In most instances, incisional endometriomas have followed surgical procedures that violated the uterine cavity and allowed the endometrium to be transplanted. Wespi and Krähenbühl suggested that the frequency might approach 5% among patients having cesarean section or hysterectomy. Metroploysy and myomectomy also increase the risk of incisional endometriosis. Indeed, endometriosis has been reported along the needle tracts after amniocentesis or saline injection for abortion. Careful flushing and irrigation of the abdomen and of the incision during closure should minimize the chance of contamination when incision into the uterine cavity is required. Episiotomy scars and cervical and vaginal lacerations also serve as implantation sites after delivery. The chance is significantly increased when postpartum curettage is performed. Pauil and Tedeschi reported 15 instances in 2,208 deliveries when curettage was carried out and no instances in 33,800 deliveries without curettage.

Management, usually best accomplished by local excision, is both diagnostic and curative. Various hormonal regimens may be appropriate if it is imperative to avoid surgery. However, malignancy can occur in each area of ectopic endometriosis, and histologic confirmation of the tentative diagnosis is recommended.

Thorax. Thoracic endometriosis is an uncommon disease with varying clinical presentations. The diagnosis is almost always established on clinical grounds. In a report of 65 cases of thoracic endometriosis (Foster et al.), pleural and lung parenchymal disease presented with different clinical features. Ninety-three percent of women with pleural disease developed pain with right-sided pneumothorax or pleural effusion. Because numerous right diaphragmatic defects were noted in patients with pleural involvement, pleural implants are believed to be secondary to tubal regurgitation and transport of endometrial tissue through the diaphragmatic defects. Other symptoms may include upper quadrant abdominal pain or referred pain to the shoulder. Disease involving the lung parenchyma produces hemothorax rather than the pleuritic symptoms. Previous pelvic surgery was more common among women who had parenchymal endometriosis; however, pelvic endometriosis was found more often in those with pleural disease.

Catamenial pneumothorax or hemothorax should alert the physician to the possibility of thoracic endometriosis. The chest roentgenogram is usually of little value in diagnosing this disease; however, cytology, aspiration biopsy, and pneumoscopy may be useful. Massive effusion and bleeding can occur, but this presentation is more commonly associated with a malignancy. GnRH agonist or surgical treatment may be effective in the symptomatic patient. Surgical pleural abrasion may be superior to hormonal treatment in the long-term management of pneumothorax.

Adjuvante Procedures of Conservative Surgery

Uterine Suspension. Uterine suspension techniques have been devised to reduce adhesion formation at denuded peritoneal surfaces of the posterior cul-de-sac, uterine serosa, and broad ligament. Elevation of the adnexa may prevent adhesion formation of the ovary or fallopian tube at a site where existing adhesions have been excised. This procedure may be particularly useful in the case of a posterior or retroflexed uterus. It is indicated in selected cases of dyspareunia after resection of posterior cul-de-sac endometriosis. There is no evidence to suggest that uterine suspension is detrimental to subsequent pregnancies, although it is of unproven efficacy in enhancing fertility or as an adjunct in the treatment of endometriosis-associated pelvic pain. The modified Gilliam procedure offers certain advantages over other uterine suspensions because of its maintenance of normal anatomic relations. Shortening the round ligament through the internal inguinal ring eliminates the opening that is made lateral to the point of the ligament’s attachment to the abdominal wall in the Olshausen suspension procedure. When a modified Gilliam suspension is performed via laparotomy, the uterus is elevated, and a 2-0 absorbable suture is placed around each round ligament about 3 to 4 cm from its insertion into the uterus (Fig. 22.10). The edge of the rectus fascia is grasped by a Kelly clamp. The rectus fascia is separated from the underlying musculature with blunt dissection. A long Kelly clamp is inserted between the fascia and muscle to the level of the inguinal ring while displacing the peritoneum superiorly. The clamp is inserted through the ring and along the round ligament by gently opening and closing the instrument. The insertion is facilitated by placing traction on the suture to stabilize the peritoneum. The peritoneum overlying the ligament is then incised at a point adjacent to the suture, and the suture is grasped by the Kelly clamp. By withdrawing the clamp, the round ligament is brought through the internal ring and outside of the peritoneal cavity; it can then be sutured to the rectus sheath with 2-0 interrupted delayed-absorbable sutures. These sutures must be placed through the round ligament without
FIGURE 22.10. Modified Gilliam suspension. A: A chromic suture is placed around the round ligament about 3 to 4 cm from the uterine cornu. B: The rectus fascia is grasped with Kocher clamps and separated from the belly of the rectus muscle bluntly with the index finger or knife handle. C: The parietal peritoneum is grasped with Kelly forceps. A long Kelly forceps is introduced through the internal inguinal ring as it passes over the belly of the rectus. D: The Kelly clamp is brought through the internal inguinal ring and along the round ligament to a point adjacent to the chromic stay suture. A knife is used to open the peritoneum. The ends of the chromic suture are grasped by the Kelly clamp. E: As traction is applied to the suture, a knuckle of the round ligament passes through the internal ring. F: Three sutures of 2-0 delayed-absorbable or silk suture are placed, fixing the ligament to the rectus fascia in a manner that will not interrupt the blood supply.
Presacral Neurectomy. Presacral neurectomy, or division of the superior hypogastric plexus, is useful as an adjunctive procedure to eliminate the uterine component of dysmenorrhea that results from endometriosis. Sixty percent to 85% of patients with secondary dysmenorrhea experience complete relief of symptoms. There is no evidence that presacral neuroectomy enhances fertility.

A significantly greater relief of midline pelvic pain is achieved when endometriosis resection is combined with presacral neurectomy compared with conservative resection alone. In a study by Jaden and colleagues, all 17 patients undergoing presacral neurectomy noted a complete resolution of midline pelvic pain. The desired outcome is to be achieved when endometriosis resection is combined with presacral neurectomy via laparotomy in 50 women with chronic pelvic pain, endometriosis, and pelvic inflammatory disease increased total postoperative pain relief from 25% to 75%, although only a small number of patients were included in this laparotomy series. Lee and coworkers performed presacral neurectomy via laparotomy in 50 women with chronic pelvic pain. Dysmenorrhea resolved in 73% of these patients, and further improvement was achieved during 77%. Two 0 absorbable or silk sutures are placed around the proximal and distal aspects of a 5-cm segment of the plexus and are loosely tied. The tonsil clamp is introduced medially next to the promontory for about 5 cm to the third or fourth sacral vertebra and cranially to just below the bifurcation of the aorta. The margin of the posterior peritoneum can be drawn upward and outward by a stay suture or an Allis clamp. A Kimura sponge is then used to dissect the areolar tissue and associated nerve fibers off the posterior aspect of the peritoneal flap. The right ureter is readily visible and can be retracted laterally, and the areolar tissue is dissected from it without disturbing its blood supply. The common iliac artery, which lies just below the ureter, is freed superiorly from the adjacent tissue. A right-angle clamp or Babcock forceps can be introduced medially next to the promontory to elevate the sheath and allow blunt dissection underneath it. Care must be taken to avoid the middle sacral vessels that may be left intact on the surface of the promontory. Injury to the middle sacral vein can result in significant blood loss. Hemorrhage is controlled with cautery, suture ligations, hot packs, hypogastric vessel ligation, use of an absorbable gelatin sponge (Gelfoam) or microfibrilar collagen (Avitene), or packing with bone wax.

The areolar tissue is taken off the left flap of peritoneum until the superior hemorrhoidal vessels are exposed. These vessels should remain on the presacral nerve bundle to be left intact on the surface of the promontory. Injury to the mesentery of the sigmoid on the left. The presacral nerve is isolated by developing the avascular space between the presacral nerve and right internal iliac artery down to the periosteum. The preserving the uterosacral ligaments were resected in half of the subjects in this study, but this did not seem to affect the overall rate of pain relief. In a randomized clinical trial of women with chronic pelvic pain, endometriosis, and pelvic inflammatory disease increased total postoperative pain relief from 25% to 75%, although only a small number of patients were included in this laparotomy series. Lee and coworkers performed presacral neurectomy via laparotomy in 50 women with chronic pelvic pain. Dysmenorrhea resolved in 73% of the cases, dyspareunia in 75%. Two 0 absorbable or silk sutures are placed around the proximal and distal aspects of a 5-cm segment of the plexus and are loosely tied. The tonsil clamp is introduced medially next to the promontory for about 5 cm to the third or fourth sacral vertebra and cranially to just below the bifurcation of the aorta. The margin of the posterior peritoneum can be drawn upward and outward by a stay suture or an Allis clamp. A Kimura sponge is then used to dissect the areolar tissue and associated nerve fibers off the posterior aspect of the peritoneal flap. The right ureter is readily visible and can be retracted laterally, and the areolar tissue is dissected from it without disturbing its blood supply. The common iliac artery, which lies just below the ureter, is freed superiorly from the adjacent tissue. The descending colon is displaced superiorly and to the left for good exposure of the left margin of the hypogastric plexus. B: A Kimner sponge is used to dissect the areolar tissue medially and off the posterior aspect of the peritoneal flap. The right ureter can be identified easily. C: The areolar nerve-bearing tissue is dissected from the peritoneum on the left side, exposing the left internal iliac vessels and superior hemorrhoidal vessels. D: The plexus is isolated and elevated off the sacral promontory. A segment of plexus about 5 cm in length is isolated with 2-0 silk sutures. E: The plexus is excised. Note relation between pedicles of the nerve bundle and adjacent structures.
moderate to severe endometriosis and pelvic pain undergoing conservative surgical therapy, Candiani and colleagues reported a recurrence of midline menstrual pain in 23% of women who underwent presacral neuroectomy versus a 42% recurrence in those who did not. This difference reached the limit of statistical significance \( p = 0.06 \).

In an uncontrolled laparoscopic study by Nezhat and associates, 50 women were subjected to vaporization of endometriosis and presacral neuroectomy, the symptoms of pelvic pain, dysmenorrhea, and dyspareunia were reduced by more than 50% in 74, 61, and 55 patients, respectively, over the 1-year follow-up period. The stage of endometriosis did not correlate with the degree of pain improvement achieved. More recently, in a prospective, randomized, double-blind, controlled trial, Zullo and colleagues reported that the performance of laparoscopic presacral neuroectomy improved the cure rate in women treated with conservative laparoscopic surgery for severe dysmenorrhea caused by endometriosis as compared with those who underwent mere ablation of endometriosis (85.7% vs. 57.1% at 12 months, \( p < 0.05 \)).

Two common side effects of the presacral neuroectomy procedure have been observed. Constipation may require laxatives or stool softeners for a period of 3 to 4 months. The vaginal dryness that develops in as many as 10% to 15% of patients is transient and usually resolves within 6 months. Difficulty with micturition is an infrequent complication that rarely lasts for more than 1 or 2 months. A painless first stage of labor has been reported in women who have undergone presacral neuroectomy.

**Uterine Nerve Ablation.** The technique of uterosacral neuroectomy was initially described by Ruggi in 1899. Later popularized by Doyle, it has since been adapted for performance during laparoscopy as a procedure for lysis of dysmenorrhea. Sympathetic fibers T10 to L1 are contained within the inferior hypogastric plexus and course along the inferior vena cava and sacrum to enter the uterus through the nerves of the uterosacral ligaments and accompanying uterine arteries. The parasympathetic components of the paracervical nerves originate from S1 through S3 or S4, travel within the nervi erigentes, and emerge in the lateral pelvis to form the Frankenhäuser ganglia lateral to the cervix. Division of the uterosacral ligaments at a point approximately 1.5 cm distal to the cervix should interrupt most sensory nerve fibers of the cervix and uterine corpus.

In general, uterine nerve ablation by laser is preferable to electrocautery because it is less likely to cause undesirable thermal damage. The course of the ureters and adjacent vasculature should be noted before commencement of dissection. The uterosacral ligaments are exposed by manipulating the uterine canal anteflex to the corpus and by applying pressure to the posterior cervix with an ancillary laparoscopic probe.

The initial incision is made on the medial aspect of the liga ment at its junction with the uterus. A second incision is made just lateral to the uterosacral ligament and medial to the ureter. The ligament is then grasped with forceps and stretched toward the sidewall. The CO₂ laser is used to vaporize a 2- to 5-cm area of each ligament to a depth of approximately 1 cm. This division should be centered approximately 1.5 cm distal to the cervix. The posterior aspect of the cervix between the insertions of the uterosacral ligaments may be superficially vaporized to interrupt the sensory fibers crossing to the contralateral side. Because extension of the beam too far lateral or posterior can result in considerable bleeding, the surgeon should have immediate access to bipolar cautery, endocooling, or hemostatic clips. Fiber lasers such as the KTP/532 offer the advantages of increased hemostasis and lack of carbon plume, compared with the CO₂ instrument. If bipolar diathermy is used to fulgurate the uterosacral ligament, laparoscopic scissors are used to excise the segment of ligament in question.

Early retrospective and often uncontrolled clinical trials suggested that the laparoscopic uterosacral neuroectomy technique might be efficacious. Feste reported significant improvement in the symptoms of primary dysmenorrhea associated with endometriosis in 71% of a series of 42 patients. In a similar series of 100 patients by Donnez and Nisolle, 50% experienced complete relief, 41% had mild to moderate relief, and 9% described no relief. Using the carbon dioxide laser, Davis observed a considerable improvement in dysmenorrhea in 135 of 146 women (92%) with endometriosis and an improvement in dyspareunia in 103 of 109 women (94%) with endometriosis who underwent uterine nerve ablation and vaporization of endometriosis. This therapeutic benefit did not seem to differ among revised ASRM classification stages of endometriosis.

Lichten and Bombard published a randomized, prospective, double-blind study of laparoscopic uterosacral nerve ablation for the treatment of severe or incapacitating dysmenorrhea unresponsive to oral contraceptives and nonsteroidal antiinflammatory agents. None of the control patients noted improvement, whereas 9 of 11 in the treated group had almost complete relief at 3 months, and 5 of 11 described complete relief from dysmenorrhea 1 year after surgery. Patients with endometriosis were not included in this small series.

Surgical resection of pelvic endometrial implants may be all that is necessary to alleviate discomfort in most endometriosis patients. In a double-blind, randomized controlled laparoscopic trial, Johnson and colleagues found that uterine nerve ablation was effective in reducing dysmenorrhea in the absence of endometriosis, but the addition of this procedure to the surgical treatment of endometriosis was not associated with a significant difference in any pain outcomes. Similarly, Vercellini and colleagues could not demonstrate the efficacy of this procedure.

Uterine nerve ablation by laparotomy fell from favor because it was revived as an endoscopic technique. The potential neurological, intestinal, orthopedic, and psychological components of pain should be considered before subjecting the patient to a procedure that, although now performed endoscopically, carries some surgical risk, and whose effectiveness has been questioned because of the small number of cases evaluated. Complications associated with transection of the uterosacral ligaments include ureteral damage, bowel damage, and postoperative hemorrhage, which, if undetected, may result in death. Uterine prolapse has recently been described as a potential long-term side effect of the procedure.

**Second-Look Laparoscopy**

Second-look laparoscopy has been suggested as an appropriate procedure for additional lysis of pelvic adhesions in patients who have undergone a laparotomy or a laparoscopy for the resection of endometriosis. If scheduled 8 days to 6 weeks after the initial dissection, second-look laparoscopy allows separation of de novo adhesions that are dynamic in nature from those that are stable.

In addition, laparoscopy after pelvic reconstructive surgery provides an opportunity to assess future prognosis for fertility.

Early second-look laparoscopy after endoscopic treatment of endometriomas has revealed a recurrence rate of de novo endometriomas of 15% to 20%. Equally significant are the nearly 20% incidence of de novo adhesion formation and the 40% to 82% recurrence rate of dense adhesions. Second-look laparoscopy
Surgical Outcomes

No classification scheme for endometriosis provides an accurate correlation between extent of disease and pregnancy rate. Nevertheless, point categorization through the revised ASRM classification does provide a framework in which to report outcomes of therapy.

Fertility

In a review of the surgical outcome expected through laparoscopic therapy for minimal and mild endometriosis, the crude pregnancy rate following cautery or laser ablation of implants was 54% to 58% (Cook and Rock). Life-table analysis showed similar conception rates following laparoscopy and laparotomy to excise minimal or mild stages of endometriosis. Hence the performance of a laparotomy is not warranted for lesser stages of disease.

Treatment of mild endometriosis via laparoscopic excision or electocauterization resulted in similar reproductive outcomes in a retrospective study by Tulandi and Al-Took. The total pregnancy rate was 53.3% in the excision group and 37.1% in the electrosurgical group. The mean interval between surgery and conception was 10.7 months in the electroygery group and 13.3 months in the excision group. Excision of tissue may result in more complete removal of infiltrating endometriomas, which should be of particular benefit to patients with deep nodules.

The stage of disease as categorized by the modified ASRM classification of endometriosis did not predict subsequent reproductive performance in a 2006 study by Vercellini and colleagues. Five hundred and thirty-seven infertile women with endometriosis undergoing first-line conservative laparoscopic surgery were followed for a mean of 32 months postoperatively. The cumulative probability of pregnancy at 3 years following laparoscopy was 47% (91% at stage I, 45% at stage II, 46% at stage III, and 44% at stage IV). Log-rank test, [chi]^2 = 1.50, P = 0.68.

Expectant management of mild to moderate endometriosis after diagnosis by laparoscopy yields a crude pregnancy rate of about 50%, which has brought into question whether surgical therapy of lesser stages of disease actually enhances fertility. In a retrospective study comparing the efficacy of electrosurgical treatment of endometriosis with the efficacy of expectant management in minimal and mild endometriosis-associated infertility, Tulandi and Mochohar reported that the cumulative probability of conception was significantly higher among patients treated surgically. Moreover, metaanalysis of the two randomized prospective trials showed that laparoscopic electrosurgery or laser to resect or ablate stage I-II endometriosis implants and adhesions resulted in a significantly higher fecundity rate as compared with the control group undergoing expectant management. The largest trial (Marcoux et al., 1997) clearly supported this outcome, with an increased chance of pregnancy (odds ratio OR 2.03, 95% confidence interval [CI] 1.28–3.24) and ongoing pregnancy rate after 20 weeks (OR 1.95, 95% CI 1.18–3.22) (Fig. 22.12), but the smaller trial (Parazzini, 1999) did not show benefit (pregnancy OR 0.76, 95% CI 0.31–1.88, live birth OR 0.83, 95% CI 0.32–2.28). When the ongoing pregnancy and live birth rates from these two studies were combined, there was a statistically significant increase with surgery (OR 1.64, 95% CI 1.05–2.57) (Jacobson et al.). The findings suggest that for every 12 patients having stage I or II endometriosis diagnosed at laparoscopy, there will be one additional successful pregnancy if ablation or excision of visible endometriosis is performed, compared with no treatment.

Operative treatment of moderate or severe disease does offer a greater likelihood of conception than does expectant management, in part because of correction of mechanical factors such as adhesions. The overall crude pregnancy rate reported by various studies of conservative laparotomy for endometriosis that stratified reproductive results by disease severity was 38%, with a monthly fecundity rate averaging 1.4% to 1.5% (Cook and Rock). Laparoscopic treatment of severe endometriosis offered a mean crude pregnancy rate of 47.6% in a small compilation of series. Hence, expert laser laparoscopy has reported results that appear to be as good as those obtained through the open abdomen, although there are inadequate data for direct comparison of outcomes of the two surgical modalities, and the correct identification and classification of disease may vary between laparotomy and laparoscopic groups. Life-table analysis demonstrated that pregnancy is most likely to occur during the first 36 months after surgery. Furthermore, the duration of infertility and, perhaps, patient age may have a greater impact on cumulative pregnancy rates than the actual stage (revised ASRM stages I through IV) of the disease.

Pain

In a prospective, randomized double-blind, controlled trial of laser laparoscopy in the treatment of pelvic pain associated with minimal to moderate endometriosis, Sutton and associates found that 82.5% of the laser-treated women reported symptom improvement at 6 months as compared with 22.6% of those treated expectantly. Symptom relief continued at 1 year in 90% of those who initially responded. Moreover, in a more recent randomized, blinded, crossover study, 80% percent of patients who underwent excisional surgery had symptomatic improvement as compared with 30% of the placebo group (Abbott et al., 2004).

The technique of surgically treating lesser stages of endometriosis may not significantly influence pain relief, as long as the surgeon is aware of the depth of extension of the lesions. In a recent randomized study by Wright and colleagues, both excision and ablation of mild endometriosis produced good symptomatic relief and reduction of pelvic tenderness (67%).
Long-term improvement in quality of life can be achieved with laparoscopic excision of endometriosis. In a prospective, observational cohort study of 176 women with chronic pelvic pain with surgically diagnosed endometriosis, pain scores were highly significantly reduced at 2 to 5 years following resection in the categories of dysmenorrhea, dyspareunia, nonmenstrual pain, and dyschezia. The chance of requiring further surgery was significantly reduced at 2 to 5 years. The primary laparoscopic stripping procedure was associated with a lower reoperation rate than that of fenestration. In a study of patients who underwent conservative laparoscopic excision of endometriosis by sharp dissection, Rock and colleagues have shown that 13.5% of patients initially treated with conservative surgery required subsequent operations. Wheeler and Malinak noted a cumulative recurrence rate of 13.5% and 40.3%, respectively. Nezhat and associates noted moderate to complete relief of pain in 162 of 175 women; however, some patients in this series had several surgical interventions. Preliminary analysis of the surgical results in 250 women in whom deep endometriosis had been excised with CO2 laser showed a cure rate of pelvic pain in 70% and a recurrence rate of less than 3% over a 3-year follow-up period. Verrelli and colleagues (2006) reported that conservative surgery for rectovaginal endometriosis in infertile women did increase the pain-free survival time, although it did not modify the reproductive prognosis over expectant management. The recurrence rate of clinically detectable endometriosis is higher when the depth of infiltration is greater than 5 mm at the time of initial surgery, no matter the site of the lesion. Persistence of dysmenorrhea and nonmenstrual pain after optimal endometriosis surgery may indicate adenomyosis. In a recent study by Parker and colleagues, chronic pelvic pain was significantly more likely to persist with uterine junctional zone thickness greater than 11 mm on preoperative MRI.

Recurrent Surgery

Rock and colleagues have shown that 13.5% of patients initially treated with conservative surgery required subsequent operative procedures. Wheeler and Malinak noted a cumulative recurrence rate at 3 and 5 years after conservative surgery of 13.5% and 40.3%, respectively. Neither the initial staging nor the ability to conceive after the initial surgery greatly affected the women’s outcomes. Redwine reported a cumulative recurrence rate of 19% at 5 years after conservative laparoscopic excision of endometriosis by sharp dissection. Laparoscopic excision of ovarian endometriomas by the stripping technique is associated with a lower reoperation rate than that of fenestration. In a study of patients who underwent laparoscopic cystectomy of ovarian endometriomas of greater than 3 cm in diameter, Busacca and colleagues reported a cumulative rate of alastronomographic recurrence of 11.7% over 48 months.

A second cytoreductive procedure may benefit some infertile women who have undergone surgery in the past if assisted reproductive technologies are not pursued. A cumulative pregnancy rate of 32.4% or 35.8 months was achieved by Fedele and colleagues (2006) after a second conservative laparoscopic stripping procedure for recurrent endometriomas. The recurrence of pain (17.4%) was similar to that experienced after the primary laparoscopic stripping procedure. However, if the initial surgery fails to restore fertility in patients with stage III or stage IV endometriosis, in vitro fertilization (IVF) may be more beneficial than reoperation for those who are otherwise asymptomatic. Pagidas and colleagues compared the outcomes of a second operation for stage III or IV endometriosis-related infertility versus proceeding directly to IVF. The cumulative pregnancy rate 9 months after surgery was 24.4%, compared with a pregnancy rate of 33.4% after one trial of IVF and a cumulative pregnancy rate of 69.6% after two trials of IVF.

Combination Medical and Surgical Treatment

Preoperative and postoperative medical therapies have been proposed as treatment for endometriosis. Endometriosis can be treated with medical or surgical therapies. However, some patients require a combination of both. Medical therapy includes gonadotropin-releasing hormone (GnRH) agonists, which reduce estrogen levels and thereby reduce the size of endometriosis implants, making them less recognizable after short-term drug therapy. In a controlled clinical trial by Muiii et al., a 3-month course of GnRH agonist treatment before laparoscopy for endometriosis excision failed to result in a reduction in operative time or recurrence rate of disease during a 1-year follow-up period. There are no substantive data to justify hormonal treatments before surgery to improve the success of surgery.

Initiation of postoperative medical therapy may inhibit the activity of any residual disease, suppress ovulation, and decrease the possibility of adverse effects of peritoneal spillage of disease at the time of resection. Postoperative medical therapy has a serious drawback, however; the patient is unable to attempt conception for several months. Andrews and Larsen have noted that the best chance for postsurgical conception occurs during the first 6 months after conservative surgery by laparotomy. Thus, suppressing ovulation during that critical period may be counterproductive. Treatment with a GnRH agonist after surgery does not improve fertility as compared with expectant management (Busacca et al.).

Contemporary management of women with endometriosis-associated pelvic pain involves both surgical and long-term medical therapy. When cytoreductive laparoscopy is followed by a 6-month course of GnRH analog, there is a significant delay in the return of endometriosis symptoms requiring further treatment. In a randomized, prospective study, Hornstein and colleagues found that this interval was more than 24 months in those receiving nafarelin versus 11.7 months in the placebo group. A shorter duration of hormonal therapy during the postoperative period may be inadequate in reducing recurrence risk. A 3-month course of nafarelin following surgical therapy of stage III and IV endometriosis was ineffective in reducing pain scores as compared with placebo. Postoperative administration of low-dose, cyclic oral contraceptives for 6 months delayed the recurrence of pain symptoms and endometriomas at 12 months, but no significant differences were detected at 24 months or 36 months following laparoscopic excision.

Hysterectomy

The number and rate of hysterectomies performed for endometriosis increased steadily from the 1960s to the 1980s, more so than for other diagnoses. The reported rate for 1982 to 1984 was more than double the rate for 1965 to 1967, although the exact reasons for the increase remain uncertain. Although statistically significant increases for hysterectomy rates were observed from 1994 through 1998, the increase was limited, and the curve remained nearly flat. Endometriosis was the primary indication for 28.8% of white women and 9.7% of black women undergoing hysterectomy in the United States.
are poor that it ever will occur. Techniques in assisted re-
surgical resection of endometriosis or within 1 year of repair
If spontaneous conception is not achieved within 3 years of

are at increased risk of recurrent pain and an 8.1 times greater risk of reoperation
tubal obstruction associated with endometriosis, the odds
surgical resection of endometriosis or pelvic inflammatory disease. Most hysterectomies for en-
do not necessarily lead to decreased pregnancy rates.
468 Surgery for Fertility
from 1994 to 1999. Because of concern over the risk of recur-
ence even after definitive surgical therapy, bilateral oophorec-
tomy was performed at the time of hysterectomy in 52% of
women 44 years of age or younger and in 81% of women 45
years of age or older.
Successful surgery offers prompt, complete, and long-term
relief of pain from endometriosis more often than do the var-
ious available medical regimens. Most hysterectomies for en-
dometriosis are performed by the abdominal route; in selected
cases, laparoscopy may allow lysis of complicating adhesions
or large implants, thus allowing safe vaginal hysterectomy. When the posterior cul-de-sac is obliterated and extensive fi-
brosis is present deep in the pelvis, subtotal hysterectomy may
be indicated.
The recurrence of cyclic pain associated with endometrio-
sis after hysterectomy with preservation of normal ovaries has
been estimated at 3% to 7%. Nevertheless, in a study of 138
women who underwent hysterectomy with the diagnosis of en-
dometriosis at the Johns Hopkins Hospital, ovarian conserva-
tion was associated with a 6.1 times greater risk of development
of recurrent pain and an 8.1 times greater risk of reoperation
as compared with oophorectomy at the time of hysterectomy.
Laparoscopic resection of invasive peritoneal and intestinal dis-
ease that persists after castration may result in an improvement
in pain symptoms. Hysterectomy does not improve symptoms
in 25% of cases of chronic pelvic pain when the uterus is be-
lieved to be the source of the pain.
Minute, hormonally active ovarian fragments may be de-
tected in women with symptomatic endometriosis, even af-
ter total abdominal hysterecomy and bilateral salpingo-
oophorectomy. This ovarian remnant syndrome is the result of
incomplete excision of cortical tissue at the time of eutopmic surgery for endometriosis or pelvic inflammatory disease. Most ovarian remnants are in an asymptomatic state, and they are
often densely adhered to pelvic sidewall structures, including
the ureter, hypogastric vessels, and bladder base. Complete sur-
gical removal may be difficult.
Estrogen replacement therapy after total hysterectomy and
bilateral oophorectomy is associated with less than a 15% rate
of recurrence of endometriosis. A cause-and-effect relation be-
tween estrogen replacement and malignancy in endometriosis
has not been established, suggesting that progestational agents
need not be prescribed together with estrogens after hysterec-
tomy for a diagnosis of endometriosis. However, administering
both progestin and estrogen may be theoretically beneficial if the disease was incompletely resected or deeply invasive, con-
tained atypical epithelial changes, or is recurrent. Women who
begin estrogen replacement therapy immediately after total
abdominal hysterecomy and bilateral salpingo-oophorectomy are
at no greater risk of recurrent pain than those who delay
estrogen therapy for more than 6 weeks postoperatively.
Women with endometriosis was shown by Modugno and
colleagues to be at increased risk of developing ovarian can-
cer (OR 1.32; 95% CI 1.06-1.65). Hysterectomy and the use of
oral contraceptives for greater than 10 years substantially
reduce this risk.
ENDOMETRIOSIS AND ASSISTED REPRODUCTIVE TECHNOLOGIES
If spontaneous conception is not achieved within 3 years of
surgical resection of endometriosis or within 1 year of repair
of tubal obstruction associated with endometriosis, the odds
are poor that it will ever occur. Techniques in assisted repro-
duction have been widely used during the past two decades
for the management of endometriosis-associated infertility un-
responsive to cytoreductive surgical or hormonal therapy. IVF
removes gametes and zygotes from a potentially harmful en-
vironment and may bypass pelvic adhesions associated with
endometriosis. Endometriosis is the sole identifiable cause of
infertility in 25% to 35% of women undergoing IVF/embryo
transfer.
The impact of endometriosis on the outcome of IVF has
been controversial. Several studies have noted that the re-
sponses to gonadotropic stimulation, the numbers of proov-
tory oocytes, the fertilization and cleavage rates, and the clin-
cal pregnancy rates associated with stage I and stage II en-
dometriosis have been equivalent to rates associated with tubal
disease and unexplained infertility. Kuvaasari et al. reported
that there was a significantly lower pregnancy rate and embryo
implantation rate per fresh embryo transfer after pooled cycles
(1-4) among women with stage III/IV endometriosis (22.6%) com-
pared with stage III (40%) or tubal infertility (36.6%). How-
ever, when adjusted for confounding variables, Barnhart and
colleagues in 2002 found that there was a significantly
negative association between endometriosis of all stages and
IVF outcome. This metaanalysis pooled data from 22 nonran-
domized studies regarding IVF success rates in patients
with endometriosis versus control patients without endometriosis
and with tubal infertility. Most of these series included small
numbers of subjects. The authors concluded that there was a
34% reduction in pregnancy rate after IVF in patients with
endometriosis and that the success was even poorer when the
staging of endometriosis was higher. Subsequent studies have
disputed these findings.
Poor IVF outcome in severe endometriosis may be related
to oocyte or embryo factors rather than decreased uterine
receivability. Diaz and colleagues found that a history of severe
endometriosis in recipients of donor oocytes had no ef-
flect on embryo implantation rates or clinical pregnancy rates
as compared with recipients who did not have a history of
endometriosis.
In general, women with endometriosis have a lower ovar-
ian response to gonadotropin stimulation. One reason for this
response may be previous ovarian resection. Studies recruit-
ing women with a history of surgical excision of a symptomatic
endometrioma and comparing subsequent ovarian responsive-
ness to gonadotropin stimulation in the affected and contralat-
eral intact gonad indicate that excision of endometriomas is
associated with a quantitative damage to ovarian follicular re-
sertion. However, this lower oocyte yield following surgery has
not necessarily led to decreased pregnancy rates.
Recent retrospective studies have suggested that routine la-
parscopic cystectomy for endometriomas before commencing
an IVF cycle does not improve IVF outcomes. Aside from a
lower peak estradiol level on the day of hCG administration
and a higher total gonadotropin dose administered to women
previously operated on for an endometrioma, no significant dif-
fereuces were found between the resected endometrioma group
and the intact endometrioma group among the different vari-
bles analyzed (Garcia-Velasco et al.). Pre-IVF excision of ovar-
ian endometriomas in symptomatic women did not impair nor
enhance IVF or intracytoplasmic sperm injection success rates.
Another recent retrospective study indicated that women
with a history of past or current endometriomas had fewer
oocytes retrieved during IVF than tubal factor controls, but
the fertilization rate, embryo quality, or pregnancy outcome
was not affected (Suzuki et al.).
Tinkanen and Kujansuu studied the effects of operative
treatment of recurrent ovarian endometriosis on the pregnancy
randomized controlled trial suggested that the reproductive outcome in women with endometriosis undergoing IVF is improved in all stages of disease, and particularly in patients with moderate-severe endometriosis, after prolonged (e.g., 3-month) down-regulation with GnRH agonist before starting ovarian stimulation.

Gamete intrafallopian transfer (GIFT) may overcome impairment of sperm transport to the fallopian tube, failed ovum capture, or abnormalities in the peritoneal environment associated with endometriosis, although the presence of any anatomic disorders of the fallopian tubes has negative prognostic significance for a successful outcome for this procedure. Hulme and colleagues performed GIFT on 46 infertile patients with minimal to moderately active endometriosis not previously treated by medical or surgical methods. The only prerequisite was patency of at least one fallopian tube. The pregnancy rate per GIFT cycle was 30.5% (18/59), which compared with a clinical pregnancy rate of 25.8% for all patients undergoing the procedure at their unit. One or more endometriomas were aspirated from the ovaries at the time of follicle aspiration in 11 patients; 4 of the 11 achieved live births with GIFT. Nevertheless, Guzick and associates, in a case-control study, found that pelvic endometriosis significantly impaired the efficacy of GIFT. Of 114 laparoscopic oocyte retrievals performed in the endometriosis group, there were 37 pregnancies (32.5%) and 25 deliveries (23.7%); of the 214 retrievals in the control group, there were 101 pregnancies (47.2%) and 76 deliveries (35.3%).

Controlled ovarian hyperstimulation (COH) with human menopausal gonadotropins or pure FSH together with intrauterine insemination (IUI) has been proposed as a method to increase cycle fecundity of patients with endometriosis, although few series have been published to date (Table 22.9). By increasing the number of oocytes released at the time of ovulation and introducing a high concentration of spermatozoa into the female reproductive tract, the chance for conception is improved, merely because of the larger number of gametes available for fertilization. In addition, subtle abnormalities of folliculogenesis, corpus luteum function, tubal motility, or sperm function may be corrected with this therapy. Cycle fecundity rates associated with COH/IUI therapy in patients with endometriosis-associated infertility have ranged from 9% to 11%, although these series did not include a nonrandomized control group. One recent prospective randomized study found

a higher pregnancy rate with COH/IUI following at least 6 weeks of GnRH against suppression in patients with advanced stages of endometriosis. Fedele and associates reported that superovulation with timed intercourse was not associated with a better cumulative, crude pregnancy rate than expectant management in infertile women with endometriosis stages I and II, although the cycle fecundity rate was improved. However, a more recent random-ized, controlled trial of COH and IUI for infertility associated with stage I and II endometriosis demonstrated a live birth rate of 11% per cycle in the treatment group and 2% in the control group. Others reported that ovarian stimulation or induction using gonadotropins results in higher fecundity rates than no treatment, but the clinical pregnancy rate after treat-ment was still significantly lower in the endometriosis group (6.3%) than in women with unexplained infertility (11%) (Nuoja-Huttunen et al.). There was no surgical treatment of endometriosis before therapy with COH and IUI in these latter studies. In a 2006 retrospective study by Webrouck and colleagues, the clinical pregnancy rate per cycle of COH and IUI in women with minimal and a mild endometriosis who underwent laparo-scopic excision of lesions within 7 months of onset of treatment was 21% or 18.9%, respectively, which was comparable to that achieved in patients with unexplained infertility, 20.5%. The mean age of the patients with endometriosis in this study was 31 years. The cumulative live birth rate of nearly 70% within four cycles suggest that COH and IUI may be appropriate first-line therapy in patients younger than 35 who have no other infertil-ity risk factors. The clinical history must be carefully weighed when planning a sequence of therapy for the infertile patient with endometriosis. Temporary exposure to very high estradiol levels in women during COH for IVF or intrauterine insemination is not a major risk factor for endometriosis recurrence in women treated with assisted reproductive technology.

**ADENOMYOSIS**

Adenomyosis is defined as heterotopic endometrial glands and stroma located deep within the myometrium. This disease can be categorized as diffuse or local in its distribution. Diffuse adenomyosis can be relatively localized but is never encap-sulated (Fig. 22.13). The uterus itself is usually mildly en-larged, rarely to more than twice-normal size, and is generally symmetric. Cut sections of the myometrium reveal a coarse trabecular pattern of interlacing musculature and fibrous tis-sue with small islands of endometrium that are often dark and hemorrhagic. Localized, encapsulated disease of the uterine wall is termed adenomyoma, to distinguish this manifes-tation of adenomyosis from the more usual diffuse pattern. An adenomyoma is always located mainly within the wall of the uterus but may project into the uterine cavity to become further known as a submucous adenomyom.a. This encap-sulated, submucous form of adenomyosis disease resembles the leiomyoma.

The most widely accepted theory of the origin of adenomyosis is that endometrial tissue within the myometrium is of mullerian origin. Its presence in this location is the result of a direct, downward extension of the endometrium of the uterine cavity. Serial sectioning of tissue has revealed a di-rect continuity between the basalis portion of the endometrium and the endometrial islands within the areas of adenomyosis.
Adenomyosis is often an incidental pathologic finding, and approximately 35% of cases are asymptomatic. Dysmenorrhea is more likely to be reported when glandular invasion exceeds 80% or more of the myometrium. Pain can be severe, cramping, or knife-like, and may occur up to 1 week before the onset of menstrual flow. The pattern of dysmenorrhea is likely associated with bleeding episodes within the deep-lying islands of endometrium. Menorrhagia can be a consequence of the increased surface area of the enlarged uterine cavity. In addition, extensive involvement of the myometrium can interfere with the normal contractility of the uterine musculature and can lead to excessive bleeding. Nevertheless, data collected from 1,851 hysterectomies for the prospective, multicenter Collaborative Review of Sterilization study indicate that adenomyosis occurs as often in asymptomatic uteri removed for prolapse (19%) as in uteri removed for excessive bleeding (22%) or pain symptoms (15%). Uterine adenomyosis is significantly associated with pelvic endometriosis, with a prevalence of up to 90%. By impairing uterine sperm transport, adenomyosis may be a leading factor of infertility in women with endometriosis.

### Symptoms

Adenomyosis should always be suspected in a woman with dysmenorrhea and menorrhagia of increasing severity in her fourth or fifth decade, particularly if the uterus is symmetrically enlarged, firm, and tender. An exact preoperative diagnosis is often difficult to establish because dysfunctional uterine bleeding and multiple small leiomyomas can present in a similar fashion. Gambone and colleagues reported that a presumptive diagnosis of adenomyosis was verified in only 38% of hysterectomy specimens. The diagnosis can be histologically established before hysterectomy only in the rare case in which excessive myometrium is removed during curettage or a polypoid submucous adenomyoma is excised. However, hysteroscopic myometrial biopsy of the posterior uterine wall with use of a 5-mm loop electrode has been shown to effectively establish the diagnosis in women with menorrhagia.

### Pelvic Findings

The uterus may be very firm to palpation and is usually enlarged to not more than twice its normal size. As it is classically described, the adenomyotic enlargement occurs in the anteroposterior dimension, a reflection of the more prominent involvement of the posterior uterine wall. In the more common diffuse type of adenomyosis, the uterus is a symmetrically enlarged, globular structure. Encapsulated adenomyomata may cause the uterus to be irregular or asymmetric, much as it is when leiomyomata are present. At times, particularly during menstruation, the enlarged uterus is tender on examination.

### Diagnosis

Adenomyosis should always be suspected in a woman with dysmenorrhea and menorrhagia of increasing severity her fourth or fifth decade, particularly if the uterus is symmetrically enlarged, firm, and tender. An exact preoperative diagnosis is often difficult to establish because dysfunctional uterine bleeding and multiple small leiomyomas can present in a similar fashion. Gambone and colleagues reported that a presumptive diagnosis of adenomyosis was verified in only 38% of hysterectomy specimens. The diagnosis can be histologically established before hysterectomy only in the rare case in which excessive myometrium is removed during curettage or a polypoid submucous adenomyoma is excised. However, hysteroscopic myometrial biopsy of the posterior uterine wall with use of a 5-mm loop electrode has been shown to effectively establish the diagnosis in women with menorrhagia.

Hysterosalpingography of the adenomyomatous uterus with water-based media can occasionally demonstrate multiple spiculations or tuft defects leading from the uterine cavity to the myometrial wall, however, similar findings can occur in cases of vascular or lymphatic extravasation. MRI has proved to be highly accurate for distinguishing adenomyosis from leiomyoma; on T2-weighted images, adenomyosis appears as an ill-defined, relatively homogeneous, low-signal-intensity area embedded with sparse, high-intensity spots. The optimal functional zone thickness value for establishing the diagnosis of adenomyosis is 12 mm or more. Several studies have shown that the sensitivity and specificity of MRI to diagnose adenomyosis ranges from 86% to 100% in a symptomatic patient population.

Recent studies have also suggested an important role for transvaginal ultrasound in distinguishing adenomyosis from leiomyomata. By using the diagnostic criterion of the presence of unencapsulated, heterogeneous, myometrial areas within round anechoic areas 1 to 3 mm in diameter, Fedele and colleagues noted a sensitivity of 80%, a specificity of 74%, a negative predictive value of 81%, and a positive predictive value of 73%. Nevertheless, when transvaginal sonography and MRI have been prospectively compared, the latter has been significantly more accurate in correctly establishing the diagnosis.

Hormone receptor studies have documented the presence of steroid receptors in adenomyotic foci. Estrogen receptors for
Surgery is indicated for correction of pain, infertility, and less tissue damage is achieved with bipolar than with monopolar cautery. Preoperative rectoscopy sigmoidoscopy and intravenous pyelography are recommended in patients with symptoms suggestive of deeply invasive endometriosis of the posterior cul-de-sac and rectovaginal septum. Preoperative ultrasound and MRI may help to categorize the extent of ovarian involvement and location of deeply infiltrating disease. A bowel prep before surgery may facilitate optimal performance and safety of the surgical procedure, particularly when deep disease is anticipated. Interventionsal radiological techniques have been described to selectively embolize the uterine vessels in women with adenomyosis. Although short-term results of uterine artery embolization to treat adenomyosis appeared encouraging, midterm results were disappointing, with only 55% of treated patients showing clinical improvement after 2 years (Pelage et al). Preliminary trials have suggested that magnetic resonance-guided focused ultrasound surgery may be used in the future to destroy focal adenomyosis.

Hysterectomy should be considered in the severely symptomatic patient when uterine adenomyosis, MRIs, or myometrial biopsy demonstrates deep adenomyosis. Surgery is indicated for correction of pain, infertility, or other symptoms in patients with extensive pelvic endometriosis, or when hormonal manipulation fails to adequately diminish pain symptoms in women with lesser stages of disease. Preoperative rectoscopy-sigmoidoscopy and intravenous pyelography are recommended in patients with symptoms suggestive of deeply invasive endometriosis. A small circular rim of tissue around the adhesion is stabilized with atraumatic forceps, and the cyst wall is grasped with biopsy forceps and stripped from the bed of normal ovarian tissue. The dissection may be facilitated by using magnification and irrigation of tissues with warmed solution. Adhesion formation can be reduced by magnification of the surgical site, avoidance of suture unless clearly indicated, reconstruction with fine nonreactive suture, precise hemostasis, and frequent irrigation of tissues with warm solution.

