated with postoperative wound infection and breakdown, as well as chronic leg edema. Although the incidence of wound breakdown is reduced significantly
when separate incisions are used for the groin dissection (Fig. 36.5) (18), chronic leg edema remains a major problem. When assessing a patient for groin dissection, the following three facts should be kept in mind:

1. The only patients with virtually no risk of lymph node metastases are those whose tumor invades the stroma to $< 1$ mm.

2. Patients who develop recurrent disease in an undissected groin have a $> 90\%$ mortality (92).

3. Based on the laterality of the vulvar lesions, an ipsilateral or bilateral lymphadenectomy becomes necessary.

Appropriate groin dissection is the single most important factor in decreasing the mortality for early vulvar cancer.

**Microinvasive Carcinoma** All patients whose tumors demonstrate more than 1 mm of stromal invasion require inguinal-femoral lymphadenectomy. A wedge biopsy specimen of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If there is still no invasive focus larger than 1 mm, groin dissection may be omitted provided there is no lymph–vascular space invasion and there are no clinically suspicious groin lymph nodes. Although an occasional patient with less than 1 mm of stromal invasion has had documented groin node metastases (93), the incidence is so low that it is of no practical significance.
Inguinal-femoral Lymphadenectomy  If groin dissection is indicated in patients with early vulvar cancer, it should be a thorough inguinal-femoral lymphadenectomy. The GOG reported six groin recurrences among 121 patients with T1 N0 tumors after a superficial (inguinal) dissection, even though the removed inguinal nodes were negative (47), and a recent study from the MD Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer and negative nodes on superficial inguinal lymphadenectomy (48). Whether all of these recurrences were in the femoral nodes is unclear, but both studies indicate that an incomplete groin dissection will increase the number of groin recurrences and, therefore, mortality. Furthermore, GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes (94). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% versus 0%). The dose of radiation was 5,000 cGy given in daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen prescribed has been criticized extensively, the therapeutic effects of an alternative radiation regimen remain to be determined.

Unilateral Versus Bilateral Groin Dissection  It is clear that it is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative. In a patient with unilateral T1 lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is 0.4% (43). However, there is an increase in the risk of contralateral nodal involvement proportional to the number of positive ipsilateral inguinal nodes (16). Thus, it is recommended that patients with any bulky or multiple microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinal-femoral lymphadenectomy as well. Bilateral inguinal-femoral lymphadenectomy should be performed for midline lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline because of the more frequent contralateral lymph flow from these regions (95).

Management of Pelvic Lymph Nodes  In the past, pelvic lymphadenectomy has been considered part of the routine surgery for invasive vulvar cancer. However, the incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement (see Table 36.2), thus a more selective approach is preferred. Patients most prone to pelvic lymph node metastasis are those with clinically suspicious or three or more pathologically positive groin nodes (12,13,15,40). In these patients, the pelvis requires treatment by pelvic lymphadenectomy or radiation. If a preoperative pelvic imaging study reveals enlarged pelvic lymph nodes, resection of these nodes should be performed via an extraperitoneal approach because of the inability of external beam radiation therapy to sterilize bulky positive pelvic nodes.

Sentinel Lymph Node Studies  A number of investigators have explored the use of intraoperative lymphatic mapping using lymphoscintigraphy with technetium-99m-labeled nanocolloid or isosulfan blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases (49,96–98). A recent systematic review of 29 mostly small studies published to date of 961 groins found lymphoscintigraphy to be the most accurate technique with a pooled sensitivity and negative likelihood ratio of 97% and 0.12, respectively (99). These preliminary studies suggest that a sentinel node can be identified in most patients (100). The sensitivity of the sentinel node assessment may be further enhanced by ultrastaging using serial sectioning or immunohistochemistry to detect micrometastases (101–103). Reliable identification of the sentinel node and foregoing a full lymphadenectomy in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node may significantly reduce the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. Intraoperative lymphatic mapping and sentinel node identification is currently being evaluated by the Gynecologic Oncology Group in a large multi-institutional...
study (GOG 173), and the European Organization for Research and Treatment of Cancer is performing an intergroup randomized controlled trial of sentinel node versus full inguinofemoral lymphadenectomy (EORTC 55001). Until these trials document the accuracy of the negative predictive value of an uninvolved sentinel node, complete inguinal-femoral lymphadenectomy remains indicated in all but stage Ia disease, given the high mortality of recurrence in an undisseected groin.

Postoperative Management

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bed rest had been advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and foster healing. Because radical local excisions are being performed with increasing frequency and groin lymphadenectomy are done through separate incisions, patients generally begin ambulation on postoperative day 1 or 2. Pneumatic calf compression or subcutaneous heparin should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Meticulous perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed once the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz baths or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

Early Postoperative Complications

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication has been reported in as many as 53% to 85% of patients having an en bloc operation (39,40). With the separate-incision approach, the incidence of wound breakdown can be reduced to about 44%; major breakdown occurs in about 14% of patients (18,41,104). With appropriate antibiotics, debridement, and wound dressings, the area will granulate and re-epithelialize over the next several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage, and, rarely, osteitis pubis. Lymphocysts or groin seromas occur in about 10% to 15% of cases and should be managed by periodic sterile aspiration. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

Late Complications

One major late complication is chronic lymphedema, which occurs on average in about 30% of patients (39–41,104,105). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Introtial stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which usually can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper’s ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.
Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction (66,80). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological trauma.

Role of Radiation Therapy

Radiation therapy traditionally has been considered to have a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance has improved significantly. Thus, radiation therapy, frequently with concurrent chemotherapy, is gaining an increasingly important role in the management of patients with vulvar cancer. It is important to remember, though, that with a rare exception, radiation therapy alone has little place in the primary management of vulvar cancer. It is generally indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are still evolving. At present, radiation seems to be clearly indicated in the following situations:

1. Preoperatively, in patients with advanced disease who would otherwise require pelvic exenteration (20,21) or suffer loss of anal or urethral sphincteric function

2. Postoperatively, to treat the pelvic lymph nodes and groin of patients with two or more microscopically positive or one grossly positive groin node (16)

Possible roles for radiation therapy include the following:

1. Postoperatively, to help prevent local recurrences in patients with involved or close surgical margins (106–108)

2. As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences (62)

No additional treatment is recommended if one microscopically positive groin node is found. The prognosis for this group of patients is excellent (13), and only careful observation is required. Even if an unilateral groin dissection has been performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases (13,16).

If clinically evident groin metastases or two or more microscopically positive groin nodes are found, which is unusual in patients with T1 vulvar cancer, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation. In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic node dissection plus groin irradiation (16). Radiation therapy consisted of 4,500 to 5,000 cGy to the midplane of the pelvis at a rate of 180 to 200 cGy per day. The survival rate for the radiation group (68% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) (p = 0.03). The survival advantage was limited to patients with clinically evident groin nodes or more than one microscopically positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy (p = 0.02). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data indicate no benefit from
pelvic irradiation compared with pelvic lymphadenectomy for the prevention of pelvic recurrence, but they do highlight the value of prophylactic groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes.

Recurrent Vulvar Cancer

Approximately two thirds of recurrences of vulvar cancer occur within the first 2 years from initial therapy (109), with groin recurrences occurring sooner (median time to recurrence 6 months) than vulvar recurrences (median time to recurrence 3 years) (110).

Recurrence of vulvar cancer correlates most closely with the number of positive groin nodes (13). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a low incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences (13,16).

Local Recurrence Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins closer than 0.8 cm (68). Margin status does not, however, predict survival (60). Local vulvar recurrences are likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph–vascular space invasion is present (106,111) and in patients with deeply invasive tumors (112). When detected early, isolated local failure is usually salvageable by additional surgical therapy (10,18,41,47,113), often with a gracilis myocutaneous graft to cover the defect. Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, at times combined with chemotherapy, has also been used to treat vulvar recurrences (114). One study reported on 10 patients treated in this manner, nine of whom were still alive with a mean follow-up of 28 months (115). However, 6 of the 10 patients developed severe radionecrosis at a median of 8.5 months after radiation, and the authors concluded that although this treatment was highly effective, it also had a high degree of morbidity.

Regional and Distant Recurrence Regional and distant recurrences are difficult to manage and are associated with a poor prognosis (106,109,110). Radiation therapy may be used in conjunction with surgery for groin recurrence, whereas chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on the use of chemotherapy for recurrent vulvar cancer consists of mainly small series. The most extensively studied regimens contain bleomycin and methotrexate, with or without cisplatin or CCNU (a nitrosourea) and bleomycin and mitomycin C (116,117), but response rates are low and the duration of response is usually disappointing. Long-term survival is very uncommon with regional or distant recurrence.

Melanoma

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women (118,119). They account for 4% to 10% of all cases and are the second most common form of vulvar malignancy (38). Most melanomas arise de novo (120), but they may arise from a pre-existing junctional nevus. Vulvar melanomas occur predominantly in post-menopausal white women. The incidence of cutaneous melanomas worldwide is increasing significantly. Vulvar melanomas appear to behave in a manner similar to that of other cutaneous melanomas (121–123).

Most patients with vulvar melanoma have no symptoms except for a pigmented lesion that may be enlarging. Some patients have itching or bleeding, and a few have a groin mass. Vulvar melanomas occur most frequently on the labia minora or the clitoris (Fig. 36.6),
and extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junc- tional and may be precursor lesions to melanoma; thus, any nevus of the vulva should be removed.

**Histopathology**

There are three basic histologic types of vulvar melanoma (Fig. 36.7).

1. The **mucosal lentiginous melanoma** is a flat freckle that may become quite extensive but tends to remain superficial.

2. The **superficial spreading melanoma** tends to remain relatively superficial early in its development.

3. The **nodular melanoma**, which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.

In the largest series reported to date, more than one fourth of the cases of melanomas were macroscopically amelanotic (118). Vulvar melanoma tends to spread early, not only lymphatically but also hematogenously.

**Staging**

The FIGO staging used for squamous lesions is not applicable to melanomas because the lesions are usually much smaller and the prognosis is related to the depth of tumor invasion rather than to the diameter of the lesion (121,124,125). The leveling system established by Clark et al. (125) for cutaneous melanomas is less readily applicable to vulvar lesions because of the different skin morphology. The vulvar skin
lacks a well-defined papillary dermis. Breslow (126) measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion. This system is more adequate for the vulva. Chung et al. (124) proposed a modified system that retained Clark’s definitions for levels I and V but arbitrarily defined levels II, III, and IV, using measurements in millimeters. A comparison of these systems is shown in Table 36.6.

The revised 2002 American Joint Committee on Cancer (AJCC) staging for cutaneous melanoma replaced the Clark level of invasion by tumor thickness and included other important prognostic factors, such as primary tumor ulceration, number of metastatic lymph nodes, micrometastatic disease based on sentinel lymph node biopsy or elective node dissection, the site(s) of distant metastatic disease, and serum LDH levels (127).

Treatment

With better understanding of the prognostic significance of the microstage, some individualization of treatment has developed. However, treatment of vulvar melanoma continues to be controversial, in part because of the lack of large retrospective studies, which makes it difficult to draw conclusions regarding its behavior and best treatment. Currently used treatments are guided by experience from cutaneous melanoma in general and squamous cell carcinomas of the vulva. Paralleling the trend toward more conservative surgical management of cutaneous melanoma, there is a shift toward more conservative management of vulvar melanoma (122,123,128,129).

It is generally accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone (124,130). With more invasive lesions, en bloc resection of the primary tumor and regional groin nodes has traditionally been recommended. In the last 15 years, however, radical vulvectomy has been performed less frequently, and survival does not seem to be compromised (131). One study reported on 32 patients with vulvar melanoma who underwent local excision (n = 14), simple vulvectomy (n = 7), or radical resection (n = 11) (132). No group had a superior survival rate, although the overall survival rate at 5 years was only 25%. More recently, another study reported on 59 patients who underwent radical vulvectomy and 19 who underwent more conservative resections (122). Survival was not improved by the more radical approach, and they recommended radical local excision for the primary tumor, with groin dissection for tumors with a thickness of more than 1 mm. Current literature on cutaneous melanoma suggests that a 1-cm margin of skin and subcutaneous tissue is sufficient for the treatment of superficial localized melanoma (Breslow tumor thickness < 0.76 mm), whereas a 2-cm margin suffices for intermediate-thickness lesions (1 to 4 mm) (133,134). Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should be taken to obtain an adequate “inner” resection margin (135). A 10-year survival rate of 61% has been shown for lateral lesions, compared with 37% for medial lesions (p = 0.027) (111).

Controversy exists as to which patients may benefit from inguinal-femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk of inguinal-femoral lymph node metastasis correlated with the Breslow microstage (123). As with cutaneous melanoma, it appears that for superficial lesions (Breslow tumor thickness < 0.76 mm), the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically to be free of disease. For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations (136). Patients with deeply invasive cutaneous melanomas (> 4-mm tumor thickness) have a high risk of regional and systemic metastases and are unlikely to benefit from regional lymphadenectomy (137). Given some of the epidemiologic, histologic, and prognostic differences between vulvar and cutaneous melanoma (138), extrapolation of these data to the vulva should be done with caution. Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes (121,122).

Pelvic node metastases do not occur in the absence of groin node metastases (135,139,140). In addition, the prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease. Immunotherapy and chemotherapy have demonstrated modest results in cutaneous melanoma. Several randomized cooperative and intergroup trials of high-risk melanoma patients have demonstrated a small but significant improvement in disease-free and overall
survival with adjuvant interferon alpha (141–143). Dacarbazine (DTIC) is considered the most active single-agent chemotherapy with a response rate of 16%, and randomized controlled trials have failed to date to demonstrate superiority of any multiagent regimen (144). Targeted therapy is an area of promising development as single agents, in combination, and combined with chemotherapy. Vaccines stimulating both antibody and T-cell responses against melanoma are a promising but still considered experimental treatment that is under investigation (145). Radiation has a role in the palliative management of brain metastasis and symptomatic bony metastases. Estrogen receptors have been demonstrated in human melanomas, and an occasional response to tamoxifen has been reported (146,147).

**Prognosis**

The behavior of melanomas can be quite unpredictable, but the overall prognosis is poor. The reported 5-year survival rate for vulvar melanoma ranges from 25% (132) to 50% (118,119). Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens (Table 36.7). Tumor volume has been reported to correlate with prognosis; patients whose lesions have a volume less than 100 mm$^3$ have an excellent prognosis (140). Additional prognostic factors are the patient’s age, AJCC stage, presence of multifocal or satellite lesions, tumor ulceration, central tumor location, histologic growth pattern, lymph–vascular space involvement, and aneuploidy (118,121–123,149).

**Bartholin Gland Carcinoma**

**Epidemiology**

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (152). Because of its rarity, individual experience with the tumor is limited, and recommendations for management must be based on the review of small published series. To date, only about 300 cases have been reported (50,152,153). Bartholin gland carcinoma is 5 times more common in postmenopausal than in premenopausal women (154).

**Histopathology**

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the
gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas, and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas.

Classification of a vulvar tumor as a Bartholin gland carcinoma has typically required that it fulfill Honan’s criteria, which are as follows:

1. The tumor is in the correct anatomic position.
2. The tumor is located deep in the labium majus.
3. The overlying skin is intact.
4. There is some recognizable normal gland present.

Strict adherence to these criteria will result in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be diagnosed on the basis of their histologic characteristics and anatomic location.

**Signs and Symptoms**

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland, and malignancies may be mistaken for benign cysts or abscesses. Therefore, delay of diagnosis is common, particularly for premenopausal patients. The differential diagnosis of any pararectovaginal neoplasm should include cloacogenic carcinoma and secondary neoplasm.

**Treatment**

Traditionally, treatment has been radical vulvectomy with bilateral groin and pelvic node dissection. However, there seems to be no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results have been reported with hemivulvectomy or radical local excision for the primary tumor. Because these lesions are deep in the vulva, extensive dissection is required in the ischiorectal fossa; even then, surgical margins are often close. Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultraradical surgery.

**Prognosis**

Because of the deep location of the gland, disease tends to be more advanced than squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. Five-year disease-free survival rates by stage are summarized in Table 36.8.

**Adenoid Cystic Carcinoma of the Bartholin Gland**

The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (50,157) (Fig. 36.8). Local recurrences are common, however, and metastases may occur, particularly to the lungs. The slowly progressive nature of these tumors and the tendency for late
recurrences is reflected in the disparity between progression-free interval and survival curves (157).

### Other Adenocarcinomas

Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget disease. They may rarely arise from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (158).

---

**Figure 36.8** Adenoid cystic tumor of the Bartholin gland. Basaloid cells form cribriform, sievelike spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor.
Adenosquamous Carcinoma

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoacanthoma of the sweat gland of Lever. The tumor has a propensity for perineural invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (159). Treatment should be radical vulvectomy and bilateral groin dissection. Postoperative radiation therapy may be appropriate.

Basal Cell Carcinoma

Basal cell carcinomas represent about 2% of vulvar cancers. As with other basal cell carcinomas, vulvar lesions commonly appear as a “rodent ulcer” with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (160). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most frequently include pruritus, soreness, and irritation (161). It is diagnosed by biopsy, and radical local excision is generally adequate treatment (162). Metastasis to regional lymph nodes has been reported but is rare (163–165). The local recurrence rate is about 10% to 20% (161,166). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (161). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (161).

About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called basosquamous carcinoma. These lesions are more aggressive and should be treated as squamous carcinomas (165). Another subtype of basal cell carcinoma is the adenoid basal cell carcinoma, which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (165).

Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (167). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (168). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associated HPV-6 and HPV-11 have been found in some studies (169), whereas others find it to have no association with HPV infection (170). Some studies have found as many as one third of the cases to have coexisting squamous carcinoma of the vulva (171), underscoring the importance of careful histopathologic assessment of these tumors.

Grossly, the tumors have a cauliflowerlike appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata (Fig. 36.9). The gross and microscopic features of a verrucous carcinoma are very similar to those of the giant condyloma of Buschke-Loewenstein, and they probably represent the same disease entity (158). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

Verrucous carcinomas usually occur in postmenopausal women, and they are slow-growing but locally destructive lesions. Even bone may be invaded.
Metastasis to regional lymph nodes is rare but has been reported (172). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (173). If the nodes contain metastases, radical vulvectomy and bilateral inguinal-femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (173,174). In addition, there is concern that radiation may induce anaplastic transformation with subsequent regional and distant metastasis (175). One study reported a corrected 5-year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (173). The latter patients had, however, more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.

Vulvar Sarcoma

Sarcomas represent 1.5% of vulvar malignancies and constitute a heterogeneous group of tumors (176). Leiomyosarcomas are the most common, and other histologic
types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas.

**Leiomyosarcomas** usually appear as enlarging, often painful masses, usually in the labium majus. Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (i) diameter $>5$ cm, (ii) infiltrating margins, (iii) 5 or more mitotic figures per 10 high-power fields, (iv) moderate-to-severe cytological atypia (177). The absence of one, or even all, of these features does not guarantee against recurrence (178). Lymphatic metastases are uncommon, and radical local excision is the usual treatment.

**Epithelioid sarcomas** characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva. In a description of two cases and review of three other reports, the authors concluded that these tumors may mimic a Bartholin cyst, thus leading to inadequate initial treatment (179). They also believed that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease. They suggested that early recognition and wide excision should improve the prognosis.

**Rhabdomyosarcomas** are the most common soft tissue sarcomas in childhood, and 20% involve the pelvis or genitourinary tract (180). Dramatic gains have been made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. More recently, a multimodal approach has evolved, and survival rates have improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhabdomyosarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (181). They were all managed with chemotherapy (*vincristine, or actinomycin D and cyclophosphamide* and *doxorubicin*), with or without radiotherapy. Wide local excision of the tumor, with or without inguinal-femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive with disease.

### Rare Vulvar Malignancies

In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.

#### Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (182). Most patients are in their third to sixth decade of life, and about three fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin’s lymphomas. The remainder are nodular or Burkitt’s lymphomas. Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is about 70% (182).

#### Endodermal Sinus Tumor

There have been four case reports of endodermal sinus tumor of the vulva, and three of the four patients died of distant metastases (183). All patients were in their third decade of life, but none was treated with modern chemotherapy.
Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin that resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (184,185). They should be locally excised and treated with cisplatin-based chemotherapy.

Dermatofibrosarcoma Protuberans

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (186). Radical local excision should be sufficient treatment.

Metastatic Tumors of the Vulva

Eight percent of vulvar tumors are metastatic. The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in about one fourth of the patients, the primary lesion and the vulvar metastasis are diagnosed simultaneously (187).

SECTION VIII  Gynecologic Oncology

SECTION VIII  Gynecologic Oncology

CHAPTER 36  Vulvar Cancer

Complete molar pregnancies are generally diploid, and all chromosomes are of paternal origin.

Partial molar pregnancies are triploid, and the extra set of chromosomes is paternal.

Complete moles are being diagnosed earlier in pregnancy and less frequently present with the classic signs and symptoms.

Single-agent chemotherapy achieves a high remission rate in nonmetastatic and low-risk metastatic gestational trophoblastic tumors.

After achieving remission with chemotherapy, patients with gestational trophoblastic tumors can generally anticipate normal reproduction in the future.

Gestational trophoblastic disease (GTD) is among the rare human tumors that can be cured even in the presence of widespread dissemination (1,2). It encompasses a spectrum of interrelated tumors, including complete and partial hydatidiform mole, placental-site trophoblastic tumor, and choriocarcinoma, which have varying propensities for local invasion and metastasis. Although persistent gestational trophoblastic tumors (GTTs) most commonly follow a molar pregnancy, they can occur after any gestational event, including induced or spontaneous abortion, ectopic pregnancy, or term pregnancy.

Hydatidiform Mole

Epidemiology

Estimates of the incidence of GTD vary dramatically in different regions of the world. For example, the incidence of molar pregnancy in Japan (2 per 1,000 pregnancies)
has been reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) (3). The variation in the incidence rates of molar pregnancy may in part result from differences between reporting population-based versus hospital-based data. The incidences of both complete and partial mole have been investigated in Ireland by reviewing all products of conception from first- and second-trimester abortions (4). Based on a thorough pathologic review, the incidence of complete and partial mole was found to be 1 per 1,945 and 1 per 695 pregnancies, respectively.

Case-control studies have been undertaken to identify risk factors for complete and partial molar pregnancy. The high incidence of molar pregnancy in some populations has been attributed to nutritional and socioeconomic factors. Case-control studies from Italy and the United States have shown that low dietary intake of carotene may be associated with an increased risk of complete molar pregnancy (5,6). Areas with a high incidence of molar pregnancy also have a high frequency of vitamin A deficiency. Dietary factors, therefore, may partly explain regional variations in the incidence of complete mole.

Maternal age older than 35 years has consistently been shown to be a risk factor for complete mole. Ova from older women may be more susceptible to abnormal fertilization. In one study, the risk for complete mole was increased 2.0-fold for women older than 35 years and 7.5-fold for women older than 40 years (7).

Limited information is available concerning risk factors for partial molar pregnancy. However, the epidemiologic characteristics of complete and partial mole may differ. The risk for partial mole has been associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (8). There is no association between maternal age and the risk for partial mole (7).

Complete versus Partial Hydatidiform Mole

Hydatidiform moles may be categorized as either complete or partial moles on the basis of gross morphology, histopathology, and karyotype (Table 37.1).

**Complete Hydatidiform Mole**

Complete hydatidiform moles exhibit characteristic swelling and trophoblastic hyperplasia (Fig. 37.1).