Less tissue damage is achieved with bipolar than with monopolar cautery. Ablation of deep disease by monopolar microdiathermy or CO2 laser vaporization rather than excision of the disease may result in inadequate resection and a greater amount of ischemic damage to the tissue, heightening the propensity toward adhesion formation. Deep lesions or more extensive peritoneal disease must be excised with a tissue margin of at least 2 to 4 mm, because macroscopic lesions are commonly present in tissue adjacent to visible implants. Twenty-five percent of patients have lesions greater than 5 mm in depth. Coagulation or vaporization of disease in the ovarian fossa may be used if the ureter is not identified. Resection of deep posterior cul-de-sac nodules requires great endoscopic expertise. A combined laparoscopic-vaginal approach may be necessary.

Inability to elevate the ovary is usually a sign of adhesions and endometriotic implants of the inferolateral surface of the ovary and the peritoneum of the ovarian fossa. When removing an endometrioma, the cortical incision should be made in a way that will preserve the normal anatomic relations of the ovary with the uterosacral ligament and fimbria ovarica. Suture on or extruding through the surface should be avoided when possible because of its adhesogenic properties. With larger endometriomas, the normal ovarian cortex is stabilized withatraumatic forceps, and the cyst wall is grasped with biopsy forceps and stripped from the bed of normal ovarian tissue. The dissection may be facilitated by removing a small circular rim of tissue around the adhesion site to begin the stripping procedure in a clearer field, where the endometrioma wall is less adhered to healthy ovarian tissue. The rate of recurrence of pelvic pain and dysmenorrhea over a 2-year postoperative period is significantly less for those patients who are managed by cytectomy as compared with those undergoing fenestration and coagulation. Moreover, the rate of reoperation is less and the cumulative pregnancy rate is higher in the cytectomy group. Extensive cauteryization or resection of ovarian tissue can lead to a rise in FSH levels postoperatively and should be avoided.

Aggressive and complete excision of deep endometriosis is justified. The recurrence rate of clinically detectable endometriosis is higher when the depth of infiltration is greater than 5 mm at the time of initial surgery. It is not justified to remove a small amount of tissue adjacent to the site of the lesion. A second cytoreductive procedure may benefit some infertile women who have undergone surgery in the past, although assisted reproductive

CHAPTER 23 ■ SURGICAL CONDITIONS OF THE VULVA
IRA R. HOROWITZ, JOSEPH BUSCEMA, AND BHAGIRATH MAJMUDAR

DEFINITIONS

Bubo—Enlarged, suppurative inguinal lymph node characteristic of chancroid.

Burow's solution—A soothing aluminum sulfate solution that can be used as a soak or wet compress for inflamed or irritated skin or mucous membrane.

Cavitron Ultrasonic Surgical Aspirator (CUSA)—An electromechanical surgical instrument that is useful in soft tissue dissection. Using focused ultrasound, superficial tissue is sheared off and aspirated through the wand tip. It has been used to treat condyloma and vulvar intraepithelial neoplasia.

Donovan body—An intracytoplasmic Gram-negative, rod-shaped bacteria characteristically identified in histocytes associated with granuloma inguinale.

Fourier's gangrene—An older term for necrotizing fasciitis.

keyes biopsy instrument—A pencil-like biopsy instrument with a sharp, hollow, cylindrical tip that is rotated while pressed against the skin. It cuts a small, cylindrical biopsy, which is then elevated with tissue forceps and cut off at the base with scissors or a knife.

Necrotizing fasciitis—A severe, rapidly progressive, life-threatening infection of the subcutaneous tissue and fascia that may involve the vulva. Synergistic bacterial infection with multiple organisms, it is associated with vascular thrombosis leading to necrosis of the skin and subcutaneous tissue of fascia. It is treated with aggressive broad-spectrum antibiotic coverage and wide surgical debridement.

Silvadene cream—A 1% silver sulfadiazine cream, which is commonly used on the vulva following laser therapy or surgery to minimize the risk of cellulitis or wound infection and to sooth the postoperative wound site.

Vulvar intraepithelial neoplasia (VIN)—A preinvasive neoplastic condition of the vulva.

Vulvar vestibulitis—A painful condition of the vulva of uncertain etiology. It is characterized by (i) severe pain on vestibular touch or attempted vaginal entry, (ii) tenderness to pressure localized within the vulvar vestibule, and (iii) minimal physical findings consisting of slight erythema within the vestibule.

Word catheter—A small latex catheter with an inflatable balloon to hold it in place. It is inserted to drain a Bartholin's duct abscess.

The vulva and the adjacent perineal skin are designated the anogenital area. These tissues are derived from ectoderm and are considered separately from the vagina and cervix, which are of endodermal origin. Multifocal diseases, particularly human papillomavirus (HPV), can affect all of the aforementioned epithelia. A complete vulvar examination should, therefore, include the vulva, perineum, anal area, urethral meatus, buttocks, and thighs. It is difficult to appreciate subtle skin changes in patients with dark skin; therefore, an adequate light source is necessary.

VULVAR DERMATOSES

In 1987, the International Society for the Study of Vulvovaginal Diseases (ISSVD) revised the terminology to describe the nonneoplastic epithelial disorders of the vulva, which include psoriasis, lichen planus, lichen simplex chronicus, candidiasis, and condyloma acuminata. In their 1976 classification, the ISSVD categorized hyperplastic dystrophy with and without atypia. In the classification of 1987, squamous cell hyperplasia is without atypia, and lesions with atypia are considered vulvar intraepithelial neoplasia (VIN).

The terms kraurosis and leukoplakia have been overused in the past. In 1877, Schwimmer reported that leukoplakia on the buccal surfaces of the mouth was a premalignant lesion, and Besky later described kraurosis as an atrophic lesion similar to lichen sclerosis. Because of these early reports, every lesion on the vulva that appeared white and constricted the vaginal outlet was called Kraurosis. Moreover, conditions as varied as leukokeratosis and invasive cancer have been called leukoplakia. Other terms, such as primary senile atrophy and atrophic leukoplakia, have been used interchangeably. They are nonspecific and should be eliminated. The epidermis may be thickened and the skin markings accentuated (lichenification), but the extent of the epithelial proliferation cannot be assessed without biopsy. Usually a 3- or 4-mm Keyes punch biopsy is used to obtain a small biopsy in the office under local anesthesia (Fig. 23.1). The specimen is oriented with the epithelial surface up on a square of filter paper or Telfa before being placed in fixative. This allows correct orientation of the tissue so that a full-thickness, montagental, microscopic section can be prepared. Occasionally, experienced clinicians make a tentative diagnosis based on history and physical examination. A trial of topical therapy may be used for 6 to 8 weeks to evaluate the response; if the response is less than satisfactory or if there is any suspicion of invasive cancer, a biopsy must be done.

Although some physicians have suggested that lichen sclerosis and kraurosis have different histopathologies, their microscopic appearance is similar. A safe approach would be for surgeons to describe the anatomic appearance (i.e., whether the vulva is shrunken and constricted or thickened and leathery), leaving it up to the pathologist, who is familiar with both histology and anatomy, to define the cellular and histologic abnormalities.
FIGURE 23.1. Biopsy of the vulva. A: The skin and subcutaneous tissue is infiltrated with local anesthetic using a small needle. B: A 3- or 4-mm Keyes punch biopsy instrument is firmly pressed against the skin to be biopsied and gently rotated. C: The small core of skin and subcutaneous tissue separated by the Keyes punch is elevated by small toothed tissue forceps and trimmed off at the base with curved iris scissors. Pressure is applied to the biopsy site, and the base is cauterized with silver nitrate sticks.

Hyperkeratosis

Both chronic infections and benign tumors, most commonly condylomata acuminata, appear white because keratin absorbs moisture, which reflects light back to the observer. To avoid the ambiguous term leukoplakia, Jeffcoate, in 1966, introduced the term dystrophy into the nomenclature of benign epithelial lesions of the vulva. Predictions about the malignant potential of vulvar dystrophy vary; of all the types of dystrophy, the one most often benign is lichen sclerosus. As noted earlier, the terminology for vulvar dystrophies has been altered. Vulvar dystrophy has been classified in three categories: squamous hyperplasia, lichen sclerosus, and VIN. Typical squamous cell hyperplasia is characterized by a thickened, hyperkeratotic squamous epithelium, elongated rete pegs, and often an infiltration of the underlying tissue with chronic inflammatory cells. Typical hyperplasia in a benign form of chronic dermatitis with hyperkeratosis and acanthosis; thus, the designation "dystrophy" should be eliminated.

Depigmentation Lesions

Leukoderma and vitiligo are terms that are used interchangeably. Treatment is not required unless the symptoms of the commonly associated chronic dermatitis cannot be controlled by local medications. The hyperkeratotic lesions comprise a number of diverse entities that share a white to grayish white epithelial appearance in a moist environment. Biopsy is the only reliable criterion for accurate assessment.

Lichen Sclerosus

Lichen sclerosus is characterized by hyperkeratosis, thinning of the epidermis, loss of rete peg architecture, collagenization of the underlying tissue, and associated middermal inflammatory infiltrate (Fig. 23.2). It can occur at any age. The disease has been noted in the prepubertal child, and it occurs during the menstrual years. Nevertheless, it is seen most often in
FIGURE 23.2. Vulvar dystrophy; lichen sclerosus. A: Distorted vulva with superficial ulcerations and extensive hyperkeratosis and loss of normal architecture. B: Microscopic picture of lichen sclerosus composed of epidermal diminution, subepidermal collagenization, and middermal lymphocytic infiltrate.

the postmenopausal woman when the lesions more commonly are symptomatic, perhaps because of the additional epithelial compromise caused by atrophy. The genetic aspects of lichen sclerosus have not been clearly identified, but the finding of lesions in both mother and child has been documented.

If biopsy specimens reveal lichen sclerosus, the patient should be treated with ultrapotent corticosteroids. Many series over the past few years have shown an excellent clinical response to 0.05% clobetasol proportionate topical ointment or cream. In a series of 81 women with biopsy-proven lichen sclerosus, Lorenz and coworkers reported that 77% had complete remission of symptoms and another 18% experienced significant improvement. Patients were treated with topical application of clobetasol cream twice daily for 1 month, at bedtime for another month, and, finally, twice a week for 3 months. They continued to use the cream on an “as needed” basis once or twice a week. Many patients continue to require occasional episodic therapy for symptomatic flare-ups, but the long-term effects of these ultrapotent steroids on the vulva have not been well studied. Some experts recommend maintenance therapy with lower potency corticosteroids, such as triamcinolone or 0.1% betamethasone. Topical testosterone has been recommended in the past, but Hornstein and associates compared the results of 2% testosterone propionate with 0.05% clobetasol dipropionate; at 1 year follow-up, 80% of the clobetasol treated patients reported symptomatic improvement compared with 40% of those treated with testosterone.

Many patients with chronic vulvar dermatitis, stenosis of the outlet specifically related to lichen sclerosus, and vestibulitis have an associated constriction of the vaginal outlet with resultant dyspareunia. Local intravaginal or vulvar applications of estrogen do not improve this condition. Plastic surgery to the outlet (Fig. 23.3) may be helpful. By excising a triangular area of skin beneath the fourchette, the surgeon can undermine and evert the adjacent vaginal epithelium, incise the transverse perineal muscle and fascia, and cover the denuded area with a flap of vaginal mucosa. The procedure is simple, and the use of delayed-absorbable suture material lessens the incidence of wound breakdown, which commonly occurs when absorbable suture is used. The results of this procedure have been most satisfactory; about 95% of patients are greatly relieved of dyspareunia. Breech and Laufer have reported good results in a few patients by suturing a protective covering of oxidized regener-ated cellulose gauze (Surgicel, Johnson & Johnson, Arlington, TX) to the raw surfaces of the inner labia and clitoris after division of intracutal adhesions to prevent recurrence.

**VULVAR INTRAEPITHELIAL NEOPLASIA**

The first two cases of carcinoma in situ (CIS) of the skin were described by Bowen in 1912. Bowen also stated that although stromal invasion had not developed in patients observed over periods of 12 to 16 years, curettage and cauterization did not eliminate recurrence of the lesions.

In 1938, Woodruff and Hildebrandt reported 13 cases of VIN. They suggested that because the histology varied from one area to another in the same section, the general term *carcinoma in situ* should be used to designate the lesion. Today, the term *vulvar intraepithelial neoplasia* is commonly used, and vulvar intraepithelial lesions were originally subdivided into VIN I, corresponding to mild dysplasia; VIN II, similar to moderate

Incision

Excision of skin at vaginal margin

FIGURE 23.3. Perineoplasty. A: The incisional line is identified. The incision must be sufficiently extensive to allow for postoperative retraction and subsequent constriction of the outlet. B: The vagina is undermined to allow for exteriorization without tension. C: The scarred skin of the fourchette is excised. The vaginal epithelium is preserved for exteriorization. The vaginal epithelium is sufficiently undermined for the margins to be approximated to the skin (D) without tension (E). Occasionally, a small incision is made into the midline of the exteriorized mucosa to allow for an adequate outlet without tension.
dysplasia; and VIN III, corresponding to severe dysplasia or CIS, similar to the classification of cervical disease. However, in 2004, the ISSVD changed the classification, eliminating the term VIN I. VIN I is thought to be secondary to viral changes and not a reproducible diagnosis. In addition to eliminating VIN I, they combined VIN II and VIN III as simply VIN, the expectation being that these lesions will be treated as high-grade preinvasive neoplasms. Jones and colleagues, in their review of 405 women with VIN, reported a decrease in the mean age of patients with VIN from 50 in 1980 to 39 in 2003. The increased prevalence of HPV infection as well as increased awareness by patients, clinicians, and pathologists has resulted in an increase in the diagnosis of VIN and, perhaps, a more common identification of these lesions in younger women.

### Symptoms

Pruritus is the predominant symptom of most vulvar disease, including cancer, yet itching was the primary symptom in only 50% of patients with in situ cancer in a series reported by Buscema and associates. Other presenting symptoms were the presence of a lump, bleeding, and pain. In a small percentage of the cases, the lesion was discovered on routine examination; but in others, the diagnosis commonly was made in patients seen during follow-up of cervical neoplasia.

### Diagnosis

The best technique for early diagnosis is careful inspection of the external genitalia—including perianal areas, thighs, and buttocks—under a bright light (Fig. 23.4). If suspicion is aroused either by history or preexisting neoplasia in the lower genital canal or by the suggestion of an abnormal configuration, magnification should be used. An experienced colposcopist can describe white lesions and areas of abnormal vasculature. As a screening procedure, however, colposcopy has not contributed to the early detection of vulvar neoplasia. The use of nuclear staining, specifically 1% toluidine blue and tetracycline fluorescence, has delineated foci of increased metabolic activity, but the false-negative and false-positive rates are high enough to make the results unpredictable.

Careful visual evaluation of the vulvar region should be directed at the focally white, hyperkeratotic areas and at the more important, slightly elevated, papillary areas of skin. Atypical pigmentation, most significantly gray-white areas that are even minimally ulcerated or slightly elevated above the surrounding skin, should be viewed with suspicion (Fig. 23.5). Biopsy provides the final diagnosis.

Multifocal areas of neoplasia that involve the external genitalia, perineum, and the epithelium of the lower genital canal are common; in fact, more than half the patients with intraepithelial disease in the lower genital tract have multifocal lesions. These lesions suggest an infectious, possibly viral origin for the neoplasia. In contrast, patients older than 60 years of age with invasive or in situ cancer more commonly have unifocal disease. When the vulva is the primary site of the lesion,
the cervix, vagina, and perianal areas are frequent sites for associ-
ated neoplastic alterations. The combination of vulvar and cer-
vical cancer makes up about 20% of all multicentric neo-
plasia in the lower genital tract.

The most pressing question about multifocal disease is whether invasive disease that develops from in situ lesions will arise in many foci or in only one focus. Only two of our patients with in situ neoplasia younger than 40 years of age have developed invasive cancer, and both cases appeared as solitary peri-
nal lesions. Because the vulva and the cervix are of different embryologic origins, the tendency to correlate the histopathol-
y of one area with that of the other may be unrewarding. For example, the full-thickness changes that signal cervical in-
traepithelial neoplasia are not as comparable when they occur on the vulva. Keratinization at the rete tips with intraepithelial pearl formation may indicate, on the other hand, a preneoplastic disease in the anogenital area anywhere.

Pathologic Diagnosis

Biopsy with a Keys punch can be performed in the office with the use of local anesthesia. Knife biopsies often are tangen-
tial and contain only the superficial layers, which results in a less than accurate histologic interpretation. Correct orientation of the tissue in the fixative is mandatory if accurate evalua-
tion of the specimen is to be rendered. Such orientation can be obtained by placing the biopsy specimen on filter paper or Telfa with the epithelial surface exposed, so that the pathol-
ologist can embed the specimen accurately. Tangential cutting may result in the erroneous diagnosis of invasive disease. Cy-
tology has not proved to be a satisfactory screening technique for the evaluation of the precursory cellular atypias in vulvar neoplasia.

The classic Bowenoid changes vary from one microscopic section to another, but typical sections show loss of polarity, hyperchomasia, anaplasia, individual cell keratinization, corps ronds, and mitotic activity on the surface (Fig. 23.6). Abnor-
mal mitosis may abound. Other gross variations include the erythroplastic lesion (erythroplasia of Queyrat) with immature cells extending from base to surface, and lesions that appear almost normal, being marked only by intraepithelial pearl for-
mation at the rete tips in a background of marked dysplasia. Papillary lesions showing changes of high-grade dysplasia were previously designated as baueronid papulosis, a term discontin-
ued by ISSVD.

Surgical Conditions of the Vulva

Treatment and Results

Although surgical excision of vulvar intraepithelial neoplasia is favored, patients typically do not require total vulvectomy. Modesit and colleagues found invasive cancer in 22% of pa-
tients with biopsies consistent with VIN III. Vulvectomy may be appro-
perate for selected patients who are elderly, particularly if they have extensive disease, or for patients with Paget dis-
case. Wide local excision usually is successful, but an attempt should be made to obtain clear margins. The adjacent loose skin of the vulva provides sufficient extra skin to cover minor defects without a skin graft and without significant deformity. The incidence of recurrence is no greater with local excision than with total vulvectomy, but it still approaches 30% to 40%. Positive margins have been indicative of an increased risk of re-
currence in some series. Unless invasive cancer is suspected in the area of the positive margins, immediate reexcision is usu-
ally not indicated, but careful follow-up is necessary because recurrence is common. Brown has suggested CO2 laser vapor-
ization around the surgical margins will decrease the risk of recurrence.

A skinning vulvectomy, in which the epidermis and underly-
ing dermis of the vulva and often the perineal area are removed and replaced by a skin graft, has been used for the treatment of extensive or multifocal vulvar in situ disease. This procedure is usually recommended in younger women with extensive lesions in an attempt to restore normal anatomy and sexual function. However, the technique requires surgery at a donor site, which produces an additional scar in a patient who usually is young. Furthermore, it imposes prolonged bed rest, near complete im-
mobilization of the lower extremities, and indwelling bladder catheterization for 5 to 6 days while the skin graft heals.

The carbon dioxide laser has been successfully used in the treatment of in situ vulvar neoplasia. This approach is of par-
ticular appeal for the younger patient with multifocal, viral proliferative disease. This subset of patients with VIN is un-
doubtedly at lower risk for occult invasion. Emphasis in ther-
apy should be directed toward preservation of maximum tissue and vulvar function. Given these considerations and the real-
ity of recurrences, laser ablation provides an effective medium. Pretreatment requirements include careful examination of the lower genital tract and the liberal use of biopsies to identify areas of possible invasion and multicentric disease. The risk of invasive cancer is greater in the older patient. The desire for cosmetic results is less, so the use of surgical excision is favored in older women.

The laser itself is directed colposcopically after examination of tissues prepared by the application of dilute acetic acid. The latter may enhance detection of minimal viral changes not read-
ily seen with the naked eye. Although benign condylomata can be adequately treated by superficial vaporization (so-called first and second plane), laser treatment of VIN must address the ex-
tension of disease into the hair follicles (pilosebaceous ducts). This mandates deeper laser vaporization beyond the squamous dermis and into the upper reticular dermis (third plane). The colposcope permits recognition of landmarks that characterize these levels. Baggish and coworkers identified skin appendage
Involvement in 36% of cases of vulvar in situ carcinoma and predicted that laser vaporization to a depth of 2.5 mm would effectively treat involved appendages in 93% of cases. Shatz and associates advocated ablation of VIN to a depth of 1 to 2 mm in nonhair and hairy skin to achieve similar success. In laser treatment of VIN, the use of appropriate power densities should be emphasized. Low-power densities lead to thermal conduction injury more than to microablative vaporization at the margins. The latter increases the risk of scarring. Power densities of greater than 750 W/cm² are recommended. However, the deeper extent of vaporization required for VIN III, particularly in hair-bearing areas of the vulva, results in considerably greater postoperative pain, a longer period of healing, and an increased risk of scarring and subsequent chronic pain and dyspareunia; therefore many experts have abandoned the use of the laser in favor of surgical excision for VIN III. Bornstein and Kaufman have proposed combining laser ablation with surgical excision in the treatment of selected patients with VIN. Laser is used particularly in areas where excision hampers preservation of anatomy, such as in the clitoral region. Laser therapy for VIN should probably be reserved for experienced laser surgeons and colposcopists.

The Ultrasonic Surgical Aspirator can assist the surgeon in ablating to depths comparable to those achieved with the CO₂ laser. The advantage of this instrument is its ability to obtain additional tissue that might identify an occult cancer. Ultrasonic Surgical Aspirator and laser ablation also may be used to treat perianal intraepithelial neoplasia. In this setting, two concerns should be kept in mind. This location appears to be associated with a greater risk for the development of invasive squamous cancer, and the likelihood of fibrosis, scarring, and stricture is heightened. As with all treatments for VIN, the potential for recurrence and the need for further follow-up must be appreciated. With ablative procedures such as laser, diligence must be exercised to exclude invasion.

Topical agents have been used in the treatment of VIN with consistent results. Most notable among these topical treatments has been 5-fluorouracil (5-FU, Efudex 5%). Efudex is not recommended by the manufacturer for this use, and they specifically recommend against its use in the vagina. The mechanism of action appears to be related to the inhibition of DNA and RNA synthesis; the latter is not specific to dysplastic or HPV-infected cells. Normal epithelium is susceptible to the agent, and a component of hypersensitivity reaction appears operative in its mode of action. For cases in which treatment is effective, denudation of the epithelium is a requisite for success. This understandably leads to localized discomfort and pain, often reported as intense burning. Treatment regimens with topical 5-FU are diverse, and no standardized administration protocol has been widely adopted. One technique is topical application on an alternate-night basis for as long as 6 weeks; patient compliance problems typically lead to earlier discontinuation. Analogous to the use of topical 5-FU, a 50% to 60% complete response rate has been reported. The hyperkeratotic VIN lesion has not proved to be as responsive to 5-FU.

In a 41-year review of 405 women, Jones and colleagues observed that more than 75% of patients treated with laser ablation or surgical resection required an additional procedure within 14 years. Fifty percent of patients with positive surgical margins required additional treatment within 5 years. In comparison with positive margins, women with negative margins had a 5% chance of requiring additional therapy. Brown and colleagues, in a small series of 33 patients, noted a decrease in recurrence with a combination of surgical excision and laser vaporization at the margins.

### Surgery for Benign Gynecologic Conditions

#### TECHNIQUE OF CONSERVATIVE (SIMPLE) VULVECTOMY

Conservative (simple) vulvectomy is recommended in many patients with widespread VIN when it may be difficult to rule out invasive cancer or Paget disease of the vulva. It may also be appropriate when preoperative biopsies suggest such sinister diseases, do not respond to medical therapy or wide local excision.

An outline of the surgical margins is made with a surgical marking pen (Fig. 23.7). The initial incision should be made at the vaginal outlet so that the surgical margins can be well demarcated and the vaginal epithelium undermining for a short distance. If the incision is begun at the lateral skin margins, bleeding can mask the area, making the incision at the outlet more difficult to define. When the first incision is made at the outlet, a small pack can be placed into the vagina to control the bleeding while the elliptic incision at the outer skin margins of the lesion is made. The skin incision usually encompasses most of the labia majora, depending on the extent of the lesion. The incision through the skin is made with a knife to avoid tissue necrosis that occurs at the skin margins when an electrosurgical instrument is used. Major vessels can be coagulated.

Major bleeding concerns may arise at the clitoris, particularly from the dorsal vein. Hemostatic sutures must be used to control the bleeding. A second point of concern is the pudendal vessels, which enter at the lower one third of the vulva close to the opening of the Bartholin duct. Branches of the pudendal vessels extend down to the anus as the inferior hemorrhiodals, and bleeding may be rather profuse in this area.

Because the lesions for which conservative vulvectomy is performed are superficial, dissection does not need to extend down to the deep fascia or to the muscles of the urogenital diaphragm. Although it is unnecessary to remove the bulbocavernous and ischiocavernous muscles, they may be difficult to avoid when the vulva is quite atrophic. Removal of some of the adipose tissue, particularly in the obese patient, allows for better approximation of the skin edges to the adjacent mucosa. The incision can be carried almost to the anal orifice; careful dissection here is important so that the external anal sphincter is not damaged. If the disease extends onto the anal mucosa or the protruding hemorrhoidal tissue, the mucosa should first be carefully dissected from the underlying external sphincter, excised with the tumor-free margins, and sutured to the perianal skin with 3–0 delayed-absorbable material. In the remaining vulva, the underlying tissues are approximated in layers with absorbable sutures, and the skin edges are approximated with interrupted absorbable sutures (Fig. 23.7). If bleeding is a problem, a small suction drain can be placed at the lower end of the incision, but it is much better to achieve meticulous hemostasis and use a firm pack against the area for 24 hours.

During closure of the perineal defect above the anal orifice and posterior vaginal introitus, the surgeon should suture the vaginal epithelium over the perineum in approximation to the anal orifice rather than suture the lateral skin edges snugly across the perineum and fourchette. Evert the vaginal mucosa allows for satisfactory cosmesis, whereas tightly approximated skin across the posterior fourchette may constrict the vaginal introitus and predispose to pain, dyspareunia, and fusuring.

When the firm packing has been removed after 24 hours, the entire area should be irrigated and cleaned. A firm pack is placed against the area for 24 hours.
FIGURE 23.7. Conservative vulvectomy for vulvar carcinoma in situ.

because it helps to keep the operative site dry and stimulates blood flow, enhancing the healing process. An indwelling urethral catheter or a suprapubic catheter is used while the suture line undergoes initial healing of the skin edges. The suprapubic catheter can be maintained for 4 to 5 days, if desired. A single dose of a cephalosporin such as Cefazolin (1g) intravenously is recommended immediately before surgery. Infrequently, a local cellulitis may develop, necessitating antibiotic therapy; extended-spectrum cephalosporins and semisynthetic penicillins have proved effective.

VULVAR RECONSTRUCTION

Procedures performed for extensive VIN 3 or Paget disease include total or partial vulvectomy, skinning vulvectomy, and multiple wide excisions. These may occasionally result in large denuded areas, creating challenges for reconstruction. With the advent of laser ablation and the Ultrasonic Surgical Aspirator, fewer procedures such as skinning vulvectomy are performed for VIN.
Reconstructive efforts for superficial excisions typically require split-thickness grafts. Such grafts are ill-suited for reconstruction after radical excision because the depth of tissue defect is too great, and poor cosmetic and functional results ensue. A buttock donor site is preferred. Perioperative antibiotics are used. Bowel preparation and slow postoperative feeding minimize contamination of the graft site.

Split-thickness skin grafts can be procured with an air-driven dermatome. The size of the vulvar defect helps to determine donor site excision. Meticulous hemostasis should be sought before application of the graft. Fine absorbable sutures are used to secure the skin edges of the graft. The donor site should be covered with an occlusive dressing, such as Opsite or Tegaderm, until significant healing occurs. A soft pressure dressing is tied over the graft site and kept in place for 5 days, accompanied by an indwelling catheter for urinary drainage.

**VULVAR PRURITUS**

The most common symptom associated with vulvar dermatoses and many other vulvar conditions is pruritus. In most cases, pruritus is a symptom of an underlying disease process, and although treatment of this annoying symptom is important, the clinician should attempt to diagnose and treat the disease that causes the symptom of pruritus.

Before any therapy for vulvar lesions caused by chronic irritation is begun, an accurate tissue diagnosis must be established. All patients should be given detailed instructions to eliminate local irritants. A history of urinary incontinence may suggest a source of chronic vulvar irritation. Associated vaginitis should be treated vigorously. Associated ablative therapy for molluscum contagiosum and condylomata acuminata. Vulvar dermatoses such as lichen sclerosus, lichen simplex chronicus, lichen planus, seborrheic dermatitis, and plasma cell vulvitis can also occur.

**Topical Agents**

Topical agents have been effective in treating vulvar pruritus and should be tried initially. When they are ineffective, often it is secondary to their inability to penetrate the thickened hyperkeratotic surface. Initially, treatment for a specific disease should be instituted. For example, topical steroids should be used for psoriasis, antifungals for candidiasis, and appropriate ablative therapy for molluscum contagiosum and condylomata acuminata. Vulvar dermatoses such as lichen sclerosus, lichen simplex chronicus, lichen planus, seborrheic dermatitis, and plasma cell vulvitis can be effectively treated with high-potency topical steroids such as betamethasone. Many of these patients also present with vulvar dysesthesia (vulvar burning) and can be treated with tricyclic medications such as amitriptyline and nortriptyline.

For historic purposes, no chapter on vulvar pruritus would be complete without mentioning alcohol injection and the Merkel procedure. Before treatment with amitriptyline became popular, patients with recalcitrant pruritus and vulvar dysesthesia were treated with local alcohol injection. The anogenital area was prepped and draped in a sterile manner after the induction of general or regional anesthesia. The region was then divided into 1-cm squares with a marking pen of brilliant green. Absolute alcohol, 0.2 mL, was then injected subcutaneously at the intersection of these lines (Fig. 23.8). Postoperatively, the...
patients were treated with cold packs and cool sitz baths for 1 week.

**Mering Procedure**

Because of the effectiveness of topical high-potency steroid creams, the Mering procedure is rarely used to treat vulvar pruritus in the United States today. It requires hospitalization and careful surgical technique (Fig. 23.9). The skin is shaved and thoroughly cleaned, and the incision is outlined with a marking pencil. The incision is made on the outer surface of the labium majus. It extends to the fascia of the urogenital diaphragm from the level of the clitoris to slightly beyond the fourchette and may continue inferiorly to the level of the anal orifice, depending on the extent of the pruritus. The nerves in the adjacent tissue are severed with a finger placed on each side, moving from the lateral aspect of the clitoris toward the midline, over the clitoris, where the fingers meet. The procedure interrupts branches of the ilioinguinal and genitofemoral nerves (Fig. 23.10). Blunt dissection extends posteriorly to the lateral side of the rectum, outside the external anal sphincter. If the perianal area is involved, blunt dissection may extend to the posterior limit of the anal orifice, where the two fingers meet behind the anus in the midline breaking up the branches of the pudendal nerve.

It is important that hemostasis be meticulously maintained. A small, flat Jackson-Pratt drain should be placed under the flap on each side. The subcutaneous tissue is approximated with absorbable sutures, and the skin is sutured with polyglycolic acid or polyglactin 910 material. The area must be packed tightly for 24 hours, and the patient should use ice packs or cool tub baths. Domeboro sitz baths (Burow’s solution) may help to relieve edema.

**VULVAR PAIN AND VULVODYNIA**

Vulvar pain is another common symptom of vulvar disease. It may be produced by a wide variety of vulvar conditions or, occasionally, primary vulvodynia without any identifiable underlying diagnosis may be encountered. The ISSVD has defined vulvodynia as “vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder.” The classification of vulvar pain is presented in Table 23.1.

There are many types of vulvar conditions that cause vulvar pain, including infections (candidiasis, herpes, etc.), inflammatory conditions (contact dermatitis), neoplasia (vulvar intraepithelial neoplasia, Paget disease, etc.) and neurologic conditions (herpetic neuralgia, neuroma, etc.). A careful diagnostic evaluation, usually including a biopsy of the vulva, is indicated to identify any of these lesions so that the correct therapy can be instituted. However, despite a careful and thorough workup, some patients will have vulvar pain for which an underlying diagnosis cannot be found. These patients are thus diagnosed with vulvodynia as defined above. The syndrome may be either localized to one area of the vulva or generalized, and the pain may be present all the time (unprovoked) or only when the vulva is touched or pressed (provoked). Vulvodynia involving the vulvar vestibule has been called vulvar vestibulitis or vestibulodynia. It is a clinical syndrome

![FIGURE 23.9. The Mering procedure. A: The incisions are made at the lateral margins of the labia majora, extending to the level of the clitoris superioorly and the anal orifice inferiorly. The depth of dissection is the deep fascia, to incise the adipose tissue and the nerves. B: The finger dissects the underlying tissue, breaking up the fibers of the pudendal, ilioinguinal, and genitofemoral nerves. C: The underlying tissues are carefully approximated to attain good hemostasis. A small drain should be inserted at the most dependent aspect of the incision to avoid the accumulation of blood in the operative sites.](image-url)
consisting of the following characteristics: (i) severe pain on vestibular touch or attempted vaginal entry, (ii) tenderness to pressure localized within the vulvar vestibule, and/or (iii) physical findings confined to vestibular erythema of varying degrees. This syndrome is chronic and multifactorial. Etiologies include chronic or recurrent candidiasis, HPV infections, recurrent bacterial vaginosis, trauma, chemical and surgical de-structive techniques, alterations of vaginal pH, irritants (soaps, detergents, douches, deodorants), and idiopathic causes.

**Medical Treatment**

A careful diagnostic evaluation is essential because of the apparent multifactorial etiology of vestibulodynia. If an infectious etiology is present, it is imperative to treat it. Recombinant alpha-interferon is efficacious in treating vulvodynia with a history of condylomata acuminata or subclinical HPV. Triamcinolone acetonide 0.1% and bupivacaine can also be injected monthly. An alternative combination is methylprednisolone and lidocaine submucosal.

Chronic recurrent candidiasis is treated with prolonged oral administration of ketoconazole or fluconazole. Topical antifungal medications should be prescribed when oral antifungal medications are discontinued. In addition to being treated for the infectious etiology, all patients should be started on a course of topical steroids. Horowitz treats all patients with vulvodynia with hydrocortisone acetate 1% or 2.5% with 1% pramoxine HCl ointment (Pramosone) for 2 to 3 months. After 3 months of this therapy, the patients are placed on desoximetasone 0.25% ointment (Topicort). Only after failing topical steroids are the patients considered for surgical treatment. Oral amitriptyline is also an important part of the therapeutic regimen. Doses of 25 to 75 mg taken 3 hours before bedtime is prescribed. Patients with vulva dysesthesis or interstitial cystitis benefit most from medical therapy with amitriptyline. Oral gabapentin is also helpful in some patients. It should be started with a gradual dose escalation and tapered off when discontinued.
Surgical Treatment

Carbon dioxide laser ablation of the vestibular glands has not been shown to be optimal and has resulted in scarring and increased dyspareunia in some patients. In 1995, Reid and associates reported long-term results with the flashlamp-excited dye laser in nonresponders to medical therapy. Those with poor responses to laser vaporization were then treated with gland resection. Overall response rates were 62% to 80%, depending on the distribution of tenderness. However, long-term follow-up has been disappointing, and this approach remains controversial.

Primary surgical therapy has produced relief of symptoms in 75% to 90% of patients. This technique was initially described by Woodruff and associates in 1981 and Friedrich in 1987, and was modified by Marinoff and Turner in 1991 to include the periurethral Skene gland openings. The outer incision extends circumferentially from the periurethral glands along Hart’s line to the contralateral glands. The proximal vaginal margin is just inside the hymenal ring. This horseshoe-shaped epithelium is superficially excised and sent for histologic diagnosis. In almost all cases, the histology consists of nonspecific periglandular chronic inflammation, much less impressive than might be expected based on the severe symptoms reported. As in a perineoplasty, the vaginal mucosa is undermined and the vagina advanced to approximate edges. The wound is closed in two interrupted layers of 3-0 polyglactin 910 (Vicryl) or polyglycolic acid (Dexon) sutures (Fig. 23.12). Postoperative treatment is the same as for perineoplasty. Coitus should be avoided for 2 to 3 months after surgery.

Several of Horowitz’s patients (unpublished report) had severe levator spasm secondary to anticipation of activities associated with vulvar pain. This learned response has been treated successfully with biofeedback in several patients. Glazer and colleagues were the first to report the treatment of vulvar vestibulitis syndrome with electromyographic biofeedback of pelvic floor musculature. Seventy-eight percent (22 of 28) resumed coitus by the end of the treatment period.

VULVAR INFECTIONS

Although infections involving the vulva are treated with antibiotics rather than surgery, their appearance may resemble carcinoma in situ or even invasive cancer of the vulva. An accurate diagnosis may require cultures, viral testing, or even biopsy. Appropriate therapy is based on a correct diagnosis. Treatment of vulvar secondary to an infectious process varies depending on the infection present. Viral infections such as HPV are strongly associated with intraepithelial neoplasia and carcinoma. These lesions are discussed later in this chapter.
Minor vestibular glands

FIGURE 23.12. The minor vestibular glands exit lateral to the hymenal ring. They are very superficial and thus seldom produce definable “nodules,” even when chronically infected.

Molluscum contagiosum, a member of the pox family, requires accurate identification and resection of the umbilicated lesions with a dermal curette. These lesions are usually circular and umbilicated. Molluscum contagiosum in an adult may be an indicator of underlying human immunodeficiency virus (HIV) infection. Therefore, the patient’s background should be appropriately discussed.

Herpes genitalis is caused by the herpes simplex virus (HSV). Between 500,000 to 1 million new cases are diagnosed annually in the United States, a ninefold increase between 1966 and 1997. More than 25% of women are seropositive for HSV type 2. The patients with primary herpes present with high fevers, malaise, myalgias, painful vulvovaginal lesions, and inguinal adenopathy. The ulcers are small but coalesce into larger ulcers. The primary treatment of these sexually transmitted diseases is presented in Table 23.2. The three categories of HSV infection are outlined in Table 23.3.

Prevention (CDC)-recommended treatment regimen is doxycycline 100 mg orally twice daily for 3 weeks and until lesions have completely healed OR Ciprofloxacin 750 mg orally twice a day for at least 3 weeks and until all lesions have completely healed OR Erythromycin base 500 mg orally four times a day for at least 3 weeks and until all lesions have completely healed OR Trimethoprim-sulfamethoxazole: one double-strength (160 mg/800 mg) tablet orally twice a day for at least 3 weeks and until all lesions have completely healed

**Lymphogranuloma venereum (LGV)** is caused by Chlamydia trachomatis types L1, L2, and L3. LGV presents with papular or vesicular lesions on the vulva that may ulcerate. LGV lesions are usually painless and heal spontaneously. As with herpes, these patients present with headaches, myalgias, arthralgias, and inguinal adenopathy. The 2006 CDC treatment guidelines recommend doxycycline 100 mg orally twice daily for 21 days. Alternatively, the patient can be treated with erythromycin base 500 mg orally four times daily for 21 days.

**Chancroid** is caused by Haemophilus ducreyi. The chancroid lesions present as multiple papules that become pustular with a raised border and an indurated base. They can present with hidradenitis suppurativa (Table 23.5). Because the entire skin is involved, so that pressure at one point may produce exudation of purulent material from sinus tracts (Fig. 23.1A). Multiple bacterial pathogens are implicated, including *Staphylococcus*, *Aureus*, *Escherichia coli*, Porphyromonas, Prevotella and Porphyromonas spp. Bacteroides fragilis, and *Clostridium difficile*. Associated vascular thrombosis leads to skin and subcutaneous tissue necrosis. Fisher's criteria have been emphasized in the diagnosis and help to exclude clostridial infections. Brooks and Frazer isolated mixed aerobic-anaerobic flora in 68% of specimens, 10% facultative or aerobic bacteria, and 22% exclusively anaerobic organisms. Diabetes mellitus is the most common predisposing condition, although other factors, such as radiation, have been identified. The most common clinical findings are necrosis, fever, tachycardia, leukocytosis, edema, and foul odor.

Devascularization of the skin proceeds with sparing of underlying muscle and bone. Early skin changes include hemorrhagic bullous formation. Typically, the underlying fascial necrosis exceeds the boundaries of visible skin involvement. Inflammatory alterations and edema usually are present. Most patients present with fever, tachycardia, and signs of systemic toxic reaction. Prompt diagnosis is important because this disorder progresses rapidly.

Treatment combines expedient surgery, antibiotics, and maintenance of circulation and tissue oxygenation. Surgical treatment should include aggressive excision of nonviable skin, subcutaneous tissue, and avascular fascia. Extensive debridement down to and including the fascia must be performed until viable, well-vascularized tissue margins are identified. Wounds are packed, not primarily closed. High-dose broad-spectrum antibiotic coverage is administered, and associated medical conditions such as diabetes are managed aggressively. These patients are frequently very sick, and renal failure and acute adult respiratory distress syndrome commonly complicate their management. The operation for additional debridement or subsequent skin grafting is also common. Fournier's gangrene presents in a manner similar to that of necrotizing fasciitis and nonclostridial myonecrosis. Infections develop in the labia and spread to the perineum, buttocks, and abdominal wall. Treatment consists of a combination of surgery, broad-spectrum antibiotics, and hyperbaric oxygen.

**Hidradenitis Suppurativa**

An infectious process commonly demanding extensive local surgery is suppurative hidradenitis. This pustular disease begins as an infection in the apocrine sweat glands. The early manifestations often are cyclic, because the secretory activity of the apocrine glands corresponds to the progestational phase of the menstrual cycle. Consequently, in the early stages of the disease or in the chronic pruritic phase (Fox-Fordyce disease), the use of hormonal therapy, such as oral contraceptives, may help to modify the secretory activity of the glands. Once the disease is infectious involves the deeper tissues, local and systemic agents usually are ineffective. Inostrozin (Acutane) has been effective in some cases, but care must be taken in prescribing this agent because it is a powerful teratogen. Culturing exudates and treating with appropriate antibiotics may provide palliation and further delay surgery. The pusules often infect the entire area, so that pressure at one point may produce exudation of purulent material from sinus tracts (Fig. 23.1A). Multiple bacteria have been isolated from patients with hidradenitis suppurativa (Table 23.5). Because the entire anogenital area is honeycombed by the underlying infection, simple incision into a few of the pusules is useless. Extensive debridement must be performed to allow healing from the base.

The incision extends into the underlying fat, and the involved skin is removed in segments, leaving bridges of normal skin between the excised pustules. Loose approximation of the skin edges can be performed with polyglycolic acid or polyglactin 910 suture material; more commonly, the entire area is left open and treated locally to promote granulation (Fig. 23.13B). Results of therapy are rewarding in most cases, and skin grafting usually is unnecessary. The patient must be treated with antibiotics based on cultures obtained from the draining sinuses both before and after surgery. Radical vulvectomy is occasionally indicated for extensive disease of the vulvar, inguinal, and perineal areas, but generally simple vulvectomy is usually effective. It is imperative that a thorough histologic evaluation be performed by the pathologist. Squamous cell carcinoma has been reported to arise in diffuse perineal suppurative hidradenitis. Myocutaneous flaps or
split-thickness skin grafts can be placed in a two-stage procedure. This will allow the infections to clear before the raw vulvar surface is grafted. Wet to dry dressings are used 48 hours to 2 weeks before grafting.

Harrison and colleagues have reported a 37% recurrence rate in patients with inguinal or perineal lesions. In their series of 106 patients, Rompel and Petres experienced 17.8% complication rate with surgery and only a 2.5% recurrence in the operative field.

**CROHN DISEASE**

Crohn disease, a chronic granulomatous inflammatory disease of the bowel, affects the vulva and perianal area in about 25% to 30% of the cases in which there is classic intestinal involvement. The draining sinuses often communicate with the vagina or the rectum, thus resulting in the formation of fistulous tracts (Fig. 23.14A). On rare occasions, the vulva may be primarily involved, even though the small and large bowel apparently are not affected or affected subsequently. Crohn disease can also present as unilateral labial hypertrophy.

Before any surgical therapy is begun, the diagnosis can be confirmed by studying the bowel or by obtaining a biopsy specimen of the affected tissues in the perineum. The presence of noncaseating granuloma without demonstrable organisms is characteristic of Crohn disease (Fig. 23.14B). Further deterioration of the tissue may result from attempts to excise a draining sinus produced by Crohn disease. Recanal incontinence can result from destruction of the anal sphincter or development of a rectovaginal fistula. Approximately 9% of rectovaginal fistulas are secondary to Crohn disease.