They usually have a 46,XX karyotype, although about 10% have a 46,XY karyotype (9). The molar chromosomes are entirely of paternal origin, although mitochondrial DNA is of maternal origin (10,11) (Fig. 37.2). It appears that complete moles usually
Figure 37.1 Photomicrograph of complete mole demonstrating enlarged villous with central cavitation and surrounding trophoblastic hyperplasia.

Figure 37.2 The karyotype of complete hydatidiform mole.
arise from an ovum that has been fertilized by a haploid sperm, which then duplicates its own chromosomes. The ovum nucleus may be either absent or inactivated (12).

Partial Hydatidiform Mole
Partial hydatidiform moles are characterized by the following pathologic features (13) (Fig. 37.3):

1. Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
2. Marked villous scalloping
3. Prominent stromal trophoblastic inclusions
4. Identifiable embryonic or fetal tissues

Partial moles generally have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes usually is derived from the father (Fig. 37.4) (14). It is possible that nontriploid partial moles do not exist (15). When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth retardation and multiple congenital malformations such as syndactyly and hydrocephaly (Fig. 37.5).

Clinical Features
Patients with complete molar pregnancy are increasingly being diagnosed earlier in pregnancy and treated before they develop the classic clinical signs and symptoms. This may
be because of changes in clinical practice, such as the frequent use of human chorionic gonadotropin (hCG) measurement and vaginal probe ultrasonography in early pregnancy in women with vaginal staining and even asymptomatic women. Following is a description of the classic and current clinical features of complete molar pregnancy (16).

**Complete Hydatidiform Mole**

**Vaginal Bleeding**  Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy. Previously it was reported to occur in 97% of cases, whereas currently it is reported to occur in 84% of patients (17). Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, one half of these patients had anemia (hemoglobin < 10 g/100 mL). Currently anemia is present in only 5% of patients.

**Excessive Uterine Size**  Excessive uterine enlargement relative to gestational age is one of the classic signs of a complete mole, although it was present in only about one half of patients. Currently, excessive uterine size occurs in only 28% of patients.

The endometrial cavity may be expanded by both chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of hCG, because uterine enlargement results in part from trophoblastic overgrowth.
Preeclampsia was once observed in 27% of patients with a complete hydatidiform mole. Preeclampsia is now reported in only 1 of 74 patients with complete mole at the initial visit (17). Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum Hyperemesis requiring antiemetic or intravenous replacement therapy once occurred in one fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Currently, only 8% of patients have hyperemesis.

Figure 37.5 Photomicrograph of a fetal hand demonstrating syndactyly. The fetus had a triploid karyotype, and the chorionic tissues were a partial mole.

Preeclampsia Preeclampsia was once observed in 27% of patients with a complete hydatidiform mole. Preeclampsia is now reported in only 1 of 74 patients with complete mole at the initial visit (17). Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum Hyperemesis requiring antiemetic or intravenous replacement therapy once occurred in one fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Currently, only 8% of patients have hyperemesis.
Hyperthyroidism  Clinically evident hyperthyroidism was once observed in 7% of patients with a complete molar gestation. These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine (T4) and tri-iodothyronine (T3). Currently, clinical evidence of hyperthyroidism with complete mole is rare.

Anesthesia or surgery may precipitate thyroid storm. Thus, if hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, β-adrenergic blocking agents should be administered. Thyroid storm may be manifested by hyperthermia, delirium, convulsions, tachyrhythmia, high-output heart failure, or cardiovascular collapse. Administration of β-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results return rapidly to normal.

Hyperthyroidism develops almost exclusively in patients with very high hCG levels. Some investigators have suggested that hCG is the thyroid stimulator in women with GTD, because positive correlations between serum hCG levels and total T4 or T3 concentrations have been observed. However, in one study in which thyroid function was measured in 47 patients with a complete mole, no significant correlation was found between serum hCG levels and serum values of free T4 index or free T3 index (18). Although some investigators have speculated about a separate chorionic thyrotropin, this substance has not yet been isolated.

Trophoblastic Embolization  Respiratory distress developed in 2% of patients with a complete mole in the past, but currently rarely occurs. Respiratory distress is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels. These patients may have chest pain, dyspnea, tachypnea, and tachycardia and may experience severe respiratory distress during and after molar evacuation. Auscultation of the chest usually reveals diffuse rales, and chest radiographic evaluation may show bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization and the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Theca Lutein Ovarian Cysts  Prominent theca lutein ovarian cysts (6 cm in diameter) develop in about one half of patients with a complete mole (19). Theca lutein ovarian cysts result from high serum hCG levels, which cause ovarian hyperstimulation (20). Because the uterus also may be excessively enlarged, theca lutein cysts may be difficult to palpate during physical examination; however, ultrasonography can accurately document their presence and size. After molar evacuation, theca lutein cysts normally regress spontaneously within 2 to 4 months.

Prominent theca lutein cysts may cause symptoms of marked pelvic pressure, and they can be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture. Early diagnosis of complete mole not only alters the clinical presentation but also changes the pathologic characteristics. First trimester complete moles have smaller chorionic villi and less extensive trophoblastic hyperplasia and may, therefore, be difficult to distinguish from partial mole or hydropic abortion (21).

Partial Hydatidiform Mole  Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. In general, these patients have the signs and symptoms of incomplete or missed abortion, and partial mole can be diagnosed after histologic review of the tissue obtained by curettage (22).
In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (23). Excessive uterine enlargement and preeclampsia were present in only three patients (3.7%) and two (2.5%) patients, respectively. No patient had theca lutein ovarian cysts, hyperemesis, or hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in only five patients (6.2%). Pre-evacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/mL in only two patients (6.6%).

Natural History

| Complete Hydatidiform Mole | Complete moles have a potential for local invasion and dissemination. After molar evacuation, local uterine invasion occurs in 15% of patients, and metastasis occurs in 4% (19). |

A review of 858 patients with complete hydatidiform mole revealed that two fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment (19):

1. hCG level >100,000 mIU/mL
2. Excessive uterine enlargement
3. Theca lutein cysts 6 cm in diameter

In this review, patients with any one of these signs were considered at high risk for developing postmolar tumor. After molar evacuation, local uterine invasion occurred in 31%, and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

Older patients are also at increased risk of developing postmolar GTT. One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (24), whereas in another study this finding occurred in 56% of women older than 50 years (25).

Partial Hydatidiform Mole  Persistent tumor, usually nonmetastatic, develops in approximately 2% to 4% of patients with a partial mole, and chemotherapy is required to achieve remission (26). Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics (27).

Diagnosis

Ultrasonography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern even in the first trimester (Fig 37.6).

Ultrasonography also may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (28). When both of these criteria are present, the positive predictive value for partial mole is 90%.
Treatment

After molar pregnancy is diagnosed, the patient should be evaluated carefully for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient’s condition has been stabilized, a decision must be made concerning the most appropriate method of evacuation.

Hysterectomy

If the patient desires surgical sterilization, a hysterectomy may be performed with the mole in situ. The ovaries may be preserved at the time of surgery, even in the presence of prominent theca lutein cysts. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; therefore, patients still require follow-up with assessment of hCG levels.

Suction Curettage

Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility. It involves the following steps:

1. **Oxytocin infusion**—This procedure is begun before the induction of anesthesia.

2. **Cervical dilation**—As the cervix is being dilated, uterine bleeding often increases. Retained blood in the endometrial cavity may be expelled during cervical dilation.
However, active uterine bleeding should not deter the prompt completion of cervical dilation.

3. **Suction curettage**—Within a few minutes of commencing suction curettage, the uterus may decrease dramatically in size, and the bleeding is generally well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.

4. **Sharp curettage**—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

Because trophoblast cells express RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

**Prophylactic Chemotherapy**

The use of prophylactic chemotherapy at the time of molar evacuation is controversial (29). The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who received prophylactically a single course of actinomycin D at the time of evacuation, local uterine invasion subsequently developed in only 10 patients (4%), and no patients experienced metastasis (29). Furthermore, all 10 patients with local invasion achieved remission after only one additional course of chemotherapy. **Prophylactic chemotherapy, therefore, not only prevented metastasis but also reduced the incidence and morbidity of local uterine invasion.**

In two prospective randomized studies of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk mole who received prophylactic chemotherapy (47% and 50% versus 14%) (30,31). **Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hCG assessments for follow-up are unavailable or unreliable.**

**Follow-up**

**Human Chorionic Gonadotropin**

After molar evacuation, patients should be monitored with weekly determinations of β-subunit hCG levels until these levels are normal for 3 consecutive weeks, followed by monthly determinations until the levels are normal for 6 consecutive months. The average time to achieve the first normal hCG level after evacuation is about 9 weeks (32). At the completion of follow-up, pregnancy may be undertaken. After a patient achieves a nondetectable hCG level, the risk of developing tumor relapse is very low and may approach zero (33).

**Contraception**

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, intrauterine devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, either oral contraceptives or barrier methods should be used.
The incidence of postmolar persistent tumor has been reported to be increased among patients who used oral contraceptives before gonadotropin remission (34). However, more recent data indicate that oral contraceptive use does not increase the risk of postmolar trophoblastic disease (35,36). It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.

**Persistent Gestational Trophoblastic Tumor**

### Nonmetastatic Disease
Locally invasive GTT develops in about 15% of patients after evacuation of a complete mole and infrequently after other gestations (1). These patients usually present with the following symptoms:

1. Irregular vaginal bleeding
2. Theca lutein cysts
3. Uterine subinvolution or asymmetric enlargement
4. Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

After molar evacuation, persistent GTT may exhibit the histologic features of either hydatidiform mole or choriocarcinoma. After a nonmolar pregnancy, however, persistent GTT always has the histologic pattern of choriocarcinoma. Histologically, choriocarcinoma is characterized by sheets of anaplastic syncytiotrophoblast and cytотrophoblast without chorionic villi.

### Placental-site Trophoblastic Tumor
Placental-site trophoblastic tumor is an uncommon but important variant of choriocarcinoma that consists predominantly of intermediate trophoblast (37). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. In contrast to other trophoblastic tumors, placental-site tumors are relatively insensitive to chemotherapy.

### Metastatic Disease
Metastatic GTT occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTT develops after nonmolar pregnancies (1). Metastasis is usually associated with choriocarcinoma, which has a tendency toward early vascular invasion with widespread dissemination. Because trophoblastic tumors often are perfused by fragile vessels, they are frequently hemorrhagic. Symptoms of metastases may result from spontaneous bleeding at metastatic foci. The most common sites of metastases are lung (80%), vagina (30%), pelvis (20%), liver (10%), and brain (10%).

#### Pulmonary
At the time of diagnosis, lung involvement is visible by chest radiography in 80% of patients with metastatic GTT. Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion visible by chest radiography. Respiratory symptoms may be acute or chronic, persisting over many months.
GTT may produce four principal pulmonary patterns:

1. An alveolar or “snowstorm” pattern
2. Discrete rounded densities
3. Pleural effusion
4. An embolic pattern caused by pulmonary arterial occlusion

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. Unfortunately, the diagnosis of GTT may be confirmed only after thoracotomy has been performed, particularly in patients with a nonmolar antecedent pregnancy.

Pulmonary hypertension may develop in patients with GTT secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a poor clinical outcome (38).

Vaginal

Vaginal metastases occurs in 30% of the patients with metastatic tumor. These lesions are usually highly vascular and may bleed vigorously when biopsied. Metastases to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

Hepatic

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor. Hepatic involvement is encountered almost exclusively when there is a protracted delay in diagnosis and the patient has an extensive tumor burden. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

Central Nervous System

Metastatic trophoblastic disease involves the brain in 10% of patients. Cerebral involvement is generally seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions may hemorrhage spontaneously, patients may develop acute focal neurologic deficits.

Staging

An anatomic staging system for GTT has been adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 37.2). It is hoped that this staging system will encourage the objective comparison of data from various centers (39).

Stage I: Patients have persistently elevated hCG levels and tumor confined to the uterus.

Stage II: Patients have metastases to the vagina and pelvis or both.

Stage III: Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement. The diagnosis is based on a rising hCG level in the presence of pulmonary lesions viewed by chest radiography.
Stage IV: Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract. These patients are in the highest risk category because they are most likely to be resistant to chemotherapy. Choriocarcinoma is usually present, and the disease commonly follows a nonmolar pregnancy.

Prognostic Scoring System

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy (40). A prognostic scoring system proposed by the World Health Organization reliably predicts the potential for resistance to chemotherapy (Table 37.3).

When the prognostic score is higher than 7, the patient is categorized as high risk and requires intensive combination chemotherapy to achieve remission. Patients with stage I disease usually have a low-risk score, and those with stage IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with stage II or III disease.
**Diagnostic Evaluation**

Optimal management of persistent GTT requires a thorough assessment of the extent of the disease before the initiation of treatment. All patients with persistent GTT should undergo a careful pretreatment evaluation, including the following:

1. Complete history and physical examination
2. Measurement of the serum hCG value
3. Hepatic, thyroid, and renal function tests
4. Determination of baseline peripheral white blood cell and platelet counts

The metastatic workup should include the following:

1. Chest radiograph or computed tomography (CT) scan
2. Ultrasonography or CT scan of the abdomen and pelvis
3. CT or magnetic resonance imaging (MRI) scan of the head

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT or MRI scanning will disclose most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head has facilitated the early diagnosis of asymptomatic cerebral lesions. Chest CT scans may detect micrometastases not visible on chest radiography. Chest CT will demonstrate pulmonary micrometastases in about 40% of patients with presumed nonmetastatic disease (41).

*The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: <4, low risk; 5–7, middle risk; ≥8, high risk.*
In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (42). However, a single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (43).

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may also aid in identifying sites of resistant uterine tumor (44). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.

Management of Persistent GTT

A protocol for the management of GTT is presented in Table 37.4.

Stage I

In patients with stage I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.
Hysterectomy plus Chemotherapy

If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:

1. To reduce the likelihood of disseminating viable tumor cells at surgery
2. To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery
3. To treat any occult metastases that may already be present at the time of surgery

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 31 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all achieved complete remission with no additional therapy.

Hysterectomy also is performed in all patients with stage I placental-site trophoblastic tumor. Because placental-site tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative treatment. Patients with metastatic placental site trophoblastic tumor may still achieve remission but their tumors are less responsive to chemotherapy (45).

Chemotherapy Alone

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility. When primary single-agent chemotherapy was administered to 495 patients with stage I GTT, 452 patients (91.3%) attained complete remission. The remaining 43 resistant patients subsequently achieved remission after combination chemotherapy or surgical intervention.

When patients are resistant to single-agent chemotherapy and desire to preserve fertility, combination chemotherapy should be administered. If the patient is resistant to both single-agent and combination chemotherapy and wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, or arteriography may help to define the site of the resistant tumor.

Stages II and III

Vaginal and Pelvic Metastasis

Low-risk patients treated with primary single-agent chemotherapy have a high (approximately 80%) rate of remission. High-risk patients often do not achieve remission with single-agent treatment and are treated with primary intensive combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases.

Pulmonary Metastasis

Of 153 patients treated with stage III disease, 152 (99%) attained complete remission. Gonadotropin remission was induced with single-agent chemotherapy in 85 of 104
(81.7%) patients with low-risk disease. All patients who were resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

**Thoracotomy**  Thoracotomy has a limited role in the management of stage III disease. If a patient has persistent viable pulmonary metastasis following intensive chemotherapy, however, thoracotomy may be attempted to excise the resistant focus. A thorough metastatic workup should be performed before surgery to exclude other sites of persistent disease. Fibrotic pulmonary nodules may persist indefinitely on chest radiography, even after complete gonadotropin remission has been attained. In patients undergoing thoracotomy for resistant disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastasis.

**Hysterectomy**  
Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis. Furthermore, in patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and thereby limit the need for multiple courses of chemotherapy.

**Follow-up**  
All patients with stage I through stage III disease should receive follow-up with:

1. Weekly measurement of hCG levels until they are normal for 3 consecutive weeks
2. Monthly measurement of hCG values until levels are normal for 12 consecutive months
3. Effective contraception during the entire interval of hormonal follow-up

**Stage IV**  
All patients with stage IV disease should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery. Before 1975, only 6 of 20 patients (30%) treated with stage IV disease attained complete remission, whereas after that time, 15 of 19 patients (78.9%) achieved remission. This improvement in survival has resulted from the use of primary combination chemotherapy in conjunction with radiation and surgical treatment. Patients with stage IV disease are at greatest risk of developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should preferably be referred to centers with special expertise in the management of trophoblastic disease.

**Hepatic Metastasis**  
The management of hepatic metastasis is particularly difficult. If a patient is resistant to systemic chemotherapy, hepatic arterial infusion of chemotherapy may induce complete remission in selected cases. Hepatic resection may also be required to control acute bleeding or to excise a focus of resistant tumor. New techniques of arterial embolization may reduce the need for surgical intervention.

**Cerebral Metastasis**  
If cerebral metastases are diagnosed, whole-brain irradiation (3,000 cGy in 10 fractions) can be instituted promptly. Because irradiation may be both hemostatic and tumoricidal, the risk of spontaneous cerebral hemorrhage may be lessened by the concurrent use of combination chemotherapy and brain irradiation. However, excellent remission rates
(86%) have been reported in patients with cranial metastases treated with intensive intravenous combination chemotherapy and intrathecal methotrexate (MTX) (46).

Craniotomy  Craniotomy may be required to provide acute decompression or to control bleeding. It should be performed to manage life-threatening complications in the hope that the patient ultimately will be cured with chemotherapy. In one study (47), the use of craniotomy to control bleeding in six patients resulted in complete remission in three patients. Infrequently, cerebral metastases that are resistant to chemotherapy may be amenable to local resection. Fortunately, patients with cerebral metastases who achieve sustained remission generally have no residual neurologic deficits.

Follow-up

Patients with stage IV disease should receive follow-up with:

1. Weekly determination of hCG levels until they are normal for 3 consecutive weeks
2. Monthly determination of hCG levels until they are normal for 24 consecutive months

These patients require prolonged gonadotropin follow-up because they are at increased risk of late recurrence.

An algorithm for the management of persistent GTT is presented in Figure 37.7.

Chemotherapy

Single-Agent Treatment  Single-agent chemotherapy with either actinomycin D (Act-D) or MTX has achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTT (48). Several protocols using these agents are available. Act-D can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, MTX can be given either in a 5-day regimen or pulsatile weekly. No study has compared all of these protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

The administration of methotrexate with folinic acid (MTX-FA) in GTT to limit systemic toxicity was first reported in 1964 (49). Subsequently, it has been confirmed that MTX-FA is both effective and safe in the management of GTT (50).

An evaluation of 185 patients treated with MTX-FA revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of MTX-FA to attain remission (50). MTX-FA induced remission in 147 of 163 patients (90.2%) with stage I GTT and in 15 of 22 patients (68.2%) with low-risk stages II and III GTT. Resistance to therapy was more common in patients with choriocarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/mL. After treatment with MTX-FA, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in only 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. Thus, MTX-FA achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.

Technique of Single-agent Treatment  The serum hCG level is measured weekly after each course of chemotherapy. The hCG regression curve serves as the primary basis for determining the need for additional treatment.
Figure 37.7 Algorithm for the management of persistent gestational trophoblastic tumor. GTN, gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin; RT, radiotherapy. (From Berkowitz RS, Goldstein DP. Gestational trophoblastic neoplasia. In: Berek JS, Hacker NF, eds. *Practical gynecologic oncology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005;618, with permission.)
After the first treatment:

1. Further chemotherapy is withheld as long as the hCG level is falling progressively.

2. Additional single-agent chemotherapy is not administered at any predetermined or fixed interval.

A second course of chemotherapy is administered under the following conditions:

1. If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again

2. If the hCG level does not decline by 1 log within 18 days after completion of the first treatment

If the patient’s response to the first treatment was adequate and a second course of MTX-FA is required, the dosage of MTX is unaltered. An adequate response is defined as a fall in the hCG level by 1 log after a course of chemotherapy.

If the response to the first treatment is inadequate, the dosage of MTX is increased from 1.0 mg/kg per day to 1.5 mg/kg per day for each of the 4 treatment days. If the response to two consecutive courses of MTX-FA is inadequate, the patient is considered to be resistant to MTX, and Act-D is promptly substituted. If the hCG levels do not decline by 1 log after treatment with Act-D, the patient also is considered resistant to Act-D as a single agent. She must then be treated intensively with combination chemotherapy to achieve remission.

Combination Chemotherapy

**Triple Therapy**

Triple therapy with MTX, Act-D, and cyclophosphamide is inadequate as an initial treatment in patients with metastasis and a high-risk prognostic score. Collectively, data from three centers indicate that triple therapy induced remission in only 21 (49%) of 43 patients with metastasis and a high-risk score (score >7) (51–53).

**EMA-CO**

Etoposide has been reported to induce complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTT (54). A new combination regimen described in 1984 included etoposide, MTX, Act-D, cyclophosphamide, and vincristine (EMA-CO) and had an 83% remission in patients with metastasis and a high-risk score (55). Another study confirmed that primary EMA-CO induced complete remission in 76% of the patients with metastatic GTT and a high-risk score (56). Still another study reported that EMA-CO induced complete sustained remission in 87 (90.6%) of 96 patients with high-risk (score >7) GTT (57). Furthermore, remission occurred with EMA-CO in 30 (86%) of 35 patients with brain metastasis (46).

The EMA-CO regimen is generally well tolerated, and treatment seldom has to be suspended because of toxicity. The EMA-CO regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score. However, the optimal combination drug protocol for management of GTT has not yet been clearly defined. If patients experience resistance to EMA-CO, they may then be treated successfully by substituting etoposide and cisplatin on day 8 (EMA-EP). EMA-EP has induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to EMA-CO.
The optimal combination drug protocol will most likely include etoposide, MTX, and Act-D and perhaps other agents administered in the most dose-intensive manner.

Duration of Therapy

Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least two additional courses of chemotherapy are administered to reduce the risk of relapse.

Subsequent Pregnancies

Pregnancies after Hydatidiform Mole

Patients with hydatidiform moles can anticipate normal reproduction in the future. From 1965 until 2001, patients who were treated for complete mole had 1,278 subsequent pregnancies that resulted in 877 term live births (68.6%), 95 premature deliveries (7.4%), 11 ectopic pregnancies (0.9%), 7 stillbirths (0.5%), and 18 repeat molar pregnancies (1.4%). First- and second-trimester spontaneous abortions occurred in 229 (17.9%) pregnancies. Major and minor congenital malformations were detected in 40 infants (4.1%), and primary cesarean delivery was performed in 70 of 373 (18.8%) term or preterm births from 1979 to 2001.

Although data regarding pregnancies after partial mole are limited (251 subsequent pregnancies), the information is reassuring. Patients with both complete and partial mole should be reassured that they are at no increased risk of complications in later gestations.

When a patient has had a molar pregnancy, she is at an increased risk of having a molar gestation in subsequent conceptions. After one molar pregnancy, the risk of having molar disease in a future gestation is about 1%. Of 34 patients with at least two documented molar pregnancies, every possible combination of repeat molar pregnancy was observed. After two molar gestations, these 34 patients had 35 later conceptions resulting in 20 (57.1%) term deliveries, 7 (20.0%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In six patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies.

Therefore, for any subsequent pregnancy, it seems prudent to undertake the following approach:

1. Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.

2. Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.