Immunocytochemistry of Crohn’s lesions has documented *Escherichia coli* and streptococcal antigens. In addition to short-term metronidazole, patients have responded to prolonged treatment (3–6 months) with broad-spectrum antibiotics such as ciprofloxacin. Methotrexate therapy is effective in reducing the requirement for prednisone in patients with chronically active Crohn disease. Other drugs used in the medical management of Crohn disease include 5-aminosalicylic acid, cyclosporine, azathioprine, 6-mercaptopurine, mesalamine, and infliximab (Remicade®).
In addition to pharmacotherapy, a submucosal anal pull-through procedure may bring relief. Layered surgical repair of a fistula caused by Crohn disease usually is unsuccessful, particularly without appropriate medical management. However, after appropriate medical therapy, surgical excision of the tract is usually effective (see Chapter 39). Results are difficult to predict because multiple areas of the terminal colon and small intestine may be affected, and any affected area may involve the vagina or perineum. Medical therapy should always be given during this type of surgical procedure and should be continued postoperatively for at least 2 months.

TRAUMA

Major trauma to the vulva most often occurs when young girls experience injuries as a result of sledding or bicycling accidents. Hematomas and occasionally lacerations can develop when the vaginal area forcefully comes in contact with the crossbar of a bicycle (as during a fall from a bicycle seat), or when the girl is thrown from a sled against an obstacle such as a tree or fence. Trauma also can result from sexual assault, and the gynecologist must be sensitive to this possibility even when the initial history suggests another etiology. Women or girls who are victims of sexual assault should receive testing for pregnancy and sexually transmitted diseases. These patients should be referred to counseling and encouraged to report the abuse to state officials. All minors should be reported to the state by the examining physician. Most traumatic injuries do not require surgical attention. An examination under anesthesia may be useful to adequately evaluate the extent of the injury. If surgical repair is not required, patients should be treated conservatively with activity restriction and the immediate and continued use of Burow’s solution (aluminum sulfate, calcium acetate; available as Domeboro tablets or powder) added to the sitz bath to reduce edema. Antibiotics may be used as prophylaxis against superinfection in damaged tissues. If a hematoma increases in size and extends well into the perineum or over the lower abdominal wall, incising the vulvar skin, evacuating the hematoma and ligating the bleeding vessels may reduce the period of convalescence. An alternative would be to use selective arterial embolization. Goldman and coworkers reported 30% of patients with genital trauma not associated with parturition have a urologic injury. When a hematoma produces urethral obstruction, evacuation may reduce the time an indwelling urethral catheter is needed. If the hematoma is not expanding, it should be followed conservatively. Most vulvar hematomas resolve spontaneously; surgical intervention, on the other hand, can result in significant morbidity, including infection. Frequently, a distinct bleeding site is not identified. If, however, the clot becomes secondarily infected, it requires prompt evacuation and drainage. Lacerations into the rectum or urethra should be repaired expeditiously.

CYSTS OF THE VULVA

Bartholin Duct Cysts

Obstruction of the Bartholin duct, usually near the orifice, is common. Although such obstructions can result from
FIGURE 23.15. The Word catheter (left) is inserted into the Bartholin duct cyst through a vaginal incision. The bulb is inflated with saline solution (right), and the end of the catheter is placed in the vagina.

gonococcal infection, other infections and trauma more commonly explain the occlusion. During a mediolateral episiotomy or a posterior colporrhaphy, for example, sutures can easily injure or even ligate the duct. The lining of the main cyst is transitional epithelium. The mucus-secreting glands are not affected by the obstruction but may be distorted by the infectious process. During the acute infection, which may precede the actual cyst formation, an abscess often develops with symptoms of tenderness, swelling, and erythema. Depending on the cause, secretion from the cyst may be mucous or cloudy.

Incision and drainage bring almost immediate relief to the patient and can be accomplished under local anesthesia. A small wick can be left in the cavity to maintain adequate drainage. A small incision (2 cm) is made in the cyst wall in the area of the normal duct orifice, and a culture is obtained for *Neisseria gonorrhoeae*, *Chlamydia*, and aerobic and anaerobic bacteria. A Word catheter (Fig. 23.15) is inserted and the catheter bulb inflated with 2 to 3 mL of saline. If the catheter remains in place for 3 to 4 weeks, the tract becomes epithelialized, and the catheter can be removed. Broad-spectrum antibiotics are given before surgery.

Marsupialization seldom can be accomplished during the acute stage, but the procedure is useful for chronic or recurrent abscesses. Injection of an antibiotic into the abscess has been tried as treatment for the acute infection but has proved to be less effective than systemic antibiotic therapy.

Most Bartholin duct cysts are uninfected and asymptomatic. They are usually found during routine pelvic examinations. Patients may even be unaware of large cysts. When symptoms do occur, most patients report discomfort during coitus or pain while sitting or walking. These require marsupialization only if they are symptomatic. Table 23.6 differentiates between a Bartholin cyst and abscess.

**Technique of Marsupialization**

Drainage of a Bartholin duct cyst by marsupialization is not as technically involved as excision and eliminates many complications. The procedure makes it possible to avoid excising the gland with the cyst and to preserve the secretory function of the gland for lubrication.

Marsupialization has had limited use since the Word catheter was introduced. The catheter accomplishes the same result as surgery with minimal or no trauma. The nipple of the catheter can be inserted into the vagina. There is essentially no discomfort with the procedure, and coitus can be resumed normally. Because this procedure can be performed with local analgesia in the office setting and yields results comparable to those of marsupialization, its use should be encouraged.

The marsupialization can be performed under local, regional, or general anesthesia. A wedged-shaped, vertical incision is made in the vaginal mucosa over the center of the cyst, just outside the hymenal ring, with a 15 blade (Fig. 23.16A). The incision should be as wide as possible to enhance the postoperative patency of the stoma. After the cyst wall is opened and the cyst is drained of its contents, the lining of the cyst is everted and approximated to the vaginal mucosa with interrupted sutures of 3-0 delayed-absorbable material (Fig. 23.16B). Drains and packs are not necessary, but the patient’s postoperative care should include daily sitz baths beginning on the third or fourth postoperative day.

As a result of closure and secondary fibrosis of the orifice after marsupialization, 10% to 15% of cysts recur. Abscess formation is another occasional sequela of marsupialization.

Surgical Conditions of the Vulva 497
Technique of Excision

It is seldom necessary to excise a Bartholin duct cyst, particularly in the younger patient, unless there is induration at the base. The latter may signify deep-seated infection that is inaccessible by marsupialization. Conversely, this may represent neoplasm in the base of the gland, an issue of greater concern in the patient older than 40 years of age or in patients with coexisting Paget disease. An elliptical incision in the vaginal mucosa is made as close as possible to the site of the gland orifice with a 15 blade (Fig. 23.17). An incision on the mucosal side is preferable because an incision through the vulvar skin makes it difficult to dissect the cyst wall from the skin without incising or tearing the skin. If an opening is accidentally made through the skin, a permanent fenestration may result. Difficulty is not usually encountered during dissection of the cyst from the inner surface of the vulvar skin when the incision is made on the mucosal side. Excising a small ellipse of mucosa with the cyst allows the surgeon to have a site for traction and reduces the risk of rupturing the cyst. Because cyst formation usually is preceded by inflammation, the wall is adherent and cannot be easily enucleated with blunt dissection only. The blunt-pointed Mayo scissors serve admirably for sharp dissection of the cyst from its bed (Fig. 23.17C). The cyst can be mobilized further with the handle of the scalpel. A large cyst may develop posteriorly and may approximate the rectum. The rectal wall can easily be distinguished from the cyst by inserting a finger into the rectum during dissection.

Complete removal of the gland tissue adherent to the cyst wall is essential because residual glandular tissue may result in the formation of a tender nodule or recurrent cyst. If the margins of the cyst have become obscured, the cyst can be opened and the wall dissected from the surrounding tissue. Directly beneath the Bartholin duct is the vestibular bulb, which is composed of anastomosing venous channels. In the dissection of the gland from the vestibular bulb, additional care must be taken to avoid troublesome bleeding. To ensure permanent hemostasis, the entire cavity must be obliterated by approximating the walls with fine delayed-absorbable suture material after excision of the cyst.

Approximation of the vaginal mucosa is best accomplished with a continuous or interrupted mucosal suture of 3-0 delayed-absorbable material. Persistent bleeding from the labia or vestibular bulb may cause a postoperative hematoma of the labia, which can progress to include the mons pubis and the abdominal wall beneath the Scarpa fascia. Bed rest, ice packs, and a pressure dressing on the vulva are the methods of treatment for a hematoma; attempts to ligate the venous bleeding points are futile. Although the blood usually reabsorbs with time, sometimes evacuation and drainage are necessary. If the bleeding deep in the bed of the gland seems uncontrollable, deep mattress sutures can be placed from the skin through the bleeding bed into the vagina. The sutures should not be tied too tightly because necrosis may result, with fenestration of the vaginal outlet. A small drain should be stitched into the bed with fine absorbable sutures to avoid the accumulation of blood and serous fluid.

Hydrocele or Cyst of the Canal of Nuck

Hydrocele is an uncommon vulvar cyst. The cyst appears as a dilatation in the labium majus and adjacent labium minus and must be differentiated from a Bartholin duct cyst. Figure 23.18 shows a hydrocele. The patient underwent two procedures for drainage of a Bartholin duct cyst, but the mass recurred after each procedure.

A hydrocele is a cystic, fluid-filled hernia of the peritoneum that accompanies the round ligament and extends from the inguinal canal into the vulva. When this sac extends into the
Surgical Conditions of the Vulva

FIGURE 23.18. A hydrocele is caused by the extension of a peritoneal sac with the round ligament from the inguinal canal into the vulva.

inguinal canal, it is known as a cyst of the canal of Nuck. On rare occasions, a loop of intestine may follow the pathway of the round ligament, forming a hernia in the vulva. When a hydrocele is treated as a Bartholin duct cyst by incision and drainage, peritoneal fluid may reaccumulate above the drainage site, and the hydrocele recurs.

Surgical treatment for a hydrocele begins with an incision into the cystic mass. The external inguinal ring is identified by inserting a finger in the cyst anteriorly to the inguinal canal. The peritoneal lining is excised from the cavity, and the external inguinal ring is closed along with the subjacent tissue in the anterior vulva. If a hernia is present, inguinal herniorrhaphy
Surgery for Benign Gynecologic Conditions

500

SOLID TUMORS OF THE VULVA

The incidence of solid, benign tumors in the vulva is low; but a variety of benign tumors, including fibromas, fibromyomas, lipomas, hemangiomas, neurofibromas, and endometriomas have all been reported. These tumors can originate from any of the three germinal layers that constitute the anogenital area. One occasionally sees a solid vulvar tumor composed of benign breast tissue or a benign fibroadenoma (Fig. 23.19). Lactational changes can be seen in this tissue. Such an event is accounted for by the embryologic milk line caudally ending in the vulvar area. Degenerative changes and necrosis often occur in the larger tumors and should not be confused with malignancy. Lipomas often are mistaken for cystic lesions because of their consistency, whereas hemismas and hydroscele of the canal of Nuck must be differentiated from neoplastic growths because they require different surgical approaches.

Most solid tumors should be excised, both to ascertain the diagnosis and to relieve the patient’s discomfort. Small, pedunculated tumors can be removed by simple ligation of the stalk; the deeply situated lesions require more extensive local dissection. All nevi showing hemorrhage, sudden enlargement, and pruritus should be suspected to be melanomas and excised widely.

The boundaries of such mesodermal tumors are difficult to delineate, but most of the tumors are benign. Even recurrence does not signify malignant alteration; a fibromyoma may recur if incompletely excised, even when the original specimen had no histologic evidence of malignancy. Although a sarcoma rarely arises in the vulva, histologic studies must be carefully made because degenerating atypical multinucleated cells of a benign or reactive tissue can be mistakenly diagnosed as malignant.

As in any vulvar surgery, hemostasis is important because compression is difficult to obtain in these soft tissues. Extravasation of blood can dissect the fascial planes well out to the vulva, thigh, flanks, and abdominal wall. Closed suction drains should be used in the wounds if hemostasis is not complete.

Condyloma Acuminatum

Condyloma acuminatum is one morphologic manifestation of HPV infection in the lower genital tract. These polyloid lesions have an incubation period ranging from several weeks to 8 months; however, clinical infection usually is apparent 6 to 8 weeks after exposure. Transmission of the virus is attributed to coitus, and the process is efficient, because most sexual partners are affected subclinically if not clinically. The disease process continues increasing in prevalence. Interestingly, clinically apparent condyloma constitute only a fraction of HPV infections. Most are undetected in asymptomatic patients with no clinical findings.

Numerous HPV subtypes have been identified. HPV subtypes 6, 11, 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, and 69 account for most genital tract infections. Careful histopathologic and virologic study of vulvar lesions has demonstrated an association of HPV 6 and HPV 11 with approximately 90% of exophytic vulvar condylomata, as well as flat cervical condylomas and some low-grade cervical dysplasias. The quadrivalent vaccine provides protection against HPV subtypes 6, 11, 16, and 18. It is not effective for the treatment of already existing condyloma or HPV infections. This vaccine is further discussed in Chapter 46.

Condylomata acuminata that manifest on the vulva are frequently associated with cervical, vaginal, and anal HPV infection. Careful clinical evaluation mandates vaginal/cervical cytology and colposcopy in patients who present with vulvar warts. This is appropriate not only to exclude cervical and vaginal dysplasia but also to define the extent of condylomatous involvement and permit appropriate tailoring of regional therapy.

Condylomata acuminata are small and usually multifocal lesions. They may be accompanied by pruritic discomfort or irritation. Warts initially may be reddish brown because of parakeratosis; however, with time and exposure to local trauma, they become gray or white. The latter appears to be associated with hyperkeratosis and the generalized keratin disturbance associated with viral infection (Fig. 23.20). Unless they are traumatized, bleeding is not a typical feature. In pregnancy, however, because of marked vascular alterations,
A condyloma of the vagina and perineum can be a source of abundant bleeding if laceration occurs. Massive vulvar and perianal condylomata may occur in certain circumstances, preventing identification of the introitus and anal orifice; conditions that foster this growth potential include immunosuppression and, less frequently, pregnancy (Fig. 23.21). Those lesions that were previously called giant condyloma are now regarded as verrucous carcinoma. In the spectrum of condylomatous growths, the dividing line between condyloma and verrucous carcinoma is indistinct because of the structural benignancy of both.

Various treatment approaches are available and are characterized by their inability to eliminate the offending agent: the virus. Interferon offers a nonspecific antiviral therapy. Flu-like effects should be anticipated for at least several weeks. Efficacy has been demonstrated with this technique, although treatment is cumbersome, can be costly, and remains investigational. Its primary role has not been defined.

**Topical Therapy**

At the present time, only a variety of ablative approaches are available for management of condyloma. These should be individualized with consideration of prior treatment, volume and location of disease, the presence or absence of associated dysplasia, and other idiosyncratic patient factors. The most common approach to vulvar condylomata is the local application of 25% podophyllum resin, often prepared in benzoin. This method, although reasonably well tolerated in the office setting, often requires numerous applications. Burning discomfort ensues after sustained contact, which is necessary for efficacy. Most recommend that the agent be left in place for 6 hours before tub baths, so compliance may be problematic. Podophyllum appears to be more effective on exophytic, rather than flat, condylomata. Use is restricted to the vulva in nonpregnant patients; vaginal application may lead to undesirable absorption and neurotoxicity. An alternative is halogenated acetic acid, either bichloroacetic or trichloroacetic (TCA). Our preference is 90% TCA. This agent quickly interacts with cellular proteins, inducing a coagulative effect, and rapidly turns lesions a brilliant white. Advantages include its ability to sustain a prompt chemical effect on the condyloma, its availability for intravaginal use and use during pregnancy, and the fact that it can be rapidly neutralized with sodium bicarbonate.
which may be dissolved in water and applied as a cooling paste.

**Excision or Ablation**

Surgical excision, electrosurgical, destruction, and laser ablation are reserved for certain patients. Criteria for selection may include the following:

- **Extensive volume of condylomata exceeding what may be resolved with chemical agents**
- **Multicentric HPV infections, particularly with involvement of the vagina, urethra, or anus**
- **Failure of concerted office therapy with topical chemical agents**
- **Immunocompromised state in some hosts**

One should certainly use biopsy liberally to evaluate presumed condylomata that are refractory to topical treatment or that have an atypical appearance. This helps prevent sustained, ineffective chemical treatment of high-grade VIN, often presenting as a flat and pigmented verrucous lesion in the younger patient, and helps exclude a frank cancer with warty features. Large, sessile condylomata or those that grow rapidly, bled abnormally, or become necrotic or invasive should arouse the suspicion of malignancy.

Cryotherapy has been used on the vulva to eradicate warts. The freezing induces localized tissue necrosis. Although healing usually is satisfactory, and numbing effects induce analgesia, application is limited by delivery systems and probe-tip sizes. Larger condylomatous masses are more difficult to treat, as are vaginal lesions. Depth of apparent tissue destruction can be difficult to assess.

Electrocautery with a loop has been used effectively, particularly with massive lesions. Analgesic needs are definitely a factor in this approach. Smaller lesions may be fulgurated. Buildup of charred tissue can be removed by abrasion to identify residual warty tissue. The precision and depth of tissue injury can be problematic.

Colposcopically directed laser ablation performed by trained personnel in appropriately selected cases may afford effective treatment. Condylomatous lesions may be vaporized; starting at the center of the lesion causes the wart to collapse inward toward the beam. The level of the adjacent normal base (see Chapter 15). Clinicians are advised to use protective eyewear during vaporization to prevent possible conjunctival superinfection. Narcotics for pain management are appropriate short-term drugs. Prophylactic systemic antibiotics do not appear to be indicated. Weekly office follow-up is advised for 2 to 3 weeks to assess tissue healing, prevent undesirable areas of tissue agglutination, and allow potential early identification of recurrences, which can be managed with chemical ablation. Patients should be followed up carefully for several months after treatment to monitor for recurrences.

The Cavitron Ultrasonic Surgical Aspirator (CUSA) has also been efficacious in treating condylomata. Tissue cell damage is 25 to 30 mm, which is similar to that caused by a cold scalpel. This contrasts with electrocautery at 75 to 100 mm. The tip vibrates at 22,000 cycles per second. Tissue is fragmented and aspirated, providing a specimen for histologic evaluation. Regardless of the selected approach to therapy, all patients should be advised to have their consorts examined to lessen the risk of reexposure to lesions with a large viral burden. This theoretically helps diminish treatment failures. Patients with HIV or other types of immunosuppression need to be more closely followed up.

**Hidradenoma (Sweat Gland Tumor) of the Vulva**

A rare benign tumor of the vulva, hidradenoma, was first described by Schickle in 1902. The tumor is characterized by its intricate papillary adenomatous pattern, which may be readily mistaken for cancer.

Clinically, a hidradenoma is small, rarely more than 1 cm in diameter (Fig. 23.22A). Its consistency can range from firm to as soft as a sebaceous cyst, with which it is often confused. Most of these lesions are found in the interlabial folds, in the labia majora, or in the perineum. Because these tumors are apocrine in origin, the labia minora location is unusual. The occasional occurrence of reddish brown pulpy material on the surface results when the tumor is excited through the duct of the sweat gland.

These lesions have been carefully studied in numerous laboratories, and the complex microscopic patterns have been repeatedly stressed (Fig. 23.22B). The superficial papillary adenomatous pattern appears aggressive, but careful inspection shows that the glandular structures are lined by a single layer of well-organized cuboidal cells. In some parts of the tumor, the pink-staining secretory elements can be identified superficial to lower power densities (200 to 300 W/cm²) to superficially dem-
A hidradenoma of the vulva is illustrated in Figure 23.22. It is a benign neoplasm derived from sweat glands. The tumor typically presents as a painless, slow-growing mass. Pathologically, it is characterized by a well-differentiated, acinar pattern of glands surrounded by a myoepithelial component. 

The basal layer. Beneath the epithelium is an indefinite layer of flattened myoepithelial cells. When the clear cell variant of the myoepithelium proliferates, an ominous picture is created, yet this clear cell hidradenoma also behaves in a benign manner. Although hidradenocarcinoma occasionally does occur, a finding of distinct adenocarcinoma in the vulva should initiate a search to rule out a metastatic lesion from another primary site.

Hidradenomas are classically asymptomatic, and most lesions are discovered during a routine pelvic examination.
Granular Cell Tumors

Granular cell tumors (GCTs) were first described by Weber in 1854. It wasn’t until 1926 that Abrikossoff coined the term myoblastoma. Later, the tumor was termed granular cell schwannoma. The current nomenclature recognizes the term granular cell tumor. Although frequently benign, GCTs can present as a malignant form that is multicentric and metastatic in vital organs. Horowitz and associates reported on 20 patients presenting with GCTs of the vulva over a 31-year period at the Emory University Teaching Hospitals. Seventy percent of the patients were African American, and the mean age was 50 years. Ninety percent of the lesions were on the labia majora, with lesion size ranging from $0.4 \times 0.4 \text{ cm}$ to $7 \times 8 \times 12 \text{ cm}$. Nineteen of 20 patients were treated with a wide local excision. The twentieth patient required radical excision because of the size of the lesion. This patient eventually died of pulmonary metastasis. Only two patients presented with multiple lesions. Twelve lesions were stained for S-100. All were positive, which suggests a neural Schwann cell origin.

Sometimes the overlying pseudoepitheliomatous changes are misinterpreted as invasive cancer (Fig. 23.23). Identification is possible with recognition of the granular cells dispersed within the underlying stroma or within the tumor. In a few patients, GCT has behaved in a malignant fashion, but an appearance of a second lesion at a site outside the vulva usually indicates multiple primary lesions rather than metastasis.

Hemangioma

Hemangiomas are common vulvar lesions that usually do not require treatment. The lesions normally are small, are often multiple, and may bleed with trauma. On occasion, keratinization causes the superficial surface to appear white or gray-white (angiokeratoma). Hemangiomas should be differentiated from small varicosities, which commonly are seen in the postmenopausal patient.
Vascular supply of the vulva.

An accurate diagnosis is imperative because a malignant melanoma can be misinterpreted as a hemangioma. The abrupt appearance of any pigmented lesion demands biopsy. In 2 of 11 melanomas seen in our clinic, the lesions were diagnosed as hematoxia or angiomata, and a correct diagnosis was provided only by histologic study. Angiokeratoma, a benign tumor, is a distinct clinicopathologic entity. Aggressive angiomymyoma, although structurally benign, is known for its large size and local recurrences. Some tumors, although benign, can be massive in size and thereby pose operative problems (Fig. 23.24).

The best treatment for congenital hemangoma is careful observation. The lesions regress spontaneously in almost all cases, and attempts at excision may be mutilating. If bleeding is a problem, the troublesome vascular channels can be treated by surgical ligation or embolization.

Varicocele and Varices

Varices are common on the vulva, and the larger lesions are almost routinely unilateral. As with most varicosities, treatment depends on size and symptoms. Whereas varicoses in the scrotum arise from dilatation of the veins in the pampiniform plexus of the inguinal canal, the lesions on the vulva arise from the pudendal veins (Fig. 23.23). Careful evaluation usu-

ally demonstrates more extensive involvement of the tributaries of the hypogastric vein with varicosities of the gluteal vessels over the buttoc.

If the patient experiences discomfort from the engorgement that follows exercise or standing for long periods, ligation is indicated with excision of the segment of vulvar skin that contains the varices. Knowledge of the intricate vascular system that supplies the external genitalia is necessary to ensure that surgery will result in long-term success and will prevent recurrences. Horowitz has treated several patients using selective embolization with success.

BEST SURGICAL PRACTICES

- Vulvar diseases are multiple and may be difficult to diagnose. Many inflammatory conditions clinically resemble cancer.
- Bartholin gland abscesses are usually treated with antibiotics and insertion of a Word catheter. Marsupialization or excision is rarely used today. The possibility of cancer of Bartholin gland should be considered in the postmenopausal women with a new mass involving Bartholin gland.
- Vulvodynia can be caused by infectious, inflammatory, neurologic, or neoplastic conditions of the vulva. When no underlying cause of vulvar pain can be determined, oral amitriptyline and gabapentin as well as topical steroid creams should be tried. Local injection with triamcinolone and bupivacaine can also be used. If vulvar vestibulodynia is diagnosed, an extended perineoplasty has been effective in many patients.
- Vulvar condyloma are caused by some types of HPV (90% are due to type 6 and 11). These lesions may be self-limiting and resolve spontaneously. They do not undergo malignant transformation. If numerous, large, or symptomatic, they can be successfully treated with topical podophyllin, podophyllum, or trichloroacetic acid. These lesions may also be destroyed or removed with electrosurgical desication, CUSA, CO2 laser, or simple excision. These lesions may be difficult or impossible to eradicate in immunocompromised patients.
- VIN should be diagnosed by biopsy. It may be caused by certain types of HPV, especially in younger women. If untreated, it may progress to invasive cancer. It can be treated by laser ablation, but surgical excision is usually recommended. A variety of techniques have been used, depending on the size and location of the lesion or lesions.

ACKNOWLEDGMENTS

The authors want to recognize the late Dr. J. Donald Woodruff, who has been a coauthor of this chapter for several editions and who has served as a mentor to the current authors.

imperforate hymen is called.

If canalization fails and there are no perforations, the vaginal vestibule, and it usually is torn early in the prepubertal years. If canalization of the most caudal portion of the vaginal plate does not canalize, a transverse vaginal septum is the result. Canalization of the most cephalad tip of the invaginating UGS establishes a patent hymen. The hymen usually is perforated during embryonic life to establish a connection between the lumen of the vaginal canal and the vaginal vestibule, and it usually is torn early in the prepubertal years. If canalization fails and there are no perforations, the hymen is called imperforate.

Imperforate hymen—The hymen usually is perforated during embryonic life to establish a connection between the lumen of the vaginal canal and the vaginal vestibule, and it usually is torn early in the prepubertal years. If canalization fails and there are no perforations, the hymen is called imperforate.

Pseudohermaphroditism—A condition in which the gonads are of one sex (genetically XX or XY), but in which the physical/phenotypical appearance is of the opposite sex. Genetically female individuals (chromosomes XX, thus with female gonads/ovaries) presenting with significant male secondary sex characteristics and genetically male individuals (chromosomes XY thus with male gonads/testes) presenting with significant female secondary sex characteristics.

THE VAGINA

The Imperforate Hymen and Its Complications

The hymen, the junction of the sinovaginal bulbs with the urogenital sinus (UGS), is a thin mucous membrane, sometimes cribiform in appearance, which is composed of endoderm from the UGS epithelium. The Mullerian ducts meet the sinovaginal bulbs at the most cephalad tip of the invaginating UGS. The vaginal plate elongates and canalizes to form the vagina. If the vaginal plate does not canalize, a transverse vaginal septum is the result. Canalization of the most cephalad portion of the vaginal plate at the UGS establishes a patent hymen. The hymen usually is perforated during embryonic life to establish a connection between the lumen of the vaginal canal and the vaginal vestibule, and it usually is torn early in the prepubertal years. If canalization fails and there are no perforations, the hymen is called imperforate.

Although variations in hymen development occur, complete blockage by the hymen of the vaginal orifice is rare, occurring in approximately 0.05% to 0.1% of newborn girls. In 1986, Mor and colleagues described the types of hymenal shape in the newborn infant from examination performed within the first 24 hours of life. In 53.3%, a smooth hymen with a central orifice was observed; a folded hymen with a central orifice was seen in 27%; a folded hymen with an eccentric orifice occurred in 4.5%; an anterior opening of the hymen was in 10.8%; a posterior opening was found in 0.6%. The researchers found that 3% had hymenal bands and 0.3% of the newborns had an almost imperforate hymen. Polkony and Kozin described the various configurations and anatomic details of the prepubertal hymen. In a case series of 265 children with known genital problems, three main hymenal configurations were observed: fimbriated, circumferential, and posterior rim. Interestingly, bleeding without a history of trauma was associated with hymenal bumps or breaks suggestive of trauma (31%) or with other hemorrhagic vulvar lesions (40%).

Stelling and colleagues have recently evaluated the genetic transmission of imperforate hymen and reported that the occurrence of imperforate hymen in two consecutive generations of a family is consistent with a dominant mode of transmission, either sex-linked or autosomal. It has also been reported that transmission may be recessively inherited. Taken together, they concluded that imperforate hymen is caused by mutations of several genes and emphasized the importance of evaluation of all family members of affected patients.

Symptoms

If an imperforate hymen is noticed before puberty, the condition can be treated when it is entirely asymptomatic. Cases that are recognized at birth present with a thin bulging membrane between the labia, which represents a mucocolpos. When the hymen is incised, the vagina is found to contain mucoid fluid that is the result of accumulated cervical secretion. This is caused by the stimulation of the infant’s cervical mucus glands by maternal estrogen in the presence of an intact hymen. Prenatal diagnosis of imperforate hymen and mucocolpos has been described with second-trimester antenatal sonography demonstrating a thin membrane that distended the vagina and spread the labia majora.

Although by performing a careful inspection of the external genitalia, an imperforate hymen may be diagnosed at any age, most commonly imperforate hymen is not detected until puberty, with girls presenting at age 13 to 15 years, when symptoms begin to appear but menstruation appears not to have begun. In 2005, Pousner and Spandorfer hypothesized that children with late diagnoses would be more likely to be symptomatic, undergo more diagnostic testing, and lack appropriate documentation in their medical records of adequate examinations compared with children with the diagnoses of imperforate hymen made at an earlier age. They reported a bimodal distribution of age at diagnosis with 43% (n = 10) of girls
A 57% (n = 13) at or older than age 8. Among older girls, 100% were symptomatic with abdominal pain and/or urinary symptoms. They found that in the young girls, in 90% of cases, the diagnosis was incidental. On review of the older girls’ medical records, they found that the majority lacked description of breast and pubic hair development, and almost half did not have menstrual history documented. The older group was more likely to present symptomatically and to undergo ancillary testing. They conclude that incorporating an examination of the external genitalia into routine practice of clinicians caring for children can prevent the significant delays in diagnosis of imperforate hymen, misdiagnosis, and potential morbidity associated with the latter group.

The symptoms girls present with after the onset of puberty are due to the accumulation of menstrual blood within the vaginal outlet tract. The blood of the first cycle period or two is collected in the vagina, which can hold a large volume of blood without undue stretching and with no other symptoms. This accumulated menstrual blood in the vagina is called hemato-
colpos. The patient may feel a slight fatigue and have cramping discomfort suggesting menstruation, but she has no history of any passage of menstrual blood through the vaginal outlet. Fig-
ure 24.1A shows bulging of the imperforate hymen, which may be dark in color because of occult blood showing through the stretched mucous membrane; Figure 24.1B shows extrusion of accumulated blood after the hymen is incised.

As menstruation continues to occur, however, the vagina becomes greatly overdistended, and the cervical canal also begins to dilate. Accumulation of menstrual blood in the uterine cavity, with subsequent hematometra, may occur. When the intrauterine pressure reaches a certain point, retrograde passage of blood into the tubes causes hematosalpinx. Associated or other adhesion formation within or at the fimbriated ends of the tubes may seal them, so that little or no blood enters the peritoneal cavity. In some cases, however, blood passes freely into the peritoneal cavity, forming hematoperitoneum (Fig. 24.2). A
tender mass often is palpable suprapubically, the result of uterine enlargement and upward displacement, bladder distention, or both. If hematoocolpos occurs, the irritation of the free blood may cause all the symptoms and signs of peritonitis.

The most common symptoms of vaginal overdistention are lower abdominal pain, discomfort in the pelvis, and pain in the lower back. Hematoocolpos should be included in the differential diagnosis of any girl presenting with persistent lower back pain. Irritation of the sacral plexus is believed to be the etiology of this referred pain pattern. The lower abdominal discomfort often is aggravated on defecation, and if extensive blood accumulation occurs in the vagina, constipation may result from pressure and obstruction of the underling rectum. Urination can be difficult as a result of pressure of the distended vagina, which can compress the urethra and prevent emptying of the bladder; urinary obstruction can ensue. Bladder symptoms can present as cramplike pains in the suprapubic region, along with symptoms of dysuria, frequency, and urgency. Overflow incontinence may eventually develop, and hydronephrosis is a rare complication. Girls presenting with severe dysmenorrhea and duplicate vagina and didelphys uterus should be evaluated for unilateral imperforate hymen.

Rock and colleagues followed surgery success subsequebtly to the surgical correction of imperforate hymen between 1945 and 1981 at the Johns Hopkins Hospital. Twenty-two patients of mean age 14.7 years were admitted for surgical correction of imperforate hymens. Associated anomalies, including urinary tract anomalies, were rare. Thirty patients subsequently conceived, and 10 patients were observed to have living children. Liang and colleagues in 2003 reported on the long-term postoperative evaluation of 15 patients with imperforate hymen. They conducted questionnaires and telephone interviews regarding sexuality, fertility, menstrual problems, micturition, and defecation. The mean postoperative follow-up was 8.5 years, with the mean age at diagnosis being 13.2 years. The women reported being markedly relieved of their presenting symptoms after hymenectomy. There were some who reported having irregular menstruation, and 6/15 reported dysmenorrhea. The authors reported that most patients fared well in terms of fertility and sexual function. Joki-Erkkila and colleagues in 2003 also reported on presenting and long-term fertility in women with obstructing vaginal anomalies. They identified 26 women with obstructive vaginal malformations. Sixteen had transverse obstructions: 13 underwent incision of an imperforate hymen and 3 excision of a complete transverse vaginal septum, with a mean follow-up period of 13 years. The remaining 10 had obstructive hemi-vagina and incision of a “longitudinal” vaginal septum with a mean follow-up period of 16 years. The transverse obstruction girls (imperforate hymen or transverse vaginal septum) were diagnosed within a month from their primary symptoms compared with 27 months for those with longitudinal obstruction. None with imperforate hymen required reoperation, but 2/3 with transverse vaginal septum did for vaginal constriction, and 3/10 with longitudi- nal vaginal septum had resection of their septum. All of the 10 women with longitudinal obstruction had uterine and renal malformations, whereas in those with a transverse vaginal obstruction, only 6 underwent renal-resalvation, and of these, 2 had double uteruses. Dysfunctional uterine bleeding was re- ported by 19% of those in the transverse and 40% of those in the longitudinal obstruction group; dyspareunia was reported in 30% of the transverse and none in the longitudinal; and dysmenorrhea was reported in 19% of transverse and 20% of lon- gitudinal. No endometriosis was found in women who had subse- quently had a laparotomy or laparoscopy (18/26). In the 14 who were attempting to conceive, difficulty with fertility was not diagnosed. Twenty-five (89%) out of 28 pregnancies ended in delivery, the live birth rate of the longitudinal group being 82%, and 94% in those with transverse obstruction. The au- thors concluded that accurate diagnosis, along with adequate treatment, can reduce the need for reoperations and that no specific long-term clinical gynecologic symptoms were identi- fied in these women with obstructing vaginal anomalies. The great distressfulness of the vagina probably protects the adoles- cent patient with an imperforate hymen from abnormal retro- grade menstruation, and the possible subsequent development of pelvic endometriosis with imperforate hymen as the cause is unlikely as long as the diagnosis is made reasonably early. The recent long-term follow-up studies are helpful in counseling pa- tients with respect to lack of a negative effect on fertility and pregnancy in women with correction of imperforate hymen.

**Treatment**

When an imperforate hymen is discovered before puberty, the hymenal membrane can simply be incised, preferably at the 2-, 4-, 8-, and 10-o’clock positions. The quadrants of the hymen are then excised, and the mucosal margins are approximated with fine delayed-absorbable suture (Fig. 24.3). To prevent scarring and stenosis, which could result in dyspareunia, the hymenal tissue should not be excised too close to the vaginal mucosa. If an unnecessary intrauterine instrumentation should be avoided because if hematocolpos has already developed (Fig. 24.2), there is the risk of perforating the thin, overstretched urethral wall.

No further surgical intervention is generally needed. If the uterine mass does not regress within 2 to 3 weeks, however, inspection and dilatation of the cervix should be performed to make certain that drainage from the uterus is satisfactory.

---

**Anomalies of the External Genitalia and Vagina**

**Construction of Female External Genitalia**

Sexually ambiguous external genitalia defects of the UGS are remarkable in appearance, regardless of the etiology of the anomaly. Such genitalia differ only in their degree of malformation and occupy a range of positions somewhere intermediate to the genitalia of a normal female and that of a normal male. These anomalies can be anatomically identical to each other, whether their etiologic factor is congenital adrenal hyperplasia (CAH), male hermaphroditism, true hermaphroditism, or some other intersex syndrome. External genitalia proceeds along the female lines except in the presence of some virilizing influence acting on the developing embryo (i.e., androgens). The conversion of testosterone to dihydrotestosterone by 5α-reductase activity occurs in the skin of the external genitalia and UGS in early gestation. Masculinization of the external genita- lia ensues in the presence of functional androgens regardless of genetic sex. In the case of female pseudohermaphroditism— XX chromosomes in the presence of a virilizing influence—the fusion of the scrotal/glabral folds may be sufficient to obscure or conceal the vagina from the outside or even to entirely suppress its formation. The urethra can be formed for varying distances or along the entire length of the phallus. Therefore, the operative procedure for reconstruction of ambiguous genitalia into feminine genitae varies in its extent depending on the severity of the cause of the intersexuality. The common goals for the female reconstruction of ambiguous genitalia include reduction of chotial size, creation of labia minora, and exterior- ization of the vagina.
Any reconstruction of the external genitalia with the objective of producing normal female appearance and function requires a full understanding of the surgical anatomy. It is essential to accurately identify the site of communication of the vagina with the UGS. In their classic paper in 1969, Hendren and Crawford recognized the variability of the communication of the vaginal insertion into the UGS. Figure 24.4 illustrates the spectrum of vaginal communication with the urethra, with Figure 24.4A representative of a low distal communication (infrasphincteric) and Figure 24.4B representative of a high proximal communication (suprasphincteric). In 95% of cases, the vaginal communication is in relation to the caudal UGS derivatives (infrasphincteric) with the vagina communicating with that portion of the UGS in a man gives rise to the membranous portion of the male urethra and that in the woman becomes the vaginal vestibule. If this usual relation is confirmed at surgery, the persistent, anomalous UGS may be excised to the vaginal communication without fear of disturbing the urinary sphincter. In less than 5% of cases, the vagina communicates high, with the portion of the UGS that becomes the prostatic urethra in the man or the entire urethra in the woman (suprasphincteric). Knowledge of the possible variants in communication of the vagina with the UGS is critical before entertaining surgical correction. Preoperatively genitography showing the relationship of the UGS, urethra, vagina, and bladder may be helpful. Contrast is injected retrogradely through the perineal meatus of the UGS. Delineation of this anatomy can be elucidated at the time of surgery with the use of endoscopy to evaluate where the vagina communicates with the UGS. In 1989, Bargy and colleagues described the anatomic lesions in the intersexual states based on clinical and anatomic observations.

One objective of the reconstruction procedure for external genitalia is to delay the procedure until the anomalous structures are of a size to permit easy identification of all structures. As observed by Azziz and coworkers, vaginal repair may be delayed until menarche, when maturity and the desire for sexual activity are usually well established. There is present debate in the need for early reconstruction for the sole purpose of cosmetics to prevent embarrassment or anxiety to the patient’s family. Crouch and Creighton have recently revisited the long-standing dictum of early surgical correction of ambiguous genitalia for intersex conditions. They report that some advocate the “one-stage” procedure in infancy, but that others advocate deferral of vaginal surgery until after puberty, especially given that many patients require further surgery at adolescence. It has been believed that the intersex child may be psychologically damaged by the “appearance” of uncorrected external genitalia if not performed at infancy, but unfortunately to date little research on this exists.

Most hermaphrodites reared as girls have a vagina or vaginal pouch, although in some instances, it is rudimentary. Only rarely is there no vagina, despite ambiguity of the external genitalia. The choice of operative procedure must conform to the observed anatomy. Thus, these choices are considered in the context of several categories based on anatomic structure of the anomaly.

When the Vagina is Present and the Vaginosinus Communication is Low. The basic operation is, in essence, a modification of one described at length by Young that was previously performed successfully by various surgeons, notably in Europe. Patients with adrenal hyperplasia usually require only reconstruction of the external genitalia. However, when exploratory laparotomy is necessary to remove contradictory sex structures in other types of intersexuality or to establish the diagnosis, reconstruction of the genitalia may be considered at the same operation.

If an operation is deemed necessary at a very young age, the structures can be so small that it is impossible to introduce a finger into the UGS, and all tissues must be grasped throughout the operation with fine delicate tissue forceps. Operating loupes...
(2.5–3) are of great benefit to the surgeon. Small bipolar forceps and microscissors are also useful. Fine 5-0 or 6-0 synthetic absorbable sutures on an atraumatic needle is used throughout the procedure.

In cases of simple labial fusion, a cutback vaginoplasty (Fig. 24.5) would be sufficient to restore “normal” female genital anatomy. In cases of low vaginal confluence with the UGS (Fig. 24.4A), reconstruction may be done either by freeing the posterior vaginal wall and suturing up to the perineal external opening (Fig. 24.6) or—if a patient has copious subcutaneous fat and difficulty exists in approximating the vagina to the perineal skin—by use of a posterior flap technique, as used by Fortunoff and coworkers (Fig. 24.7).

Initially, the UGS may be thoroughly investigated with a small McCarthy panendoscope to determine accurately the position and size of the vaginal communication. If a sound or catheter can be easily introduced into the meatus of the UGS and into the vagina, use of the endoscope may be omitted. Special care is needed not to introduce the sound into the urethra. A sound accidentally introduced into the urethra poses the danger of incising the distal urethral meatus. After the UGS is incised (to within 2 or 3 cm of the anus), the urethral orifice may be identified (Fig. 24.6A and B). A small Foley catheter may then be introduced through the urinary meatus for purposes of identification throughout the remainder of the operation. To attach the edges of the vagina to the skin, it is usually necessary to free the vagina posteriorly and laterally to secure sufficient mobilization so that these structures meet with no tension. It is unnecessary to free the vagina anteriorly, because this requires its separation from the urethra. Sufficient mobilization can ordinarily be obtained by lateral and posterior dissection. When sufficient freedom has been attained, the edges of the vagina may be secured to the skin with interrupted 5-0 sutures on an atraumatic reserve-cutting needle. In the infant, four or five sutures around the edge of the vagina are usually sufficient. The edges of the incised sinus membrane may then be sutured to the skin anteriorly (Fig. 24.6D–G). A small sponge impregnated with petroleum jelly may be introduced into the vagina to maintain its patency during the healing process. The indwelling catheter may be left in place for a few days until edema of the surrounding structures has subsided. An indwelling catheter is particularly useful in children with metabolic disorders that require accurate urine collection. A pressure dressing for 24 hours reduces the incidence of incisional hematoma.

Figure 24.7 illustrates vaginoplasty with a posterior flap as advocated by Fortunoff and is useful in cases with anticipated difficulty in bringing the vaginal orifice to the outside. Briefly, a posterior-based U-flap is drawn, with corners on either side of the perineal body near the rectum (Fig. 24.7A–C). This flap must be wide enough for tension-free anastomosis. This posterior flap is dissected in the midline and is carried out between the rectum and UGS.

Sutures are individually placed through the posterior-based flap and into the split posterior vagina. Sutures are tied after all have been placed. Because the anterior wall is not disturbed, no anterior flap is required. Finally, the phallic skin is
FIGURE 24.6. A: The external genitalia of an 18-month-old girl with congenital adrenal hyperplasia. The operation is the same, regardless of the etiology of the "virilizing" deformity. B: Beginning of the operation. Incision into the urogenital sinus. If the external meatus is large enough and the urogenital sinus will accommodate it, it is sometimes possible to introduce a catheter into the bladder through the urethra and introduce a sound into the vagina beside this. When the structures are large enough, this maneuver greatly facilitates the operative procedure by ensuring their identification. C: Lateral view showing the relations among the various structures. D: Situation after incision of the urogenital sinus. E: With the glass catheter in the bladder, the posterior vaginal wall is freed to make it possible to bring it to the skin edge without undue tension. F: The operative situation after the edges of the vagina are sutured to the skin and after the edges of the mucous membrane of the urogenital sinus are also sutured to the skin along the line of incision. G: Lateral view at the completion of the operation.

FIGURE 24.7. A posterior flap technique for when there is difficulty bringing the vaginal orifice to the outside.
FIGURE 24.8. Clitoral reduction via the clitoral flap technique. A: The initial incision. B: The flap must be as wide as possible at the base to preserve the circulation for the glans. The glans cannot be preserved completely because the blood supply will be insufficient to maintain it. It must be as thin a shell of the glans as possible. C: The shaft of the phallus has been removed. D: There has been some closure of the space from which the corpora were removed. E: The flap has been sutured into place.