Pregnancies after Persistent Gestational Trophoblastic Tumor

Patients with GTT who are treated successfully with chemotherapy can expect normal reproduction in the future. Patients who were treated with chemotherapy at the authors’ institution from 1965 to 2001 had 581 subsequent pregnancies that resulted in 393 term live births (67.6%), 35 preterm deliveries (6.0%), 7 ectopic pregnancies (1.2%), 9 stillbirths (1.5%), and 8 repeat molar pregnancies (1.4%) (59). First- and second-trimester
spontaneous abortions occurred in 99 (17.0%) pregnancies. Major and minor congenital malformations were detected in 10 infants (2.3%). Primary cesarean delivery was performed in 68 (20.3%) of 335 subsequent term and preterm births from 1979 to 2001. It is particularly reassuring that the frequency of congenital anomalies is not increased, although chemotherapeutic agents are known to have teratogenic and mutagenic potential.

CHAPTER 37 Gestational Trophoblastic Disease

Breast Cancer

Kristine E. Calhoun
Armando E. Giuliano

Breast cancer accounts for one third of cancers in women. The risk of breast cancer increases with a positive family history and the use of hormone therapy. Breast cancer may be either in situ (ductal carcinoma in situ or lobular carcinoma in situ) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma).

The standard screening modalities for detection of breast cancer include yearly mammography and physical examination.

Tissue diagnosis is achieved using fine-needle aspiration cytology (FNAC) or core needle biopsy (CNB). Open biopsy is performed if FNAC or CNB has not been performed or if these results are negative, equivocal, or discordant with the clinical findings.

The combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy is equivalent to modified radical mastectomy for the management of certain patients with stages I and II breast cancer.

Axillary lymph node status and the number of involved nodes is the most important prognostic indicator in primary breast cancer.

Adjuvant systemic therapy prolongs survival in selected breast cancer patients and is recommended for women with a greater than 10% chance of relapse within 10 years.

Breast cancer accounts for approximately one third of all cancers in women and is second only to lung cancer as the leading cause of cancer deaths among women. Breast cancer, however, has the highest incidence rate of all cancers. According to statistics from the American Cancer Society, 213,000 new cases of invasive breast cancer, as well as nearly 62,000 cases of in situ cancers, will be diagnosed during 2006 in the United States, with 41,000 women succumbing to the disease during the same period (1). Over the past 50 years, the incidence of breast cancer in the United States has increased significantly; currently one in every seven women will develop the disease during her lifetime. Fortunately, the mortality rate has declined since 1990.
Predisposing Factors

Fewer than 1% of breast cancers occur in women younger than 25 years of age. After age 30, however, there is a sharp increase in the incidence of breast cancer. Except for a short plateau between the ages of 45 and 50 years, the incidence increases steadily with age (2).

Family History Of women who develop breast cancer, 20% to 30% have a family history of the disease. Although any family history of breast cancer increases the overall relative risk (3), this risk is not significantly increased if the disease was diagnosed post-menopausally in a first degree or more distant relative. If a woman’s mother or sister had unilateral breast cancer premenopausally, her lifetime risk of developing the disease approaches 30%, whereas a woman whose mother or sister had bilateral breast cancers premenopausally has at least a 40% to 50% lifetime risk. The increased incidence in these women is probably due to inherited oncogenes.

Approximately 5% to 10% of breast cancers have an inherited basis. All inherited genes are autosomal dominant but have variable penetrance. Men carry the gene 50% of the time. The most common mutations are the BRCA1 (chromosome 17q21) and BRCA2 (chromosome 13q12–13) gene deletions. Carriers of these germline mutations have up to a 4%-per-year risk of developing breast cancer and a lifetime risk that ranges from 35% to 85% (4). In addition, these individuals have up to a 65% risk of developing a contralateral breast cancer. The BRCA1 mutation also is associated with an increased risk of ovarian and prostate cancer, whereas BRCA2 carriers, although less common, demonstrate increased risks of male breast and prostate cancers. Both mutations are rare in the general public (0.1%) but are more commonly identified in Jews of Ashkenazi descent (1%–2.3%) (5). Genetic testing is available and should be considered if there is a high likelihood that results will be positive and will be used to influence decisions regarding the clinical management of the care of the patient and her family.

Diet, Obesity, and Alcohol There are marked geographic differences in the incidence of breast cancer that may be related to diet. A recent meta-analysis demonstrated an association between higher intakes of total fat and an increased risk of breast cancer (6). Although a definitive relationship between total alcohol consumption and an increased risk of breast cancer has yet to be determined, high wine intake has been shown to be associated with elevated risk (7).

Reproductive and Hormonal Factors The risk of breast cancer increases with the length of a woman’s reproductive phase (8). Although early menarche has been reported among breast cancer patients, early menopause appears to protect against the development of the disease, with artificial menopause from oophorectomy lowering the risk more than early natural menopause (9). There is no clear association between the risk of breast cancer and menstrual irregularity and the duration of menses. Although lactation does not affect the incidence of breast cancer, women who have never been pregnant have a higher risk of breast cancer than those who are multiparous. Also, women who give birth to their first child later in life have a higher incidence of breast cancer than do younger primigravida women (10).

An historic well-controlled study from the Centers for Disease Control and Prevention showed that oral contraceptive use does not increase the risk of breast cancer, regardless of duration of use, family history, or coexistence of benign breast
disease (11). However, a more recent pooled analysis from 54 epidemiologic studies showed current users of oral contraceptives had a small but significant increased risk when compared with nonusers. Ten years after discontinuation, the risk of past users declined to that of the normal population (12).

Although it was previously reported that short-term estrogen treatment for menopausal symptoms did not increase the risk of breast cancer, this belief was refuted by publication of the results of the Women’s Health Initiative randomized trial. This prospective trial, involving 16,000 postmenopausal women randomly assigned to receive estrogen plus progesterone or placebo, revealed an association between hormone therapy use and the development of breast cancer. In addition, when invasive breast cancer did develop, it was diagnosed at a more advanced stage compared with tumors that developed among placebo users. Based on interim analysis, the trial was stopped early and the investigators concluded that even relatively short-term use of combined estrogen–progesterone therapy increases the development of invasive breast cancer (13). The risk demonstrated by this study must be considered when postmenopausal hormone therapy is used to treat conditions such as hot flashes and osteoporosis.

### History of Cancer

Women with a history of breast cancer have a 50% risk of developing microscopic cancer and a 20% to 25% risk of developing clinically apparent cancer in the contralateral breast, which occurs at a rate of 1% to 2% per year (14). Lobular carcinoma has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial, ovarian, or colon cancer also is associated with an increased risk of subsequent breast cancer, as is a history of radiation therapy for Hodgkin’s lymphoma.

### Diagnosis

Breast cancer most commonly arises in the upper outer quadrant, where there is proportionally more breast tissue. Masses are most often discovered by the patient and less frequently by the physician during routine breast examination. The increasing use of screening mammography has enhanced the ability to detect nonpalpable breast abnormalities. Metastatic breast cancer is found as an axillary mass without obvious malignancy in less than 1% of cases.

The standard screening modalities of mammography and physical examination are complementary. Approximately 10% to 50% of cancers detected mammographically are not palpable, whereas physical examination detects 10% to 20% of cancers not seen radiographically (15). The purpose of screening is to detect tumors when they are small (less than 1 cm) and have the highest potential for surgical cure. Most trials have shown a 20% to 30% reduction in breast cancer mortality for women age 50 and older who undergo annual screening mammography. Data on screening women younger than 40 years have been more controversial. Results from the Gothenburg screening trial showed a 45% reduction in mortality for women screened between the ages of 40 and 49 (16). Because of these findings, it is recommended that all women undergo yearly screening mammography starting at age 40, along with clinical breast examination and breast self-examination. No other tests, including ultrasonography, computed tomography (CT) scans, sestamibi scans, positron emission tomography (PET) scans, or serum blood markers, have been shown to be effective screening modalities. Screening guidelines recommended by the American College of Radiology and the American Cancer Society are presented in Table 38.1. Recently, MRI was identified as a valuable adjunct to screening mammography for women with either a familial or genetic predisposition to breast cancer, although exact guidelines for its implementation have yet to be defined (17).
Unfortunately, although breast MRI is exceptionally sensitive in the detection of breast abnormalities, the technology is currently not specific enough for this imaging modality to be used for routine screening.

Masses are easier to palpate in older women with fatty breasts than in younger women with dense, nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction, or skin erosion, while obvious, are later-stage disease signs. Algorithms for the evaluation of breast masses in premenopausal and postmenopausal women are presented in Chapter 19.

When a dominant breast mass is identified, the presence of a carcinoma must be considered, and biopsy should be performed to establish a tissue diagnosis. About 30% to 40% of lesions believed clinically to be malignant will be benign on histologic examination (18). Conversely, 25% of clinically benign-appearing lesions will be malignant when biopsied (19).

Biopsy Techniques

In rare cases, it may be reasonable to perform frozen section analysis on a biopsy specimen immediately before mastectomy or other definitive surgical treatment. It is preferable, however, for the patient to be involved in the planning of her therapy. In most instances, initial biopsy is better followed by definitive treatment at a later date. This approach allows the physician to discuss alternative forms of surgical therapy with the patient who has a malignancy. It also gives the patient an opportunity to obtain a second opinion before undergoing definitive treatment.

Fine-needle Aspiration Cytology

Fine-needle aspiration cytology (FNAC) is usually performed on palpable lesions or under ultrasound guidance using a 20- or 22-gauge needle. The technique has a high level of diagnostic accuracy, with low false-negative rates and rare, but persistent, false-positive results (20). In most reported series, false-negative rates range from 10% to 15%, and false-positive rates are generally less than 1%, whereas insufficient specimens account for about 15% of samples (21). If a mass appears to be malignant on physical
examination, mammography, or both, FNAC cytology results can be used for definitive diagnosis. Negative FNAC results do not exclude malignancy and should be evaluated by either a core needle or traditional excisional biopsy for suspicious lesions. In younger women, it is prudent to monitor a benign-appearing mass for one or two menstrual cycles. Confirmation of a clinically apparent fibroadenoma with FNAC can serve as the basis for observational follow-up without excision.

Core Needle Biopsy

Core needle biopsy can be performed on both palpable and nonpalpable breast masses. **Performing a core biopsy instead of FNAC on a palpable lesion has the advantage of obtaining more tissue for diagnostic purposes, including tests for estrogen and progesterone receptors and Her2/neu.** Core biopsy of nonpalpable breast lesions usually is performed using mammographic or ultrasonographic guidance. Mammographic units with computerized stereotactic modifications can be used to localize abnormalities and perform CNB without surgery. **Under mammographic guidance, a biopsy needle is inserted into the lesion and a core of tissue is removed for histologic examination.** Devices with suction assistance are often used to increase the volume of tissue removed for evaluation. A titanium clip often is used to mark the biopsy site and serve as a guide should further excision be required. Ultrasonography may also be used to perform core biopsy on a nonpalpable lesion. Because it is less invasive and less expensive than open mammographic localization biopsy, CNB is preferred for accessible lesions. If a definitive diagnosis is not established, these procedures must also be followed by open biopsy.

Open Biopsy

Open biopsy may be performed if FNAC or CNB has not been performed or if needle biopsy results are negative, equivocal, or discordant with the clinical findings. **An unequivocal histologic diagnosis of cancer should be obtained before treatment of breast cancer is undertaken.** Cytologic diagnosis may be relied on if the mass clinically or mammographically appears to be malignant.

**Open biopsy can be performed in the outpatient setting with local anesthesia** in the following manner:

1. The patient is positioned and the location of the mass confirmed.

2. Local anesthesia is used to infiltrate the skin and subcutaneous tissue surrounding the palpable mass.

3. The skin in incised directly over the mass. Placement of this incision is critical. It should be situated in such a way that it can be excised with an ellipse of skin should the patient require a subsequent mastectomy or placed cosmetically so that partial mastectomy can be performed through it successfully. Para-areolar incisions are appropriate only for lesions in proximity to the nipple–areolar complex.

4. The mass is gently grasped with Allis forceps or with a stay suture and moved into the operative field.

5. The mass should be excised completely whenever possible. Larger lesions that are difficult to totally excise can be incised for diagnostic purposes only. When an incisional biopsy is performed, a frozen section should be obtained to confirm that appropriate tissue for diagnosis is present. Such masses, however, are preferably sampled with FNAC or CNB, with incisional biopsy rarely indicated.

6. Once the mass is removed, hemostasis is achieved and the incision is closed. A cosmetically superior result will be achieved if the deep breast parenchyma is not
reapproximated. The most superficial subcutaneous fat can be reapproximated with fine absorbable sutures, and the skin can be closed with a subcuticular suture and adhesive strips.

**Image-Guided Localization Biopsy**

Biopsy of nonpalpable lesions is a potentially difficult procedure that requires close cooperation between the surgeon and radiologist. Using ultrasonographic or mammographic guidance, a needle or specialized wire is placed into the breast parenchyma at or near the site of the suspected abnormality. Some mammographers will also inject a biologic dye into the breast parenchyma to assist localization further. The surgeon reviews the films and localizes the abnormality with respect to the tip of the wire or needle. Alternatively, the surgeon will perform ultrasonography intraoperatively to directly localize the lesion. An incision is made directly over the abnormality, and a small portion of the breast tissue suspected of containing the abnormality is excised. For mammographically detected lesions, a specimen radiograph is obtained to ensure that the abnormality has been recovered. Often, the radiologist can place a needle in the specimen at the site of the abnormality to facilitate histologic evaluation and ensure that the pathologist examines the site of the abnormality.

**Pathology and Natural History**

Breast cancer may arise in the intermediate-sized ducts, terminal ducts, or lobules. In most cases, the diagnosis of lobular and intraductal carcinoma is based more on histologic appearance than site of origin. The cancer may be either *in situ* (ductal carcinoma *in situ* or lobular carcinoma *in situ*) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma). Morphologic subtypes of infiltrating ductal carcinoma include scirrhous, tubular, medullary, and mucinous carcinoma.

**True invasive ductal carcinoma** accounts for 80% of all invasive tumors, with the final 20% split evenly between lobular carcinoma and special variants of infiltrating ductal carcinoma (22). Mammographically, invasive ductal cancers are characterized by a stellate density or microcalcifications. Macroscopically, gritty, chalky streaks are present within the tumor that most likely represent a desmoplastic response. Finally, invasion of the surrounding stroma and fat, with a fibrotic, desmoplastic reaction surrounding the invasive carcinoma, generally are present.

Special types of infiltrating ductal carcinoma are uncommon and typically account for nearly 10% of all invasive cancers. **Medullary carcinoma**, which accounts for 5% to 8% of breast carcinomas, arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor appears to be a slower growing and less-aggressive malignancy than other forms of carcinoma. Even when axillary disease is present, the prognosis with medullary carcinoma is better than that of other variants of invasive ductal carcinoma. **Mucinous (colloid) carcinoma** accounts for 5% of all breast cancers. Grossly, areas of the tumor may appear mucinous or gelatinous, whereas microscopically they are relatively acellular. Infiltrating comedo carcinoma accounts for less than 1% of all breast malignancies and is an invasive cancer characterized by foci of necrosis that exude a comedonecrosislike substance when biopsied. Usually, comedocarcinomas are *in situ* malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma. **Tubular carcinoma**, a well-differentiated breast cancer that accounts for 1% to 2% of all malignant breast neoplasms, tends to have a better prognosis than infiltrating ductal carcinoma and rarely metastasizes to axillary lymph nodes. Finally, **adenoid cystic carcinomas** are extremely rare breast tumors that histologically are similar to those seen in the salivary glands. They generally are well-differentiated cancers that are slow to metastasize.
Growth Patterns

The growth potential of breast cancer and the patient’s resistance to malignancy vary widely with the individual and the stage of disease. The doubling time of breast cancer ranges from several weeks for rapidly growing tumors to months or years for slowly growing lesions. If the doubling time of a breast tumor was constant and a tumor originated from one cell, a doubling time of 100 days would result in a 1-cm tumor in about 8 years (Fig. 38.1) (23). During the preclinical phase, tumor cells may be circulating throughout the body. Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis. Although cancer cells may be released from the tumor before diagnosis, variations in the tumor’s ability to grow in other organs and the host’s response to tumor cells may inhibit dissemination of the disease. Many women with breast cancer can be treated successfully with surgery alone, and some patients have been cured even in the presence of palpable axillary disease. Thus, a pessimistic attitude that breast cancer is systemic and incurable at diagnosis is unwarranted.

A more realistic approach may be to view breast cancer as a two-component disease involving the breast and the body as a whole. Although the primary breast tumor and issues of local control must be managed, the possibility of systemic metastases with their life-threatening consequences should not be overlooked.

Although breast cancer can metastasize to any organ, involvement of bone, lungs, or liver occurs in up to 85% of women who develop distant disease (24,25). In addition to these sites, invasive lobular carcinoma is known to disseminate to the abdominal viscera, uterus, ovaries, and peritoneal surfaces.

**Staging**

After the diagnosis of breast cancer has been definitively established, the clinical stage of the disease should be determined. The Columbia Clinical Staging System was used historically (26) but has been replaced by the tumor–nodes–metastases (TNM) staging system.
system of the American Joint Committee on Cancer (27). The TNM system allows both preoperative clinical staging and postoperative pathologic staging to be determined (Tables 38.2 and 38.3).

### Treatment

#### Preoperative Evaluation

The extent of the preoperative workup varies with the initial stage of the disease (28). For most patients with small tumors, clinically negative lymph nodes, and no evidence of metastasis (TNM stage I), the preoperative evaluation should consist of bilateral mammography, chest radiography, complete blood count, and screening blood chemistry tests. Bone, CT, and MRI scanning are unnecessary unless there are symptoms or abnormal blood chemistry levels to suggest the existence of bone or intra-abdominal involvement. For patients with clinical stage II, node-positive disease, a bone scan is recommended, but CT scan of the abdomen is not necessary unless symptoms or laboratories suggest liver disease. Patients with clinical stage III or stage IV disease should undergo both bone and liver scanning.

#### Radical Mastectomy

Traditionally, the treatment of breast cancer has been surgical, but the type of procedure has remained a controversial and highly emotional issue. During the nineteenth century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. The radical mastectomy was based on the principle that breast...
carcinoma was a locally infiltrative process that spread in a stepwise fashion from breast, to nodes, to distant sites (29). Thus, radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity (30) (Fig. 38.2A). A report of 51 years of experience with radical mastectomy, which included 1,036 patients with a follow-up of 47 years, is thus far unequaled in evaluating any single method of treating breast cancer (31).
During the twentieth century, extensions and modifications of the radical mastectomy were devised that involved removal of more local and regional tissue. At one time, supraclavicular lymph node dissections were considered a routine component of surgical treatment (32). In addition, supraclavicular, mediastinal, and internal mammary lymph node dissections were performed (33).

An *en bloc* internal mammary lymph node dissection was added to the standard radical mastectomy in the 1960s (34). This technique became popular and is the operation commonly referred to as the *extended radical mastectomy*. Unfortunately, extended radical mastectomy did not enhance overall survival rates (35), because only 3% to 5% of patients with negative axillary nodes will have involvement of internal mammary nodes. Locally destructive surgery is not justified, however, based on current understanding of the biologic behavior of breast cancer.

**Modified Radical Mastectomy**

In contrast to radical mastectomy, modified radical mastectomy preserves the *pectoralis major muscle* (36,37) (Fig. 38.2B). The breast is removed in a manner similar to that of radical mastectomy, but neither the axillary lymph node dissection nor the skin excision is as extensive. Consequently, there is no need for skin grafting. Although there are no differences in survival rates between radical and modified radical mastectomy, the latter procedure has a better functional outcome and a superior cosmetic result (38). Modified radical mastectomy has therefore replaced radical mastectomy in the United States.

**Total Mastectomy**

Total mastectomy involves removal of the entire breast, nipple, and areolar complex without resection of the underlying muscles or intentional excision of axillary lymph nodes. Low-lying lymph nodes, however, in the upper outer portion of the breast and low axilla often are excised. Total mastectomy has local control rates comparable with those of radical or modified radical mastectomy but has a higher risk of axillary recurrence. Regional recurrence will occur in at least 15% to 20% of patients treated with total mastectomy alone.

**Postmastectomy Radiation Therapy**

McWhirther developed the combination of total mastectomy followed by radiation (39). Many have advocated adjuvant radiation therapy used in combination with various operative procedures. Unfortunately, studies claiming improvements in overall survival usually are flawed by the use of historical controls and inaccurate preoperative staging. Classic trials, both prospective randomized and historical control studies, have showed that adjuvant radiation therapy improves local control but not overall survival rates (40–43). In a prospective randomized trial performed by the National Surgical Adjuvant Breast Project (NSABP), the roles of postoperative radiation therapy and axillary treatment were examined. Patients were randomly assigned to either total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. This trial showed no difference in survival among the three treatment arms, whereas radiation therapy and axillary treatment improved local and regional control. Twenty-five-year follow-up data continue to support these conclusions (44).

Three randomized control studies from the 1990s showed that postmastectomy radiation therapy reduced the risk of local-regional failure by 20% and produced an absolute survival benefit of 10% at 10 years among women with stage II to III breast cancer, regardless of menopausal status (45–47). More recently, additional trials challenged the need for postmastectomy radiation among women with only one to three involved axillary nodes and $T_1$ or $T_2$ primary tumors. These studies showed adequate local-regional control rates with mastectomy and chemotherapy alone (48–50). Current guidelines from the American Society of Clinical Oncology recommend postmastectomy
radiation therapy for women with $T_3 (>5 \text{ cm})$ primary tumors and four or more positive axillary lymph nodes (51).
improved the local control rate, no significant differences in overall survival or disease-free survival rates were detected among the three treatment arms; there was a trend, however, in favor of patients who received radiation. This NSABP study established, now with 25-year follow-up, that the combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy is as effective as modified radical mastectomy for the management of patients with stage I and II breast cancer (58). A number of additional studies also demonstrated no decrease in overall survival among women being treated with breast preservation therapy (59–61).

Axillary lymph node status and the number of involved nodes is the most important prognostic indicator for patients with primary breast cancer (62). For these reasons, axillary lymphadenectomy traditionally was used to detect and quantify the extent of nodal metastasis (63). Before the introduction of sentinel lymph node dissection in the 1990s, axillary lymph node dissection was performed routinely on all patients with early breast cancer. Although axillary dissection is associated with a very low risk of regional recurrence (1%–3%), the rate of acute complications is as high as 30% (64). Similarly, the risk of chronic lymphedema ranges from 6% to as high 30% (65). Limiting the dissection to level I nodes or random sampling is associated with unacceptably high false-negative rates and should not be done (66). Only one third of patients with a clinically negative axilla will be found to have nodal metastasis after histopathologic examination of all harvested lymph nodes (67). This means that two thirds of patients will be exposed to the morbidity of axillary lymph node dissection without proven benefit when performed routinely in the presence of invasive breast cancer.

In 1991, intraoperative lymphatic mapping and sentinel lymph node dissection were introduced to address these problems (68). The concept behind sentinel lymph node dissection is best described by the definition of a sentinel node. The sentinel node is the lymph node that has the greatest potential to harbor metastasis if axillary disease is present. The sentinel lymph node dissection thus accurately predicts the status of the entire nodal basin. Removing only one or two lymph nodes can accurately stage the axilla with minimal morbidity. Numerous investigators have demonstrated that, with proper training, sentinel lymph node dissection identification rates range from 90% to 99%, with false-negative rates of less than 5% found in most large studies (69). In one study of 107 patients with T1 and T2 breast cancer who underwent sentinel lymph node dissection followed by axillary lymph node dissection, the sentinel node was successfully identified in 100 patients (93.5%). There were no false-negative results, and the sentinel node accurately predicted axillary status in all 100 patients.