FIGURE 24.9. Dorsal approach to subtotal resection of the corpora. The nerve supply to the glans is preserved with its neurovascular supply intact along Buck's fascia and the dorsal tunic of the gland. This approach is theoretically desirable and can be recommended for suitable cases.

In 1999, Baskin and colleagues described the anatomic studies of the human clitoris. As in the human penis, the nerves in the clitoris form an extensive network surrounding the tunica of the corporeal body with a nerve-free zone at the 12-o’clock position. The normal clitoris has corporeal bodies that are smaller but analogous to those of the penis. The surgeon should be mindful of their function if extensive resection is considered with care to preserve the dorsal aspect of the glans.

In 1999, Baskin and colleagues described the anatomic studies of the human clitoris. As in the human penis, the nerves in the clitoris form an extensive network surrounding the tunica of the corporeal body with a nerve-free zone at the 12-o’clock position. The normal clitoris has corporeal bodies that are smaller but analogous to those of the penis. The surgeon should be mindful of their function if extensive resection is considered with care to preserve the dorsal aspect of the glans.
corpora, yet the cavernous erectile tissue is excised. Figure 24.10 illustrates this surgical management; additionally, the phallus is degloved, and this skin is used to create the labia minora. An incision is made around the corona of the phallus and continued inferiorly around the urethral meatus. Preservation of this meatal plate improves cosmesis and increases blood supply to the glans. The neurovascular bundle is identified, with lateral incisions into the tunica of the corpora along the phallus from the glans backward proximal to the corporal bifurcation. The cavernous erectile tissue is dissected from the
inferior aspect of the dorsal tunic and excised, and the proxi-
mal and dorsal corpora are suture ligated. The glans is secured
to the inferior aspect of the pubis or to the corporal stumps.

In a pilot study of six women in 2003, Crouch and col-
leagues reported on genital sensation after feminizing genito-
plasty for women with CAH. These women were assessed for
thermal, vibratory, and light-touch sensory thresholds in the cli-
toris and vagina using a genitosensory analyzer and von Frey
filaments. Highly abnormal results for sensation in the clitoris
were found in the six women studied. In three who had an
introitus capable of admitting a vaginal probe, the vaginal sen-
sory data was considered normal. Given an abnormal clitoral
sensation and normal vaginal sensation, the authors hypoth-
thesize that the abnormal clitoral findings may result from the
surgical reconstruction rather than an effect of CAH. A self-
administered sexual function assessment revealed that these
women had sexual difficulties, particularly in the areas of in-
frequency of intercourse and anorgasmia. The authors voiced
their concerns with the stated superiority of modern surgery.
They stated that the vascularity of the glans remains vulnera-
ble and that the risk of damage to the neurovascular bundles is
inherent in any technique that entails their separation from the
corporeal tissue. They concluded that even after seemingly suc-
cessful clitoral reduction, the sensory function is significantly
impaired, and this should be taken into consideration during
counseling. Larger studies are presently under way to further
evaluate these findings.

When the Vaginal Orifice is Obscured. As mentioned previ-
ously, preoperative identification and catheterization or sound-
ing of the vaginal orifice is key to the performance of a
successful, one-stage procedure. When the vagina cannot be
located by sounding, it sometimes can be seen by endoscopy.
When sounding and vision both fail, an attempt before surgery
to introduce a small (no. 4 or 5) ureteral catheter into the
vagina by blindly probing through the endoscope along the
posterior wall of the UGS may assist in the identification of
the vagina. Sometimes this catheter finds the orifice. If so, it
may be left within the vagina as a guide during surgical ex-
posure of the area (Fig. 24.11). If the vaginal orifice cannot
be located, a planned two-stage operation is indicated. The
objective of the first stage would be to obtain cosmically

![Figure 24.11](image-url)
satisfactory female genitalia by reducing the clitoris and partially excising the UGS without exteriorizing the vagina. During the planned second stage, exteriorization of the vagina can be performed. The second stage should be postponed until identification of the vaginal orifice by sounding becomes possible. This may require waiting for puberty for estrogenization of the area. If dilators are needed for patency postoperatively, this surgery should be delayed until the girl is sufficiently mature for their appropriate use. This will maximize the success of the reoperation.

When the Vaginosinus Communication is Blocked. Rarely does the vagina not communicate with the UGS. The vagina with the UGS is homologous with the hymenal area, and the hymen rarely is imperforate in an otherwise normal woman. For such a circumstance, we have found it helpful to pass a uterine sound downward through the fundus via hysterotomy into the vagina, thus forming a protrusion on the perineum. With such a guide, the edges of the vaginal epithelium can be located and sutured to the skin (Fig. 24.12). Until the uterus enlarges somewhat from its infantile state, the cavity is not large enough to accommodate even a uterine sound. Therefore, if such an operation is contemplated, it should not be done until there is a palpable enlargement of the uterus at the onset of puberty. Evaluation of uterine volume sonographically as a predictor of uterine size adequacy may be helpful.

When the Vaginosinus Communication is High. Hendren has been especially interested in patients whose vaginosinus communication involves the proximal urethra (suprasphincteric). He has advocated an operation that disconnects the vagina from the urethra and repositions the vaginal orifice in the perineum, the “pull-through” vaginoplasty. In his hands, this procedure seems to have been satisfactory for some patients. The procedure requires positioning the new vaginal orifice in the perineum (Fig. 24.13). The vast majority of patients with ambiguous external genitalia and a vagina have a vaginosinus communication well distal to the proximal urethra (infra sphincteric), and consideration of the procedure advocated by Hendren is not necessary. In patients in whom the vagina enters the UGS proximal to the external sphincter, the pull-through vaginoplasty of Hendren and Crawford or the method described by Passerini-Glazel can be used to prevent incontinence. Hendren and Crawford's vaginal pull-through remains the basis for reconstruction today. Modification to this procedure has evolved in an attempt to decrease the complexity and decrease the tendency of an isolated vagina toward stenosis. Rink and coworkers have favored a one-stage procedure using a perineal prone approach with no division of the rectum.

Results of Revision of External Genitalia. Among 28 patients with adrenogenital syndrome and good follow-up treated at the Johns Hopkins Hospital, 22 (87.6%) needed further vaginal reconstructive surgery to achieve an adequate vaginal size.

to allow comfortable intercourse. Of the 22 patients, five had undergone more than one surgical attempt at reconstruction. The mean age of patients undergoing repeat procedures was 7.1 years. The mean age at first surgery for the whole group was 23.6 months. Vaginal reconstructive surgery was performed on 18 of these patients and was successful in 13 (72%) of the procedures. It generally is recommended that exterozization of the vagina be postponed until near puberty, when feminization occurs and the young woman is sufficiently mature to comply with a postoperative dilatation program. The results of exterozization performed during infancy must be followed up carefully for evidence of narrowing. In 1997, Costa and colleagues evaluated the vaginal size and sexual activity after different techniques of feminization of external genitalia in patients with pseudohermaphrodisism. In their series of patients, all who underwent clitoroplasty reported orgasms, and 29% of the patients who had clitoridectomy reported no orgasms. Fifty percent of the patients who submitted to neovaginoplasty reported pain or bleeding during sexual intercourse. Satisfactory sexual intercourse was reported by 87% after vaginal dilation with acrylic molds.

In 2000, Krege and colleagues reported on the long-term follow-up of female patients with CAH from 21-hydroxylase deficiency, with special emphasis on the results of vaginoplasty. They reported that the main problem during the long-term follow-up was intravaginal stenosis, with all those affected—9 of 23 (36%)—having undergone a single-stage procedure early in life to correct ambiguous genitalia (mean age, 4.7 years; range, 2 to 9 years). The authors suggested that vaginoplasty should be undertaken at the beginning of puberty, because higher estrogen levels may prevent stenosis and dilatation may be performed. In addition, 16 patients answered questionnaires that included psychological profile, and the researchers found that 14 had problems with their overall body image. Patients with correction of vaginal stenosis were particularly anxious about sexual intercourse and had problems with orgasm. Creighton and colleagues in 2001 retrospectively evaluated the cosmetic and anatomical outcomes of 44 adolescent patients who had undergone feminizing surgery for ambiguous genitalia during their childhood. The authors reported that cosmetic results were judged as poor in 18 (41%) and that 43/44 (98%) required further treatment to the genitalia for cosmetic, tampon use, or intercourse. Of the genitoplasties planned as one-stage procedures, 23/26 (89%) required further major surgery.

Davies and colleagues in 2005 reported on urinary symptoms in adult women with CAH. The authors reported on 19 women with CAH, of whom 16 had childhood feminizing genital surgery, and compared them with age-matched women without CAH. The Bristol Female Lower Urinary Tract Symptoms (BFLUTS) questionnaire was given to all the women. Sixty-eight percent of the women with CAH reported urge incontinence compared with 16% of controls (p = 0.003). Stress incontinence was present in 47% of CAH and 26% of the controls. Nine of the CAH women reported that their urinary symptoms had an adverse effect on their lives, whereas only one of the controls did (p = 0.008). The authors concluded that women with CAH are more likely to have urinary symptoms than controls. It is important to emphasize that it is not known whether these results are associated with the surgical procedures that the women underwent or an effect of CAH itself. For counseling purposes, this information is important because in two thirds of these CAH women, urinary symptoms persisted.

Historically, it has been assumed that psychosocial development of infants with intersex disorders is mostly due to rearing
Surgical Conditions of the Vagina and Urethra

rather than being intrinsic. Over the past decade, the role of testosterone imprinting of the fetal brain has been studied to evaluate the role of this hormone in determining male sexual orientation. Studies in the 1990s of girls with CAH have confirmed that such children engage in more rough-and-tumble play than their affected peers and that difficulties with adjustment to their assigned sex may exist. Nonetheless, few studies have been conducted to address the social, psychological, and sexual outcomes for affected adolescents and adults, although it appears that most function in the normal range and are well adjusted. The majority of girls appear not to overtly demonstrate sexual identity problems.

Ozbey and coauthors reported on the experience of sex (re)assignment in genotypic female (46XX) patients with CAH when complicated by delayed presentation and inadvertent assignment. They reported on 70 patients with CAH who between 1983 and 2002 were counseled for sex assignment. They evaluated age at diagnosis and operation, the degree of virilization, parental consanguinity, and the sex preference of the families as factors determining sex (re)assignment decision-making.

Forty-nine of seventy were reared as girls and 21 were reared as “boys.” Of these 21 “boys,” only nine could be reassigned as girls (mean age 7.9 months), and the other 12, with mean age at presentation of 55.8 months, were reared as “boys” in compliance with the parents’ and the study group’s decision. These “boys” underwent appropriate masculinizing reconstructive surgery. They concluded that age of presentation was crucial for the ability to correctly assign the sex of patients with CAH.
Secondary Operations. A secondary operation on the vaginal outlet may be required. This is generally the case if the basic operation is deliberately accomplished in two stages, whatever the reason. A secondary operation may be indicated, for example, when an infant’s vaginal orifice is not readily identifiable, yet it seems desirable to construct cosmetically acceptable female genitalia at a very early age. Care should be taken when considering the appropriate age for performing a clitoroplasty. Some have recommended that this can be done in the newborn and that the vagina may be exteriorized at puberty as a secondary operation. Alizai and colleagues reported on the outcome of feminizing genitoplasty in 14 postpubertal girls (mean age 13.1 years) with CAH. These girls were assessed under anesthesia by a pediatric urologist, plastic/reconstructive surgeon, and gynecologist. Thirteen of fourteen had previously undergone feminizing genitoplasty in early childhood. The authors reported that the outcome of clitoral surgery was unsatisfactory (clitoral atrophy or prominent glans) in six of the girls. Additional vaginal surgery was necessary for normal comfortable intercourse in 13 of the girls. In the girls with a history of vaginal reconstruction in infancy, fibrosis and scarring were prominent. The authors concluded that these results were disappointing, even in the girls who had their surgery performed by specialist surgeons. The authors highlighted the importance of late follow-up and the challenges in the prevailing assumption that total correction can be achieved with a single-stage operation in infancy. When the complete operation is attempted at an early age, the vagina is sometimes not satisfactorily exteriorized. Vaginal stenosis may require reconstruction at the time of puberty (Fig. 24.14). In this circumstance, there usually has
been a failure to carry the midline incision far enough posteriorly, and a second procedure is required to complete the first one by continuing the midline incision far enough posteriorly. In other cases, contraction at the vaginal outlet may occur even if the operation is adequately performed. A minor revision of the vaginal orifice is required to enlarge the vaginal orifice by making an incision in the midline and closing it at 90 degrees to the original axis of the incision (Fig. 24.15). In some instances, it may be necessary to create flaps to enlarge the vaginal orifice (Fig. 24.16).

FIGURE 24.15. A: Repeated operation on the vaginal outlet when the operation was not completed at the first procedure. B: The posterior incision. C: The vagina is exposed. D: The closure.

FIGURE 24.16. Labial cutaneous flap. A: An incision is made through the labia skin and subcutaneous fat. B: The flap is rotated into the perineotomy incision. C: The flap is sutured in place by interrupted 3–0 delayed-absorbable sutures. This may be repeated on the other side if required.
It should be emphasized that simple exteriorization of the lower vaginal tract can be combined with cosmetic correction of virilized external genitalia in infancy, but in most cases, it is best to defer definitive reconstruction of the intermediate or high vagina until after puberty.

**Bladder Exstrophy**

Exstrophy of the bladder is a rare congenital anomaly occurring in live births in a 1:25,000 to 1:40,000 ratio. There is a male predominance over females in a ratio of about 2:1. Classic bladder exstrophy is characterized by (i) absence of the lower anterior abdominal wall, (ii) absence of the anterior wall of the bladder so that the posterior bladder wall and the ureteric orifices are exposed, (iii) a poorly defined bladder neck and urethra, and (iv) wide separation of the pubic symphysis. A genital abnormality typically present in girls with bladder exstrophy is anterior displacement and narrowing of the vagina (Fig. 24.17) and separation of the clitoris into two distinct bodies (Fig. 24.18).

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy epispadias complex. These defects have been attributed to failure of the normal process of ingrowth of mesoderm and the consequent lack of reinforcement of the cloacal membrane. The normal cloacal membrane is bilaminar and occupies the caudal end of the germinal disc. An ingrowth of mesenchyme between the ectodermal and endodermal layers of the cloacal membrane forms the lower abdominal wall musculature and the pelvic bones. After mesenchymal ingrowth occurs, descent of the urorectal septum divides the cloacal membrane into the bladder anteriorly and the rectum posteriorly. The urorectal septum eventually meets with the posterior remnant of the cloacal membrane, which perforates to form the anal and UGS openings. The paired genital tubercles migrate medially and fuse in the midline anterior to the cloacal membrane before perforation. Without its normal support from mesenchymal derivatives, the cloacal membrane is subject to premature rupture. Depending on the extent of the infraumbilical defect and the stage of development when rupture occurs, bladder exstrophy, cloacal exstrophy, or epispadias develops (Fig. 24.19).

**Treatment.** Our understanding of appropriate urologic management of bladder exstrophy has evolved greatly over the past few decades, and improved management has markedly increased the life expectancy and quality of life of patients with this anomaly. Historical methods of treatment involved bladder excision and a urinary diversion procedure such as ureterosigmoidostomy. These techniques are complicated by serious sequelae, including pyelonephritis, hyperchloremic acidosis, rectal incontinence, ureteral obstruction, and later development of malignancy.

Modern urologic management of bladder exstrophy relies on a staged approach to functional bladder closure. The initial procedure consists of primary bladder closure with or without iliac osteotomies to aid closure of the pelvic ring and growth and improvement of bladder capacity. The second-stage procedures usually involve bladder neck reconstruction to improve continence and bilateral ureteral reimplantations to prevent reflux. Both failures and primary reconstruction have also been performed using continent urostomy techniques, such as the Mainz II pouch. Mingin and coworkers and Gerharz and colleagues have reported their success using this technique.

The prognosis using modern-day procedures is good. Although deficiency of the pelvic floor and a predisposition for pelvic organ prolapse are not unusual with bladder exstrophy, the condition of bladder exstrophy itself can often be corrected.
and associated genital anomalies can be managed to allow comfortable sexual activity and possibly even pregnancy.

The adjunctive procedures that may be important with surgical correction of bladder exstrophy are those that address the correction of anterior displacement and narrowing of the vagina, and separation of the clitoris into two distinct bodies that are so typically associated with bladder exstrophy.

The procedure for correcting the external genitalia has evolved from one that was first described by Howard Jones Jr. in 1973. Particular emphasis is placed on attainment of an adequate vaginal diameter without further predisposing to subsequent prolapse. The first step is vertical incision into the posterior raphe of what resembles fused scrotolabial folds; next, Allis clamps are placed laterally for traction. Fine-needle point electrosurgery is then used to further open the incision, with special care taken not to take this incision too far posteriorly. The lateral portions of the incision are secured with 3-0 nonreactive absorbable sutures for further traction. The posterior vaginal edges are undermined to allow their mobilization to the exterior. The vaginal mucosa is then approximated to the perineal surface with interrupted and figure-of-eight sutures, incorporating the superficial perineal muscles into the closure. In the more posterior portion of the closure, 2-0 nonreactive absorbable suture is used, because this is the area of greatest tension. At completion, there is a significant increase in the diameter of the vagina, and the vaginal orifice usually accommodates two fingers.

Postoperative active dilatation therapy has recently been advocated. Experience with management of ambiguous genitalia has shown a decrease in the incidence of postoperative vaginal stenosis if dilatation therapy is employed during the constrictive phase (the first 6 weeks) of healing. For this reason, following reconstruction of the external genitalia and exteriorization of the vagina, appropriately sized Lucite dilators are used once or twice a day for this 6-week period or until healing is complete.

Reapproximation of the bifid clitoris (Fig. 24.20) is primarily cosmetic and is not always performed. The technique involves excising a diamond-shaped area of skin and subcutaneous tissue between the clitoral bodies. The medial aspect of each side of the clitoris is then denuded and undermined to allow a central reapproximation with a side-to-side closure.

Adjunctive Treatments. Stanton mentioned that perineotomy was performed in six patients with bladder exstrophy in which the labia and clitoris were reapproximated by a Z-plasty technique. Still others have described rather extraordinary efforts to restore the mons pubis and female escutcheon with skin flaps of hair-bearing areas. These latter reports, however, fail to mention correction of the vaginal anomaly.

Other series have described a wide range of both genital and extragenital abnormalities in association with bladder exstrophy. Stanton reviewed 70 patients with bladder exstrophy and observed an increased incidence of various müllerian
anomalies. Eleven patients were also observed to have associated rectal prolapse. Blakely and Mills observed various extra-genital abnormalities in their series, including rectal prolapse, imperforate anus, exophthalmos, renal agenesis, and spina bifida.

Results. Jones reviewed the records of all female patients diagnosed with bladder extrophy at Johns Hopkins Hospital over a 20-year time span. Of 18 patients with adequately described external genitalia, 13 had small, anteriorly displaced vaginal orifices, and the remaining five patients had vaginal orifices of normal size and location. Therefore, although demonstrating phenomena very typical of bladder extrophy, all female patients do not demonstrate the defect of narrowing of the vagina. Damario and colleagues have recently updated the Hopkins series, documenting continuing excellent long-term results.

Several series have reviewed subsequent pregnancy outcomes in patients with bladder extrophy. Clementson extensively reviewed the literature in 1958 and found 45 patients who underwent 64 pregnancies. A very high incidence of uterine prolapse was observed both before and after pregnancy. In addition, there was a higher incidence of premature labor and malpresentations (24%). Kruloff and colleagues also reported a high incidence of uterine prolapse related to pregnancy, which occurred in 6 of 7 women. Burbige and coworkers reported on 14 pregnancies in patients with a history of bladder extrophy. Uterine prolapse occurred in 7 of 11 patients, all of whom had undergone a previous urinary diversion procedure.

The mode of delivery in patients with prior urinary diversion procedures has primarily been spontaneous vaginal delivery. The increased incidence of premature labor and malpresentation, however, has warranted an increased rate of cesarean sections for obstetric indications. In patients with a prior bladder reconstruction, most surgeons advocate an elective cesarean section to eliminate stress on the pelvic floor and to avoid trauma to the delicate urinary sphincter mechanism.

Management of Uterine Prolapse with Bladder Extrophy. Several mechanisms have been proposed to explain the high incidence of uterine prolapse in patients with bladder extrophy. These mechanisms include (i) a deficiency of the pelvic floor that is due to the wide separation of the pubic symphysis, (ii) an inherent deficiency of the cardinal ligament complex, and (iii) the abnormal axis and short length of the vagina. Because wide separation of the pubic symphyses results in an enlarged genital hiatus and deficiency of the pelvic floor, it is possible that iliac ostotomies may be helpful in detaining pelvic organ prolapse by closer approximation of the levator ani and puborectal muscles. Although Gearhart and Jeffs suggest that iliac ostotomies may not be necessary if primary bladder closure is performed in the first 72 hours of life, perhaps the procedure should be given increased consideration in female patients who present such a high risk for uterine prolapse later in life.

It appears important not to extend the midline perineal incision too far posteriorly in revision of the genitalia in these patients. As the incision proceeds posteriorly, the midline septum thickens to approximately 2 cm. At this point, the levator ani muscles may be severed, further enlarging the genital hiatus. It is prudent, therefore, to be more conservative; postoperative dilator therapy may aid in achieving further vaginal diameter if needed.

A case referred to us illustrated this point. A 16-year-old nulliparous patient with bladder extrophy and a history of staged bladder reconstruction underwent revision of the external genitalia. A large posterior incision into the perineal body left a gaping introitus, and uterine prolapse had occurred several months after this procedure. Our initial approach was to reconstruct the perineal body to help contain the uterus and improve support to the pelvic floor. This reconstruction has been successful, without further prolapse 3 years after the procedure. Blakely and Mills, who observed uterine prolapse occurring very soon after enlargement of the vaginal introitus, reported a similar case.

Management of uterine prolapse associated with bladder extrophy may be difficult. The patient frequently desires preservation of her childbearing capacity. Sacrospinous fixation of the cervix may be considered, although an abnormally short vagina may produce difficulty in obtaining the suspension without significant suture bridges. An abdominal sacro-cervicopexy may also be considered. DeWeese and coworkers described this approach in 1980. They suspended the uterus to the sacrum using Ivalon suture in a patient with procidentia following repair of bladder extrophy.

FIGURE 24.20. Schematic depiction of procedure to reaproximate the clitoris. A vulvovaginoplasty has already been performed to exteriorize the vagina. A: A diamond-shaped piece of skin and subcutaneous tissue between the clitoral bodies is excised. B: The clitoral bod-
ies are then undermined and mobilized to the center for a side-to-side reaproximation.
The high historical incidence of uterine prolapse and the potential difficulties managing this problem highlight the need for the reconstructive surgeon to give extra thought and care to revision of the external genitalia in women with bladder extrophy. Appropriate reconstruction may actually accelerate genital prolapse. In addition, elective cesarean section may be the most judicious mode of delivery for limiting traumatic insults to the pelvic floor that could further increase the propensity for prolapse. Ricci and coworkers evaluated 17 patients (13 children, 2 young adults) with bladder extrophy for latex allergy. Twelve shared latex sensitization, with five demonstrating symptoms. The multiple operative and cystoscope procedures performed on this group of patients has resulted in significant latex exposure and sensitization similar to that seen in health care workers.

Carcinoma of the Vagina
Carcinoma of the vagina is uncommon, occurring in less than 2% of patients with gynecologic malignancies. The average age at presentation is 60 years. Vaginal carcinoma is most frequently secondary to metastases from tumors of the cervix and vulva rather than originating in the vagina. Lesions that encroach on the outer vagina from the vulva must be separated from lesions that originate in the vaginal canal to be considered a vaginal primary.

The International Federation of Obstetrics and Gynecology (FIGO) has agreed on the following exclusionary criteria for the classification of vaginal cancer:

1. A vaginal growth extending to the portio of the cervix and reaching the area of the external os should always be considered a carcinoma of the cervix.
2. A vulvar growth that has extended to the vagina should be classified as carcinoma of the vulva.
3. A vaginal growth that is limited to the urethra should be classified separately as carcinoma of the urethra.

Clinicians now satisfy the staging criteria for the diagnosis of primary carcinoma of the vagina by showing a histologically negative cervix, urethra, vulva, and endometrium.

The criteria for the definition of primary carcinoma of the vagina were established after many clinicians reported the recurrence of vaginal lesions after treatment of carcinoma in situ of the cervix. Tumors recur in 1% to 6% of cases. Today, extension of carcinoma in situ and invasive carcinoma of the cervix to the vaginal fornices or upper vagina can be easily identified with the use of colposcopy.

The clinical stages of carcinoma of the vagina agreed on by FIGO are listed in Table 24.1. In 1973, Perez and coworkers proposed that stage II be divided into stage IIA and IIB to provide a more accurate definition of the extent of the lesion. In the proposed modified FIGO classification, stage IIA includes subvaginal infiltration not extending into the parametrial regions, whereas stage IIB includes parametrial or paravaginal infiltration not extending to the pelvic wall. This classification has not been accepted by FIGO. Creasman and colleagues queried the National Cancer Data Base (NCDB), a central registry of health care workers.

The most common histologic type of primary vaginal tumor is squamous carcinoma, which accounts for 84% to 90% of all vaginal cancers (Table 24.2). Adenocarcinoma, including endometrioid adenocarcinoma (EA), is the next most common type, representing about 4% to 9% of vaginal cancers. Sarcomas, including leiomyosarcoma and sarcoma botryoides, account for 2% to 3% of vaginal lesions, and melanomas account for 1% to 2% of malignant neoplasms of the vagina. Rare tumors, such as endometrial stromal tumors or neoplasms originating in embryologic urothelial remnants, may form a transitional cell neoplasm that involves the vagina.

Squamous carcinoma of the vagina is discovered in 10% to 15% of cases after the finding of squamous cancer in other parts of the lower genital tract, such as the vulva or cervix. This has led to the theory of multicentric origin of squamous cancer
ties. have anatomic cervical, vaginal, and urinary tract abnormali-
ness, however, are exposed in utero 25% of women exposed in utero
development of the vagina. The effect of the DES drug provided an
greatly increased our understanding of the embryologic devel-
were exposed to DES. Fortunately, the incidence of vaginal adenocarcinoma in these young women has been quite low, ranging from 0.14 to 1.6 in 1,000 exposed women. More than 500 documented cases have been reported to the DES registry to date. Observations of the development of vaginal adenosis and adenocarcinoma in teenage girls whose mothers were given DES before the 1st week of pregnancy brought new insights to the study of squamous tumor cells in the lower genital tract and greatly increased our understanding of the embryologic develop-

in the lower genital tract. Woodruff and Parmley and others emphasize this correlation and have recommended that patients with squamous cancer in one area be categorized as high risk for the development of squamous carcinoma in other sites of the lower genital tract. A viral etiology, such as the human papillomavirus, is most likely responsible for these findings. Carcinoma may arise in the neovagina lined with a split-
depth thickness skin graft from the buttock or lateral thigh. Canti-
oma of the neovagina is a rare cancer; only nine cases have been reported. The primary carcinoma seems to be related to the transplanted tissue. In three cases, adenocarcinoma was as-
associated with the use of a large or small bowel intestinal graft for vagnal reconstruction. Five cases of squamous cell cancer arising from the graft have been documented. The trans-
planted epithelium in the vagina may be exposed to an undet-
tified carcinogen or mutagen, as has been documented with the vulva, and can undergo malignant transformation in this envi-
ronment. These observations underscore the need for regular pelvic examinations after operative vaginoplasty with either a bowel graft or a split-thickness skin graft. DES, a nonsteroidal estrogenic hormone thought to enhance embryo implantation and placental development, was intro-
duced into clinical obstetrics in 1944 in Boston and became popular and widely used during the next two decades. Women with a history of previous spontaneous abortions or other risk factors for early pregnancy loss of multiple gestations were given DES. It is known now that DES use during the first trimester of pregnancy may cause vaginal neoplasia. It was not until the late 1960s, however—when a cluster of cases of ade-
nocarcinoma appeared in young women younger than age 25 years (all offspring of DES-treated women)—that Herbst and colleagues connected the result with the unusual cause.

The DES-associated adenocarcinoma originally was thought to arise from mesonephric remnants in the vagina, and the disease consequently was mislabeled as a clear cell carcinoma. However, electron microscopic analysis of the ultrastructure of both the adenocarcinoma and the vaginal adenosis allowed Fenoglio and colleagues to clearly define these lesions as composed of columnar epithelium, similar in all respects to endocervical epithelium, and of paramesonephric (mullerian) origin. The colposcopic studies of Stall and Mattingly and of others confirm these observations. Vaginal adenosis has been found by colposcopic examin-
tion to occur in 34% to 90% of exposed offspring and vaginal adenocarcinoma in 50%. Although the hypothesis is not proven, there is a strong possibility that the benign vaginal lesion is the cell of origin for vaginal adenocarcinoma. The risk of development of clear cell adenocarcinoma in an exposed woman between birth and age 34 is 1 in 1,000.

Etiology

During embryologic development, the vagina is formed from the columnar epithelium of the mullerian ducts and UGS. The tissue then transforms into squamous epithelium, so that the vaginal and cervical epithelium have a common embryologic origin. Squamous metaplasia within the vaginal adenosis has been observed with a colposcope, and transformation of the metaplastic tissue also has been demonstrated in the develop-
ment of intraepithelial neoplasia. Although many agents have been postulated as carcinogenic factors, none have been posi-
demonstrated. It is quite possible that squamous car-
cinoma arises from the effects of an oncogenic agent on the transformation zone within the foci of vaginal adenosis. The studies now being done on the effects of DES may find some interesting causative factors that influence vaginal carcinomas.

Carcinoma of the vagina also may share a common causative denominator with cervical carcinoma. Because slightly more than 50% of the cases occur in the posterior wall of the upper third of the vagina, which is the end point of vaginal coitus, vaginal carcinoma should be generally induced. As with cervical carcinoma, primary carcinoma of the vagina usually occurs in sexually active women. Except for the cases of adenocarcinoma in young women exposed to DES, squamous carcinoma of the vagina is unquestionably associated with sex-
ual activity. As with cervical intraepithelial neoplasia and car-
cinoma, the human papillomavirus is probably responsible for the majority of vaginal carcinomas.

Site of Lesion

Plentl and Friedman found that 51% of vaginal carcinoma le-
sions occur in the upper third of the vagina, 30% in the lower third, and 19% in the middle third. In the lower third, lesions most often occur in the anterior wall, whereas in the upper third, lesions most often appear in the posterior vaginal wall. Although the location is observed on diagnosis, the precise site of origin is difficult to pinpoint because the tumors usually have spread to various parts of the vagina by that time.

Pathways of Spread

The lymphatic drainage of the vagina takes place through dif-
ferent pathways. The upper third drains by way of the cervi-
cal lymphatics, the lower third passes by way of the vaginal lymphatics, and the middle third communicates with both the upper and the lower lymphatic channels. The vaginal vault and the anterior wall of the upper vagina drain to the inter-
iliac pelvic lymph nodes, where they communicate with the
external iliac, the hypogastric, and the common iliac nodes. The lymphatic drainage of the posterior vagina communicates directly with the deep pelvic nodes, including the inferior gluteal, sacral, and rectal nodes.

Because the major pathways of lymphatic drainage are to the superior and inferior gluteal muscles and the common iliac lymph nodes, the potential for extrapelvic spread of vaginal carcinoma is great. When extrapelvic spread occurs, prognosis usually is poor. The primary site of origin of the tumor is an important indicator of lymph node metastases, whether the tumor will metastasize to the inguinal-femoral chain or to the deep pelvic lymph nodes. When the disease involves the lower third of the vagina, 6% to 7% of patients have metastases to the inguinal-femoral lymph nodes.

Diagnosis

In general, invasive carcinoma of the vagina appears as either a raised exophytic lesion or an ulcerative, depressed lesion in the vaginal wall. Biopsy can be performed on both types of lesions easily, and diagnosis can be established without difficulty. Vaginal cytology usually is positive if an adequate cell sample is obtained from the exfoliated lesion, although, as often happens with cervical carcinoma, many cases of false-negative cytology occur even when an invasive lesion is present. Colposcopy, Lugol solution, or both can be used to demarcate the areas for biopsy, although iodine staining usually is unnecessary if the lesion is clearly visible.

Identifying vaginal carcinoma at an early stage can be a major problem because the first lesions appear within the epithelial cells, frequently indistinguishable from the remainder of the vaginal epithelium. Only by colposcopic examination or with iodine staining can alterations in the surface epithelium of the vagina be identified. Lugol and associates have achieved an accuracy of 88% to 90% in detecting dysplastic lesions in DES-exposed patients with adenosis, but their technique requires separate, four-quadrant vaginal smears from the walls of the vagina to increase the sensitivity of the Papanicolaou smear. The use of colposcopy combined with the advantage of iodine staining of the vagina to reveal occult lesions that may be associated with adenosis. Staff and Mattingly reported an accuracy of 96% in detecting abnormal epithelial lesions of the vagina in DES-exposed women by careful examination and colposcopy.

Because the vaginal speculum can obscure surface lesions and delay early diagnosis, the instrument should be rotated during the examination so that the entire canal can be inspected. With iodine staining, the clinician can detect multifocal lesions, but the entire vagina also should be cytologically tested. A thorough colposcopic examination can be used to detect vaginal carcinoma if the clinician has that expertise.

Treatment

Primary vaginal carcinoma is treated either with surgery or with radiotherapy. The choice of treatment depends on three factors: the site of the lesion, the location of the tumor in the vagina, and the clinical stage of the disease.

Stage 0 Lesions. Easiest to treat by far is vaginal intraepithelial neoplasia III (VAIN III), and it offers the most hopeful prognosis. Either surgery or radiotherapy can be used, depending on the location of the lesion. If the disease is located in the upper vagina and the margins of the disease are distinct, a partial vaginectomy, with or without hysterectomy, is a practical and successful method of treatment.

Surgical Conditions of the Vagina and Urethra

The carbon dioxide laser has proved to be a simple, effective means of treating noninvasive vaginal carcinoma. Laser therapy offers conservative treatment for both focal and multifocal lesions without impairment of normal coital function. Because there is a risk of residual disease in 10% of laser-treated patients, careful colposcopic and cytologic follow-up are critical. Histologic study is difficult after the carbon dioxide laser vaporizes the treated lesion, so the diagnosis of recurrence may be made by the ultrasonic surgical aspirator, the tip of which vibrates 23,000 times per second, fragmenting and aspirating the tissue in contact with it. This technique permits histologic evaluation of the collected tissue fragments. The operative site also heals faster secondary to decreased thermal damage. Robinson and colleagues reported their experience in treating 46 patients with VAIN. Sixty-six percent (29) of those initially treated with ultrasonic surgical aspiration did not have recurrence. Fifty-two percent of patients treated for recurrent disease (17) did not experience a recurrence. The mean duration of follow-up was 21 months.

Noninvasive methods such as administration of 5-fluorouracil vaginal cream have also proved efficacious in treating VAIN.

Radiation therapy is rarely used to treat VAIN. However, radiation is an excellent modality for suspected invasion when the medical risk for further evaluation by surgery is too great. A vaginal cylinder, such as the Bloedorn applicator, can be used for radiotherapeutic treatment to deliver 70 Gy to the vaginal surface over a period of about 72 hours. If the lesion is confined to the vaginal fornices, vaginal colpostats can be used to deliver a similar dosage. Lesions in the lower third of the vagina may be treated by partial vaginectomy or by intravaginal irradiation using a variety of brachytherapy techniques.

Stage I Lesions. Surgery, radiation, or both are the primary modalities for treating vaginal carcinomas. Lesions in the vaginal fornix can be treated with a radical Wertheim hysterectomy, partial vaginectomy, and bilateral pelvic lymphadenectomy. Treatment for this lesion is similar to that for invasive cervical carcinoma. If pelvic lymph nodes are histologically positive or if paraaortic lymph nodes look suspicious, a paraaortic lymphadenectomy should be performed. If the lymph nodes are histologically positive for carcinoma, pelvic radiation with or without paraaortic radiation should be administered. As with cervical carcinoma, the size of the lesion is prognostic of our ability to adequately treat these patients with primary surgery. Large lesions not permitting clear surgical margins (e.g., proximity to the bladder or rectum) should be treated with primary radiation therapy. Radical surgery also may require the replacement of the upper vagina with a split-thickness skin graft to reestablish normal vaginal length for a sexually active woman. Irradiation therapy is an alternative treatment for this stage of disease.

The radical Wertheim hysterectomy has been quite successful in treating stage I adenocarcinoma in young women who were exposed to DES in utero. More than 75% of patients are cured. Magrina and associates treated a patient with stage I disease at their institution with laparoscopic radical parametrectomy and pelvic and aortic lymphadenectomy. The role of laparoscopy in the treatment of vaginal carcinoma will continue to expand. Although its role in paraaortic lymphadenectomy may be debated, laparoscopy to excise the pelvic and paraaortic nodes before radiation may be beneficial to patients with advanced disease.

Sentinel Node Detection. Sentinel node detection in vaginal carcinoma has not gained universal acceptance. Gynecologic...
tumor—such as cervical and vulvar—have been much more amenable to sentinel node detection and biopsy. Van Dam and colleagues used 99mTc-labeled nanocolloids in primary and recurrent vaginal carcinomas. Nodes were identified laparoscopically and resected. Three of four patients had nodes identified through sentinel node detection.

Radiation therapy is the preferable treatment for large proximal lesions or middle or distal vaginal tumors. A combination of teletherapy (external beam) and interstitial or intracavitary therapy is used.

Stage II and Stage III Lesions. More extensive lesions of the vagina pose an extremely difficult therapeutic problem for the gynecologist. Because the levator ani muscles of the pelvic diaphragm surround the vagina, penetration of the lateral wall of the vagina by the invasive tumor frequently is associated with fixation of the disease to the adjacent pelvic musculature. Even radical surgery cannot effectively control the disease when it extends beyond the confines of the vagina into the paravaginal tissues. Instead, the major method of treatment for stage II and stage III lesions is radiotherapy.

When stage II lesions involve the anterior or posterior wall of the vaginal septum, an anterior or posterior exenteration with pelvic node dissection may be required. When the disease includes the lower third of the vagina, a groin dissection is necessary also. Because surgery must be so extensive, its usefulness is limited when the disease affects the paravaginal region (stage IIb) or the lateral vaginal wall (stage III).

Stage IV Lesions. When advanced lesions involve only the bladder or the rectum, exenteration may be required to control the disease effectively. Unfortunately, pelvic exenteration, either anterior or posterior, can be used only when there is no other extension of the disease, and it is rare for the bladder and rectum to be involved without involvement of the adjacent paravaginal tissues. If the patient is not an acceptable surgical risk for exenteration, external beam megavoltage irradiation therapy followed by intravaginal or interstitial irradiation can be used to control the local disease and to offer palliation. If the tumor does not respond after 5,000 cGy of irradiation treatment to the whole pelvis, an exenteration may be required to control the disease in properly selected patients. Exenteration is also recommended for central recurrences without lymph node metastasis.

Advanced/Recurrent Disease. Pelvic exenteration is the best treatment for patients who have failed primary irradiation therapy of vaginal carcinoma. As with cervical carcinoma, it is imperative that the recurrences be central and nodes radiographically negative. Before performing the exenteration, pelvic and paraaortic nodes are sent for frozen section. Depending on the age of the patient, continent urinary diversions, neovaginal, and primary end-to-end colon anastomosis are performed when possible. Berek and colleagues reported on their 45-year pelvic exenteration experience at UCLA. Survival for cervical/vaginal cancers was 73% at 1 year, 57% at 3 years, and 34% at 5 years (Fig. 24.21). Positive margins had a deleterious effect on survival (Fig. 24.22).

Irradiation Therapy

Irradiation treatment of vaginal carcinoma is easily divided between lesions in the upper and middle thirds and the lower third of the vagina.

Upper and Middle Thirds of the Vagina. Because the lymphatic drainage of the upper and middle vagina extends through the hypogastric and pelvic nodes, full pelvic irradiation is necessary. Treatment usually includes a combination of techniques. External beam megavoltage therapy using 4,500 to 5,000 cGy focused on the midplane of the pelvis is used to treat the full pelvis and to encompass the vagina. A vaginal implant of

absence of tumor in the groin nodes is a poor prognostic sign, suggesting that the deep pelvic nodes also may be involved in about 6% to 7% of cases. Because the incidence of vaginal cancer is so low, the exact frequency of pelvic node involvement is not known. One report indicates that about 6% of 300 women with stage II vaginal disease had evidence of pelvic node involvement by X-ray, and another report indicates that the incidence probably occurs more frequently than it is diagnosed; however, the condition has not been well recognized by the medical profession. Despite the many documented cases of urethral diverticuloma, the female urethra develops from the caudal end of the UGS after it separates from the vaginal canal between the 8th and 12th week of embryologic life. Because the vagina and urethra are so closely integrated, the urethra shares many common disease processes and anatomic defects with the vagina. Bacteria in the lower genital tract frequently colonize in the outer urethra, harbor in the paraurethral glands, and enter the bladder to produce acute infections. A bacterial infection in the lower genital tract may not become clinically manifest for several years, until a Skene duct cyst or a urethral diverticulum develops.

Estrogen deficiency causes atrophic changes of the vaginal mucosa and can have a similar effect on the urethral mucosa. Thinning of the epithelium and irritation of the sensory nerve fibers can cause urinary frequency and dysuria. Prolapse at the external meatus also may result from atrophic changes of the urethra.

d Not included in the figures are 15 patients of the total patient group of 134 who were stage 0.

e Data from Pecorelli S, ed. FIGO annual report on the results of treatment in gynecological cancer. Int J Gynecol Obstet 2003;83:27.
whenever an article reporting on urethral diverticulum appears in the literature, there is a coincident upsurge in the number of cases diagnosed. According to the National Hospital Discharge Survey Data Base (1978–1998), 27,000 inpatient procedures were performed for the repair of urethral diverticula in the United States over a 19-year period. The surgical treatment is three times as high in African American women. Moreover, the rate of inpatient surgery is declining.

**Etiology**

In 1941, Parmenter suggested several congenital factors that could develop into a urethral diverticulum, including Gartner duct, a faulty union of primal folds, cell nets, and wolffian ducts or vaginal cysts that rupture into the urethra. Additional possible causes include trauma at childbirth, surgical trauma, urethral stone, urethral stricture, and infection of the urethral glands.

Of the many possible causes of urethral diverticula that have been considered, none have been proved. Two of the most probable causes are Gonococcus meningitis infection (although gonococci are seldom cultured) and infection of the suburethral tissue by vaginal flora. Huffman’s experiments support the notion that a suburethral infection can develop into an abscess that becomes lined with epithelium. Huffman demonstrated periurethral openings by constructing wax models of infected tissue by vaginal flora. Huffman’s experiments support the notion that a suburethral infection can develop into an abscess that becomes lined with epithelium. Huffman demonstrated periurethral openings by constructing wax models of infected tissue by vaginal flora.

**Symptoms**

Dysuria, urgency, frequency, and hematuria occurred together in 85% to 90% of 12 cases reviewed by Peters and Vaughn. Other frequently occurring symptoms are a lump in the vagina caused by protrusion of the diverticulum sac into the vagina, dyspareunia (intermittent discharge from the urethra), and pain on walking. Pyuria and cystitis also occur, depending on the location of the diverticular orifice. If the opening is sufficiently close to the outer end of the urethra, there may be no leakage of purulent exudate back into the bladder, which may explain the absence of symptoms of cystitis in 5% of cases. If the diverticulum is located in the posterior urethra near the urethrovaginal junction, stress urinary incontinence may be a significant symptom. In a review of 70 cases from the Johns Hopkins Hospital, Ginsberg and Genadry found that 17% of the diverticula were located in the proximal (outer) urethra, 43% in the midurethra, and 31% in the distal (posterior) urethra; in the remaining cases, the site was not specifically identified.

Not only are urinary tract symptoms the most common clinical expression of the urethral lesion, but a history of recurrent refractory cystitis is a clue that a diverticulum is the source of the infection.

**Diagnosis**

Urethral diverticula usually are small, varying from 3 mm to 3 cm in diameter. Some of the larger sacs cover the entire length of the urethra. On palpation of a suburethral mass, tenderness commonly is found. Pressure on the mass may cause the escape of urine or exudate from the urethral orifice. An examination of the floor of the urethra through the water cystoscope while suburethral pressure is being applied reveals an opening in 50% to 70% of cases. The pressure may force contents of the diverticulum into the urethra while it is being viewed. Some of the openings are extremely small and may be missed. Inflammatory swelling can result in edema of the orifice, which makes visualization difficult or impossible.