The technique of sentinel lymph node dissection has been validated by a number of authors using a variety of techniques (70,71). The information obtained from sentinel lymph node dissection appears to be equivalent to that of axillary lymph node dissection in the trials conducted to date. One prospective study demonstrated that in node-negative patients undergoing sentinel lymph node dissection, only the recurrence rate in the axilla was zero at a median follow-up of 39 months (72). An additional randomized trial demonstrated sentinel node biopsy to be both safe and accurate when compared with axillary dissection, with fewer complications and no axillary recurrences among the sentinel node trial arm (73). This degree of accuracy in predicting axillary metastasis, combined with its very low morbidity rate, makes sentinel lymph node dissection the preferred procedure for staging the axilla in breast cancer today.

**Adjuvant Systemic Therapy**

For many patients, local and regional control of breast cancer is achieved with surgery and radiation therapy alone. About 90% of patients will never experience an in-breast recurrence; these patients, however, may still develop metastatic disease. The goal of adjuvant...
Adjuvant systemic therapy will prolong survival in selected breast cancer patients. In patients with favorable tumors and a low risk of recurrence and subsequent death, however, such as those with node-negative cancers smaller than 1 cm or node-negative cancers smaller than 2 cm with grade 1 histology, this benefit is small and may not justify the risks of systemic therapy. Adjuvant systemic therapy reduces the odds of death by 25% per year in both node-negative and node-positive patients (75). Because this risk reduction is relatively constant, patients with favorable, node-negative disease have a much smaller absolute benefit compared with patients who have higher-risk, node-positive disease. For patients with node-negative disease, the absolute benefit may be minimal versus 10% to 20% for those with nodal involvement.

Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when treatment decisions are made. Although there are many known acute side effects with current standard regimens, there is growing evidence that patients who undergo chemotherapy report more frequent chronic neurocognitive deficits than do untreated controls (76). The impact of these deficits remains undefined. Similarly, systemic therapy with tamoxifen has been associated with an increased incidence of uterine cancer, vaginal dryness, and hot flashes, whereas aromatase inhibitors have been linked to osteoporosis and musculoskeletal symptoms. Choosing those patients who should receive adjuvant therapy can be a difficult decision that often entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk.

Based on available data, adjuvant chemotherapy is currently recommended for women with greater than a 10% chance of relapse within 10 years. The choice of therapy generally depends on an evaluation of specific risk factors. Recently, gene assays such as the Oncotype DX have been introduced to help identify those estrogen receptor–positive, lymph node–negative patients who will benefit most from systemic chemotherapy. This test, which calculates a recurrence risk score for each individual, allows the treating physician to determine the average rate of distant disease at 10 years and make treatment recommendations based on this risk (77).

**Prognostic Indicators**

Factors that determine each patient’s risk of recurrence include nodal involvement, tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and biologic markers such as Her2/neu status. These prognostic factors and their effects on recurrence are summarized in Table 38.4. Patients with high-risk prognostic factors are more likely to benefit from adjuvant cytotoxic or hormonal therapy and usually are offered such treatment.

Patients with lymph node metastasis have a higher risk of recurrence than patients with node-negative disease. The 10-year survival rate for women with palpable metastatic axillary lymph nodes who fail to receive systemic therapy is only about 50% to 60%. The number of lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Another prognostic indicator of relapse is primary tumor size. In an evaluation of 767 patients with node-negative disease who underwent radical or modified radical mastectomy without adjuvant chemotherapy, the relapse rate in patients with tumors larger than 1 cm or special tumor types larger than 3 cm (tubular, mucinous, or papillary) was 27% at 10 years, compared with 9% for tumors smaller than 1 cm (78).

Hormone receptor status is an important predictor not only of long-term prognosis but also of response to endocrine therapy. Several studies demonstrated that patients with positive estrogen and progesterone receptor status have improved overall
survival (79,80). Receptor status should be known when determining the need for and choice of adjuvant therapy. Histologic grade also appears to predict overall survival. Patients with well-differentiated tumors tend to have more favorable outcomes than those with poorly differentiated ones (Table 38.5). In a British study of 1,168 women, histologic grade, along with tumor size and lymph node status, was an independent predictor of overall survival at 10 years (81).

Finally, the possible roles of specific tumor markers in predicting which patients will respond to chemotherapy regimens have been investigated. The most thoroughly researched of these markers is HER-2/neu. In an NSABP study, patients with HER-2/neu overexpression who were not treated with anthracycline-based regimens fared worse (82). Another study showed that the addition of trastuzumab (Herceptin), an antibody directed against the HER-2/neu receptor, significantly increased the response rate to therapy over standard chemotherapy alone in the presence of metastatic disease (83). At the 2005 meeting of the American Society of Clinical Oncology, data were reported from trials investigating the adjuvant use of Herceptin for women with early-stage Her2/neu breast cancers. Significant improvements in disease-free survival were reported for those women receiving Herceptin (84), suggesting that its routine use as an adjuvant therapy is inevitable.

AJCC, American Joint Committee on Cancer.
Based on the results of more than 100 prospective, randomized trials examining the role of adjuvant chemotherapy in breast cancer, a variety of systemic regimens have emerged. Systemic therapy includes cytotoxic agents and hormonal agents, used alone or in combination. Following is a brief description of the more commonly used regimens. Initially, trials involved a single perioperative course of chemotherapy aimed at eradicating circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of cyclophosphamide improved overall survival rates (85). Subsequently, numerous trials demonstrated the benefit of adjuvant chemotherapy for certain subgroups of patients (86). In the initial NSABP adjuvant trial, a 2-year course of melphalan was shown to be superior to no treatment (87), and further trials demonstrated enhanced beneficial effect with the use of multiple drugs as well as with the combination of hormonal manipulation with chemotherapy (88).

Historically, the most frequently used adjuvant combination chemotherapy has been CMF: cyclophosphamide (C), methotrexate (M), and 5-fluorouracil (5-FU). In the original study by Bonadonna et al., patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of CMF or no therapy after radical mastectomy (89). A statistically significant benefit was found with CMF treatment for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of CMF to be as effective as 12 cycles (90). Interestingly, no significant effect was seen for postmenopausal women, which was probably related in part to the fact that these women were less likely to tolerate the full course of therapy (91). After 20 years of follow-up, this trial demonstrated a persistent survival advantage for premenopausal women receiving CMF adjuvant therapy (92). In a later study involving node-negative, estrogen receptor–negative breast cancer patients, after 12 years of follow-up, 71% of patients treated with adjuvant CMF remained disease free compared with 48% in the control group, regardless of menopausal status (93).

Currently, anthracyclines (A) are more commonly used in the adjuvant and metastatic treatment of breast cancer than any other agents. A large randomized NSABP study compared CMF with AC regimens in node-positive patients and found similar treatment outcomes among both groups. The AC regimen, however, was preferred because of its shorter duration (four cycles for 3 months versus six cycles for 6 months) and better tolerance (94).

Taxanes are also being used in a variety of multiple-agent chemotherapy regimens because of their demonstrated activity in metastatic breast cancer patients (95). In a randomized trial of 3,170 node-positive patients who received four cycles of AC followed by four cycles of paclitaxel for 4 weeks or no additional therapy, survival rates improved from 84% to 87% in the treated group after 36 months of follow-up. Benefits were similar in both premenopausal and postmenopausal women (96). Although the role of taxanes in the adjuvant setting for women with node-negative disease has yet to be definitively defined, early results suggest an improvement in overall survival when taxanes are used in the treatment of women with early-stage breast cancer (97).

The use of neoadjuvant chemotherapy traditionally was limited to those individuals with either inoperable locally advanced or inflammatory breast cancers. The goal of preoperative systemic therapy was to convert inoperable patients into resectable candidates on the basis of pathologic and clinical responses (98). More recently, indications for neoadjuvant chemotherapy have been broadened to include individuals presenting with large operable tumors who desire to attempt breast preservation instead of mastectomy. Recent reports indicate that breast conservation therapy is possible and that low rates of in-breast or local-regional recurrences occur when neoadjuvant chemotherapy results in clinical and pathological tumor downstaging (99). In addition to large, operable tumors, neoadjuvant therapy continues to have a role in the treatment of inflammatory breast cancers and those presenting in a locally advanced state.
Hormonal Therapy

Hormonal manipulation with tamoxifen or an aromatase inhibitor, used alone or in combination with a cytotoxic regimen, is beneficial in select groups of women. Tamoxifen, an estrogen analogue, offers substantial benefits in both premenopausal and postmenopausal women. Taken at a dose of 20 mg per day for 5 years, tamoxifen reduces the annual risk of recurrence by about 50% and the annual risk of death by about 25%. These benefits were seen in women with estrogen receptor–positive disease regardless of chemotherapy treatment (100).

Tamoxifen, when used in combination with cytotoxic chemotherapy, improves survival in women with positive axillary lymph nodes and positive estrogen receptor expression (101). In patients with node-negative, estrogen receptor–positive disease, the addition of tamoxifen to chemotherapy improved disease-free survival rates after 5 years of follow-up (102). In NSABP study B-14, 2,644 patients with estrogen receptor–positive tumors and no axillary metastases were randomized to either tamoxifen (10 mg orally twice daily for 5 years) or a placebo control. After a 4-year median follow-up, the disease-free survival rate for the 1,318 patients treated with tamoxifen was 82% compared with 77% for the 1,326 patients treated with placebo (P = 0.00001), again regardless of menopausal status.

The Early Breast Cancer Trialists’ Collaborative Group performed a meta-analysis of adjuvant systemic therapy for breast cancer. They analyzed randomized trials involving adjuvant systemic hormonal, cytotoxic, or immune therapy administered to more than 75,000 women with stage I or II carcinoma. The investigators concluded that for postmenopausal women with estrogen receptor–positive tumors, tamoxifen daily for at least 2 years had a significant beneficial effect on disease-free survival rates, with these effects lasting up to 10 years. The incidence of both carcinoma in the contralateral breast and death rate from heart disease decreased.

In addition to tamoxifen, aromatase inhibitors have been approved for use in the adjuvant treatment of patients with estrogen-receptor positive cancers. Aromatase inhibitors act by inhibiting the aromatase enzyme, thus blocking the conversion of androgens into estrogens. These drugs should be used only in postmenopausal patients or premenopausal women who have undergone chemical ovarian suppression or oophorectomy. Although aromatase inhibitors cause fewer episodes of thrombotic events, hot flashes, and endometrial cancers, musculoskeletal symptoms and osteoporosis are more commonly encountered among aromatase inhibitor users than those taking tamoxifen. Results from the Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial showed overall lower recurrence rates, as well as fewer contralateral tumors, among women treated with Arimidex alone after 68 months of follow up (103). Based on these results, aromatase inhibitors are now often offered as a first-line treatment option for adjuvant therapy. In addition, recent research suggests that conversion of patients from tamoxifen to an aromatase inhibitor, such as Femara, after 2.5 or 5 years may improve survival, although concurrent use of the two agents offers no benefit (103,104).

General Recommendations

Adjuvant systemic therapy lowers the incidence of recurrence by 25% to 30%. It is important to understand that the proportional reduction in risk of relapse is relatively constant regardless of absolute risk (105) (Table 38.6). As mentioned earlier, adjuvant cytotoxic chemotherapy appears to affect the natural history of patients with either axillary node-negative or node-positive breast cancer. All high-risk patients with node-negative disease are now considered candidates for adjuvant cytotoxic therapy.