The diagnosis of urethral diverticulum is firmly established by means of positive-pressure urethrography (PPUG). A special catheter is used to block the urethra at both ends and to fill it and the diverticulum under pressure with water-soluble contrast medium (Figs. 24.23–24.25). If the urethral orifice to the diverticulum is quite large, a voiding cystourethrogram

together with a positive pelvic film may demonstrate the diverticulum. Although not as sensitive as PPUG, VCUG (voiding cystourethrography) may assist in identifying a urethral diverticulum. Wang and Wang compared VCUG and PPUG in evaluating 120 women. Twenty of 120 women demonstrated diverticulum. Thirteen were positive on PPUG and 10 with VCUG. If the surgeon’s suspicion is high for urethral diverticulum, magnetic resonance imaging (MRI) should be considered if both the PPUG and VCUG studies are negative.

More recently, Chou and associates have suggested that a new method, virtual computerized tomography urethroscopy, increases the accuracy of diagnoses. The diverticulum orifice is less likely to be missed, especially when an inflammatory process or obstructed orifice exists. Gerrard and colleagues have suggested that transvaginal ultrasound is effective for evaluating patients with suspected urethral diverticulum. The technique is accurate, low cost, and readily available and should be considered as an initial screening technique for women when one suspects a urethral diverticulum. Computerized tomography and MRI have better defined diverticular anatomy. Neitlich and colleagues have suggested MRI to be more sensitive than double balloon urethrography. These techniques should be considered after other conventional methods have not defined the diverticulum.

Occasionally a diverticulum occurs with no clinical evidence of inflammation. If the diverticulum is diagnosed during a careful pelvic examination, and if the patient is completely asymptomatic except for a previous history of urinary tract problems, surgery is not necessary. With a complication rate of 15% to 20%, diverticulectomy should not be considered a quick and easy procedure. Removal of an asymptomatic urethral diverticulum may create more problems than it prevents, particularly if the sac is small or located in the floor of the posterior urethra. Only if a patient experiences acute or recurrent symptoms should urethral surgery be performed. Leng and McGuire classify urethral diverticulum as true versus pseudodiverticulum (Table 24.5).

**Treatment**

A diverticulum that requires treatment must be completely excised before the defect in the urethra can be closed. Failure to remove the entire diverticulum results only in recurrence of the problem. Many techniques have been used to identify the anatomic boundaries of the diverticulum. One popular method is to pass a sound into the diverticulum through the urethral orifice. Another method is to distend the diverticulum by injecting it with fibrinogen and thrombin mixed in a syringe to form a firm fibrin clot. However, direct anatomic dissection of the diverticulum from the paraurethral fascia and vaginal wall without visual enhancement of the anatomic boundaries offers a better success rate. The smooth covering of a diverticulum protruding into the vagina can be easily distinguished from the rugal folds of the vaginal mucosa.

If the wall of the diverticulum is left unopened until the dissection has reached the base of the diverticulum sac, its neck can be visualized directly while it is removed. Inadvertent removal of a portion of the urethral floor along the base of the diverticulum is too common an error; if the mucosa is closed with too much tension, a urethral stricture or a postoperative fistula may result.

**Excision and Layered Closure.** A midline incision is made through the vaginal mucosa, which is then separated from the wall of the diverticulum (Fig. 24.26A). The wall of the
diverticulum also is dissected from the paraurethral fascia in as wide a circumference as can be developed. The diverticulum is opened and the interior of the cavity is inspected. If the orifice of the diverticulum is large, the opening of the urethra can easily be seen, especially if a catheter has been placed in the urethra and bladder (Fig. 24.26B). The rest of the thin, friable mucosa of the diverticulum is separated from the vaginal mucosa and fascia before the neck of the diverticulum is trimmed near the urethral orifice. The lining of the diverticulum is friable because of inflammatory changes and the thin layer fragments during the dissection. Meticulous sharp dissection is required to separate the lining completely from the vagina and from the floor of the urethra. We repeat, in caution, that the neck of the diverticulum should be carefully resected to avoid eversion and to prevent the removal of mucosa from the urethral floor.

The urethral defect is closed with 3-0 delayed-absorbable sutures interrupted so that the edges can be inverted (Fig. 24.26C). After the interrupted sutures are tied, the paraurethral fascia is closed in a double-layer “vest-over-pants” technique in which the top layer of fascia is sutured beneath the opposite and overlapping fascia and fastened to the urethral wall on that opposite side. The top layer of fascia is then sutured at its edge to the underlying fascial layer. The fascial margins are sutured by more durable 2-0 delayed-absorbable sutures (Fig. 24.26D and E), and the vaginal mucosa finally is trimmed and closed, also with interrupted 2-0 delayed-absorbable sutures. Faerber as well as Leng and McGuire have advocated diverticulectomy and placement of pubovaginal slings. Faerber uses the sling for intrinsic sphincter deficiency, whereas Leng and McGuire have recommended fascial slings to close the defect if it is too large for reinforcement.

The bladder is filled with 300 mL of distilled water, and a suprapubic Silastic catheter is inserted and left in place until the morning of the fifth postoperative day. A suprapubic catheter is used in preference to a urethral catheter for three major reasons: to avoid trauma to the operative site, to avoid the necessity for transurethral catheterization during attempts to initiate voiding, and to avoid the discomfort of a urethral catheter. On the fifth day after surgery, the patient should attempt to void with the three-way stopcock of the suprapubic catheter closed to allow the bladder to fill.

Urethrotomy. Urethrotomy has been used by Edwards and Beebe and by Kropp to treat diverticula. Splitting the floor of the urethra from the meatus down its full length to the site of the orifice of the diverticulum allows the sac to be well visualized during excision. As a rule, however, cases of urethral

FIGURE 24.26. Suburethral diverticulum. A: A midline vaginal incision is made over the diverticulum. B: The diverticulum is dissected from the vaginal mucosa and surrounding fascia. Freed diverticulum is excised from the floor of the urethra, avoiding removal of an excessive amount of the urethral wall. C: The urethra is closed with interrupted 3-0 delayed-absorbable sutures placed through the muscularis and mucosa to ensure mucosa-to-mucosa approximation. The paraurethral fascia is mobilized with sharp dissection from the vaginal mucosa. D: The paraurethral fascia is plicated beneath the urethral incision, using the vest-over-pants technique. The inner layer of fascia is sutured to the undersurface of the outer layer using horizontal mattress sutures of 2-0 delayed-absorbable material. The inset is a cross-sectional view of suture placement. E: Completion of vest-over-pants plication of paraurethral fascia over the floor of the urethra. The free margin of the outer fascia is sutured to the inner fascial layer. The inset is a cross-sectional view of suture placement.
diverticula can be successfully repaired without such an extensive incision that requires the floor of the urethra to heal along its entire length. Healing is particularly a problem if there has been recent infection in the diverticulum.

Marsupialization. In 1970, Spence and Duckett recommended marsupialization of the diverticulum to prevent recurrence, to minimize operating time, and to reduce blood loss. This procedure has been endorsed by Lichtman and Robertson and by Ginsberg and Genadry. Stress urinary incontinence has not been reported as a complication, but only, we suspect, because marsupialization is not used to treat lesions in the posterior urethra near the bladder base. Marsupialization is a useful procedure when diverticula occur in the outer third of the urethra, where a permanent opening in the outer floor of the urethra would not adversely influence intraurethral pressure.

Complications of Diverticulectomy

Complications arise in about 20% of cases treated for diverticula of the urethra. Urethral stricture can occur when too much urethral mucosa is removed, but strictures usually can be resolved by urethral dilatations. Urethral fistula, a serious and troublesome complication of diverticulectomy, occurs in about 5% of treated patients.

Postoperative fistulas frequently develop when acute or subacute infection in the walls of the diverticulum causes the urethral mucosa to become friable; the urinary incontinence that develops from urethral fistulas is far more troublesome than the initial symptoms of the diverticulum. Closure of a urethral fistula is difficult because the blood supply to the floor of the urethra is delicate, and scarring and infection often develop with repeated efforts to close the urethra. A fistula in the outer part of the urethra may be asymptomatic and may not need to be repaired, but there normally are reports with an outer fistula of spraying of urine when voiding.

Urethral Prolapse

Although there have been few recent reports of urethral prolapse, nearly 400 cases have been published in the English literature since 1732. More than half these cases occurred in infants and children; the remainder occurred in elderly patients.

Urethral prolapse is characterized by a sliding outward of the urethral mucosa around the entire urethral meatus. The urethra may become cyanotic, edematous, and infarcted (Fig. 24.27). Symptoms vary greatly. Prolapse may cause no discomfort, in which case it is detected only by bloody discharge of congested tissues that are breaking down, but more often there are reports of severe and continuous pain, urinary frequency, and tenesmus. Occasionally, in a small child, tissue reaction and edema of the outer urethra produces urinary retention rather than the more usual urinary frequency. Urethral prolapse is thought to be the result of poor development of or atrophic changes in the collagen and elastic tissues of the submucosa. In infants, prolapse usually follows a severe coughing or crying spell. In some older patients, too, prolapse has followed paroxysms of coughing. In older patients, diminished tone and elasticity of tissue alone may be sufficient to cause some cases of urethral prolapse.

Treatment of urethral prolapse may be palliative or surgical. Hot, moist compresses provide temporary comfort. A small mass of tissue can be reduced, but recurrence is common.

Surgical Techniques

Several surgical procedures have been suggested, including the one advocated by Kelly and Burnam, in which the prolapsed mucosa is excised by a circular incision (Fig. 24.28A). The cut edges are then sutured with 3-0 delayed-absorbable suture.
material, avoiding an excessive number of stitches, which can result in stricture of the urethral meatus (Fig. 24.28B). In most cases, this circumcision technique has proved to be the preferred method of correction.

Cryosurgery also has been used to treat urethral prolapse. The method is extremely effective in producing complete annular necrosis and healing of the prolapsed tissue (Fig. 24.29).

The cryosurgery procedure can be performed without anesthesia, although for a young child, a local anesthetic is advisable. A suprapubic Silastic catheter is inserted and is left in postoperatively to permit bladder drainage until complete, spontaneous voiding can occur. The catheter also helps to prevent postoperative trauma at the suture line around the meatus.

BEST SURGICAL PRACTICES

- Incorporating an exam of the external genitalia into routine practice of clinicians caring for children can prevent delays in diagnosing imperforate hymen, misdiagnosis, and potential morbidity. To prevent scarring, stenosis, and subsequent dyspareunia in women with imperforate hymen, the hymenal tissue should not be excised too close to the vaginal mucosa.

- Sexually ambiguous external genitalia defects of the UGS are remarkably constant in appearance regardless of the etiology and differ only in degree of malformation, ranging somewhere intermediate to that of a normal girl and that of a normal boy. Thus, operative procedure for reconstruction of ambiguous genitalia into feminine genitalia does not vary in its essential elements.

- The common goals for the female reconstruction of ambiguous genitalia include reduction of clitoral size, creation of labia minora, and exteriorization of the vagina. Any reconstruction of the external genitalia with the objective of producing normal female appearance and function requires a full understanding of the surgical anatomy.

- It is essential to accurately identify the site of communication of the vagina with the UGS in female reconstruction of ambiguous genitalia. Knowledge of the possible variants in communication of the vagina with the UGS is critical before entertaining surgical correction.

- One objective of the reconstruction procedure for external genitalia is to delay the procedure until the anomalous structures are of a size to permit easy identification of all structures. Repair may be delayed until menarche, when maturity and the desire for sexual activity are usually well established.

- Surgical efforts of clitoral reduction focus on concealment, plication, resection, and reduction, with an attempt to provide a normal cosmesis without sacrificing sensation or vascularity of the glans. Even after seemingly successful clitoral reduction, the sensory function is significantly impaired, and this should be taken into consideration during counseling.

- Preoperative identification and catheterization or sounding of the vaginal orifice is key to the performance of a successful, one-stage procedure.

- It generally is recommended that exteriorization of the vagina be postponed until near puberty because higher estrogen levels may prevent stenosis, and sufficiently maturity in the patient is needed to comply with a postoperative dilatation program.

- When the complete operation is attempted at an early age, the vagina is sometimes not satisfactorily exteriorized. It should be emphasized that simple exteriorization of the lower vaginal tract can be combined with cosmetic correction of virilized external genitalia in infancy, but in most cases, it is best to defer definitive reconstruction of the intermediate or high vagina until after puberty.

CHAPTER 25 ■ SURGERY FOR ANOMALIES OF THE MÜLLERIAN DUCTS
JOHN A. ROCK AND LESLEY L. BREECH

DEFINITIONS
Hematometra—The distension of the uterus with blood or menstrual fluid.
Hematometrocolpos—The distension of the uterus and vagina with blood or menstrual fluid; because the vaginal wall is more distensible, the vagina will preferentially fill before the uterus.
Hydrocolpos—The distension of the vagina with fluid; often seen in infants with complex reproductive anomalies.
Metroplasty—Uterine reconstructive procedure.
Uterine anlagen—An underdeveloped uterine structure that is a remnant of a single embryologic mullerian duct.

Maldevelopment of the mullerian ducts occurs in a variety of forms, and each anomaly is distinctive. Nevertheless, some generalizations can be made. Classifications of vaginal anomalies based on certain anatomic findings are useful in organizing the type of malformation, but there usually are exceptions to each rule. Thus, what appears, after a preliminary diagnostic evaluation, to be an apparently isolated vaginal malformation may be found later to be associated with a uterine or renal anomaly. A comprehensive preoperative evaluation of patients with suspected malformations of the mullerian ducts is essential, but a clear understanding of the particular anomaly may not be established until the time of surgical correction. Reproductive surgeons must therefore be equally skilled in both uterine and vaginal reconstruction.

The patient with a uterovaginal anomaly often relies entirely on her physician to clarify the reproductive consequences associated with her diagnosis. The physician can help to allay her anxieties by making a prompt evaluation and giving a full and accurate description of the reproductive implications or the obstetric consequences of her particular uterovaginal anomaly.

CLASSIFICATION OF UTEROVAGINAL ANOMALIES
Classifications of uterovaginal anomalies originally were organized on the basis of clinical findings. Our improved understanding of the embryologic development of most uterovaginal anomalies has enabled categorization on this basis. The 1988 American Fertility Society (AFS) classification of mullerian anomalies (Table 25.1) offers an alternative based on the degree of failure of normal uterine development. Anomalies are grouped according to similarities of clinical manifestations, treatment, and prognosis for fetal salvage. The AFS classification system is weighted primarily toward disorders of lateral fusion and does not include associated vaginal anomalies, although the scheme does allow the user to describe anomalies involving the vagina, tubes, and urinary tract as associated malformations.

No classification of mullerian maldevelopment can focus entirely on the uterus, however. The vagina is often involved, and sometimes the tubes are involved as well. This discussion follows a suggested modification of the AFS classification of uterovaginal anomalies (Table 25.2) that comprises four groups based on embryologic considerations.

Class I: Dysgenesis of the Mullerian Ducts
Dysgenesis of the mullerian ducts, which includes agenesis of the uterus and vagina (the Mayer-Rokitansky-Küster-Hauser syndrome), is an impairment of the reproductive system characterized by no reproductive potential other than that achieved by in vitro fertilization in a host uterus.

Class II: Disorders of Vertical Fusion of the Mullerian Ducts
Disorders of vertical fusion can be considered to represent faults in the junction between the down-growing mullerian ducts (mullerian tubercle) and the up-growing derivative of the urogenital sinus. Typically, these disorders are characterized by an atretic portion of vagina that can be quite thick, extending through more than half the distance of the vagina, or it can be quite thin and limited to a small obstructing membrane.

Regardless of the length of the septum, a disorder of vertical fusion should be regarded as a transverse vaginal septum and classified as either obstructed or unobstructed. The so-called partial vaginal agenesis with uterus and cervix present is probably a misnomer for a large segment of atretic vagina. Cervical agenesis or dysgenesis is also included in the group of disorders of vertical fusion.

Class III: Disorders of Lateral Fusion of the Mullerian Ducts
Disorders of lateral fusion of the two mullerian ducts can be symmetric-unobstructed, as with the double vagina, or asymmetric-obstructed, as with unilateral vaginal obstruction. Obstructions associated with disorders of lateral fusion are particularly noteworthy in that they are observed clinically only as unilateral obstructions that almost invariably are associated with absence of the ipsilateral kidney. Bilateral obstruction is

*The classification allows the user to indicate the malformation type and provides additional findings to describe associated variations involving the vagina, cervix, tubes (right, left), and kidneys (right, left).*

thought to be associated with bilateral kidney agenesis and subsequent nonviability of the developing embryo.

The three varieties of asymmetric obstruction with ipsilateral renal agenesis are as follows:

1. Unicornuate uterus with a noncommunicating horn that contains menstruating endometrium
2. Unilateral obstruction of a cavity of a double uterus
3. Unilateral vaginal obstruction

The five groups of symmetric-unobstructed disorders of lateral fusion are as follows:

1. The didelphic uterus
2. The septate uterus
3. The bicornuate uterus
4. The T-shaped uterine cavity, which may be hypoplastic and irregular, and which is associated with diethylstilbestrol (DES) exposure or utero
5. The unicornuate uterus with or without a rudimentary horn

The first three groups are types of double uteri; differentiation between a septate uterus (second group) and a bicornuate uterus (third group) requires visualization of the fundus. The septum within the septate uterus is complete or partial. When the septum is complete, there inevitably are two cavities of a longitudinal vaginal septum that can extend to the introitus or partially down the vagina. The bicornuate uterus also can have a partial or almost complete separation of the uterine cavities. The term arcuate uterus is used primarily by radiologists to refer to a slight septum in the uterine fundus that forms no clear separation of the uterine cavities. This type of uterus is usually included in the category of partial septate uterus.

they eventually meet in the midline and become fused together. Ducts continue to grow in a medial and caudal direction until coelomic opening. The lumina extend gradually to the caudal elongate, a lumen appears in the cranial part, beginning at each ducts forms a solid bud. Each bud penetrates the mesenchyme proper below. It is lined by an internal layer of vaginal epithelium and an external layer of epithelium derived from the urogenital sinus (both of endodermal origin), with mesoderm between the two. It is not derived from the mullerian ducts.

Surgery for Anomalies of the Mullerian Ducts

Class IV: Unusual Configurations of Vertical-Lateral Fusion Defects

This final category includes combinations of urovaginal anomalies and other disorders. Unusual urovaginal configurations have been described that do not fit a particular category, and vertical and lateral fusion disorders can coexist. Unusual configurations of vertical-lateral fusion defects can be seen with abnormalities of the lower urinary tract. Singh and coworkers have described a patient who was noted to have a persistent hymen and a longitudinal vaginal septum with a double urethra and bladder and left renal agenesis.

Obstructive lesions require immediate attention to relieve retrograde flow of trapped mucus and menstrual blood and increasing pressure on surrounding organs and structures. When no obstruction is present, attention may not be required immediately, but it will always be required eventually to establish or improve reproductive or coital function.

EMBRYOLOGY

The reproductive organs in the female (and in the male) consist of external genitalia, gonads, and an internal duct system between the two. These three components originate embryologically from different primordia and in close association with the urinary system and hanggut. Thus, the developmental history is complex (Figs. 25.1 and 25.2). Even in the 3.5- to 4-mm embryo, it is possible to recognize the bilateral thickening of the coelomic epithelium known as the gonadal ridges medial to the mesonephros (primitive kidney) in the dorsum of the coelomic cavity. At about the sixth week of gestation, in the 17- to 20-mm embryo, the gonad can be distinguished as either a testis or an ovary.

In the female, the labia minora and majora develop from the labioscrotal folds, which are ectodermal in origin. The phalic portion of the urogenital sinus gives rise to the urethra. The mullerian (paramesonephric) duct system is stimulated to develop preferentially over the Wolffian (mesonephric) duct system, which regresses in early female fetal life. The cranial parts of the Wolffian ducts persist and attain complete development to result of condensation of stromal cells at a specific site around the urogenital sinus. The caudal parts can persist as Gartner’s ducts. The mullerian ducts persist and attain complete development to form the fallopian tubes, the uterine corpus and cervix, and a portion of the vagina.

Origin of the Mullerian Ducts

About 37 days after fertilization, the mullerian ducts first appear lateral to each Wolffian duct as invaginations of the dorsal coelomic epithelium. The site of origin of the invaginations remains open and ultimately forms the fimbriated ends of the fallopian tubes. At their point of origin, each of the mullerian ducts forms a solid bud. Each bud penetrates the mesenchyme lateral and parallel to each Wolffian duct. As the solid buds elongate, a lumen appears in the cranial part, beginning at each coelomic opening. The lumina extend gradually to the caudal growing tips of the ducts.

The cranial end of each mullerian duct crosses the ventral aspect of the Wolffian duct. The paired mullerian ducts continue to grow in a medial and caudal direction until they eventually meet in the midline and become fused together.

Development of the Vagina

The vagina is formed from the lower end of the urovaginal canal, which developed from the mullerian ducts and the urogenital sinus (Fig. 23.2). The point of contact between the two is the mullerian tubercle. A solid vaginal cord results from proliferation of the cells at the caudal tip of the fused mullerian ducts. The cord gradually elongates to meet the bilateral endodermal evaginations (sinovaginal bulbs) from the posterior aspect of the urogenital sinus below. These sinovaginal bulbs extend cranially to fuse with the caudal end of the vaginal cord, forming the vaginal plate. Subsequent canalization of the vaginal cord occurs, followed by epithelialization with cells derived mostly from endoderm of the urogenital sinus. Recent proposals hold that only the upper one third of the vagina is formed from the mullerian ducts and that the lower vagina develops from the vaginal plate of the urogenital sinus. Recent studies also suggest that the vaginal canal is actually open and connected to a patent uterus and tubes, even in early embryonic life, and that the vagina does not form and later become canalized from an epithelial cord of squamous cells growing upward from the urogenital sinus. Most investigators now suggest that the vagina develops under the influence of the mullerian ducts and estrogenic stimulation. There is agreement that the vagina is a composite formed partly from the mullerian ducts and partly from the urogenital sinus.

At about the 20th week, the cervix takes form as a result of condensation of stromal cells at a specific site around the fused mullerian ducts. The mesenchyme surrounding the mullerian ducts becomes condensed early in embryonic development and eventually forms the musculature of the female genital tract. The hymen is the embryologic septum between the sinusovaginal bulbs above and the urogenital sinus proper below. It is lined by an internal layer of vaginal epithelium and an external layer of epithelium derived from the urogenital sinus (both of endodermal origin), with mesoderm between the two. It is not derived from the mullerian ducts.
FIGURE 25.1. Diagrammatic representation of the development of the female reproductive organs and structures in early embryogenesis. A: At the 18- to 20-somite stage (fourth week), the gonadal ridges have not yet begun to form. B: In the 3.5- to 4-mm embryo (fifth week), the gonadal ridges can be recognized as thickenings of the coelomic cavity just medial to the mesonephric tubules. (Gonadal differentiation into either testis or ovary does not occur until the sixth week of development.) The allantoenteric diverticulum is joined caudally to the dilated cloaca. C and D: The genital tubercle and labial folds form in the region just anterior to the cloaca. The cloaca later drains into the ventral urogenital sinus and the dorsal rectum. The development of the urinary system closely parallels that of the reproductive system. The nonfunctioning pronephric tubules shown in (A) develop to form the mesonephric ducts shown in (B) and (C). The permanent kidneys eventually develop from the metanephric tissue, and the urinary collecting system develops from the mesonephric ducts. The paramesonephric (müllerian) ducts are apparent by the 12- to 14-mm stage (D). (Their subsequent development is illustrated in Figure 25.2.)
Further development of the paramesonephric (müllerian) ducts and the urogenital sinus. A: Early development of the paramesonephric ducts. The cranial ends of the paramesonephric ducts develop first. These ends remain open to form the fimbriated ends of the fallopian tubes. The paramesonephric ducts grow caudally and cross the mesonephric ducts ventrally. B: Eventually, they fuse together to form the uterovaginal canal. C: Further caudal development brings this structure into contact with the wall of the urogenital sinus, producing the müllerian tubercle. The caudal ends of the fused paramesonephric ducts form the uterine corpus and cervix. Together with the urogenital sinus, they also form the vagina. The cranial point of fusion of the paramesonephric ducts marks the location of the future uterine fundus. The fallopian tubes form from the unfused cranial parts of the paramesonephric (müllerian) ducts. The proliferation of the lining of the uterovaginal canal above the upward growth of the sinovaginal bulb from below (D) forms the vaginal plate (E), which later becomes canalized to leave an open vaginal canal. Thus, the vagina is of composite origin. The mesonephric ducts in the female degenerate but can persist into adult life as Gartner’s ducts.
Anomalies in Organogenesis of the Vagina

Abnormalities in the organogenesis of the vagina are easily understood: if there is failure of development of the müllerian ducts at any time between their origin from the coelomic epithelium at 5 weeks of embryonic age and their fusion with the urogenital sinus at 8 weeks, the sinovaginal bulbs will fail to proliferate from the urogenital sinus, and the uterus and vagina will fail to develop. Congenital absence of the uterus and vagina, known as the Mayer-Rokitansky-Küster-Hauser syndrome, is the most common clinical example of this anomaly.

Transverse Vaginal Septum

A transverse vaginal septum can develop at any location in the vagina but is more common in the upper vagina at the point of junction between the vaginal plate and the caudal end of the fused müllerian ducts. This defect presumably is caused by failure of absorption of the tissue that separates the two or by failure of complete fusion of the two embryologic components of the vagina. A large segment of vagina can be atretic. In past reviews, this has been termed partial vaginal agenesis with a uterine present. Elucidation of the cause of a high transverse vaginal septum is more difficult. A local abnormality of the vaginal mesoderm or failure of canalization of the epithelial vaginal plate can provide the answer, but why the abnormality should occur at this particular site is not evident. The proportion of the vagina originating from the urogenital sinus can at times be considerably more than one fifth, and a high transverse vaginal septum thus may represent the junction of an abnormally long urogenital sinus contribution and a short müllerian portion. Alternatively, the high transverse septum could be the sequela of a local infection of the septum at the end of the vagina. Septa in other areas of the vagina are unexplained by this theory, which has not gained widespread acceptance.

Disorders of Ineffective Suppression of Müllerian Ducts

When abnormal gonadal development is caused by ineffective suppression of the müllerian ducts, ambiguous external genitalia frequently are accompanied by a small rudimentary uterus or a partially developed vagina. Additionally, when there is a genetic loss of cytoplasmic receptor proteins within androgenic target cells, such as occurs in the androgen insensitivity syndrome (formerly called testicular feminization syndrome), the vagina is incompletely developed because the existing male gonads suppress the development of the müllerian ducts. Because these genetically male patients are seen clinically as phenotypic XY females without a completely formed vagina, it is important that a vagina be surgically constructed so that these patients may have satisfactory sexual function in their female gender role.

Congenital rectovaginal fistula, imperforate (covered) anus, hypospadias, and other anatomic variants of cloacal dysgenesis also can occur. These anomalies can be associated with maldevelopment of the müllerian and mesonephric duct derivatives.

Müllerian Duct Abnormalities

Abnormalities in the formation or fusion of the müllerian ducts can result in a variety of anomalies of the uterus and vagina: single, multiple, combined, or separate. Just as the entirely separate origin of the ovaries from the gonadal ridges accounts for the frequent association of uterovaginal anomalies with ovarian abnormalities (see Chapter 25), so do the close developmental relationships of the müllerian and wolffian ducts explain the frequency with which anomalies of the female genital system and urinary tract are associated. Failure of development of a müllerian duct is likewise associated with failure of development of a ureteric bud from the caudal end of the wolffian duct. Thus, the entire kidney can be absent on the side ipsilateral to the agenesis of a müllerian duct.

Depending on the timing of the teratogenic influence, renal units can be absent, fused, or in unusual locations in the pelvis. Ureters can be duplicated or can open in unusual places, such as the vagina or uterus. Jones and Rock have pointed out that failure of lateral fusion of the müllerian ducts with unilateral obstruction is associated consistently with absence of the kidney on the side with obstruction. Bilateral obstruction has not been observed clinically, presumably because it would be associated with bilateral renal agenesis, a condition that would not allow the embryo to develop. According to Thompson and Lynn, 40% of female patients with congenital absence of the kidney are found to have associated genital anomalies.

Much investigation has been undertaken to determine a genetic relationship in the development of disorders of the müllerian ducts. Familial aggregates of the most common disorders of the müllerian differentiation are best explained on the basis of polygenic or multifactorial inheritance. No information exists on the number and chromosomal location of responsible genes. Single mutant genes are responsible for the McKusick-Kaufman syndrome and the hand-foot-genital syndrome. Hand-foot-genital syndrome is a rare, dominantly inherited condition that affects both the dystal limbs and the genitalia. A nonsense mutation of the HOXA13 gene has been identified in several families. HOX gene mutations have been reported in several families with multiple müllerian abnormalities. To date, involvement of the Y chromosome in the pathogenesis of müllerian anomalies has not been considered. The 2004 report by Plevrakis and colleagues suggests the possible role of testis-specific protein 1-Y gene in patients with uni- or bilateral gonadal agenesis and uterovaginal dysgenesis. Timmreck and colleagues narrowed the genetic considerations by noting that in an evaluation of 40 women with developmental abnormalities of the uterus and vagina and 12 normal controls, no mutations of the WNT7A gene—a gene associated with murine Müllerian duct development—were found. Reproductive abnormalities involving the uterus and vagina may also be associated with other more complex malformation syndromes, in which the molecular basis of many of the syndromes remains unknown.

CONGENITAL ABSENCE OF THE MULLERIAN DUCTS

The disorders of müllerian agenesis include congenital absence of the vagina and uterus. Often referred to in the literature simply as congenital absence of the vagina (vaginal agenesis), this condition is more accurately labeled aplasia (or dysplasia) of the müllerian ducts because the lower vagina generally is normal, but the middle and upper two thirds are missing. Depending on the absence of the uterus, rudimentary uterine primordia are found that are comparable to each other in size and appearance. Tubes and ovaries in patients with congenital absence of the
mullerian ducts generally are normal. The syndrome, usually referred to as the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, is associated with a heterogeneous group of disorders that have a variety of genetic, endocrine, and metabolic manifestations and associated anomalies of other body systems.

Characteristics of Women with Müllerian Agenesis

- Congenital absence of the uterus and vagina (small rudimentary uterine bulbs are usually present with rudimentary fallopian tubes)
- Normal ovarian function, including ovulation
- Sex of rearing: female
- Phenotypic sex: female (normal development of breasts, body proportions, hair distribution, and external genitalia)
- Genetic sex: female (46,XX karyotype)
- Frequent association of other congenital anomalies (skeletal, urologic, and especially renal)

Partial agenesis of the vagina with the uterus present and a transverse vaginal septum both are categorized as disorders of vertical fusion. These two disorders have a low incidence of associated urinary tract anomalies, another circumstance that sets them apart from the MRKH syndrome.

Realdus Columbus first described congenital absence of the vagina in 1559. In 1829, Mayer described congenital absence of the vagina as one of the abnormalities found in stillborn infants with multiple birth defects. Rokitansky in 1838 and Küster in 1910 described an entity in which the vagina was absent, a small bipartite uterus was present, the ovaries were normal, and anomalies of other organ systems (renal and skeletal) were frequently observed. Hauser and associates emphasized the spectrum of associated anomalies. Pinsky suggested that congenital absence of the vagina is part of a symptom complex and not a true syndrome. Over the years, the disorder has come to be known as the Mayer-Rokitansky-Küster-Hauser syndrome, the Rokitansky-Küster-Hauser syndrome, or simply the Rokitansky syndrome (Fig. 25.3). Counsellor found that the condition occurred once in 4,000 female admissions to the Mayo Clinic. Evans estimated that vaginal agenesis occurred once in 10,388 female births in Michigan from 1953 to 1957.
Individuals with an absent vagina and the classic MRKH syndrome usually are first seen by a gynecologist at age 14 to 15 years, when the absence of menses causes concern. Such young women have a normal complement of chromosomes (46,XX) and usually have normal ovaries and secondary sex characteristics, including external genitalia. Menstruation does not appear at the usual age because the uterus is absent, but ovulation occurs regularly. There are some exceptions to the rule of normal ovaries. For example, polycystic ovaries and gonadal dysgenesis have been reported in patients with congenital absence of the vagina. Plevraki and colleagues reinforced the importance of consideration of such conditions, as one of the six women with MRKH evaluated over a 12-month period demonstrated hypergonadotropic hypogonadism that was due to the bilateral absence of gonadal tissue. Additionally, nested polymerase chain reaction demonstrated the presence of testis-specific protein 1-Y-linked (TSPY) gene in two women.

**Etiologic Factors**

An exclusively genetic etiology cannot be ascribed to vaginal agenesis because almost all patients have a normal karyotype (46,XX) and because the discordance of vaginal agenesis in three sets of monozygotic twins has been reported. The occurrence of complete vaginal agenesis in sisters with a 46,XX karyotype suggests an autosomal mode of inheritance for these patients. Shokeir investigated the families of 13 unrelated females with aplasia of müllerian duct derivatives. Similarly affected females were found in 10 families. Usually there was an affected female paternal relative, suggesting female-limited autosomal dominant inheritance of a mutant gene transmitted by male relatives.

Other investigators point to the variety of associated anomalies as support for the etiologic concept of variable expression of a genetic defect possibly precipitated by teratogenic exposure between the 37th and the 41st gestational day, the time during which the vagina is formed. Knab has suggested five possible etiologic factors of the MRKH syndrome:

1. Inappropriate production of müllerian regressive factor in the female embryonic gonad
2. Regional absence or deficiency of estrogen receptors limited to the lower müllerian duct
3. Arrest of müllerian duct development by a teratogenic agent
4. Mesenchymal inductive defect
5. Sporadic gene mutation

Knab believes that the teratogenic and the mutant gene etiologies are the most probable.

**Anomalies Associated with Müllerian Agenesis**

Many patients with müllerian agenesis have associated anomalies of the upper müllerian duct system together with associated anomalies of other organ systems. By gentle rectal examination, the physician can feel an absence of the midline müllerian structure that should represent the uterus. The physician instead feels a smooth band (possibly a remnant of the uterosacral ligaments) that extends from one side of the pelvis to the other. In MRKH syndrome, the uterus is represented by bilateral rudimentary uterine bulbs that vary in size, are not usually palpable, are connected to small fallopian tubes, and are located on the lateral pelvic side wall adjacent to normal ovaries. Depending on their size, these rudimentary uterine bulbs may or may not contain a cavity lined by endometrial tissue (Fig. 25.4). If present, the endometrial tissue can appear immature or, rarely, can show evidence of cyclic response to ovarian hormones. The endometrial cavity does not communicate often with the peritoneal cavity because the tube may not be patent at the point of junction between the tube and the rudimentary uterine bulb. In rare instances, however, active endometrium can exist within the uterine anlagen and the endometrial cavity, enabling communication with the peritoneal cavity through patent fallopian tubes. Reports have described several patients with functioning endometrial tissue in one or both rudimentary uterine bulbs (Fig. 25.4B). The patient can develop a large hematometra because of cyclic accumulation of trapped blood. Cyclic abdominal pain is relieved by excision of the active uterine anlagen. A patient with MRKH syndrome was reported who had a 4-cm endometrioma removed from the left ovary by laparotomy at the time of operation to create a vagina. Myomas have been reported in association with MRKH syndrome. Surgery for Benign Gynecologic Conditions

**FIGURE 25.4.** Patients with congenital absence of the vagina can show variation in the development of the upper müllerian ducts. A: Bilateral rudimentary uterine bulbs without endometrium. B: Bilateral rudimentary uterine bulbs containing a cavity lined with functioning endometrial tissue. Cross-sectional view shows presence of menstrual blood.
known to form in the muscular wall, and mild dysmenorrhea has been attributed to their presence. A small myoma has been found, in addition to the tube and ovary, in the inguinal canal and in the inguinal hernia sac.

Chakravarty and colleagues and Singh and Devi have demonstrated that the rudimentary bulbs have the potential for function. These authors used these rudimentary uterine bulbs to reconstruct a midline uterus. The reconstructed uterus was then connected to a newly constructed vagina. A surprising number of patients who have undergone this procedure have experienced cyclic menstruation, although recurrent stenosis and obstruction of the rudimentary horns are the most common results of such efforts. The authors of this chapter have had no experience with this technique and question its usefulness. However, these rudimentary uterine bulbs usually are insignificant structures that cause no problems.

Associated Urologic and Renal Anomalies

Fore and associates reported that 47% of patients in whom evaluation of the urinary tract was performed had associated urologic anomalies. In other studies, approximately one third of patients with complete vaginal agenesis were found to have significant urinary anomalies, including unilateral renal agenesis, unilateral or bilateral pelvic kidney, horseshoe kidney, hydroureter, hydronephrosis, and a variety of patterns of ureteral duplication. A significant number of patients with partial vaginal agenesis also have associated urinary tract anomalies.

Associated Skeletal and Other Anomalies

Associated skeletal anomalies have been recognized since congenital absence of the vagina was first described. In a review of 574 reported cases, Griffin and associates found a 12% incidence of skeletal abnormalities. Most of these abnormalities involve the spine (wedge vertebrae, fusions, rudimentary vertebral bodies, and supernumerary vertebrae), but the limbs and ribs also can be involved. Other anomalies include syndactyly, absence of a digit, congenital heart disease, and inguinal hernias, although the latter are more often present in patients with androgen insensitivity syndrome than in patients with MRKH syndrome (Fig. 25.3). Consideration of cardiac anomalies is also important, as Pittock and colleagues reported a substantial incidence of cardiac defects (16%) when reviewing a group of 25 patients with MRKH syndrome (Fig. 25.3). These authors used these rudimentary uterine bulbs to reconstruct a midline uterus. The reconstructed uterus was then connected to a newly constructed vagina. A surprising number of patients who have undergone this procedure have experienced cyclic menstruation, although recurrent stenosis and obstruction of the rudimentary horns are the most common results of such efforts. The authors of this chapter have had no experience with this technique and question its usefulness. However, these rudimentary uterine bulbs usually are insignificant structures that cause no problems.

Psychological Preparation of the Patient

Insufficient attention has been given to the psychological aspects of this problem. The patient with congenital absence of the vagina cannot be made into a whole person simply by creating a perineal pouch for intercourse. Establishment of sexual function is only one concern and may be the easiest problem to correct. Evans reported that 15% of his patients have real psychiatric difficulty. He and David and associates suggest that psychiatric help should be initiated before the operation. Wensborg and ter Kuile described the effect of a group program on women with Rokitansky syndrome. The authors held group sessions conducted by a gynecologist, a female social worker, and a woman with Rokitansky syndrome. Seventeen patients participated. Three women had elected not to create a vagina, six women created a vagina by dilatation or sexual activity, and eight women had undergone a vaginoplasty. Indices of psychological distress were measured before the program, at initiation of the program, and at the last group session. The results demonstrated that women with Rokitansky syndrome felt less anxious, less depressed, and less sensitive to interpersonal contact after participation in the semistructured program. These data support the value of group interaction in patients with Rokitansky syndrome.

Learning about this anomaly, especially at a young age, is a shock and is accompanied by diminished self-esteem. Such patients can be encouraged by having their gynecologist offer appropriate surgery to establish coital function. The gynecologist can point out that, functionally, the patient will be like thousands of young women who have had a hysterectomy because of serious pelvic disease and who have satisfied their desire to be a parent through adoption or gestational surrogacy.

When counseling patients at the time of diagnosis, gestational surrogacy should definitely be included in the discussion. Until recently, the literature had provided only sparse evidence regarding the use of this modality in this population. Reski and colleagues confirmed the use of gestational surrogacy in a small population. The treatment cycles resulted in six clinical pregnancies (42.9% pregnancy rate per embryo transfer and 54.5% per oocyte retrieval) and three live births (21.4% per embryo transfer, 27.3% per retrieval, and 50% per patient). Several authors have reported on the genetic offspring of patients with vaginal agenesis. Petrozza and colleagues reported a retrospective study in 1997, describing a large number of patients who have received this treatment.
number of treatment cycles for patients with Rokitansky syn-
drome. The authors attempted to determine an inheritance pat-
tern of the syndrome through a questionnaire sent to all centers
performing surrogacy treatment in the United States. A total
of 162 in vitro fertilization/surrogacy treatment cycles were re-
viewed for 58 patients with congenital agenesis of the uterus
and vagina. The treatment resulted in 34 live births (17 girls,
17 boys). One child had a nonspecific middle ear defect and
hearing loss. The authors concluded that congenital absence of
the uterus and vagina is not commonly inherited in a dom-
inant fashion. These findings suggest inheritance of this dis-
order in children of affected mothers is likely via a polygenic
mechanism.

Patient Cooperation
Regardless of which operative technique is chosen, the patient
must cooperate if the operation is to be successful. When a
McIndoe operation is performed, patients must understand
the need to wear a form continuously for several months and
intermittently for several years until the vagina is no longer
subject to constriction and until regular intercourse is taking
place. The operation should not be performed until prepara-
tory interviews determine that the patient understands her es-
sential role in its success. This is especially important when
the patient is a young teenager. The single most important
factor in determining the success of vaginoplasty is the psy-
chosocial adjustment of the patient to her congenital vaginal
anomaly.

Laboratory and Diagnostic Testing
A complete chromosomal analysis should be performed in all
patients. If there is a suspicion of ovarian dysgenesis, andro-
gen insensitivity syndrome, or some alteration of the clas-
sic MRKH syndrome, then a consideration of additional SRY
analysis should be entertained to assess the possible presence
of any Y chromosome. An intravenous pyelogram should be
done preoperatively. This also provides an adequate survey for
anomalies of the spine. If a pelvic mass is present, then ad-
ditional special studies, including ultrasonography, should be
performed to differentiate between hematometra, hematocol-
pos, endometrial and other ovarian cysts, and pelvic kidney. In
some centers, magnetic resonance imaging (MRI), combined
with a magnetic resonance urogram, may facilitate the evalu-
ation of the reproductive, urologic, and skeletal systems with
one radiographic study.

Evaluation of Cyclic Pain
Some patients without a pelvic mass report cyclic pain. This
pain can be ovulatory or possibly a result of dysmenorrhea
originating in well-developed rudimentary uterine bulbs. The
physician can differentiate between the two by asking the pa-
tient to keep a basal body temperature chart and to mark the
days when pelvic pain is present. Occasionally there is a ques-
tion about whether a patient has congenital absence of the
vagina or an imperforate hymen with cryptomenorrhea. The
diagnosis is clarified before operative intervention by using ra-
diographic imaging. Pelvic ultrasonography can often detect
hematocolpos or an obstructed uterine anlagen distended with
menstrual blood. An MRI can differentiate the two diagnoses,
if necessary.

| METHODS OF CREATING A VAGINA |

There is no unanimity of opinion regarding the correct ap-
proach to the problem of vaginal agenesis (Table 25.3). With
the development of the Ingram method for vaginal dilatation,
fewer patients require surgical vaginoplasty. The role of tis-
sue expanders in vaginoplasty has been reviewed by Patil and
Hixon. Labial expansion with an expander having a capacity
of 250 mL provides a flap 10 cm long and 8 cm wide with a
4-cm projection. Thus, well-vascularized flaps can be available
to provide an outlet for stenosis-free vaginoplasty. This ap-
proach has been suggested to maximize the success of surgical
vaginoplasty. A review of the methods devised for the forma-
tion of a vagina follows. The editors of this book have found
the modified McIndoe technique to give the most consistently
satisfactory results.

Nonsurgical Methods
In 1938, Frank described a method of creating an artificial
vagina without operation. In 1940, he reported remarkably
satisfactory results in eight patients treated with this method.
His follow-up study showed that a vagina formed in this man-
ner remained permanent in depth and caliber, even in patients
who neglected dilatation for more than 1 year. It has been em-
phasized that the pelvic floor itself is embryologically deficient
in some patients. Indeed, the ease with which some patients
are able to create a vagina with intercourse alone or with other
intermittent pressure techniques can be explained on this basis.
Five patients were reported to have developed enterocoeles, one
after cecostomy, three after a Williams vulvovaginoplasty,
and three after a McIndoe operation. This complication can
develop when the vaginal mucosa is brought in close proximity to the pelvic peritoneum, but a relative embryologic weakness or an absence of endopelvic fascia can also contribute to this complication. Rock, Reeves, and associates at the Johns Hopkins Hospital reported that an initial trial of vaginal dilatation was successful in 9 of 21 patients. Prompted by the rewarding results of Broadbent and Woolf, Ingram has described a passive dilatation technique of creating a new vagina. Instructing his patients in the insertion of dilators (Fig. 25.5) specially designed for use with a bicycle seat stool, Ingram was able to produce satisfactory vaginal depth and coital function in 10 of 12 cases of vaginal agenesis and 32 of 40 cases of various types of stenosis.

The patient is shown how to sit on a racing type bicycle seat that is placed on a stool 24 inches above the floor. She is instructed to sit leaning slightly forward with the dilator in place for at least 2 hours per day at intervals of 15 to 30 minutes. Follow-up is usually at monthly intervals, and the patient can expect to graduate to the next size larger dilator about every month. An attempt at sexual intercourse may be suggested after the use of the largest dilator for 1 or 2 months. Continued dilatation is recommended if intercourse is infrequent. In our experience, functional success rates are outstanding. Rock and Roberts reported the largest series of vaginal agenesis patients who used the Ingram method of dilatation to create a neovagina. The records of 51 patients with müllerian agenesis were reviewed. 37 patients attempted vaginal dilatation and 14 young women underwent a surgical intervention. Functional success was defined as satisfactorily achieving intercourse or accepting the largest dilator without discomfort in the clinic visit. All patients were followed up for at least 2 years and for an average of 9.25 years. Functional success was achieved in 91.9% of those who attempted dilatation (Table 25.4). Thus, passive dilatation should be suggested as an initial therapy for vaginal creation. If dilatation is unsuccessful, operative vaginoplasty is indicated.

## Surgical Methods

During the past 3 decades, experience has proved the Abbe-Wharton-McIndoe procedure (more popularly called the McIndoe operation) for dealing with complete absence of a vagina to be generally superior to others in most cases. In special circumstances, alternative methods of creation of a neovagina may be indicated.

### Historical Development of Surgical Procedures

In 1907, Baldwin used a double loop of ileum to line a space dissected between the rectum and bladder, leaving the mesentery connected to the bowel. The continuity of the intestinal tract was reestablished by an end-to-end anastomosis. He reported that the new vagina was absolutely normal in every way. In 1910, Popaw constructed a vagina using a portion of the rectum that was moved anteriorly. This operation was modified by Schubert in 1911. The rectum was severed above the anal sphincter and moved anteriorly to serve as the vagina. The sigmoid was sutured to the anus to reestablish the continuity of the intestinal tract. Both operations had soberingly high morbidity and mortality rates, and their popularity declined. Today, segments of sigmoid are used most often to create a vaginal pouch or extend vaginal length in patients who have lost vaginal function as a result of extensive surgery or irradiation for...
pelvic malignancy. Some patients who are treated for multiple
genitourinary or gastrointestinal abnormalities may be treated
with a bowel vaginoplasty during a combined procedure.

Less formidable procedures involving dissection of a space
between the bladder and rectum and lining of this space with
flaps of skin from the labia or inner thighs also were tried.
Marked scarring resulted, and hair usually grew in the vagina.
Extensive plastic procedures to construct a vagina are no longer
necessary or desirable and have been discarded in favor of safer
procedures unless there is the problem of maintaining a vagi-
nal canal after an extensive exenterative operation for pelvic
malignancy. In this case, the physician may want to consider
using the gracilis myocutaneous flap technique described by
McCraw and associates in 1976.

The Abbe-Wharton-McIndoe Operation

The operation most popular today for creating a new vagina
began with simple surgical attempts to create a space between
the bladder and the rectum. These early attempts were often
made in patients with cryptomenorrhea. However, such a space
usually would constrict because the surgeon would fail to rec-
ognize the importance of prolonged continuous dilatation
until the constructive phase of healing was complete.

At the Johns Hopkins Hospital in 1938, Wharton combined
an adequate dissection of the vaginal space with continuous di-
latation by a balsa form that was covered with a thin rubber
sheath and was left in the space. He did not use a split-thickness
skin graft. Instead, he based his operation on the principle
that the vaginal epithelium has remarkable powers of prolif-
eration and in a relatively short time will cover the raw surface.
Recalling that a similar process occurs in the fetus when the ep-
ithelium of the sinovaginal bulbs and the urogenital sinus form
the upper portion. In Counseller's 1948 report from the Mayo
Clinic, it was stated that the disadvantages of persistent
eral years, the vault of the vagina remains without epithelial
covering. Coital bleeding and leukorrhea result from the per-

1. Dissection of an adequate space between the rectum and the
   bladder
2. Inlay split-thickness skin grafting
3. The cardinal principle of continuous and prolonged dilata-
   tion during the contractile phase of healing

Other tissues such as amnion and peritoneum have been
used to line the new vaginal space, but they have not had sub-
stantial success. However, Tancer and associates reported good
results with human amnion. Karnofsky and associates stated
that a more physiologic result was achieved with an amnion
graft than with a skin graft. Nevertheless, concerns about the
transmission of human immunodeficiency virus with human
amnion now limit this option.

Technique of Abbe-Wharton-McIndoe Operation

Taking the graft. After a careful pelvic examination is per-
formed under anesthesia to verify previous findings, the patient
is positioned for taking a skin graft from the buttocks. For cos-
cmetic reasons, the graft should not be taken from the thigh or
hip unless for some reason it cannot be obtained from the but-
tocks. Patients may be asked to sunbathe in a brief bathing suit
before coming to the hospital so that its outline can be seen; an
attempt should be made to take the graft from both buttocks
within these borders. The quality of the graft determines to a
great extent the success of the operation. We have found the
Padgett electrodermatome to be the most satisfactory instru-
ment for taking the graft. With relatively little experience and
practice, the gynecologic surgeon can successfully cut a graft
of controlled width and thickness (Fig. 25.6). The instrument
is set and checked for taking a graft approximately 0.018 inch
thick and 8 to 9 cm wide. The total graft length should be 16
to 20 cm. If the entire graft cannot be taken from one buttock,
then a graft 8 to 10 cm long is needed from each buttock.

The skin of the donor site is prepared with an antiseptic
solution (povidone-iodine), which is then thoroughly washed
away. The skin is then lubricated with mineral oil as assistants
work to stretch the skin tight. Considerable pressure should
be applied uniformly across the dermatome blade. The thick-
ness of the graft must be determined accurately. A graft that is
little too thick is better than one that is a little too thin. There
should be no breaks in the continuity of the graft. The graft is
placed between two layers of moist gauze and the donor sites
are dressed. The donor site is soaked with a dilute solution of
epinephrine for hemostasis, and a sterile dressing is applied.
A pressure dressing is then placed over the site. This dressing
is removed on the seventh postoperative day. The ster-
ile dressing dries in place over the donor site and ultimately
should be no breaks in the continuity of the graft. The graft is
placed between two layers of moist gauze and the donor sites
are dressed. The donor site is soaked with a dilute solution of
epinephrine for hemostasis, and a sterile dressing is applied.
A pressure dressing is then placed over the site. This dressing
is removed on the seventh postoperative day. The ster-
ile dressing dries in place over the donor site and ultimately
will fall off by itself. Moistened areas on the dressing can be
dried with cool air. If there is separation and evidence of some
superficial infection, then merbromin can be applied to these
areas.

FIGURE 25.6. Section of split-thickness skin grafts. Grafts should be
uniform in thickness. The Padgett dermatome is set to take a
graft approximately 0.018 inch thick. A graft that is slightly thick is
better than a thin graft.
Creating the neovaginal space. The patient is placed in the lithotomy position, and a transverse incision is made through the mucosa of the vaginal vestibule (Fig. 25.7A). The space between the urethra and bladder anteriorly and the rectum posteriorly is dissected until the undersurface of the peritoneum is reached. This step may be safer with a catheter in the urethra and sometimes a finger in the rectum to guide the dissection in the proper plane. After incising the mucosa of the vaginal vestibule transversely, the physician often is able to create a channel on each side of a median raphe (Fig. 25.7B), starting with blunt dissection and then dilating each channel with Hegar dilators or with finger dissection. In some instances, it may be necessary to develop the neovaginal space by dissecting laterally and bringing the fingers toward the midline. The median raphe is then divided, thus joining the two channels. This maneuver is helpful in dissecting an adequate space without causing injury to surrounding structures.

To avoid subsequent narrowing of the vagina at the level of the urogenital diaphragm, it may be helpful to incise the margin of the pubococcygeus bilaterally along the midportion of the medial margin (Fig. 25.7C). Although useful in all circumstances, incision of the pubococcygeus muscle is more important in cases of androgen insensitivity syndrome with android pelvis, in which the levator muscles are more taut against the pelvic diaphragm, than in cases of gynecoid pelvis. Incision of the pubococcygeus muscle causes no difficulty with fecal incontinence, significantly improves the ease with which the vaginal form can be inserted into the canal in the postoperative period, and has eliminated the problem of contracture of the upper vagina caused by a poorly applied form. The dissection should be carried as high as possible without entering the peritoneal cavity and without cleaning away all tissue beneath the peritoneum. A split-thickness skin graft will not take well when applied against a base of thin peritoneum. All bleeders should...
be ligated by clamping and tying them with very fine sutures. It is essential that the vaginal cavity be dry to prevent bleeding beneath the graft. Bleeding causes the graft to separate from its bed, resulting in the inevitable failure of the graft to implant in that area and in local graft necrosis.

Preparing the vaginal form. Early skin grafts were formed over balsa, which has the advantages of being an inexpensive, easily available, light wood that can be sterilized without difficulty. It also can be whittled easily in the operating room to a proper shape to fit the new vaginal space. However, uneven pressure from the form can cause a skin graft to slough in places, and pressure spots are associated with an increased risk of fistula formation. The Counseller-Flor modification of the McIndoe technique (Fig. 25.8) uses, instead of the rigid balsa form, a foam rubber mold shaped for the vaginal cavity from a foam rubber block and covered with a condom. The foam rubber is gas sterilized in blocks measuring approximately $10 \times 10 \times 20$ cm. The block is shaped with scissors to approximately twice the desired size, compressed into a condom.

![FIGURE 25.8. Counseller-Flor modification of the McIndoe technique. A: A form is cut from a foam rubber block. B: A condom is placed over the form. C: The form is compressed and placed into the vagina. D: Air is allowed to expand the foam rubber, which accommodates to the neovaginal space. The condom is closed and the form removed. A second condom is placed over the form (E) and tied securely (F). G: The graft is then sewn over the form with interrupted 5-0 nonreactive sutures. H: The undersurfaces of the sutured edges of the graft are exteriorized. The vaginal form is ready for insertion into the neovagina.](image-url)
and placed into the neovagina (Fig. 25.8A through C). The form is left in place for 20 to 30 seconds with the condom open to allow the foam rubber to expand and conform to the neovaginal space (Fig. 25.8D). The condom is then closed, and the form is withdrawn. The external end is tied with 2-0 silk, and an additional condom is placed over the form and tied securely (Fig. 25.8E and F).

Sawing the graft over the vaginal form. The skin graft is then placed over the form and its undersurface exteriorized and sewn over the form with interrupted vertical mattress 5-0 nonreactive sutures (Fig. 25.8G and H). Where the graft is approximated, the undersurfaces of the sutured edges are also exteriorized.

The graft should not be “mashed” to make it stretch farther, and the edges of the graft should be approximated meticulously around the form without gaps. Granulation tissue develops at any place where the form is not covered with skin. Contraction usually occurs where granulation tissue forms. After the form has been placed in the neovaginal space, the edges of the graft are sutured to the skin edge with 3-0 nonreactive absorbable sutures, with sufficient space left between sutures for drainage to occur. The physician must be careful not to have the form so large that it causes undue pressure on the urethra or rectum. A balsa form should have a groove to accommodate the urethra. With a foam rubber form, this is unnecessary. A supapubic silicone catheter is placed in the bladder for drainage. If the labia are of sufficient length, then the form can be held in place by suturing the labia together with two or three nonreactive sutures.

Replacing a new form. After 7 to 10 days, the form is removed and the vaginal cavity is irrigated with warm saline solution and inspected. This is usually performed with mild sedation and without an anesthetic. The cavity should be inspected carefully to determine whether the graft has taken satisfactorily in all areas of the new vagina. Any undue pressure by the form should be noted and corrected. It is especially important that there not be too much pressure superiorly against the peritoneum of the cul-de-sac. Such a constant upward pressure could result in weakness with subsequent enterocoele formation. The new vaginal cavity must be inspected frequently to detect and to prevent pressure necrosis of the skin graft.

The patient is given instructions on daily removal and reinsertion of the form and is taught how to administer a low-pressure douche of clear warm water. She is advised to remove the form at the time of urination and defecation, but otherwise to wear it continuously for 6 weeks. A neoprene form, which is much easier to remove and keep clean than a foam rubber form, is substituted for the original form in 6 weeks. A new form is molded with a sterile sheet cover (condom) to fit the size of the vaginal canal. The patient is instructed to use the form during the night for the following 12 months. If there has been no change in the caliber of the vagina by that time, then it is unlikely to occur later, and insertion of the form at night can be done intermittently until coitus is a frequent occurrence. However, if there is the slightest difficulty in inserting the form, then the patient should be advised to use the form continuously again. Most patients are able to maintain the form in place simply by wearing tighter underclothes and a perineal pad. Douches are advisable during residual vaginal healing and discharge.

Results and Complications. Results with the McIndoe operation have improved over the years. Recently reported percentages of satisfactory results have ranged from 80% to 100%.

The serious complications formerly associated with the McIndoe operation have been significantly reduced by improvements in technique and greater experience. Serious complications do still occur, however, including a 4% postoperative fistula rate (urethrovaginal, vesicovaginal, and rectovaginal), postoperative infection, and intraoperative and postoperative hemorrhage. Failure of graft take is also still reported as an occasional complication. Failure of graft take often leads to the development of granulation tissue, which might require reoperation, curettage of the granulation tissue down to a healthy base, and even regrafting. Minor granulation can be treated with silver nitrate application. The functional result is more important than the anatomic result in evaluating the success of this operation. Although a vagina of only 4 cm is adequate for some couples, in most instances a vagina smaller than 4 cm causes major problems.

The postoperative results have improved significantly since the balsa vaginal form was replaced by the foam rubber form. Between 1950 and 1989, the McIndoe operation was performed on 94 patients at the Johns Hopkins Hospital. During these 39 years, 83% of the 94 patients had a 100% take of the graft; in only three cases was there a significant area over which the graft failed.

Urethrovaginal fistula has become even more infrequent since the introduction of the suprapubic catheter and the foam rubber form. The catheter is removed when the patient is voiding well and has no residual urine. In general, the patient is able to void without difficulty within the first few days of the procedure. Prophylactic broad-spectrum antibiotics started within 12 hours of surgery and continued for 7 days are of definite value in reducing the incidence of graft failures from infection in the operative site.

Because of the excellent results obtained after a modified McIndoe vaginoplasty, this procedure is recommended as a procedure of choice for women unable or unwilling to obtain a neovagina with dilatation methods. Women with a flat perineum with no dimple or pouch have no alternative other than the McIndoe vaginoplasty to obtain a neovagina for comfortable sexual relations.

Desirability of the modified McIndoe procedure may be increased by the use of alternative graft harvest sites to conceal possible aesthetic concerns of the buttock site, as proposed by Hückel and colleagues. The authors proposed the use of split skin harvesting from the scalp because thin (0.25-mm) split skin grafts do not seem to hamper hair growth at the donor site nor lead to hair growth at the recipient site. Because alopecia has been reported as a complication associated with technical errors, more experience is necessary before advocating the scalp as a potential graft harvest site.

It is important that a McIndoe operation be performed correctly the first time. If the vagina becomes constricted because of granulation tissue formation, injury to adjacent structures, or failure to use the form properly, then subsequent attempts to create a satisfactory vagina are more difficult. The first operation has the best chance of success.

One, like many other surgeons, modified the McIndoe procedure by describing an X-type perineal incision and the use of a perforated vaginal mold during the postoperative period. He postulated that this incision minimized stricture at the vaginal introitus and provided greater ease of dissection of the vaginal cavity. He reinforced that the overall procedure is simple with a generally uneventful postoperative course. Complications included infection, failure of skin graft take, urinary incontinence, partial graft loss, and vaginal stricture. All were treated satisfactorily except the patient with stress urinary incontinence.
Despite any minor modifications of the McIndoe vaginoplasty, the essential components of dissection of an adequate space, split-thickness skin grafting, and continuous dilatation during the contractile phase of healing remain unchanged. Recent reviews continue to support the safety and efficacy of the procedure. Hougaard and Villadsen reported 26 patients who underwent vaginoplasty, 18 of whom had Rokitansky syndrome. The median age at the time of the procedure was 19 years (range = 15–13 years) following surgical intervention with a McIndoe procedure. Ninety-seven percent of patients had a neovaginal length of at least 5 cm. An indwelling bladder catheter is used. The presence of a neovaginal length of at least 5 cm is as follows (Fig. 25.9). A horseshoe-shaped incision is made in the vulva to extend across the perineum and up the medial side of the labia to the level of the external urethral meatus. The surgery is performed in two stages. The first stage involves mobilization, the inner skin margins are sutured together with several interrupted sutures, and the second stage involves suturing the outer skin margins. Failure of the suture line to heal by primary intention results in a large area of granulation tissue and most likely an unsatisfactory result. Williams believes that if the urethral meatus is patulous, a vaginoplasty should not be performed because the urethra might be stretched further by coitus. He suggests that varying deficiencies in muscular and fascial tissue can explain why some patients with uterovaginal agenesis are able to develop a satisfactory vaginal canal with simple intermittent pressure and by Creatsas. The technique of vaginoplasty described by Williams is as follows (Fig. 25.9). A horseshoe-shaped incision is made in the vulva to extend across the perineum and up the medial side of the labia to the level of the external urethral meatus. The success of the operation depends on the appropriateness of the neovaginal length, the amount of skin excised, or 80% were sexually active at the time of evaluation. The most frequent difficulty reported was vaginal dryness and lack of lubrication with sexual intercourse. Ninety percent of the patients expressed satisfaction that sexual ability was acceptable. This experience also supports the role of the McIndoe vaginoplasty in providing young women with vaginal agenesis long-term satisfactorily and minimal disabilities.

**Development of malignancies.** Several case reports exist of malignant disease developing in a vagina created by various techniques; these reports were reviewed by Galligo and colleagues, as well as others. The authors reported a patient who was initially treated for intraepithelial malignancy by total vaginectomy combined with a split-thickness skin graft vaginoplasty to reconstruct a functional vagina. The authors noted a lesion in her vaginal apex 7 years later. These findings suggest that epithelium transplanted to the vagina can assume the oncogenic potential of the lower reproductive tract. The evidence supports a risk of neoplastic change in both skin and bowel grafts, with a reported average interval from vaginoplasty to diagnosis on the order of 19 years. Epithelium transplanted to the vagina will assume the oncogenic potential of the lower reproductive tract. The evidence supports a plan for surveillance and counseling. One regarding transmission risk for virally related dysplastic change in the lower genital tract is also extremely important for any patients undergoing neovaginoplasty.
separations or bleeding with intercourse were reported; however, these complications did occur in 20% of the patients who underwent the Williams vaginoplasty (10 young women). An assessment of sexual satisfaction was performed on the entire population; 94.4% of patients described her sexual life as satisfactory. Deligeoroglou and colleagues in Greece published supportive data regarding the Creatsas modification by describing both anatomic and functional success of 116 adolescents who underwent the procedure over a 15-year period. The physical exam findings were documented; however, the follow-up period was not clearly addressed.

The Williams vulvovaginoplasty is a useful operation and should certainly be considered the operation of choice for patients needing a follow-up to an unsatisfactory McIndoe operation or a supplement to a small vagina resulting from extensive surgery or radiation therapy. It remains an option for the rare patient with a solitary kidney low in the pelvis who does not have room for dissection of an adequate vaginal space.

**Alternative Techniques**

Schätz and colleagues reported three patients who underwent the George modification of the Wharton-Sheares neovaginoplasty technique. Wharton combined an adequate dissection of the vaginal space with continuous dilatation by a balsa form that was covered with a thin rubber sheath and was left in the space. His operation was based on the principle that the vaginal epithelium will proliferate and, in a relatively short time, will cover the raw surface. This modification of an already simple procedure may provide an alternative in areas where multidisciplinary, reconstructive pelvic surgery teams are not available. Because the procedure includes the mere dilatation of the bilateral Mullerian ducts and lining of the superior aspect with peritoneum, it eliminates some of the more complex aspects of the other surgical options. However, with a mean follow-up period reported as only 12 months (range of 2–23 months), reported long-term complications associated with the Wharton method (persistent granulation tissue, coital bleeding, leukorrhea, and scarring of the upper portion) cannot be fully evaluated. Longer follow-up and a larger patient experience are both necessary to consider if this procedure should an option for patients with MRKH.

Moyotoma and colleagues described 10 patients who were diagnosed with vaginal agenesis and were treated with oxidative regenerated cellulose fabric (Interceed). Operative time (<30 minutes) and postoperative hospitalization (2 days) were significantly shorter than that for a traditional skin graft. Vaginal depth was 8 to 10 cm, and no significant operative...
Surgery for Benign Gynecologic Conditions

Complications were reported. At the time of publication, patients had only been followed for 6 months; however, vaginal intercourse was already reported as easy and successful. Several authors, including Adamyan and Soong, and Templeman and colleagues, have described the laparoscopic use of the peritoneum to create a neovagina in patients with vaginal agenesis. Adamyan and Soong reported a group of 45 patients without complications. The most common postoperative problem involved the formation of granulation tissue at the vaginal vault. Templeman and colleagues described the laparoscopic mobilization of peritoneum for the creation of a neovagina in only one patient. The peritoneum was grasped through a perineal dissection and sutured to the introitus. A pursestring closure was placed at the apex. Stenting of the neovagina was continued for 3 months postoperatively followed by rigid dilation use. At 9-month follow-up evaluation, an 8- by 2-cm vagina was described, with squamous epithelialization present. Both groups describe the technique as safe and effective, producing a neovagina with apical granulation tissue as the only complication.

Guasnis and colleagues reported an assessment of sexual activity via a self-report questionnaire after the laparoscopic Davydov procedure. The Female Sexual Function Index (FSFI), a validated measure in the vaginal reconstruction population, was administered to both 28 women who underwent a laparoscopic Davydov procedure and 28 age-matched controls. The anatomical result was judged to be satisfactory (>6 cm) in 26 of 28 patients with a mean vaginal length of 7.2 ± 1.5 cm. No statistical difference was found between the subjects and the controls in all six domains of the FSFI, however, the authors note that 6 of the 25 (24%) operative subjects who completed the entire FSFI had a poor FSFI result. Of note, the areas of greatest concern were in the areas of lubrication and pain.

The Vecchietti operation was first described in 1965 by Giuseppe Vecchietti. He subsequently reported his cumulative 14-year experience in 1979 and 1980. Voronius and colleagues reviewed the use of the technique and described a laparoscopic modification that uses cystoscopy to confirm bladder integrity. The Vecchietti procedure is a surgical technique for the treatment of vaginal agenesis that constructs a dilatation-type neovagina in 7 to 9 days. The procedure uses specialized equipment including a traction device, a ligature carrier, and an acrylshaped olive. The process is in two steps, with essential operative and postoperative components. The operative phase involves positioning the olive at the perineum and the traction sutures extraperitoneally. Classically performed through a Pfannenstiel incision, the ligature carrier introduces the suture into a newly dissected vesicorectal space. The olive is threaded with suture at the perineum, and the suture is reintroduced at the abdomen. The suture is then guided through the peritoneal parietal layer in a subperiosteal fashion and advanced along the sidewall. The traction device, which provides constant traction on the olive, is positioned on the abdomen. During the postoperative invagination phase, the neovagina is created by applying constant traction to the olive. The procedure reportedly occurs at a rate of 1.0 to 1.5 cm per day, developing a 10- to 12-cm vagina in 7 to 9 days. Patients are instructed on the use of a vaginal obturator to be used as an outpatient. Borruto reported on Vecchietti's personal series of vaginal agenesis patients, comprising 522 consecutive patients. The surgical complications included one bladder perforation and one rectal puncture that required suture repair. In 1995, Laffarque and others described a laparoscopic intervention, creating a neovagina in three patients without dissection of the vesicorectal space. At completion of the procedure, cystoscopy was used to confirm bladder integrity. Some experts believe that the theoretical risk of bladder or rectal perforation without the dissection of the vesicorectal space is unacceptable high. Fedele and colleagues modified the approach to use a combined laparoscopic-ultrasonographic technique. The ultrasound assists in identifying the space of connective tissue between the bladder and rectum. The operating time for this modified procedure was only 40 minutes. After 10 days, the patient engaged in sexual intercourse. One-month evaluation confirmed a 12-cm vaginal length. Long-term follow-up outcomes are not available.

Sexuality after the laparoscopic Vecchietti procedure is poorly documented. Fedele and colleagues provide the only report, describing 50 of 52 cases (96%) with a vaginal length greater than 7 centimeters. All patients succeeded in having vaginal intercourse, 49 (82.6%) had a stable sexual relationship, and 49 (94.2%) were globally satisfied with their sexual life.

Bowel vaginoplasty is a well-known alternative for creation of a neovagina. The Ruge procedure and others are characterized by the formation of a neovagina using sigmoid colon grafts. Advocates propose that scar formation and vaginal stenosis occur less often than with other procedures; however, the disadvantage is the necessity of an abdominal laparotomy. Ota and colleagues reported on a modified Ruge procedure. Mesenteric dissection and sigmoid resection were performed laparoscopically. A 3.5-cm incision was used for appropriate bowel suturing. The segment of sigmoid colon was mobilized and brought to the introitus. The serosal layer of the pediculate end was stabilized to pelvic peritoneum. The patient remained hospitalized for 14 days. The benefit of this modification is certainly the accomplishment of a difficult surgical procedure endoscopically. Other advantages include the functional, ample vaginal length (12 cm) without postoperative dilation. Disadvantages include the extended postoperative hospitalization period and the small number of patients evaluated.

Reported surgical outcomes by authors such as Hensle and colleagues and Communal and associates report the role of sigmoid neovaginoplasty, especially in patients with MRKH. Until recently, long-term data regarding sexual function had not been available. Parsons and colleagues retrospectively reviewed 28 cases at a mean of 6.2 years after sigmoid vaginoplasty. Seventy-nine percent of patients were reportedly “very satisfied” with sexual function, and 21% were “comfortable” with the outcome. Communal and colleagues administered the FSFI to 11 patients after creation of a sigmoid neovagina. The mean score of the 8 women who were attempting intercourse was reported to be “satisfied” with sexual function, and 21% were “comfortable” with the outcome. Communal and colleagues administered the FSFI to 11 patients after creation of a sigmoid neovagina. The mean score of the 8 women who were attempting intercourse was reported to be “satisfied” with sexual function, and 21% were “comfortable” with the outcome. Communal and colleagues administered the FSFI to 11 patients after creation of a sigmoid neovagina.
Forty-two of the patients were reported to have MRKH. Eight patients underwent ileovaginoplasty; two patients were then subsequently treated with a colonic neovagina. The follow-up period varied from 18 months to 24 years with a mean of 8.8 years. Outcomes were evaluated both by a retrospective chart review and the female sexual dysfunction questionnaire (FSQI) described as an Institutional Review Board–approved, validated questionnaire. Of the 16 patients who responded, 31 were sexually active. Seventy-eight percent of the entire group of patients, including additional diagnoses precipitating neo-vaginoplasty, reported sexual desire, 33% sexual arousal, 78% sexual satisfaction. Also, 56% reported frequent orgasms, 22% occasional orgasms, and 22% no orgasms. Thirty-two patients (89%) reported adequate lubrication for sexual activity; 38 patients used home douching, and 20 required pads for mucus production.

Pratt, and by McCraw and associates.

The fluid undoubtedly comes from endocervical glands and müllerian glandular epithelium in the upper vagina that have been stimulated by the placental transfer of maternal estrogen. Continued fluid collection in infants, even after the first year, has been reported; thus, the possibility of a fistula between the upper vagina and the urinary tract should be considered. The distended upper vagina creates a large pelvic and lower abdominal mass that can displace the bladder anteriorly, displace the ureters laterally with hydroureter and hydronephrosis, compress the rectum with associated obstruction and even intestinal obstruction, and limit diaphragmatic excursion to indirectly compress the vena cava and produce cardiorespiratory failure. Fatalities have been reported. The hydrocolpos develops along the axis of the upper vagina and therefore may not necessarily cause the outlet or perineum to bulge when there is compression of the mass from above. After careful preoperative radiologic and endoscopic investigations of the infant, the septum should be removed through a perineal approach.
required in later years to allow satisfactory menstruation and coitus.

A hematocolpos may not develop until puberty. Symptoms include cyclic lower abdominal pain, no visible menstrual discharge, and gradual development of a central lower abdominal and pelvic mass. Sometimes a small tract opens in the septum, some menstrual blood escapes periodically, and symptoms are variable. A septum large enough to allow pregnancy to occur can still cause dystocia during labor. Cyclic hematuria may be present if a communication between the bladder and upper vagina exists. The pelvic organs of a woman with a transverse vaginal septum are shown in Figure 25.11. The woman developed severe cyclic pain at the time of onset of menstruation, but there was no external bleeding until menstrual blood finally began to flow through the small sinus. Pelvic examination revealed a cervix and a normal-sized corpus. The ovaries were palpable but adherent, probably because of organized blood from hematosalpinx and hematoperitoneum. Remarkably, the woman had little dysmenorrhea after beginning to menstruate externally. Coitus was fairly satisfactory before surgical correction, but the shortness of the vagina was something of a handicap. The obstructing membrane was excised, and an anastomosis of the upper and lower vagina was performed.

The findings of 26 patients with complete transverse vaginal septum reported from the Johns Hopkins Hospital by Rock, Zacur, and colleagues have shown that associated congenital anomalies include urinary tract anomalies, coarctation of the aorta, atrial septal defect, and malformations of the lumbar spine. Vaginal patency and coital function were successfully established in all patients, and 7 of 19 patients attempting pregnancy eventually had children. The incidence of endometriosis and spontaneous abortion was high. A lower pregnancy rate and more extensive endometriosis were present when the transverse septum was located high in the vagina, suggesting that retrograde flow through the uterus and fallopian tubes occurs earlier in these patients. More extensive dissection between the bladder and rectum was required to identify the upper vagina when the septum was thick and high. Exploratory laparotomy was necessary in five patients to guide a probe through the uterine fundus and cervix and to assist in locating a high hematocolpos.

**Surgical Technique for a Transverse Vaginal Septum**

A transverse incision is made through the vault of the short vagina (Fig. 25.11A). A probe is introduced through the septum after a portion of the barrier has been separated by sharp and blunt dissection. The physician usually finds some areolar tissue in dissecting the space between the vagina and the rectum. Palpation of a urethral catheter anteriorly and insertion of a double-gloved finger along the anterior wall of the rectum posteriorly provides the proper surgical guidelines so that the bladder and rectum can be avoided during this blind procedure. After the dissection is continued for a short distance, the cervix can usually be palpated, and continuity can be established with the upper segment of the vagina (Fig. 25.11B and C). The lateral margins of the excised septum are extended widely by sharp knife dissection to avoid postoperative stricture formation. The edges of the upper and the lower vaginal

FIGURE 25.11. Surgical correction of transverse vaginal septum. A: The upper end of a short vagina. The small sinus tract opening, through which the patient menstruated, is shown. The line of incision is drawn through the mucous membrane between the vaginal dimple and the sinus. B: Areolar tissue is dissected through to the pocket of mucosa that covered the cervix. The mucosa is incised. C: An anastomosis is made between the lower vagina and the upper vagina. D: Completed vagina. It is slightly shorter than normal but of normal caliber.

Mucosa are undermined and mobilized enough to permit anastomosis with the use of interrupted delayed-absorbable sutures (Fig. 25.11C). Figure 25.11D shows the completed anastomosis with a vagina that is of normal caliber but has a length slightly shorter than average. A soft foam rubber vaginal form covered with a sterile latex sheath can be placed in the vagina and removed in 10 days for evaluation of the healing process. The form can be worn for 4 to 6 weeks until complete healing has occurred. After this, coitus is permitted. If the patient is not sexually active, then vaginal dilatation may be necessary to maintain established patency. Alternatively, a silicone elastomer (Silastic) vaginal form can be inserted at night until the constrictive phase of healing is complete.

High Transverse Vaginal Septum. If the length of the obstructing transverse vaginal septum is such that reanastomosis of the upper and lower vagina is impossible, as is the case with a high transverse vaginal septum, in which a significant portion of vagina is atretic, then a space is created between the rectum and bladder to permit identification of the obstructed vagina (Fig. 25.12). The mass that has resulted from accumulated menstrual blood must be distinguished from the bladder anteriorly and the rectum posteriorly, a process that is facilitated by the mass itself. When differentiation is impossible, however, exploratory laparotomy can be performed. During this procedure, a probe is passed through the fundus of the uterus to tent out the vaginal septum and enable the surgeon to excise it from below and resect it safely.

In most surgical procedures to remove the high transverse vaginal septum, the obstructing membrane can be readily identified (Fig. 25.13), after which the operator can probe the mass with an aspirating needle to identify old menstrual blood. The upper vagina is then opened and the septum excised. Because
Correction of an atretic vagina. 

A: A large portion of atretic vagina is palpated with two fingers. Once the vaginal space is developed, it may be necessary to open the abdomen via laparotomy and pass a probe through to the uterine fundus (B) to tent out the septum, which may then be safely excised. 

C: An acrylic resin (Lucite) form is then placed into the vagina and secured with rubber straps.

The distance between the septum and the upper vagina is too great to permit an anastomosis, an indwelling acrylic resin (Lucite) form, consisting of a bulbous end and a channel through which menstrual blood can drain, is placed into the vagina and anchored with a retaining harness. The bulbous end of the form, in most instances, is retained in the upper vagina and should be left in place for 4 to 6 months while epithelialization is accomplished. After its removal, vaginal dilatation should be practiced on a daily basis for 2 to 4 months to prevent contracture of the space. It is essential to the success of the operation that the new space not become constricted; to avoid constriction, the form must be worn for many months during the contractive phase of healing. As an alternative to the Lucite form, the physician can consider using a split-thickness graft to bridge the gap. The graft is usually sutured in situ in the vagina rather than sutured to a form. An ingenious but rather complicated Z-plasty method of bridging the gap has been described by Garcia and by Musset. A simpler flap method was described by Brenner and associates.

A transverse vaginal septum diagnosed after the onset of puberty presents numerous problems. Often, a large segment of the vagina is absent, making anastomosis of the upper and lower segments difficult. Furthermore, postoperative vaginal dilatation is necessary to prevent stenosis at the anastomosis site. Poor compliance with dilatation in a poorly motivated pubertal patient is always a concern. However, rarely is the surgeon able to delay vaginoplasty until the patient is more mature because of increasingly severe cyclic abdominal pain caused by the hematocolpos. Thus, a difficult vaginoplasty can have less than optimal results.

Hurst and Rock have described an alternative approach to maximize surgical resection and anastomosis in women with a high transverse vaginal septum. Aspiration of the hematocolpos under ultrasound guidance was necessary to relieve the acute pain and delay surgery. Continuous oral contraceptives were used to delay recurrence of hematocolpos. Most important, vaginal dilatation was used to lengthen the lower vaginal segment to facilitate resection and anastomosis. In all three patients, the approach was successful.

**Congenital Absence or Dysgenesis of the Cervix**

Agenesis or atresia of the cervix (AFS class IB) is a relatively infrequent müllerian anomaly. When this anomaly does occur, it is often in association with absence of a portion or all of the vagina. In many cases of cervical agenesis or atresia, retention of menstrual blood initiates symptoms of cyclic lower abdominal pain without menstrual flow, causing the patient to seek gynecologic evaluation and care. In past times, diagnosis was suspected on the basis of a history and physical findings but was not proved until the time of surgery. Today, diagnosis of cervical agenesis or atresia is still usually difficult before operation, but the possibility of making a correct diagnosis before surgery does exist, with the help of modern diagnostic tools. Early diagnosis offers significant advantages in patient care, the most important of which is effective presurgical planning and preparation.
FIGURE 25.13. A high transverse vaginal septum. A: The neovaginal space is dissected, revealing a high obstructing vaginal membrane. B: This can be palpated with the middle finger. C: A needle is then placed into the mass. D: The incision is made with a sharp knife, and considerable bleeding can occur. E: The septum is excised. F: The septum is removed. G: After the septum is removed, the wall of the septum is oversewn with interrupted sutures of 2-0 chromic catgut. H: Because the distance between the septum and the upper vagina is too great to allow anastomosis, an acrylic resin (Lucite) form is placed in the vagina so that epithelialization can occur over the form while vaginal patency is maintained. The form, in place, is fitted with a plastic retainer. Rubber straps can be placed through the retainer and attached to a waist belt to allow constant upper pressure so that the form is retained in the upper vagina. Modification of this method includes a small adapter to allow drainage through the acrylic resin (Lucite) form, preventing the accumulation of old blood and mucus in the upper vagina. (From Rock J. Anomalous development of the vagina. *Semin Reprod Endocrinol* 1986;4:24, with permission.)

Diagnosis of Cervical Dysgenesis
Patients with congenital absence of the cervix present a diagnostic challenge. Patients with cervical aplasia with a functioning midline uterine corpus have aplasia of the lower two thirds of the vagina with an upper vaginal pouch. Similarly, some patients have a considerable atretic segment of vagina and an upper vaginal pouch with a properly developed uterine cervix and corpus above. Differentiation of these two müllerian anomalies is essential. Ultrasonography may be helpful. Valdes and associates have reported the use of preoperative ultrasonography in the evaluation of two patients with atresia of the vagina and cervix. MRI has been found to be helpful in confirming this diagnosis, as reported by Markham and associates. The lower uterine segment and cervical tissue can be carefully examined (Fig. 25.15). With cervical dysgenesis, there is no vaginal dilatation with the accumulation of blood, as seen with a high transverse vaginal septum. Both ultrasonography and MRI are most helpful when they are correlated with the findings of a careful pelvic examination under anesthesia.

Anatomic Variations of Congenital Cervical Anomalies
Two basic categories of cervical anomalies have been observed in several configurations. Patients exhibiting the first type,
cervical aplasia, lack a uterine cervix (Fig. 25.16A), and the lower uterine segment narrows to terminate in a peritoneal sleeve at a point well above the normal communication with the vaginal apex. The second type, cervical dysgenesis, can be described as four subtypes:

1. Cervical body consisting of a fibrous band of variable length and diameter (endocervical glands may be noted on pathologic examination) (Fig. 25.16B)
2. Intact cervical body with obstruction of the cervical os (the cervix is usually well formed, but a portion of the endocervical lumen is obliterated) (Fig. 25.16C)
3. Stricture of the midportion of the cervix (which is hypoplastic with a bulbous tip and no identifiable cervical lumen) (Fig. 25.16D)
4. Fragmentation of the cervix (with portions that can be palpated below the fundus and that are not connected to the lower uterine segment) (Fig. 25.16E)

Associated anomalies of the urinary tract are rare, but they do occur. Variable portions of the vagina can be atretic. Cervical obstruction is most often associated with a vagina of normal length.

Treatment

When both the vagina and cervix are absent and a functioning uterine corpus is present, it is difficult to obtain a satisfactory fistulous tract through which menstruation can occur. Many methods have been tried, most of them involving creation of a passage through the dense fibrous tissue between the uterine cavity and the vagina and placement of a stent to keep the tract open. Occasional successes in maintaining an open passageway and normal cyclic menstruation have been reported, but endocervical glands do not develop, and there is no way to compensate for the absence of the cervical mucus, which plays an important role in sperm transport. Even though cyclic ovulatory periods can be achieved in a few patients, pregnancy is unlikely. Eventually the uterovaginal tract closes from constriction by fibrous tissue. Endometriosis can develop along the tract. Endometriosis also can develop in ovaries and other pelvic sites because of retrograde menstruation. Recurrent and severe pelvic infection is a common problem and may require total hysterectomy and removal of both ovaries. As in vitro fertilization procedures began to offer the possibility for a host uterus to carry a pregnancy to term, procedures to establish a fistulous tract were abandoned. Nevertheless, Cukier and associates in 1986 reported treating a patient with congenital absence of the cervix by construction of a splint that extended into the neocervical canal such that a split-thickness skin graft could actually be placed within the endocervical canal. This patient has continued to menstruate without difficulty, although pregnancy has not been accomplished.

Many authors have recommended hysterectomy as an initial procedure for a patient with a functioning uterine corpus and congenital absence of the cervix and vagina. A hysterectomy eliminates much needless suffering from associated problems such as cryptomenorrhea, sepsis, endometriosis, and multiple operations. If the hysterectomy is performed soon enough, before the problems become great, it may be possible to conserve the ovaries and their useful functions. The reconstructive surgeon should be prepared to perform a vaginoplasty with use of a split-thickness graft if hysterectomy is performed, particularly if there has been a vaginal dissection. If the neovaginal space is allowed to close and scar, then future operations to develop an adequate neovagina are associated with increased risks of graft failure and f gaze formation.

Despite the overall poor results from reconstruction for congenital absence of both the cervix and the vagina, clinical experience suggests that cannulization procedures can be worthwhile for a few carefully selected cases with adequate stroma to allow a cervicovaginal anastomosis. If a long segment of cervix is fibrous cord, a cervical grafting technique may be required. If a fragmented cervix is noted, then hysterectomy is usually warranted. Those few patients who have achieved a pregnancy after cervical reconstruction have had a well-formed cervical body.

Anecdotal case reports occasionally appear in the literature confirming the necessity of palpable cervical tissue. Lettere described the development of a cervicovaginal tract in an adolescent patient with a core of cervical tissue. The tract remained patent for menstrual flow for 2 years; however, pregnancy had not yet been attempted. Data published by the senior author regarding the long-term follow-up of 21 patients with abnormal cervical development support the success of cannulization in only selected patients with sufficient rudimentary cervical tissue. All of the patients with fragmentation of the cervix (n = 4) eventually underwent hysterectomy. Only those patients with a well-formed cervical body, with at least a palpable cord or only distal obstruction, achieved successful surgical outcomes (4/7 patients). Only one patient, with distal obstruction, treated with can nu lization using a full-thickness skin graft, achieved pregnancy.

Others have reported the anastomosis of a well-developed distal vagina to a substantial midline uterine body. Cregg and colleagues described the use of the laparoscope for this procedure; however, Deffarges and associates examined the outcomes of 18 patients after open uterovaginal anastomosis. Twenty-two percent of patients required additional surgery. Eighty-three percent of the cases were associated with upper genital tract complications. Six spontaneous pregnancies were also reported in four of the patients. Despite the small potential for pregnancy, it is imperative to realize the potential for complications, including sepsis and even death as a result of ascending infection.
FIGURE 25.16. Congenital cervical anomalies. A: The fundus of the uterus is noted without a cervix. B: The cervical body consists of a fibrous band of variable length and diameter that can contain endocervical glands. C: The cervical body is intact with obstruction of the cervical os. Variable portions of the cervical lumen are obliterated. D: Stricture of the midportion of the cervix, which is hypoplastic with a bulbous tip. No cervical lumen is identified. E: Cervical fragmentation in which portions of the cervix are noted with no connection to the uterine body. Hypoplasia of the uterine cavity can be associated with cervical cord fragmentation.
The surgical approach for the rare opportunity for cervical cannulation remains a challenge. Several additional factors may also influence the surgical outcome: the size of the created channel, the duration of stenting of the channel, the presence of rudimentary endocervical glands in the region of the created channel, the presence of a native vagina adjacent to the created channel, or the number of menses allowed to flow through the stent. Because the surgical approach for cervical cannulation is based only on several case reports, there is truly limited data regarding safety and efficacy to share with patients and families. A frank discussion with both the patient and her family regarding the potential risks and morbidity is imperative. Even reportedly successful attempts have involved multiple surgical interventions, such as a reported cervicocolpomy with bladder mucosa described by Bugmann and colleagues; the 12-year-old patient had to undergo at least one previously failed attempt at reconstruction before the reported successful procedure. Very young adolescents may be subjected to multiple surgical procedures without good evidence of success.

**DISORDERS OF LATERAL FUSION**

Failures of lateral fusion of the two mullerian ducts cause vaginal anomalies that are grouped as obstructed or unobstructed.