In postmenopausal, estrogen receptor–positive women, chemotherapy is about one half as effective as tamoxifen in the adjuvant setting (106). For most postmenopausal women with hormone-responsive disease (estrogen- and progesterone-responsive positivity),
including node-positive patients, hormonal therapy alone may be adequate treatment. High-risk patients with hormone-resistant disease benefit from cytotoxic systemic therapy. Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with a high risk of recurrence are likely to receive the greatest benefit. Regardless, comorbidities must always be considered on an individual basis.

The current recommendations for adjuvant systemic therapy in breast cancer are summarized as follows:

1. Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. Tamoxifen should be added for patients with estrogen receptor–positive tumors following cytotoxic therapy.

2. Premenopausal women without evidence of axillary lymph node involvement but with large (≥1 cm) size, aneuploid, or estrogen receptor–negative tumors should be treated with combination chemotherapy. Tamoxifen should be given to patients with estrogen receptor–positive tumors.

3. Postmenopausal patients with negative lymph nodes who are hormone receptor positive should receive adjuvant tamoxifen or aromatase inhibitor therapy. Those with positive lymph nodes may receive tamoxifen or an aromatase inhibitor alone, multidrug cytotoxic therapy, or a combination thereof.

4. Postmenopausal women with lymph node metastases who are hormone receptor negative may be treated with adjuvant chemotherapy.

5. Adjuvant systemic therapy is not recommended for patients with favorable tumors smaller than 1 cm. Hormonal therapy may be considered if the patient is estrogen receptor positive.

Prognosis

The treatment of advanced, metastatic breast cancer is largely palliative. For most physicians, quality-of-life issues are paramount when choosing which type of therapy is
offered. In patients with locally advanced disease in conjunction with distant metastasis, palliative radiotherapy may be advised to control pain or avoid pathologic fractures. This approach is best exemplified in the treatment of isolated bone metastases, chest wall recurrences, brain metastases, and spinal cord compression.

**Systemic disease may be controlled by hormonal or cytotoxic therapy.** Because the quality of life during an endocrine-induced remission is usually superior to one following cytotoxic chemotherapy, it is preferable to try endocrine manipulation first. As many as one third of patients with disseminated disease respond favorably to either functional end-organ ablation (ovary, pituitary, adrenal glands) or administration of drugs that block hormonal function. For patients with estrogen receptor–positive tumors, this response rate may be as high as 60%. Because only 5% to 10% of women with estrogen receptor–negative cancers respond to endocrine treatment, they should not routinely receive hormonal therapy except in unusual cases, such as elderly women who are intolerant of cytotoxic therapy (107).

Cytotoxic chemotherapy should be considered for the treatment of metastatic breast cancer if organ involvement is potentially life-threatening (brain, lung, or liver), if hormonal treatment is unsuccessful, if the disease has progressed after an initial response to endocrine manipulation, or if the tumor is estrogen receptor negative. The most useful single chemotherapeutic agent is an anthracycline such as doxorubicin, which has an estimated response rate of 40% to 50%. Combination therapy using multiple agents has response rates as high as 60% to 80% (108). Clinical trials, including those investigating the use of Herceptin for Her-2/neu-positive women with metastases, are under way to examine a variety of combinations for stage IV disease. The historically prominent side effects of debilitating nausea and vomiting are now well controlled with central-acting antiemetics. The importance of controlling these potentially devastating symptoms cannot be overemphasized.

**Special Breast Cancers**

**Paget Disease**

In the 1870s, Sir James Paget first described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy (109). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. Although the origin of these cells has been much debated by pathologists, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient’s presenting symptom will be nipple discharge, which is actually a combination of serum and blood from the involved ducts.

The **overall prognosis for patients with this rare form of breast cancer depends on the stage of the underlying malignancy.** When an intraductal carcinoma alone is identified, the prognosis remains favorable, whereas patients with infiltrating ductal carcinoma metastatic to the regional lymph nodes have worse outcomes. Traditionally, treatment has almost always been total mastectomy and lymph node dissection, although breast conservation therapy with resection of the tumor and nipple–areolar complex, followed by whole breast radiation, is being performed in appropriately identified patients (110).

**Inflammatory Carcinoma**

Patients presenting with inflammatory carcinoma initially appear to have acute inflammation of the breast with corresponding redness and edema. Additional clinical findings are variable and range from complete absence of a dominant mass to the presence of either satellite skin nodules or a large palpable abnormality.
Inflammatory cancer, rather than infiltrating ductal carcinoma, should be diagnosed when more than one third of the breast is involved with erythema and edema and when biopsy of the involved area, including the skin, demonstrates metastatic cancer in the subdermal lymphatics. Most of these tumors are poorly differentiated. Mammographically, the breast shows skin thickening with an infiltrative process and may or may not identify a mass or calcifications.

Except for biopsy of the lesion to establish the diagnosis, surgery is not part of the initial management of inflammatory carcinoma. Mastectomy usually fails locally within 2 years of the initial diagnosis and does not improve overall or disease-free survival rates. Better results are achieved with a combination of chemotherapy and radiation therapy. Mastectomy may be indicated for patients who remain free of distant metastatic disease after initial chemotherapy and radiation (111).

In Situ Carcinomas

Both lobular and ductal carcinoma may be confined by the basement membrane of the ducts. These carcinomas do not invade the surrounding tissue and, theoretically, lack the ability to spread.

**Lobular Carcinoma In Situ**

Lobular carcinoma in situ should not be considered a true malignancy but rather a risk factor for the subsequent development of invasive ductal or lobular carcinoma in either breast (112). A more appropriate nomenclature for lobular carcinoma in situ may be lobular neoplasia. Most women with lobular carcinoma in situ are premenopausal and have neither clinical nor mammographic signs of an abnormality. The lesion typically is not a discrete mass, but rather a multifocal entity within one or both breasts incidentally discovered by the pathologist during the evaluation of a completely unrelated issue. Lobular carcinoma in situ usually is managed with an excisional biopsy followed by careful surveillance with clinical breast examinations and mammography. Occasionally, a patient may request either bilateral prophylactic mastectomy or tamoxifen for chemoprevention. Women with lobular carcinoma in situ have a 1% per year and up to a 30% lifetime risk of developing an invasive cancer.

**Ductal Carcinoma In Situ**

Ductal carcinoma in situ is more common in postmenopausal women. It may manifest as a palpable mass but usually is detected mammographically as a cluster of branched or Y-shaped pleomorphic microcalcifications. By definition, intraductal disease does not invade beyond the basement membrane. Unlike patients with lobular carcinoma in situ, 30% to 50% of patients with ductal carcinoma in situ will develop an invasive ductal cancer within the same breast if treated by excisional biopsy alone (113).

Although modified radical mastectomy was previously the standard treatment for intraductal carcinoma, more conservative surgery, with or without radiation therapy, has been shown to yield good results. In NSABP trial B17, 818 patients were randomly assigned to excision alone or excision followed by radiation therapy. The mean extent of ductal carcinoma in situ lesions was 13 mm, and 88% were larger than 20 mm. All lesions were completely resected with negative margins. After a median follow-up of 43 months, the actuarial 5-year local recurrence rate was 10.4% without radiation versus 7.5% with radiation ($P = 0.055$) for noninvasive cancers, and 10.5% without radiation versus 2.9% with radiation ($P > 0.001$) for invasive cancers. Of 83 recurrences, only 9 (11%) were not in the index quadrant. A recent reanalysis with a mean follow up of 90 months confirmed these results (114). These data suggest that segmental mastectomy offers excellent local control.

Axillary metastases occur in fewer than 5% of patients diagnosed with ductal carcinoma in situ, making routine axillary dissection unnecessary. When axillary disease is
identified, further evaluation of the breast or surgical specimen or both is warranted because nodal metastases indicate that an invasive ductal component was missed. Sentinel node biopsy may be offered to certain individuals with ductal carcinoma in situ, especially if the lesion is high grade, contains comedonecrosis, or was diagnosed on core biopsy and has clinical or radiographic features suggesting invasive disease. About 5% of patients whose initial biopsy results show intraductal carcinoma will be found to have infiltrating ductal carcinoma when treated with mastectomy, whereas core biopsy may underestimate the invasiveness of the disease in up to 20% of patients. The incidence of contralateral breast cancer in women with intraductal carcinoma is the same as in those with invasive ductal carcinoma (5%–8%) (115).

Breast Cancer in Pregnancy

Breast cancer complicates 1 in 3,000 pregnancies (116,117). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer (118). Initial studies suggested a significantly worse prognosis for patients first diagnosed during pregnancy, but recent data indicate that the hormonal changes associated with pregnancy seem to have little, if any, influence on prognosis. When pregnant patients are matched stage for stage with nonpregnant patients, survival rates seem equivalent (119). Patients typically present with a painless mass. Up to 60% will have concurrent lymph node involvement. The evaluation includes imaging with ultrasonography and mammography, which, although controversial, expose the fetus to less than 0.02 cGy of radiation and may be obtained with proper abdominal shielding (120). If biopsy is warranted, the procedure can be performed safely and should not be delayed until after delivery. Needle biopsy is safe and easily accomplished in the office setting.

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient’s age and desire to continue the pregnancy. The overall prognosis should be considered, especially when axillary lymph nodes are involved, because adjuvant chemotherapy can be teratogenic or lethal to the fetus during the first trimester, but may be given later in the pregnancy. It is believed that interruption of pregnancy does not alter the prognosis for patients with potentially curable breast cancer.

Following are generalized recommendations for treatment of pregnant women with breast cancer:

1. Traditionally, cancers diagnosed during the first or second trimester of pregnancy have been treated with modified radical mastectomy. Sentinel node biopsy remains a controversial procedure in pregnancy; the use of blue dye is contraindicated, and the safety of radiocolloid has not been documented. In addition, most centers do not offer breast conservation therapy based on the theory that radiation therapy should not be given to the gravid patient. In a patient diagnosed before the third trimester, waiting until after delivery may result in an unacceptable delay in the initiation of therapy and should not be encouraged. Adjuvant chemotherapy can be given after the first trimester, although many oncologists prefer not to give it to pregnant women outside of clinical trials. A classic study reported the risk of fetal malformations to be 20% during the first trimester, a rate which dropped to 1.5% during the second and third trimesters (121). Tamoxifen, however, is a class D drug and should not be given to pregnant or lactating patients with breast cancer.

2. Localized tumors found during the third trimester of pregnancy can be managed with breast conservation therapy, with radiation delayed until after delivery, or with modified radical mastectomy. Initially, tumors should
be excised early in the third trimester using local anesthesia. If delivery is imminent, standard therapy can be performed immediately postpartum. In the patient with a viable fetus, it may be preferable to induce early labor to avoid delaying definitive cancer therapy.

3. If the breast cancer is diagnosed during lactation, lactation should be suppressed and the cancer should be treated definitively.

4. Advanced, incurable cancer should be treated with palliative therapy. Decisions regarding continuation of the pregnancy should be based on the therapy necessary and the desires of the mother.

Counseling regarding future childbearing is important for women who have had carcinoma of the breast. Although it generally has been assumed that subsequent pregnancies are detrimental because of the high levels of circulating estrogens, there is no clear difference in survival for women who become pregnant after the diagnosis of breast cancer. One study evaluated the effect of subsequent pregnancy on overall survival after the diagnosis of early-stage breast cancer. Although approximately 40% of the women in the study had node-positive disease, 5- and 10-year survival rates were better in women who became pregnant than in matched pair controls who did not. This study suggests that subsequent pregnancy does not adversely affect the prognosis of early-stage breast cancer (122). A subsequent investigation demonstrated no increase in the relative risk of death for patients who gave birth more than 10 months after their initial diagnosis of cancer (123). Theoretically, it may be that only women with estrogen receptor–positive or progesterone-positive tumors would be affected deleteriously by subsequent pregnancy, but this possibility has not been studied. Because recurrences are most frequent within the first 2 to 3 years after diagnosis, patients with receptor-positive tumors and advanced-stage disease probably should wait until after that time before becoming pregnant again.