**The Unobstructed Double Uterus (Bicornuate, Septate, or Didelphic Uterus)**

Complete failure of medial fusion of the two mullerian ducts can result in complete duplication of the vagina, cervix, and uterus. Partial failure of fusion can result in a single vagina with a single or duplicate cervix and complete or partial duplication of the uterine corpus. A failure of absorption of the uterine septum between the two fused mullerian ducts causes the septum to persist inside the uterus to a variable extent while the external appearance remains that of a single uterus. The septum can be so complete that it divides both the uterine cavity and endocervical canal into two equal or unequal components. More often, incomplete disappearance of the septum leaves only the upper uterine cavities divided. Each of these and a variety of other forms of double uteri have their own individual features of clinical significance. When no obstruction is present, surgical reconstruction is performed primarily because of difficulties with reproduction.

Some aspects of lateral fusion disorders remain controversial because information is still inaccurate or incomplete. Many reports are based on small samples of selected patients, patients who have been diagnosed as having one anomaly or another based on incomplete data, and patients who have received unification operations without preliminary studies to rule out other causes of reproductive difficulty. A comparison of results from one series to the next is difficult because authors have used different classifications based on a variety of embryologic, anatomic, physiologic, functional, and radiologic considerations. Unknown numbers of uterine anomalies may have escaped detection because reproductive performance is generally acceptable and gynecologic difficulties do not necessarily occur.

The mullerian ducts undergo multiple steps in development, including caudal, medial growth followed by fusion and later resorption of the remaining septum. Apoptosis has been proposed as a mechanism by which the septum regresses. Bcl-2, a protein involved in regulating apoptosis, was found to be absent from the septa of several uteri. The absence of this critical protein may play a pivotal role in the persistence of the septum and lateral fusion disorders.

**Historical Development of Surgical Procedures**

Ruge, in 1882, first reported excision of a uterine septum in a woman who had suffered two pregnancy losses. The woman subsequently carried a pregnancy to term. Paul Strassmann of Berlin and later Erwin Strassmann, his son, were strong advocates of uterine unification operations. The studies of Jones and Jones have contributed greatly to modern understanding of the management of uterine anomalies. Their studies began with a report in 1953 of a series that was started in 1936. Updates have been published from time to time. Wheelless, Rock, Andrews, and others have joined in these reports.

**Diagnosis of Uterine Anomalies**

If a uterine anomaly is associated with obstruction of menstrual flow, then it causes symptoms that will come to the attention of the gynecologist shortly after menarche. Unobstructed uterine anomalies are diagnosed later in a variety of circumstances. Young girls may notice difficulty in using tampons or later difficulty in coitus if a longitudinal vaginal septum is present. This can lead to the diagnosis of an associated uterine anomaly. A patient with an anomalous upper urinary tract on intravenous pyelogram may be found to have a uterine anomaly on gynecologic evaluation. A uterine anomaly is occasionally found when a patient reports dysmenorrhea or menorrhagia or when a dilatation and curettage (D&C) is performed for abortion or some other indication. A palpable mass may be a uterine anomaly but should be confirmed as such by ultrasonography, hysteroscopy, or laparoscopy. Woolfer and colleagues recently described the use of three-dimensional ultrasonography in screening for congenital uterine anomalies. During an investigation of the correlation of uterine anomalies with obstetric complications, the authors assessed the potential value of three-dimensional ultrasonography for screening. More than 100 women with uterine anomalies were identified. Seventy-two arcuate uteri, 29 septate, and five bicornuate uteri were described. The authors emphasized how the three-dimensional ultrasound may overcome the limitations of conventional two-dimensional ultrasonography in providing a coronal view of the uterus, thus differentiating between arcuate, bicornuate, and septate uteri. This technique remains investigational. Semmens has pointed out that the diagnosis of a uterine anomaly can also be made from observation of an abnormal uterine contour during pregnancy, either in the antepartum period or at the time of abdominal or vaginal delivery. The abnormal contour is caused by a combination of fetal malpresentation and an anomalous uterus. An anomalous uterus can also be diagnosed when a pregnancy occurs despite the presence of an intrauterine contraceptive device. Persistent postmenopausal bleeding despite recent D&C can lead to a diagnosis of an anomalous uterus. Sometimes the diagnosis is made as an incidental finding at laparotomy. However, most uterine anomalies are diagnosed after hysterosalpingography to evaluate infertility or reproductive loss, usually from repeated spontaneous abortion.

**Uterine Anomalies and Reproductive History**

Although some uterine anomalies can cause infertility, most patients with uterine anomalies are able to conceive without difficulty. There is no question that uterine anomalies can be associated with perfectly normal reproductive performance. Overall, however, the incidences of spontaneous abortion,
premature birth, fetal loss, malpresentation, and cesarean section are clearly increased when a uterine anomaly is present. It is impossible to predict which patients with uterine anomalies will have these problems.

**Etiology of Reproductive Failure**

The etiology of reproductive failure in patients with uterine anomalies remains unclear. Mahgoub believes that the presence of a uterine septum can lead to abortion because of diminished intrauterine space for fetal growth or because of implantation of the blastocyst on a poorly vascularized septum. Minos and associates have attached importance to the inadequacy of vascularization of the uterine septum. Associated cervical incompetence, luteal phase insufficiency, and distortion of the uterine milieu have all been implicated in the etiology of increased reproductive failure. However, it has been reported that the chance for a liveborn child increases with each pregnancy loss. It is unknown whether this apparent “conditioning” of the uterus is due to better vascularization, better myometrial stretching and accommodation, or some other factor.

A medical history of three or more episodes of spontaneous abortion or premature labor merits hysterosalpingography to determine whether structural abnormalities of the uterus are present. An abnormality is found in about 10% of such cases. Among chronic early second-trimester aborters, the incidence may be higher. The etiology of spontaneous abortion is complex, and a complete workup should be done even if an anomalous uterus has been found. A careful history should include detailed discussions of each previous pregnancy loss and inquiry into DES exposure or other drug or chemical toxicity, specific medical illnesses, and exposure to contagious diseases. A family history should emphasize reproductive failures among family members of both the patient and the husband. Specific medical diseases such as thyroid disease, diabetes mellitus, renal disease, and systemic lupus erythematosus should be ruled out. The possibility of infection by such agents as Neisseria gonorrhoeae, Chlamydia, Mycoplasma, Ureaplasma, and Listeria should be considered. Chromosome analyses should be done. Abnormalities in aborted tissue are found in more than 50% of spontaneous abortions, and abnormalities appear in up to one fourth of couples with a history of habitual abortion. Identifying such couples makes it possible to offer genetic counseling for subsequent pregnancies. Uterine leiomyomas, especially lower uterine segment and submucous leiomyomas, can cause spontaneous abortion. Basal body temperature charts, serum progesterone determinations, and endometrial biopsies timed in the luteal phase help determine the presence of luteal phase deficiency. The cervix should be studied for incompetence.

Couples with multiple etiologies for reproductive loss should have all other problems corrected before metroplasty is considered. Indeed, correcting other factors first may correct the problem of reproductive loss without metroplasty. In 1977, Rock and Jones reported on seven patients who had anomalies of uterine development and extrauterine factors in the etiology of their reproductive failure. These patients had already had 16 pregnancies, 5 (29%) of which resulted in a liveborn child. After therapy to correct the extrauterine factor, the success rate increased to 71%. Stoot and Mastboom reported an impressive increase in reproductive performance among uterine anomaly patients by simple improvement of abnormal carbohydrate metabolism.

Hysterographic Studies

Proper technique during the performance of hysterosalpingography to diagnose uterine anomalies is important. The hystero-gram must be taken at right angles to the axis of the uterus for a true assessment of the deformity to be made. The study is best done under fluoroscopy. A septate uterus cannot be distinguished from a bicornuate uterus by hystrogram alone (Fig. 23.17). The external uterine configuration also cannot usually be determined by pelvic examination alone, but some idea of the configuration can be obtained by ultrasonography. McDonagh and Tho have suggested the use of double-contour pelvic pneumoperitoneum-hystergographic studies for precise identification of müllerian malformations. Of course, laparoscopy is even more certain. If the uterine corpus has not been previously visualized, the physician must be prepared to correct either anomaly (i.e., obstructed or unobstructed), depending on the findings at laparotomy.

Additional Testing

A complete investigation should also include an assessment of tubal patency and an intravenous pyelogram. A variety of upper urinary tract anomalies are seen, including absence of one kidney, horseshoe kidney, pelvic kidney, duplication of the collecting system, and ectopically located ureteral orifices. The lower urinary tract (bladder and urethra) is much less often anomalous.

The Double Uterus and Obstetric Outcome

The percentage of full-term pregnancies with various types of double uterus in an unselected series of women who have not been operated on is unknown. For all types combined, it is probably approximately 23%. In patients selected for operation, it probably increases from approximately 5% to 10% to approximately 80% to 90%. Because patients with uterine anomalies who have relatively normal obstetric histories cannot be identified, there is confusion in the literature about which anomalies are more often associated with obstetric difficulties and which are relatively benign in their effect. Special diagnostic procedures to detect uterine anomalies are not usually performed before pregnancy is desired. A didelphys is the exception. This anomaly can be diagnosed easily on routine pelvic examination by identification of two complete cervices and perhaps also a longitudinal vaginal septum. A study by Heinonen in Finland of 182 women with uterine anomalies indicated that pregnancies in the separate uterus had a better fetal survival rate (86%) than they did in the complete bicornuate uterus (50%) or in the unicornuate uterus (40%). These findings differ from prevailing opinions that the septate uterus is associated with the highest reproductive loss, as proposed by Jones and Jones. A recent report by Woerther and associates supports Jones and Jones’s opinions by noting that women with a septate uterus had a significantly higher proportion of first trimester loss than women with a normal uterus.

In 1968, Capraro and colleagues reported on 85 patients with uterine anomalies seen between 1962 and 1966. One uterine anomaly was seen for every 645 admissions (0.145%). Metroplasty was considered necessary in only 14 (16%) of these 85 cases. According to Jones and Jones, only one third of patients with a double uterus have important reproductive problems, in most instances, the presence of a double uterus is not in itself an indication for metroplasty.

In 1985, Jewelewicz and coworkers estimated the spontaneous abortion rate to be 33.8% in women with a bicornuate uterus.
FIGURE 25.17. A: A hysterogram of a double uterus. A bicornuate uterus (B) and a septate uterus (C) are types of double uteri. Visualization of the fundus is required to determine the type of uterus.

uterus, 22.2% in those with a septate uterus, and 34.6% in those with a unicornuate uterus. More recently, Ludmir and associates reported that high-risk obstetric intervention did not significantly increase the fetal survival rate for uncorrected uterine anomalies. Capraro and associates found a preoperative fetal salvage rate of 33.3% for the septate uterus, 10% for the bicornuate uterus, and 0% for the didelphic uterus. Postoperatively, the fetal salvage rate was 100% for the bicornuate uterus, 80% for the septate uterus, and 66% for the didelphic uterus. The report gives the improved salvage figures, compared with several previous studies, after abdominal metroplasty.

Ravasia and colleagues described the incidence of uterine rupture in a cohort of women with müllerian duct anomalies who attempted vaginal birth after cesarean delivery (VBAC). Of the 1,813 patients who attempted VBAC between 1992 and 1997, only 25 patients with known müllerian duct anomalies attempted a trial of labor. This included 14 patients with a bicornuate uterus, five with a septate uterus, four with a unicornuate uterus, and two with uterine didelphys. Uterine rupture was diagnosed in two patients with müllerian anomalies. The authors proposed several mechanisms for the greater incidence of uterine rupture in this population: abnormal development of the lower uterine segment, previous scar similar to a vertical or classic incision, and the possibility of abnormal traction on the uterine scar during labor.

The Didelphic Uterus. A didelphic uterus with two hemicorpora is easily diagnosed because all patients have two hemiscervices visible on speculum examination, and most, if not all, have a longitudinal sagittal vaginal septum. In the series reported by Heinoenen and associates, all 21 patients with a didelphic uterus had a vaginal septum. Conversely, a patient with a longitudinal vaginal septum usually has a didelphic uterus. The indication for uterine unification is related to the role of this anomaly as an etiologic factor in reproductive loss. Of all the uterine anomalies (except arcuate uterus), the didelphic uterus is associated with the best possibility of a successful pregnancy. However, there is still some increase in perinatal mortality, pre-mature birth, breech presentation, and cesarean section for delivery. Heinonen and associates reported a fetal survival rate of 64% without metroplasty. Musich and Behrman stated that the didelphic uterus offers the best chance for a successful pregnancy (57%) and should not be considered an appropriate indication for metroplasty. However, W. S. Jones considered the didelphic uterus to give the worst obstetric outcome. In the opinion of the editors of this book, a unification operation for a didelphic uterus is not often indicated, and the results may be disappointing, especially when an attempt is made to unify the cervix. Not only is this procedure technically difficult in a complete didelphic anomaly, but it can also result in cervical incompetence or cervical stenosis.

The Septate Uterus. Most patients who are evaluated for repeated abortion and who are found to have a uterine anomaly have a septate uterus. A few have other anomalies, mostly the bicornuate uterus. Proctor and Haney’s review of women with recurrent first-trimester pregnancy loss reinforce the role of the septate uterus in repeated pregnancy loss. Of 35 women reviewed with a divided uterine cavity on hysterosalpingogram, all women were found through diagnostic hysteroscopy and laparoscopy to have a septate uterus. In our experience, fetal survival rates are higher after septate uterus repair than after other repairs. In 1977, Rock and Jones reported on 43 patients with septate uterus selected for Jones metroplasty at the Johns Hopkins Hospital. Of these 43 patients, 95% became
pregnant postoperatively, 73% carried to term, and 77% delivered a liveborn child. Similarly, hysteroscopic metroplasty for the septate uterus provides a substantial improvement in obstetric outcome. Data obtained from retrospective studies suggest that hysteroscopic metroplasty is associated with favorable outcomes, with a pregnancy rate of approximately 80% and a miscarriage rate of only approximately 13%. Recent prospective observational studies reported similar findings. Fabbe and Gomel reported the reproductive outcome of 61 patients; however, the patients had unexplained infertility and nearly 15% were also treated with cervical cerclage. Litta and colleagues also reported an 83.3% term delivery rate in their population of women with a septate uterus who underwent hysteroscopic metroplasty. Parton and colleagues described 16 women with a complete uterine septum. The preoperative pregnancy loss rate was 81%. Eleven of the fourteen septa treated with a hysteroscopic approach were successfully removed. The remaining three unsuccessful hysteroscopic procedures and two additional patients were treated using the Tompkins metroplasty. Postoperatively, 9 women conceived after hysteroscopic surgery, and twin live births occurred in 9 of 12 (75%) conceptions. The most controversial area remains the resection of the cervical portion of the septum. Parsanezhad and colleagues reported a multicenter, randomized controlled trial regarding the management of the cervical septum. Surgical issues, complications, and pregnancy outcomes were compared. Operating times, distending media deficits, and perioperative complications were all substantially better in the cervical septum resection group. The reproductive outcomes were similar; however, the cesarean section rate was higher in the group in which the cervical septum was spared. The histologic features of the septum in this abnormal uterus have been described. Dahi-rashkafi and colleagues noted less connective tissue in uterine septa. Poor decidualization and placentation were suggested as a cause.

Finally, the AFS class VA uterus (a double cervix and uterine cavity with a single fundus) can result from a rotation abnormality during the descent of the Müllerian ducts. Among the reported cases of the septate uterus, the incidence of the complete septum involving the cervix varies from 4% to 29%. If the dextrorotating Müllerian ducts overrotate, the senior author theories that the septum fails to absorb after fusion of the ducts (J. A. Rock, personal observations, 1991). In virtually every patient with a complete septate uterus, the left cervix is higher than the right. In one patient, one cervix has been noted above the other (Fig. 25.18). This rotation abnormality may be a factor associated with lack of absorption of the uterine septum in these patients.

Uterine Anomalies and Menstrual Difficulties
Dysmenorrhea and abnormal and heavy menstrual bleeding have been reported to occur more frequently with any form of congenital vaginal septum. Traditionally, the septate uterus has been unified with either the Jones or the Tompkins procedure. Clinical reports by Chernovak and Neuwirth; by Daly, Walters, and colleagues; by DeCherney and associates; and by Israel and March have favorably compared hysteroscopic or resectoscopic incision of a uterine septum with the more traditional transabdominal approach. Term pregnancy rates after these procedures have approached 80% to 85%. Several attempts may be necessary to incise a wide septum, although the septum usually can be incised completely at the first operation.

Transcervical Lysis of the Uterine Septum. Abdominal metroplasty for transfundal incision or for excision of the septum associated with the septate uterus generally has been abandoned. With hysteroscopic scissors, the procedure can be abandoned. With hysteroscopic scissors, the procedure can be
tedious, especially with a large, broad septum. Although the hysteroscope and scissors are still used for cutting the septum, the resectoscope has been found to be comparable. The optics are excellent, and the septum can be electrosurgically incised with little difficulty. Laser-assisted procedures have also been described.

Before transcervical lysis of a uterine septum, a gonadotropin-releasing hormone agonist may be given for 2 months to reduce the amount of endometrium that can obscure the surgeon’s view during the procedure. Many authors do not consider routine preoperative preparation of the endometrium essential and may only use medications in procedures involving exceptionally wide septa or complete septa that involve the lower one third of the uterine cavity or the cervical canal. If medical preparation is not used, surgical intervention should be scheduled during the early proliferative phase of the cycle to avoid bleeding and impaired visualization from a vascular endometrium associated with the secretory phase. Transcervical lysis is usually performed in conjunction with laparoscopy under general endotracheal anesthesia. The uterine cavity is distended with dextran 70 (Hyskon) by way of the resectoscope, which is inserted into the cervix. The septum is then electrosurgically incised by advancing the cutting loupes, using the trigger mechanism of the resectoscope. The uterine septum is incised until the tubal ostia are visualized and there is no appreciable evidence of the septum. The procedure is performed under simultaneous laparoscopy to limit the risks of uterine perforation.

After transcervical lysis of a uterine septum, a 2-month delay before attempting pregnancy is suggested to allow complete resorption of the septum. Delivery may be vaginal. The Jones procedure is used to repair a septate uterus when a particularly broad septum cannot be easily incised with the resectoscope. The Strassmann procedure is used for unification of a bicornuate uterus. The safety and efficacy of hysteroscopic resection of the uterine septum in patients with a class VA septate uterus has been demonstrated by the senior author. Historically, case reports, such as that of Hundley and colleagues, were the only source of information about this interesting variant; however, one of the largest populations of patients with a complete septum was reported in 1999 by Roberts and Rock. The patients underwent hysteroscopic metroplasty with preservation of the cervical portion of the septum. With the exception of one case for 5 days after surgery to limit the risks of infection. If excessive bleeding occurs after the procedure, a Foley catheter should be placed in the uterine cavity for tamponade and removed in 4 to 6 hours. Hormonal therapy is the most commonly used postoperative treatment regimen. The aim of the treatment is the promotion of rapid epithelialization. Dabir rashrafi and colleagues reported that estrogen therapy did not appear to demonstrate a benefit. Further evidence is necessary before dismissing the current trend of postoperative estrogen therapy.

Transcervical lysis also can be performed to repair a complete septate uterus (i.e., a single fundus with two cavities and two cervices). In this instance, a Foley catheter is inserted into one cervix and indigo carmine is injected into the cavity. The other cavity is distended with dextran 70 (Hyskon) by way of the resectoscope. The septum is electrosurgically incised at a point above the internal cervical os until the Foley catheter is visualized. The septum is then incised in a superior direction until the tubal ostium is visualized and there is no appreciable septum (Fig. 25.19).

FIGURE 25.19. Resectoscopic metroplasty. At A, a Foley catheter is placed in one cavity of a complete septate uterus (American Fertility Society class VA uterus). The resectoscope is inserted in the opposite cavity, and the septum is incised until the Foley is visualized. The septum can be easily incised with the resectoscope until both internal os are visible. B: A septate uterus with a single cervix. The septum can be incised with the straight loupes of the resectoscope.
of pulmonary edema, no significant intraoperative or postoperative complications were reported. Postoperative hysteroscopy revealed only minor fundal septal remnants without clinical significance.

The Modified Jones Metroplasty. In the modified Jones unification operation (Fig. 25.20), the abdomen is generally opened through a transverse incision. If only the unification operation is planned, then a Pfannenstiel incision is permissible. The pelvic viscera are inspected. The septate uterus may demonstrate a median raphe across the fundus, but it is surprising how often the corpus looks normal. To facilitate manipulation, a traction suture of heavy silk is placed through the top of the septum. This suture is removed from the site when the septum is excised.

No attempt is made to stain the uterine cavity with methylene blue. Normal unstained endometrial tissue can be easily differentiated from the myometrium.

There are essentially two methods to control bleeding during this procedure. In the first, a tourniquet is applied at the junction of the lower uterine segment and cervix by inserting a 0.5-inch Penrose drain through an avascular space in the broad ligaments just lateral to the uterine vessels on each side. The tourniquet is placed around the lower uterine segment and is tied anterior to the uterus. Because the uterine corpus receives a significant blood supply through the ovarian arteries, tourniquets should also be tied around the infundibulopelvic ligaments on each side, using the same hole in the broad ligament. All tourniquets must be tied tightly enough to occlude both the arterial supply to and the venous drainage from the uterus. If only the venous drainage is occluded, then the corpus becomes engorged and congested, and bleeding is increased. If the arterial supply is occluded, then the uterus blanches, and the bleeding is minimal. A sterile Doppler can be used to establish disappearance of uterine artery pulsations. Hypotensive anesthetic techniques used in conjunction with the tourniquets allow a uterine unification operation to be accomplished with negligible blood loss.

The alternative method for hemostasis uses up to 20 units of vasoressin that is diluted in 20 mL of saline and injected
into the anterior and posterior walls of the uterus before the incision is made.

The uterine septum should be surgically excised as a wedge (Fig. 25.20D). The incisions begin at the fundus of the uterus. The approach to the endometrial cavity should be handled carefully so that it is not transected (Fig. 25.20E). The original incisions at the top of the fundus are usually within 1 cm—and sometimes even less—of the insertion of the fallopian tubes. If the incision is directed toward the apex of the wedge, however, there seems to be little danger of transecting the tube across its interstitial transit in the myometrium.

After the wedge has been removed, the uterus is closed in three layers with interrupted stitches; 2-0 nonreactive suture on anatraumatic tapered needle is convenient. Two sizes of needles are needed: a half-inch needle for the inner and intermediate layers and a large needle (three fourths half-round) for the outer muscular layer. The inner layer of stitches must include about one third of the thickness of the myometrium, because the endometrium alone is too delicate to hold a suture and will be cut through. The inner sutures should be placed through the endometrium and the myometrium in such a way that the knot is tied within the endometrial cavity (Fig. 25.20G–H). While the suture is being tied, the two lateral halves of the uterus should be pressed together both manually and with the guy sutures to relieve tension on the suture line and to reduce the possibility of cutting through. These sutures are placed alternately, first anterior and then posterior. After the first few stitches are placed and before the first layer is completed, the second layer can be started to reduce tension.

As the operation proceeds, the third layer of stitches is begun in the serosa both anteriorly and posteriorly (Fig. 25.20I–K). Finer, nonreactive suture material can be used to approximate the serosal edges of the uterus more precisely to prevent adhesion formation to the suture line (Fig. 25.20K–L). By the
The Wedge Metroplasty Versus The Tompkins Procedure. The technique of modified Jones metroplasty is a compromise between the classic Jones metroplasty and the Tompkins metroplasty. In the Tompkins operation, a single median incision divides the uterine corpus and septum in half. The incision is carried inferiorty until the endometrial cavity is reached. Each lateral septal half is then incised to within 1 cm of the tubes. No septal tissue is removed. The myometrium is reapproximated, taking care not to place sutures too close to the interstitial portion of the tubes. Proponents of the Tompkins technique suggest that their operation is simpler than the classic Jones procedure, that it conserves all myometrial tissue and leaves the uterotubal junction in a more normal and lateral position, and that it provides opportunities to heal, a delay of 4 to 6 months in attempting pregnancy is advised after abdominal metroplasty.

The Strassmann Metroplasty. The Strassmann procedure is not easily adapted to the septate uterus, but it is the procedure of choice for unification of the two endometrial cavities of an externally divided uterus, both bicornuate and didelphic (Fig. 25.21). A bicornuate uterus cannot be repaired through a transcervical incision because perforation will result. When there has been failure of fusion of the two Mullerian ducts, inspection of the pelvic cavity often reveals a broad peritoneal band that lies in the middle between the two lateral hemisepas. This rectoceleical incision is attached anteriorly to the bladder, folds over this rectoceleical incision, extends posteriorly through the cul-de-sac, and ends with its attachment to the anterior wall of the sigmoid and rectum. It is not invariably present, but when it is, its potential significance in the etiology of the anomaly, possibly by preventing the two Mullerian ducts from joining, must be considered. This rectocervical ligament must be removed before a unification procedure can be performed (Fig. 25.21A).

For hemostasis, touch-various are used in a manner similar to that described for the modified Jones procedure. The two uterine cornua are incised on their median sides in their longitudinal axes, deeply enough to expose the uterine cavities (Fig. 25.21B). Superiorly, the incision must not be too close to the interstitial portion of the fallopian tubes. Inferiorly, the incision is carried far enough to join the two sides into a single endocervical canal. If it appears that a deeper incision will compromise the competence of the cervix, then a double cervical canal can be left. If the cervix is already duplex, then it should not be joined. As the incision in the myometrium releases the internal stresses in the walls of the hemi-corpus, each one everts and is perfectly positioned for apposition, almost as if the original cervical os will result. To allow the uterine incision the best possible opportunity to heal, a delay of 4 to 6 months in attempting pregnancy is advised after abdominal metroplasty.
FIGURE 25.21. The Strassmann metroplasty with modification. A: If a rectovesical ligament is found, it should be removed. B: An incision is made on the medial side of each hemicorpus and carried deep enough to enter the uterine cavity. The edges of the myometrium will evert to face the opposite side. C and D: The myometrium is approximated by use of interrupted vertical figure-of-eight 3–0 polyglycolic acid sutures. One should avoid placing sutures too close to the interstitial portion of the fallopian tubes. E: A continuous 5–0 polyglycolic acid subserosal suture is used as a final layer. Tourniquets are removed, and defects in the broad ligament are closed.
Attempts to unify a double cervix or a septate cervix also are not recommended because of the possibility of causing cervical incompetence. However, a double or septate cervix can adversely affect the outcome of delivery if vaginal delivery is attempted, and delivery should be by cesarean section if it appears that the cervix will cause dystocia.

**Mode of Delivery after Metroplasty**

The scar formed in the myometrium after unification is as strong as, if not stronger than, the scar formed after cesarean section. The biologic conditions under which healing occurs are entirely different in these two situations. Endometriosis is a common complication after cesarean section but is not a complication of uterine unification. Of 71 known pregnancies in Strasman's collected series reported in 1952, 61 were delivered vaginally. There were no cases of uterine rupture during pregnancy or delivery. Losits and colleagues reported the reproductive outcome of 22 women who underwent the Strasman metroplasty for a bicornuate uterus; 88% achieved pregnancies that ended with the delivery of a viable infant. All were delivered by cesarean section without evidence of scar rupture. Despite evidence that the uterine scar heals securely after unification operations, our policy is to recommend delivery by elective cesarean section in all patients who have undergone abdominal metroplasty. Patients can deliver vaginally after a metroplasty by hysteroscope or resectoscope.

**Diethylstilbestrol-Related Uterine Anomalies**

Exposure of the female fetus to DES can cause significant anomalous development of the uterus, as reported by Kaufman and associates and by Haney and colleagues. The T-shaped uterus is the variant most commonly seen. It is associated with an increased rate of spontaneous abortions, preterm deliveries, and ectopic pregnancies.

Nagel and Malo determined the feasibility of correcting the uterine malformations seen in DES-exposed women by incising constriction rings and septa. Their goal was to incise the irregular uterine walls until the cavity assumed a smooth, straight line from the lower uterine cavity to the uterine tubal ostium. Their results suggested that metroplasty can decrease pregnancy loss but does not enhance fertility. The editors of this book suggest that the rare patient can benefit from a uterine reconstructive procedure, but that most will not. Surgeons may never develop a large series to document efficacy of surgical outcomes because patients with this anomaly will eventually age beyond reproductive years, and some latitude is required in cases that might possibly benefit from metroplasty.

DES-exposed patients must be monitored closely for evidence of dilatation and effacement of the cervix early in pregnancy. Cervical cerclage may be indicated in some patients.

**Uncinuate Uterus**

A uncinuate uterus can be present alone or with a rudimentary horn or bulb on the opposite side. In a series reported by Heinonen and associates, 11 of 13 patients with a uncinuate uterus had a rudimentary horn, and two did not. The rudimentary anlage (uterine muscle bundle or bulb) can communicate directly with the uncinuate uterus. In some instances, there is no cavity within the anlage, or there is no rudimentary horn. Most rudimentary horns are noncommunicating (90% according to O'Leary and O'Leary). The two sides may be connected by a fibromuscular band, or there may be no connection and no communication between the two uterine cavities. Fedele and associates have found sonography useful in determining the presence of not only a rudimentary horn but also a cavity within.

**Associated Anomalies**

Urinary tract anomalies are often associated with a uncinuate horn. On the side opposite the horn, there may be a horseshoe or a pelvic kidney, or the kidney may be hypoplastic or absent. This is especially true if there is associated Mullerian duct obstruction. When all Mullerian duct derivatives and the kidney are absent on one side, this implies failure of development of the entire urogenital ridge, including the genital ridge where the ovary forms. In addition, the ovary may be malpositioned (Fig. 25.22). Rock, Parmley, and associates reported a unilateral ovary located above the pelvic brim in four cases of uterine anomalies. The orifice of the Mullerian duct develops at about the level of the fourth thoracic vertebra (T4) in the embryo. The tip subsequently migrates along the course of the Mullerian duct into the pelvis. The orifice of the duct or the fimbriated end of the tube comes to lie in the pelvis as a result of differential growth of the fetus. The subsequent differential growth is retarded so that the portion of the urogenital ridge that gives rise to both the gonad and tube does not displace into the pelvis. Malpositions of the ovary and tube are the result.

**Reproductive Performance**

According to Heinonen and associates, the uncinuate uterus carries the poorest fetal survival rate (40%) of all uterine anomalies. In 1957, Jones reported similar findings. The abnormal shape, the insufficient muscular mass of the uterus, and the reduced uterine volume and inability to expand may explain the poor obstetric outcome.

Moutos and colleagues compared the reproductive performance of the uncinuate uterus with that of the didelphic uterus. Twenty of the 29 women with a uncinuate uterus produced a total of 40 pregnancies, whereas 13 women with a didelphic uterus produced a total of 28 pregnancies. The percentages of pregnancies resulting in preterm delivery, term delivery, and living children were similar in both groups. The authors concluded that reproductive performance of the uncinuate uterus was not different from that of the didelphic uterus, that it is uncommon for either malformation to be a primary cause of infertility, and that there is insufficient information to support recommendation of placement of a cervical cerclage in the absence of cervical incompetence. Thus, there is no evidence that uterine reconstruction should be performed for patients with a uncinuate (or a didelphic) uterus.

Because most cases of uncinuate uteri have a noncommunicating rudimentary uterine horn on the opposite side, there is danger of pregnancy in the rudimentary horn from transperitoneal migration of sperm or ovum from the opposite side. According to Holdren and Hare, approximately 350 cases of pregnancy in a rudimentary horn have been reported since the original case report by Mauritsen in 1669. O’Leary and O’Leary found the corpus luteum on the side contralateral to the rudimentary horn containing a pregnancy in 8% of cases. Signs and symptoms of an ectopic pregnancy develop with eventual rupture of the horn if the pregnancy is not detected early. Rupture through the wall of the vascular rudimentary horn is associated with sudden and severe intraperitoneal hemorrhage and shock. Death can occur in a few minutes. It is surprising that the current mortality rate has decreased to 5%.

Very little, if anything, can be done to improve the reproductive performance of patients with a uncinuate uterus. The physician should observe closely for cervical incompetence and...
perform cerclage as indicated. Andrews and Jones have suggested that removal of the rudimentary uterine horn may improve the chances of a successful pregnancy, but the experience is too small to support a definite recommendation. Cases of asymmetric development of the unicornuate uterus with an opposing rudimentary uterine horn are not amenable to unification.

**Longitudinal Vaginal Septum**

Failure of fusion of the lower müllerian ducts that form the vagina can result in a vagina with a longitudinal septum. The septum can be partial or complete. Young patients have difficulty using tampons. In cases of didelphys uterus with a longitudinal vaginal septum, one uterine hemicorpus is usually better developed than the other. If intercourse consistently occurs on the vaginal side connected to the uterine hemicorpus that is less well developed, then infertility or repeated abortion could result. For these reasons, the septum should be removed (when the patient is not pregnant) unless there is a contraindication. This can usually be accomplished easily with reasonable precautions against injury to the urethra, bladder, and rectum.

Haddad and colleagues reported their experience over a 24-year period with management of the longitudinal vaginal septum. The retrospective review of 202 patient charts described a complete septum (extending from cervix to introitus) in 45.6% of patients, high partial in 36.1%, and a medium or low partial, involving only the distal vagina, in 18.3%. Uterine malformations were noted in 87.8% of cases. The frequency of uterine malformations was 99.4% in cases of complete or partial high septum and 30.3% in cases of partial medium or low septum. The most common malformation was class VA complete septate uterus in 59.5% of malformations, followed by class III didelphys uterus (24.3%) and class VB partial septate uterus (15%). Section or resection was performed in 201 cases. Bladder injury in one patient was the only reported complication.

As highlighted by the high prevalence of associated uterine malformations in this review, management should always include an assessment of uterine anatomy.

**Asymmetric Obstruction of the Uterus or Vagina**

**Unicornuate Uterus and Noncommunicating Uterine Anlagen Containing Functional Endometrium**

If one müllerian duct develops normally while the opposite müllerian duct fails to develop or develops incompletely, then a relatively normal unicornuate uterus is found on one side and the cervix, musculature, uterine cavity, endometrium, fallopian tube, blood supply, and ligamentous attachments are...
absent or hypoplastic to a varying degree on the other side. Obstruction to menstruation can also occur to varying degrees on the improperly developed side. For example, if a rudimentary uterine horn does not communicate externally but does have an endometrium-lined uterine cavity, then clear symptoms of obstructed menstruation may begin soon after menarche, and severe dysmenorrhea will be present. Cryptomenorrhea can be overlooked as the diagnosis because there is cyclic menstruation from the opposite side. It is important to make the diagnosis as soon as possible, because if the lumen of the tube communicates with the endometrial cavity of the rudimentary uterus, then retrograde menstruation and pelvic endometriosis...
will develop, and reproductive potential can be destroyed. During the operation illustrated in Figure 25.23, which was performed to remove an obstructed rudimentary uterine horn, the fallopian tube was obstructed, and retrograde menstruation was impossible. Occasionally, the fallopian tube connected to the rudimentary uterine horn may not be patent because of incomplete development. Multiple case reports regarding the laparoscopic resection of obstructed uterine anlagen have supported the use of multiple techniques (stapling, bipolar or monopolar cautery, and the harmonic scalpel). Fedele and colleagues reported a series of 10 patients who have done well; however, the follow-up was only reported out to 6 months postprocedure. The authors strongly recommend the removal of the associated fallopian tube to minimize the risk of an ectopic pregnancy.

Unilateral Obstruction of a Cavity of a Double Uterus

Another example of a rare obstructed lateral fusion problem is the complete septum between two uterine cavities illustrated in Figure 25.24. One cavity communicated with a cervix and the other did not. This could represent an example of unilateral failure of cervical development. The patient reported incapacitating dysmenorrhea that appeared shortly after the menarche and lasted 5 days. A tense, cystic mass was palpable in the right half of the pelvis. The operation, described originally by Jones in the second edition of this book, consisted of making an incision through the anterior wall of the cystic right portion of the uterus. It was found to contain old menstrual blood. The entire septum was excised, and the uterus was reconstructed by anastomosis of the two cavities. A continuous lockstitch was reinforced by interrupted myometrial sutures, and the plastic reconstruction of the uterus was completed by a third layer of interrupted sutures uniting myometrium and serosa. Steinkampf and colleagues reported a similar case in a 17-year-old girl with progressive pelvic pain. The authors described an accessory noncommunicating uterine cavity, which they treated by excision at laparotomy.

Sanders and colleagues described several cases in which the role of interventional radiology was crucial in the management of obstructive anomalies. The report described the drainage of a noncommunicating right uterine cavity distended with blood in a unicornuate uterus in a 14-year-old patient. Adequate access was established by using ultrasound-guided

FIGURE 25.24. (Continued) B: The septum of the double uterus has been excised and anastomosis is performed to unite the two cavities. C: Anastomosis is completed. The small incision in the left uterine cavity was made before the septum was removed for the purpose of orientation.

Double Uterus with Obstructed Hemivagina and Ipsilateral Renal Agenesis

The unique clinical syndrome consisting of a double uterus, obstruction of the vagina (unilateral, partial, or complete), and ipsilateral renal agenesis is rare. The renal agenesis (mesonephric involution) on the side of the obstructed vagina associated with a double uterus and double cervix is suggestive of an embryologic arrest at 8 weeks of pregnancy that simultaneously affects the Mullerian and metanephric ducts. The exact cause is unknown.

Diagnostic Groups

Clinical symptoms vary depending on the uterovaginal relations in individual cases, but the syndrome can be described generally in three groups. Group 1 patients have complete unilateral vaginal obstruction without uterine communication, resulting in a paravaginal mass and symptoms of severe dysmenorrhea and lower abdominal pain. Menses are regular. Group 2 patients have an incomplete unilateral vaginal obstruction.
Bicornuate uterus
Cervical orifices
Vaginal septum
Vagina
Hematocolpos
Hematosalpinx

Figure 25.25. A double uterus with unilateral complete vaginal obstruction and ipsilateral renal agenesis. Magnetic resonance imaging reveals the left hematocolpos, both uteri, and absence of the left kidney on the side of the vaginal obstruction.

without uterine communication. The presenting symptoms are lower abdominal pain, severe dysmenorrhea, excessive foul mucopurulent discharge, and, in some instances, intermenstrual bleeding. Group 3 patients have complete vaginal obstruction with a laterally communicating double uterus. They have a paravaginal mass, lower abdominal pain, and dysmenorrhea. Menses are regular. A 10-year review of patients with this anomaly was published by Phupong and colleagues. Most patients presented with dysmenorrhea (73%) or a pelvic or paravaginal mass (71%). The right uterus and vagina were affected in 63.5% of patients.

Because menses in patients with this syndrome are rarely irregular, the possibility of this syndrome as a diagnosis can easily be overlooked. A careful pelvic examination is necessary to make the correct diagnosis. MRI can identify the obstructed vagina, double uterus, and absence of a kidney on the side of the obstruction (Fig. 25.25), but it may not be helpful if there is incomplete vaginal obstruction or a uterine communication.

Complete unilateral vaginal obstruction (group 1) can go unrecognized for a number of years after the onset of menses. The vagina is quite distensible and can accommodate a large amount of accumulated blood in the obstructed side. There is sufficient absorption of menstrual blood between periods so that each subsequent flow can add to the increments of accumulated blood without pain. Nevertheless, once retrograde menstruation occurs, endometriosis invariably is the result.

Surgical Treatment
Careful excision of the vaginal septum is the treatment of choice for a unilateral vaginal obstruction. Prophylactic antibiotics should be administered before surgery. After opening the vaginal pouch, the surgeon should use suction and lavage to remove the pooled blood and mucus. Phupong and colleagues' review also confirms the successful use of this primary therapy in 84.3% of patients. Haddad and colleagues reported a similar experience in a report describing patient management over a 27-year period. Excision of the vaginal septum was successful in 88% of patients, with complete excision in one procedure in 92% of those patients. In cases of pyocolpos or hematocolpos, distention and stretching of the septal tissue may increase the risk of inadequate resection and possible postoperative stenosis; the authors found the use of a two-step graduated resection advantageous to ensure adequate resection. A limited resection (3 cm) was performed to allow adequate drainage, followed by a return to the operating room in approximately 1 month to remove any remaining septum.

Because the obstructing septum is usually thick, removal can be difficult. Clamps should be used to isolate a generous vaginal pedicle while the suture is being tied in place to prevent slippage of tissue. Such pedicles generally retract during healing, and formation of a vaginal stenosis is avoided. In most instances, surgery is restricted to excision of the septum, and abdominal exploration is unnecessary. Uterine reconstruction is not indicated for cases of lateral communication of the uterine horns. Some authors have reported the use of hysterectomy in patients with a high, thick-walled obstruction, massive ovarian involvement, endometriosis, or adenomyosis; however, this is generally not recommended in young patients.

Reproductive Performance
Reproductive performance for patients with this disorder is usually consistent with that of patients with a double uterus unless the delay in diagnosis and resection of the obstructing septum has been sufficient to destroy tubal function or to cause the development of endometriosis. Haddad and colleagues'
review was notable for a predominance of pregnancies (80%) in the contralateral endometrial cavity.

**UNUSUAL CONFIGURATIONS OF VERTICAL-LATERAL FUSION DEFECTS**

Unusual configurations of both vertical and lateral fusion defects may occur simultaneously. Figure 25.26 depicts the radiographic evaluation (MRI) of a young woman in whom cryptomenorrhea developed above a transverse vaginal septum. The MRI study depicted the hematocolpos also suggests the longitudinal vaginal septum. Incision, drainage, and resection of the transverse vaginal septum allowed appropriate evaluation of the more proximal müllerian anatomy. The artist’s depiction in Figure 25.26 demonstrates the unusual constellation of a didelphys uterus with an intravaginal communication of the cavities and a longitudinal vaginal septum. This type of atypical combination occurs frequently enough to emphasize the importance of proper delineation of individual anatomy preoperatively for proper surgical preparation.

Müllerian duct anomalies can occur in association with a variety of other problems. For example, Stanton reported that in a series of 70 patients with bladder exstrophy, 30 (43%) had reproductive tract abnormalities. He suggested that the true figures were actually higher. Müllerian abnormalities included absence of the vagina; septate vagina; unicornuate, bicornuate, and didelphic uterus; and absent uterus. Fewer müllerian anomalies are seen with epispadias. Jones investigated anomalies of the external genitalia and vagina in 30 patients with bladder exstrophy seen at the Johns Hopkins Hospital and suggested operative techniques for correction of these anomalies. Techniques for the management of other gynecologic and obstetric problems (especially uterine prolapse) also have been discussed by Weed and McKee and by Blakeley and Mills. A number of other rare combinations of congenital malformations of the vagina and perineum have been found in association with uterine anomalies. Their surgical correction, especially in children, is reported by Hendren and Donaldson and by others. Several authors have considered the uterovaginal anomalies that occur in association with multiple other gastrointestinal and genitourinary abnormalities. Goh and colleagues described an infant girl with complete duplication of the bladder, urethra, uterus, and vagina associated with a urogenital sinus and an anterior ectopic anus. Gastol and colleagues and Magalhaes and associates also described children with complete duplication of the bladder, urethra, vagina, and anus. These complex anomalies include significantly more defects than lateral fusion concerns in the müllerian ducts. These cases emphasize the variable anatomy in this rare group of anomalies and that a substantial effort should be placed on defining anatomy before surgical exploration and management. Sheldon and colleagues reviewed 13 consecutive cases of vaginal reconstruction in pediatric patients with müllerian duct anomalies. These cases emphasize the variable anatomy in this rare group of anomalies and that a substantial effort should be placed on defining anatomy before surgical exploration and management. Sheldon and colleagues reviewed 13 consecutive cases of vaginal reconstruction in pediatric patients with müllerian duct anomalies. The review emphasized several important principles involved in the surgical management: (i) all anticipated perineal reconstruction should be performed in a single stage, (ii) urethral catheterization has an important role, (iii) urinary reconstruction is often intimately involved in the vaginal reconstruction, (iv) avoidance of overlapping suture lines is essential for optimal healing, (v) maximum growth potential of the neovagina should be considered, and (vi) meticulous follow-up of proper routine dilatation of the neovagina should be expected. Coordinated reconstruction of all organ systems is especially important in these complex cases.

Müllerian duct anomalies are seen with the McKusick-Kaufman syndrome, an autosomal recessive disorder. Other clinical findings reported with this syndrome include hydrometrocolpos, postaxial polydactyly, syndactyly, congenital heart disease, intrauterine displacement of the urethral meatus, and anorectal anomalies. In 1982, Jabs and colleagues added an unusual case to the few cases previously reported in the literature.
Müllerian duct anomalies may also affect the development of the fallopian tube. Although extremely rare, episodes of unilateral or bilateral absence of the fallopian tube have been reported. Of the less than 10 cases in the literature, Eustace reported two of the described cases. He hypothesized that compromise of the local blood supply to the caudal aspect of the müllerian duct was a more likely cause than a fusion disorder. This situation could affect fallopian tube development to a variable extent with even some effect on ovarian development.

**BEST SURGICAL PRACTICES**

- Vaginal dilation should be the first line of treatment for creation of a neovagina in patients with müllerian agenesis.
- The gynecologic literature continues to support the role of the Michod neovaginoplasty as a safe and effective procedure for surgical creation of a neovagina, when necessary.
- Appropriate preoperative evaluation of reproductive and pelvic anatomy remains a critical step before a patient is taken to the operating room for treatment of any müllerian anomaly.
- In patients with müllerian agenesis, removal of uterine lumen that contains endometrium and have the potential to cause obstruction and subsequent pelvic pain should be strongly considered.
- Hysteroscopic metroplasty is a successful, minimally invasive technique for removal of a uterine septum.
- Resection of a uterine septum has been shown to improve pregnancy success in patients with a history of recurrent pregnancy loss.
- Strassman metroplasty should be considered in select women with a bicornate uterus who have experienced recurrent pregnancy loss or preterm delivery.

CHAPTER 26 ■ NORMAL AND ABNORMAL UTERINE BLEEDING
WILLIAM J. BUTLER AND DAVID E. CARNOVALE

DEFINITIONS

Amenorrhea—The absence of menstrual bleeding for more than 6 months.

Breakthrough bleeding—Intermenstrual bleeding that occurs despite the use of exogenous hormones.

Dysfunctional uterine bleeding (DUB)—Abnormal uterine bleeding occurring in the absence of identifiable pathology. It is often subdivided into ovulatory DUB and anovulatory DUB. DUB is a diagnosis of exclusion.

Dysmenorrhea—Painful menstruation.

Interval bleeding—Bleeding between menstrual cycles.

Menorrhagia—Prolonged menstrual bleeding that is excessive in amount, duration, or both that occurs at regular intervals.

Menometrorrhagia—Menstrual bleeding occurring at irregular intervals that is normal in amount and may or may not be prolonged.

Oligomenorrhea—A menstrual cycle interval of more than 37 days.

Polymenorrhea—A menstrual cycle interval of less than 21 days.

Postmenopausal bleeding—Uterine bleeding occurring more than 12 months after the last menstrual period of a menopausal woman.

Reproductive capability in a young woman begins at the point of menarche, which is the beginning of cyclic uterine bleeding in the anatomically and physiologically normal female. Menarche marks the beginning of an important stage in a young woman’s physical reproductive maturation and development. Even before the onset of this entirely natural but potentially disturbing function, a young woman’s early psychological reactions to menstruation, and probably also her lifelong view, can be influenced by the accuracy of her information and the degree of empathy with which this knowledge has been conveyed to her.

Many women, perhaps appropriately, conclude that any departure from their personal menstrual experience is abnormal, and they will seek treatment for these departures. Conversely, some women accept or perhaps ignore even significant variations in their menstrual function, sometimes to the extent that serious health impairment occurs (e.g., severe iron-deficiency anemia).

Clinical experience has led to empiric definitions of variations in menstrual pattern that constitute abnormal uterine bleeding. Various terms are in general use to facilitate description and record keeping regarding patterns of uterine bleeding. We define above some of the terms used in this discussion.

Current medical therapies are quite effective in the management of most of the disturbances of menstrual function that occur in the absence of infection, gestation, or uterine tumor. The success of these therapies depends on a complete understanding of normal menstrual physiology and of the effects of the various agents available for treatment. New surgical diagnostic and therapeutic technologies are becoming available to aid in the management of patients who fail to respond to conventional endocrine manipulation by medical therapies.

NORMAL MENSTRUAL PHYSIOLOGY

Menstruation is the physiologic shedding of the endometrium associated with uterine bleeding that occurs at monthly intervals from menarche to menopause. In the years between these two physiologic landmarks, menstruation will occur 400 to 500 times in the average woman. According to the classical theory of the physiology of menstruation, it is the superficial functional layer of the endometrium that is shed during menstruation, and regeneration proceeds from the remaining intact basalis. Recent work in humans has confirmed the presence of endometrial stem cells, which most likely are located in niches within the basalis layer. Additionally, it appears that these progenitor cells are hormonally independent. The proliferative potential of these cells is maintained in the noncycling state as demonstrated by their ability to regenerate endometrium in postmenopausal women given hormone replacement therapy.

The amazing regenerating properties of the endometrium and its ability to support and nourish a fertilized ovum is an extremely complex system that appears to involve numerous endocrine, paracrine, and autocrine interactions. At the endometrial level, all three inhibin subunits are expressed in the human. It is believed that these dimeric glycoproteins may be involved in endometrial maturation, such as angiogenesis, decidualization, and tissue remodeling. Epidermal growth factors (EGF) are extremely important in human embryo genesis, development, and proliferation differentiation. Human endometrial cells have been shown to express all four EGF receptors and two ligands amphiregulin (AF) and transforming growth factor alpha (TGF-α). Other substances with known angiogenic properties, such as leptin and erythropoietin, have also been shown to be expressed along with their receptors by human endometrium.

This process of monthly shedding and regeneration can occur as often as it does without producing permanent tissue damage possibly because most of the functional endometrium is conserved during menses and because the metamorphosis from proliferative to secretory endometria is controlled not only by processes of cell desquamation and repopulation but also by...
dynamic and interactive processes of the endocrinologic and reproductive systems involving many organs. Any interruption of these normal but quite complex cyclic processes can lead to irregularities in endometrial breakdown and to dysfunctional uterine bleeding (DUB).

ENDOCRINOLOGY

The endometrium is an endocrine organ that responds to circulating blood levels of estrogen and progesterone. These two steroids alone are sufficient to induce growth and maturation of an endometrium that can support blastocyst implantation, as has been demonstrated by their sequential administration to patients with ovarian failure to prepare for the transfer of donated embryos. Estradiol (E$_2$) production by the developing follicle stimulates metabolic activity in the endometrium. E$_2$ has multiple effects that are mediated through binding to estrogen receptors. There are two estrogen receptors: alpha and beta. The estrogen receptors are members of a hormone receptor family that includes not only the other steroid receptors but also receptors for vitamin D and thyroid hormone. All receptors in this family have three domains. The regulatory domain at the amino acid terminal binds regulatory protein factors. The hormone-binding domain on the carboxy terminal, with its contiguous hinge region, undergoes conformational changes when a steroid hormone binds to it, allowing DNA binding. The DNA-binding domain binds to the hormone-responsive elements in the target gene. The conformation of the DNA-binding domain consists of the highly conserved zinc finger structures that interact with complementary patterns in the DNA.

Steroid hormones have relatively low molecular weights and are rapidly transported into cells by passive diffusion. Binding of a steroid hormone to the intranuclear receptors transforms the hormone receptor complex to allow DNA binding to specific hormone response elements and initiates subsequent transcription. Both estrogen and progesterone receptor complexes bind to their response elements as dimers. After gene activation, the hormone receptor complex undergoes processing with dissociation and loss of activity.

Transcription of target genes with mRNA synthesis leads to translation with synthesis of proteins on ribosomes in the endometrium. The biologic effects of E$_2$ are mediated through this protein synthesis.

Estrogen and Progesterone Receptor Induction

One important function of estrogen is the induction of synthesis of its own and other steroid hormone receptors, called replenishment. Estrogen receptors reach a maximum concentration in the middle-to-late proliferative phase of the menstrual cycle. Progesterone receptors are also induced, and their concentration peaks in the late proliferative phase. Progesterone then blocks the estrogen replenishment mechanism, possibly by accelerating receptor turnover and inhibiting E$_2$-induced gene transcription. Enough progesterone receptors persist through the luteal phase, however, to maintain endometrial responsiveness and induction of decidualization.

Estrogen and Progesterone Target Genes

Target genes of the E$_2$ receptor complex code for the synthesis of numerous proteins, including structural proteins, enzymes, and growth factors. The relative roles played by the alpha and beta estrogen receptors in the endometrium have yet to be completely elucidated. The net effect of estrogenic stimulation is to induce DNA synthesis and mitotic activity with proliferation of the endometrial glands and stroma. The result is cessation of menstrual flow and an increase in the thickness of the endometrium. Progesterone also has multiple biologic effects mediated through its receptors. It actively inhibits synthesis of both its own receptors and estrogen receptors, although sufficient progesterone receptors remain throughout the luteal phase of the cycle to mediate maturation and secretory differentiation of the endometrium. The net effect is to antagonize estrogenic metabolic activity with suppression of DNA synthesis in endometrial cells, which results in dynamic inhibition of cell mitosis. Progesterone is also responsible for the active induction of synthesis of various cytoplasmic enzymes, the secretion of proteins such as prolactin-dependent and progesterone-dependent endometrial peptide from decidualized stromal cells, and the stabilization of lysosomes, all of which may play an important role in the onset of menstruation.

Histology and Physiology

The postmenstrual endometrium that remains after collapse and partial shedding during menstruation consists of a thin but stable layer of basal cells and the dense irregular remnants of the stromal cell-derived stratum spongiosum. The glands are narrow and lined by low cuboidal epithelial cells with few mitoses. The glandular stromal cells are small and spindly with little cytoplasm or mitotic activity. Protein synthesis and secretory activity are minimal. It is on this substrate of basal and stromal cells that estrogen induces a proliferative response.

Early Proliferative Phase

Mitic activity results in growth and pseudoproliferation of the glandular epithelial cells. With development and elongation of the glands, the epithelial cells assume a more columnar shape, with secretory granules in the cytoplasm, and glycogen begins to collect in the basal vacuoles. Arteriolar vessels grow up into the endometrium as part of the general proliferative response. The stromal cells also proliferate and expand from a dense compact state to an expanded matrix by transient edema. The combined effects of proliferation and expansion cause the endometrium to grow in this phase to a thickness of 3 to 5 mm. The increased mitotic activity that results in proliferation is mediated by way of estrogen induction of various peptide growth factors. Epidermal growth factor and insulin-like growth factor 1 (IGF-1) are two potent mitogens with synthesis that is stimulated by estrogen in endometrial epithelial and stromal cells. Endothelin-1 is a vasoactive peptide with mitogenic activity; its synthesis is induced by both estrogen and growth factors, and its metabolism is enhanced by progesterone. Endothelin-1 may play a role in proliferation and in menstruation. The various peptides that are secreted from stromal and epithelial cells to form the extracellular matrix of the endometrium can be either induced or suppressed by both estrogen and progesterone. Fibronectin, for example, is suppressed by progesterone, whereas several integrin subtypes are stimulated by progesterone. These peptides may have a functional role in proliferation, differentiation, and embryo implantation.
Angiogenesis allows both repair of the endometrium after menstruation and supports cellular proliferation for regrowth during the follicular phase. It is supported and promoted by multiple growth factors. An important role is played by vascular endothelial growth factor (VEGF). VEGF mRNA expression is induced by E2 and increases from the early proliferative phase through the secretory phase (Torry and Torry). VEGF is produced by the glandular epithelial cells, although some stromal expression is evident in the secretory phase. The increased expression throughout the cycle supports a possible role of VEGF in expansion and coiling of the spiral arteries. Changes in VEGF expression have been detected in women with abnormal uterine bleeding, supporting a possible role in the pathogenesis of menorrhagia [Koooy et al.].

E2 induces several enzymes [alkaline phosphatase, Su-reductase, and possibly phospholipase A2]. Phospholipase A2, which releases arachidonic acid from phospholipid esters, controls the rate-limiting step in prostaglandin synthesis. E1 also stimulates cyclooxygenase synthesis of prostaglandin F2α (PGF2α) and prostaglandin E2 (PGE2), both of which have a role in menstrual function. PGE2 has vasodilator and muscle contraction effects. PGF2α is generally a vasodilator but can also cause contractions in uterine smooth muscle. Alterations in the relative levels of PGF2α and PGE2 are known to change menstrual bleeding patterns.

Late Proliferative Phase

Ovulation with corpus luteum formation and significant progesterone secretion leads to secretory transformation in the late proliferative-phase endometrium. Progesterone inhibits both estrogen and progesterone receptor synthesis and inhibits DNA synthesis and mitosis. This inhibition process is accompanied by predecidual development of RNA-filled channels between the nucleoli and nuclear membranes that are responsible for the progesterone-induced active synthesis of cytoplasmic enzymes during the secretory phase of the cycle.

The Secretory Phase

The cytoplasmic enzymes 17β- and 20α-hydroxysteroid dehydrogenase (HSD) are induced by progesterone and modulate steroid activity. The enzyme 17β-HSD catalyzes the conversion of E2 to the relatively weaker estrogen estrone, which, when sulfated by estrogen sulfotransferase, can no longer bind to estrogen receptors. The enzyme 20α-HSD alters progesterone receptor binding and activity. Cytoplasmic lytic enzymes such as acid phosphatase are also induced by progesterone but are kept inactive within Golgi-derived lysosomes, the membranes of which are stabilized by progesterone. IGF II is synthesized locally by the endometrial cells and possibly also from leukocytes. The release of lysosomal enzymes from activated leukocytes may be involved in the initiation of menstruation.

Late Secretory Phase

Progesterone has also been induced to produce the activity of metalloendopeptidase, which degrades the endothelin-1 propeptide. Withdrawal of progesterone can lead to increased endothelin-1 activity with vasospasm and initiation of menstrual bleeding. Several investigators have described increased levels of protease inhibitors, such as α1-antitrypsin and antithrombin III, in secretory-phase uterine fluid, which may also be involved in the mechanism of menstrual bleeding.

The Luteal Phase

Morphologically, secretory transformation of the endometrium results in coiling of the spiral arteries, the deeper spongiosum. The spongiosum has a loose edematous matrix that is the consequence of increased capillary permeability, mediated possibly by prostaglandins. The predecidual, late secretory-phase stromal cells produce several metabolically active substances, as previously described, and are infiltrated by migratory leukocytes. The release of lysozyme enzymes from endometrial cells and possibly also from leukocytes may be involved in the regulation of menstruation.

Menstruation

Menstruation is controlled by many complex, interrelated, and incompletely understood factors. Normal menstruation results from progesterone withdrawal from the estrogen-primed endometrium. Changes that occur in the endometrium during menstruation were described by Markle by observation of endometrial tissue transplanted to the anterior chamber of the eyes of rhesus monkeys. Markle described cyclic changes in endometrial vascularity and the development of coiled vessels supplying the superficial two thirds of the endometrium. The endometrium of the follicular phase is compact, with relatively underdeveloped vasculature. Progesterone converts this endometrium into a thick, edematous, secretory lining that is glycogen enriched and prepares the metabolically active stroma and glands with an increased vasculature to receive and nourish a fertilized ovum. If implantation does not occur, estrogen and progesterone levels fall, prostaglandin synthesis occurs, and lysosomal membranes rupture, causing constriction of the spiral arterioles, ischemic necrosis, and sloughing of the endometrial superficial to the basal layer. Lysosomal release and ischemic necrosis has been believed to be the main mechanism for normal menstrual bleeding for many years. However, the difficulty in detecting cell necrosis during menstruation and viability of menstrual fragments has raised a number of questions about this theory. Current data support the “metalloproteinase theory” as the mechanism leading to menstrual tissue breakdown and shedding. Matrix metalloproteinases (MMPs), lytic enzymes in conjunction with activated endometrial stromal granulocytes, macrophages, and mast cells together are now thought by most investigators to cause menstruation. It is believed that tissue inhibitors of metalloproteinases (TIMPs) remain constant throughout the menstrual cycle. Before menstruation, production and activation of MMPs increases in an environment of stable amounts of TIMPs, leading to an altered MMPs/TIMPs ratio, resulting in tissue breakdown. Estrogen and progesterone, along with cytokines, appear to play a significant role in the regulation and expression of the MMPs. High levels of progesterone are
believed to inhibit MMP production and activity. This would explain endometrial tissue breakdown that occurs coincident with dropping progesterone levels from an involuting corpus luteum.

In the second part of the menstrual phase, mitotic activity resumes, and epithelial regeneration begins. This process occurs even while menstrual bleeding continues. Horizontal growth from stem cells of the glands present in niches within the basalis layer continues the regenerative process. New blood capillaries are formed by the stimulating effect vascular endothelial growth factor (VEGF) and thymidine phosphorylase (TP) secreted by both epithelial and stromal cells. Continuous processes of stem cell activity is ensured by high telomerase activity.

This process begins in the premenstrual phase of the cycle with cessation of synthesis and impregnation of ground substance and supporting tissues by lytic enzymes released from lysosomes, which causes loss of fluids and compression of the endometrium, tonic contractions of spiral arteries with reduction of blood flow to the tissues, loss of stromal edema, and kinking of the coiled spiral arteries caused by the reduction in endometrial thickness.

A generalized state of ischemia develops in the superficial layers of endometrium, and bleeding into the stroma begins. Acid phosphatase and prosta-glandins substances released from autolyzed cells, together with increased endothelin-1 activity, cause more intense vasoconstriction of spiral arteries, and devitalized tissues finally slough as small hemorrhages in the stroma coalesce. According to Fehley, coagulation factors are decreased in normal menstrual discharge. Fibrogenin is absent, plasminogen is converted to plasmin by released peptidases, and the amount of plasmin inhibitor is decreased. Menstrual blood generally does not clot, but it can form red blood cell aggregates with mucoid substances, mucoproteins, and glycogen as it collects in the vagina. These red cell aggregates may appear to be blood clots, but they contain no fibrin. In the presence of very heavy flow, however, clotting can occur.

According to classical theory, during menstruation the superficial compacta and the intermediate stratum spongiosum layers of the endometrium are shed, leaving only the basalis layer intact. New endometrium is regenerated from the basalis. Regeneration of new capillaries from the basalis has been observed by Markee, and restoration of the endometrial circulation has been correlated with the cessation of menstrual bleeding. Blood loss from the process of normal menstruation is limited by recovery of tone in the myometrium and endometrial vasculature, cessation of cellular autolysis, eventual clotting over the endometrial surface, and eventual active regeneration of glands, stroma, and vessels in the basalis layer in response to rising estrogen levels in the new cycle. The retained basalis endometrium is protected from destruction by lysosomal enzymes by a mucinous carbohydrate coat that covers the free surfaces of endometrial cells. This mechanism for retention of some endometrium during menstruation may explain the lack of permanent damage during the months of menstruation.

Endometrial regression during menstruation is described by classical theory as the result of four processes: autophagia, heterophagia, extravasation of secretory products, and elimination of fluids with some, but not complete, shedding of tissue. Autophagia and heterophagia are the kindred processes of intracellular lytic digestion of debris in vacuoles and of extracellular lytic digestion of debris taken up by phagosomes. Both processes result in damaged tissue to allow regeneration of normal endometrial cells. With fluid loss and secretion, the functionalis (the remaining functional basalis) regresses to a resting state, ready to regenerate in the next cycle. These two processes can only partially explain the observation that initial endometrial regeneration occurs in the absence of estrogen. This initial lack of estrogen dependence can also be secondary to the lesser proliferative response required after regression, compared with complete endometrial shedding. Much work remains to be done to define the complex processes involved in menstruation.

Given the complexities and varieties of possible alterations of the systems that control menstruation, it is not surprising that abnormal uterine bleeding should occur even in the absence of obvious disease. Prolonged estrogen stimulation can result in endometrium that outgrows its blood supply and has asynchronous development of endometrial glands, stroma, and blood vessels. Any failure of progesterone production can also profoundly affect endometrial glands, stroma, and blood vessels. Abnormal synthesis of acid mucopolysaccharides can result in the release of excessive amounts of hydrolytic enzymes into the stroma. Lysosome release from endometrial glands, influenced by plasma progesterone levels, can affect menstrual flow. The endometrium and myometrium of patients with menorrhagia produce altered types of prosta-glandins. Smith and associates have shown that the amount of menstrual flow is influenced by a change in the endometrial conversion of prosta-glandin endoperoxide from PGE2 to PGF2, and that women with menorrhagia synthesize mainly the vasodilator PGE2 in the endometrium.

Menstruation has three clinical characteristics: the menstrual interval or cycle length, and an amount of flow. The mean cycle length is 28 to 29 days, although a menstrual interval of 21 to 37 days can be considered normal. A menstrual interval shorter than 21 days is defined as oligomenorrhea. A menstrual interval longer than 37 days is defined as oligomenorrhea. Amenorrhea is the absence of menses for 6 months or longer. The menstrual interval can vary from month to month by several days. Regularity of the menstrual cycle is more important than exact approximation to the 28-day mean menstrual interval. Variation in the length of the menstrual interval in regular ovulatory cycles usually occurs in the preovulatory (proliferative) phase of the cycle and is more frequent among postmenarchal teenagers and in women approaching menopause.

A duration of flow of 7 days or less is considered normal. A patient bleeding beyond 7 days enters the intermenstrual phase of the cycle, which is defined as metrorrhagia. Regardless of the length of the menstrual flow, 70% of the blood loss usually occurs by the second day and 90% by the third day. The mean menstrual blood loss for a normal period is about 40 mL. A total blood loss of 20 to 80 mL, representing 10 to 35 mg iron, has long been accepted as within the normal range. Menstrual blood loss of 80 mL or less was established as the upper limit of normal, as this is the 95th percentile in healthy women with normal iron stores measured in a population of Swedish women in the 1960s. Clinically, the use of such a statistical cutoff for a value that is not likely to be measured and is likely to vary among populations depending on diet, health, and genetics is very limited. Additionally, it has recently been shown that the 80 mL value has neither the sensitivity or specificity for disease, compromised iron status, or adverse impact of periods. The determination of the normalcy of menstrual bleeding amount is better addressed in the context of the particular
Normal and Abnormal Uterine Bleeding

DYSFUNCTIONAL UTERINE BLEEDING

DUB is a symptom complex that includes any condition of abnormal uterine bleeding in the absence of pregnancy, neoplasia, infection, or other intrauterine lesion. Such bleeding is most often the result of endocrinologic dysfunction that inhibits normal ovulation.

Chronic Anovulation and Dysfunctional Uterine Bleeding

The state of chronic anovulation is the result of unopposed estrogen stimulation of the endometrium with consequent irregular breakthrough and bleeding. Chronic anovulation syndrome is a “wastebasket” diagnosis for multiple endocrine etiologies. Hyperthyroidism and hypothyroidism, hyperprolactinemia, hormone-producing ovarian tumors, and Cushing disease are all endocrine syndromes that can induce anovulation, but they are not, therefore, true DUB patients by strict definition.

Diagnostic Imaging Techniques

Diagnostic vaginal ultrasound can be particularly useful in cases of ovulatory abnormal uterine bleeding. A nonrandomized study of 45 otherwise unselected patients with abnormal uterine bleeding demonstrated anatomic pathology in 31% by vaginal ultrasound compared with 9% by clinical examination. Pathologic findings included leiomyoma uteri, polyps, and abnormal endometrial architecture. If these data are confirmed by later studies, the implication is that true DUB in ovulatory patients may be even more rare than the currently accepted figure of 15% to 20%. Endovaginal ultrasound is also of particular value in cases of perimenopausal and postmenopausal abnormal bleeding, which will be discussed later (Fig. 26.1). Saline infusion sonography (SIS) is a technique to improve visualization of the endometrial cavity during transvaginal ultrasonography. The technique involves a pelvic examination with placement of an open-sided bivalve speculum. The cervix is prepared with antisecretonic solution, and a small catheter is inserted through the cervical os for instillation of sterile saline. A number of catheters are available both with and without small balloons, which are useful in the case of a parsus cervix. The speculum is then removed, and the endometrial cavity is descended with sterile saline during transvaginal ultrasonography. Deutsch and colleagues compared the accuracy of saline infusion sonography with transvaginal sonography, hysteroscopy, and magnetic resonance imaging (MRI). In 108 patients with abnormal uterine bleeding, pain, endometriosis, or myomas,
SIS had an overall sensitivity comparable to the gold standard of hysteroscopy and better than either MRI or transvaginal sonography. MRI had the highest sensitivity for submucous myomas, but a relatively low sensitivity for other intrauterine pathology, such as polyps. As SIS is a less invasive procedure than a surgical technique, such as hysteroscopy, and is much less expensive than MRI, it should be the procedure of choice for imaging of the endometrial cavity in patients with abnormal uterine bleeding.

Proper evaluation of abnormal bleeding in the ovulatory patient demands assessment for other less common causes of bleeding. According to Claessens and Cowell, bleeding dyscrasias are particularly common in perimenarchal patients, up to 19% of whom have a primary coagulation disorder, such as idiopathic thrombocytopenic purpura or von Willebrand disease. An ad hoc consensus conference that met in May 2004 concluded that underlying hemostatic disorders were a more common cause of menorrhagia in adult women than has been currently recognized (Munrow and Lukes). The most common of these coagulopathies is von Willebrand disease. The incidence of von Willebrand disease in the general population has been estimated at 0.8% to 1.3%. The consensus conference calculated, by review of the literature, an incidence of 13.2% (range 11.2%–15.5%) in healthy women with menorrhagia. Conversely, women with von Willebrand disease report menorrhagia in 78% to 93% of patients. Other inherited disorders of hemostasis are relatively rare. Other disorders of platelet number and function have variable effects on menstrual bleeding, depending on their severity. Treatment of abnormal uterine bleeding secondary to coagulopathy may involve medical management with tranexamic acid, desmopressin acetate (DDAVP), hormonal therapy, or a progesterin-containing intrauterine device (IUD). Endometrial ablation is also appropriate in these patients.

Hemorrhagic diatheses can occur with leukemia, with chemotherapy treatment, or as secondary to oral anticoagulant therapy or ingestion of foods or drugs that inhibit platelet aggregation. Infection has been shown to cause abnormal uterine bleeding. Mobiluncus species identified in cases of abnormal bleeding respond to oral metronidazole therapy. Chlamydia has been implicated in abnormal bleeding, particularly with concurrent use of oral contraceptives. Menorrhagia has been described as an early symptom in patients with subclinical hypothyroidism before diagnosis of overt disease. Thyroid replacement in a normal physiologic dosage will resolve the abnormal bleeding.
Arteriovenous malformation is a very rare cause of ovulatory bleeding. In a report by Fleming and colleagues, only two cases were diagnosed before definitive surgery; the diagnosis was by pelvic angiography.

The reported association between tubal ligation and new onset of abnormal uterine bleeding should also be noted. Although numerous anecdotal reports exist, no underlying pathologic changes in anatomy or hormone production have ever been documented. Long-term follow-up studies do not confirm an increased incidence of abnormal bleeding in these patients but do implicate biased patient perception. Patients who discontinue oral contraceptive use after tubal ligation have heavier and more painful bleeding, whereas patients who have intrauterine devices removed after sterilization have improved menstrual symptomatology.

Pathophysiology

As stated earlier, the most common etiology for DUB is estrogen withdrawal or estrogen breakthrough bleeding in an anovulatory patient. In the absence of progesterone exposure to cause inhibition of DNA synthesis and mitosis, the estrogenic proliferative response causes stromal cell growth to exceed the structural integrity of its stromal matrix, and the endometrium breaks down with irregular bleeding. Unopposed estrogen results in vascular endometrial tissue with relatively scant stroma, giving glands a back-to-back appearance. The endometrium is fragile and undergoes repetitive spontaneous breakdown. In the absence of normal control mechanisms to limit menstrual blood loss, bleeding can be prolonged and excessive.

Other contributing factors are the lack of coordinated vasoconstriction and the release of lytic enzymes, which occurs in a normal progesterone-stimulated endometrium. The absence of progesterone stimulation of metalloendopeptidase increases endothelin-1 activity, which contributes to vasospasm. Lysosomal enzymes inappropriately released in the absence of progesterone stimulation of the lysosomal membrane further contribute to structural breakdown.

Many questions still remain about the mechanisms responsible for all cases of DUB. Although the above makes sense in certain circumstances, it does not explain clinical scenarios such as bleeding unresponsive to hormonal manipulation after structural lesions have been ruled out. The same lytic enzymes, MMPs, and their inhibitors involved in normal menstrual bleeding have been found to have aberrant locally restricted expression, activation, and uncontrolled activity in the endometrial tissue biopsy specimens from women with metrorrhagia.

Hemostasis in a bleeding endometrium depends both on coagulation, with thrombus formation forming plugs in superficial blood vessels, and on vasoconstriction of spiral arterioles; generalized endometrial collapse with compression of bleeding vessels can also contribute. The lack of coordinated vasoconstriction and the irregular structural collapse lead to irregular and often heavy bleeding. The amount of bleeding correlates directly with the level of estrogen stimulation. The chronic high estrogen milieu seen in cases of obesity and chronic anovulation, and in perimenarchal and perimenopausal patients, cause the greatest amount of DUB blood loss.

Unopposed estrogen stimulation can, over time, induce a hyperplastic response in the proliferating endometrium (Fig. 26.2A). Such hyperplasia can eventually develop the cytologic changes associated with neoplasia: atypical adenomatous hyperplasia or even low-grade adenocarcinoma. Such cellular transformation takes time, as much as 10 to 20 years; a young patient with DUB has a low risk of hyperplasia or neoplasia and generally does not require endometrial sampling. The perimenopausal patient has a substantially higher risk, however, and sampling is mandated.

Making the Differential Diagnosis

DUB occurs most frequently at the extremes of menstrual life, but it can develop at any intervening time. The characteristics of DUB are variable, from infrequent heavy flow (oligomenorrhea) to almost continuous spotting or bleeding. The age at onset and duration of irregularity can provide important
clues to etiology. Anovulation is common in the perimenopausal woman. More than 50% of cycles are anovulatory in the first 2 years after menopause. Complications of pregnancy are also common in this age group and must be ruled out before initiation of treatment for DUB. New sensitive radiocommunooassays for the beta subunit of human chorionic gonadotropin are accurate for evaluating the possibility of pregnancy without invasively confirming it as these assays are not foetal specifically. Anovulatory bleeding is common with polycystic ovarian disease, with functional cysts of the ovary, and perhaps in some cases of luteal phase deficiency. The patient workup for abnormal uterine bleeding should include a complete history and physical examination. Pelvic examination may disclose an abnormal mass, evidence of genital trauma or laceration, or a fibroid uterus. Laboratory studies should include thyroid function tests and the evaluation of levels of human chorionic gonadotropin, FSH, LH, prolactin, and serum androgens, if indicated. A significant increase in dehydroepiandrosterone sulfate indicates a need to screen for nonclassical adrenal hyperplasia. A serum progesterone level measurement is useful for assessment of ovulatory status. A complete blood count with platelet and coagulation studies is appropriate, and a bleeding time may be indicated to assess platelet function. As mentioned earlier, endovaginal ultrason and SN are valuable adjuncts to pelvic examination. They are particularly informative for assessment of intruterine or extraterine pregnancies and pelvic masses detected on examination. Occasionally, they may also reveal anatomic pathology not detected by other means (Fig. 26.1). Invasive tissue-sampling procedures include endometrial sampling and D&C. A D&C is preferable in the perimenopausal or postmenopausal patient and may also be indicated when there is clinical suspicion of an abnormal pregnancy. A D&C is relatively contraindicated in the adolescent. Hysterosalpingography and hysteroscopy also have potential benefit and will be reviewed later in this chapter.

**Treatment**

Because most patients with DUB have an underlying etiology of chronic anovulation with unopposed estrogen stimulation of the endometrium, medical treatment with progestational compounds is the mainstay of therapy. Precise amounts can differ depending on the patient's age, but adequate progestin stimulation of the endometrium will usually decrease uterine bleeding. Submucous leiomyomata and endometrial polyps can be present in older women but are not a problem in the differential diagnosis of adolescents. Excessive anovulatory bleeding is common with polycystic ovarian disease, with functional cysts of the ovary, and perhaps in some cases of luteal phase deficiency. The patient workup for abnormal uterine bleeding should include a complete history and physical examination. Pelvic examination may disclose an abnormal mass, evidence of genital trauma or laceration, or a fibroid uterus. Laboratory studies should include thyroid function tests and the evaluation of levels of human chorionic gonadotropin, FSH, LH, prolactin, and serum androgens, if indicated. A significant increase in dehydroepiandrosterone sulfate indicates a need to screen for nonclassical adrenal hyperplasia. A serum progesterone level measurement is useful for assessment of ovulatory status. A complete blood count with platelet and coagulation studies is appropriate, and a bleeding time may be indicated to assess platelet function. As mentioned earlier, endovaginal ultrason and SN are valuable adjuncts to pelvic examination. They are particularly informative for assessment of intruterine or extraterine pregnancies and pelvic masses detected on examination. Occasionally, they may also reveal anatomic pathology not detected by other means (Fig. 26.1). Invasive tissue-sampling procedures include endometrial sampling and D&C. A D&C is preferable in the perimenopausal or postmenopausal patient and may also be indicated when there is clinical suspicion of an abnormal pregnancy. A D&C is relatively contraindicated in the adolescent. Hysterosalpingography and hysteroscopy also have potential benefit and will be reviewed later in this chapter.
Failure to withdraw could signify pregnancy, development of a hypoestrogenic state, or, rarely, induction of ovulation by progestin stimulation of the estrogen-primed patient. In such a case of endogenous progesterone production, the menopause can be delayed 2 weeks. A word of caution: This regimen is not contraceptive.

An alternative method for delivery of a progestin to control DUB in patients using a progestin-impregnated IUD. Numerous studies have demonstrated significant reductions in menstrual blood loss in patients using the progestin-impregnated IUD. Xiao and colleagues showed reductions of more than 80% at up to 16 months. Irwin and associates performed a randomized trial of 44 women with menorrhagia, comparing a levonorgestrel IUD with cyclic progestin therapy. The IUD group had blood loss reduced by 90%, along with higher patient satisfaction, compliance, and continuation. A comparison of endometrial resection with the levonorgestrel IUD showed highly significant decreases in menstrual blood loss with both treatment arms (Kauaruma et al.). The incidence of complications was similar in both groups, and 3-year follow-up rates were similar. Seventeen percent of the resection group required follow-up surgery. Other studies have shown a significant cost benefit to use of the levonorgestrel IUD compared with surgical management of abnormal uterine bleeding, including hysterectomy. As noted earlier, the levonorgestrel IUD has also shown to be effective in controlling menorrhagia in patients with hemostatic disorders such as von Willebrand disease.

Chronic unopposed estrogen can produce a very lush endometrium that can bleed heavily during progestin withdrawal. Speroff and colleagues recommend treatment using combination oral contraceptives in a step-down regimen. Two to four pills are given daily, one every 6 to 12 hours, for 5 to 7 days for effective control of bleeding. This will usually control acute bleeding within 24 to 48 hours, allowing time to complete the diagnostic evaluation. Withdrawal of medication will result in a heavy bleed. On the fifth day of this bleed, a low-dose cyclic oral contraceptive is started and repeated for three cycles to allow orderly renaturation of the provisional proliferative endometrium. Alternatively, the dosage of combination pills can be tapered (four times a day, then three times a day, then two times a day) over 3 to 6 days and then continued at one pill every day. Combination oral contraceptives induce atrophy of the endometrium because the chronic estrogen–progestin exposure suppresses pituitary gonadotropins and inhibits endogenous steroidogenesis. They are useful for long-term management of DUB in patients without contraindications and have the added benefit of pregnancy prevention. Particularly in perimenarcheal patients, heavy prolonged bleeding can denude the basal endometrium and make it unresponsive to progestins. Curetage for control of hemorrhage is contraindicated because of a high risk of development of intrauterine synchiaria (Asherman syndrome) if the basalis is curetted. High-dose intravenous estrogen (conjugated estrogens 25 mg every 4 hours until bleeding abates) will give acute control by proliferative repair of the endometrium and by direct effects on coagulation, including increased fibrinogen and platelet aggregation. Megestrol 20 mg twice daily is also an excellent method for obtaining acute control of abnormal uterine bleeding without the side effects of intravenous estrogen treatment. It will be effective in any situation other than one in which the entire endometrium has sloughed, leaving only basalis. A progestin alone or oral contraceptive in combination with a progestin can then be used to induce orderly withdrawal bleeding.

Hysterectomy of patients who fail to respond to hormonal therapy may reveal previously missed pathology, such as a submucous myoma or polyp. These diagnoses are particularly common in patients with ovulatory dysfunctional bleeding. If a diagnostic curettage has not been previously performed, one can be performed in conjunction with the hysteroscopy, both for diagnosis and for temporary therapy. If atypical hyperplasia has been identified and preservation of fertility is desired, more aggressive progestin therapy is recommended. Medroxyprogesterone acetate, 30 mg in local instillation, may be given as a single dose or divided dosage for 3 months should be monitored by repeat endometrial sampling to assess the efficiency of the medical treatment (Fig. 26.2B). If atypical hyperplasia persists, very high-dose progestin protocols can be tried, but hysterectomy must be considered.

Menorrhagia can be reduced when prostaglandin E2 and progestins are synthesized are decreased by nonsteroidal anti-inflammatory medications. These drugs inhibit the cyclooxygenase enzyme necessary for endometrial production of prostaglandin under estrogen stimulation and thus alter the relative production of the proaggregation vasoconstrictor thromboxane A2 and the antiaggregation vasodilator prostacyclin. Pathology studies have confirmed that this improves both platelet aggregation and vasoconstriction. Fraser and colleagues (1991) demonstrated these compounds to be most effective when given in therapeutic dosages for 7 to 10 days before the expected onset of the next menstrual period in ovulatory DUB patients, but they are commonly started with the onset of menses and continued throughout the bleeding episode with good success.

For coagulation disorders, 1-desamino-8-arginine vasopressin (also known as desmopressin, or simply DDAVP) increases coagulation factor VIII with a therapeutic effect lasting about 6 hours. It is best administered intravenously, 0.3 µg/kg in 50 mL saline over 15 to 30 minutes, but can be used intranasally. Antifibrinolytic agents such as tranexamic acid and traxanamic acid can decrease blood loss up to 50%, but their significant central nervous system and gastrointestinal side effects and the purported risk of intracranial arterial thrombosis have traditionally limited their applicability. New data do not support a significant thrombotic risk, and tranexamic acid is widely available in Europe for use in menorrhagia. Ergot derivatives are ineffective for treatment of menorrhagia.

Local delivery of progestational agents is an important advance in the treatment of abnormal uterine bleeding. Numerous studies have demonstrated significant reductions in menstrual blood loss in patients using the progestin-impregnated IUD. Ablation or destruction of the endometrium has been advocated for treatment of chronic abnormal bleeding unresponsive to medical management in the presence of a normal endometrial cavity and the absence of submucous leiomyomata, endometrial hyperplasia, or neoplasia. Although there has been significant disagreement regarding the appropriate indications for this procedure, it has been widely applied with varying success. The original methods included use of hysteroscopy with the Nd:YAG laser, electrosurgical roller-ball cauterization, or endometrial resection using a loop electrode. These hysteroscopic surgical techniques require special training. More recently, new techniques have been described to ablate the endometrial cavity without the requirement for hysteroscopy. These include thermal balloon ablation, direct instillation of heated saline, cryoablation with a cryoprobe, microwave endometrial ablation, and use of radiofrequency electromagnetic energy (Corson et al.; O’Connor and Magos; Rutherford et al.; Sharp et al.; Singer et al.; Winberg et al.). Success rates reported with the various techniques have ranged from 60% to 95% of patients achieving either hypomenorrhea or amenorrhea. Pretreatment with danazol, GnRH analogs, or suction curettage to thin the endometrium appears to improve long-term success rates (Brooks; Donnez et al.). Seeras and Gilliland reported resumption of menstruation in 44% of women after ablation if they had not received preoperative endometrial suppression.

A number of comparison studies have looked at success rates of the various techniques to determine relative efficacy, complication rates, and relative cost. Meyer and colleagues compared roller-ball ablation with thermal balloon ablation in a prospective, randomized trial. A greater percentage of women in the roller-ball group (27.2%) were amenorrheic at their 12-month follow-up than were women in the uterine balloon group (15.2%). The rates of hypomenorrhea plus amenorrhea were not significantly different (balloon, 80.2%; roller ball, 84.3%). Overall patient satisfaction was equivalent. The complication rate was 3.2% in the hysteroscopic roller-ball group with no significant intraoperative complications in the thermal balloon group. A comparison of thermal balloon ablation with the progesterin-containing IUD showed similar results as far as overall satisfaction; however, bleeding scores were lower and amenorrhea rates higher in the IUD group (Busfield et al.). Corson, with follow-up by Goldrath, performed a prospective randomized trial of endometrial ablation using the Hydro ThermAblator (HTA; Boston Scientific Corporation, Natick, MA, USA) versus roller ball (Figs. 26.3 and 26.4). This system uses heated saline flowing free under low pressure to ablate the endometrium under hysteroscopic guidance. Success rates for both groups were comparable at 3 years with amenorrhea rates of 53% for HTA and 46% for roller ball, and overall satisfaction rates of 98% and 97%, respectively. There were no significant differences in complication rates or repeat surgical procedures.

The Novasure system (Cytyc Corporation, Palo Alto, CA, USA) uses radiofrequency current through a mesh electrode that conforms to the endometrial cavity to ablate the endometrium. Tissue desiccation is rapid compared with thermal devices and requires no pretreatment of the endometrium. The overall success rate of 88.3% and amenorrhea rate of
was done. though in most cases, no direct endometrial cavity assessment was attributed to the possible presence of intrauterine synechiae, although overall patient satisfaction rates were equivalent. Difficulty of surgery and mean fluid deficit were both described as greater in the resection group. Comparison of endometrial ablation with laser versus endometrial resection showed equivalent amenorrhea rates of approximately 45%, with overall patient satisfaction rates of 90% (Battacharya et al.).

Operative hysteroscopic techniques require specialized training, and complications, although relatively infrequent, can be significant. A multinational survey in The Netherlands reported an overall complication rate for hysterectomy of 0.28% (Janssen et al.). Diagnostic hysteroscopy had a significantly lower complication rate than that of operative hysteroscopy (0.13% vs. 0.95%). The most frequent surgical complication was perforation (0.2%). Reported complication rates for hysteroscopic ablation procedures are significantly higher. O’Connor and Magos followed 25 women for up to 5 years after endometrial resection. They reported a 6% incidence of intraoperative complications and a 3% incidence of postoperative complications. They also reported a 1.5% complication rate in patients who required a repeat ablative procedure. The “Misterette” survey from the Royal College of Obstetricians and Gynaecologists recorded endometrial resection complications rates of 7.2% but only 4% for roller-ball and laser ablations (Overton et al.). A prospective trial of thermal balloon versus roller-ball ablation reported intraoperative complications in 3.2% of the roller-ball patients but no significant intraoperative complications in the thermal balloon patients (Meyer et al.). Reported complications include uterine perforation with hemorrhage, laser or electrosurgical damage to the bowel, excessive absorption of distending medium with fluid overload, hynapertasia and pulmonary edema, and persistence of bleeding requiring repeat ablation or hysterecopy. The reported complication rates do compare favorably with reported morbidity rates for women undergoing hysterecopy, which range from 7% to 15% (Summitt et al.).

There is concern regarding the potential outcome of pregnancies conceived after endometrial ablation. A literature review by Koo et al. reports a miscarriage rate of 21.7%, a preterm rate of 26.1%, and a perinatal mortality rate of 11.8%. Of those pregnancies that continued beyond 20 weeks, 35.3% resulted in a miscarriage or stillbirth. These outcomes were attributed to the possible presence of intrauterine synchiea, although in most cases, no direct endometrial cavity assessment was done.

Another concern has been possible obliteration of warning signs heralding the development of endometrial carcinoma, with subsequent delay in diagnosis. Endometrial ablation procedures usually result in a narrowed tubular uterine cavity without the obliteration seen in Asherman syndrome, but are rarely expected to result in total ablation of all endometrial tissue. Several cases of postablation endometrial carcinoma have now been reported (Brooks-Carter et al., Copperman et al.). The cost of endometrial ablation does compare favorably with that of hysterecopy, with hysterecopy reported as 58% more expensive when all costs, including lost work time, are considered (Vilos et al.).

D&G is both diagnostic and therapeutic. Removal of the structurally fragile bleeding endometrium allows restoration of normal hemostatic events, with regeneration of the integrity of the endometrium and restoration of the normal proliferative response. If the patient fails to respond to medical therapy, repeated curettage, or even endometrial ablation, then more definitive therapy, such as hysterectomy, should be considered, taking into account the age of the patient and her desire for future childbearing. It has been estimated that 2 million women in the United States are seen annually with reports of excessive uterine bleeding, and about $50,000 undergo hysterectomy, which accounts for 20% to 30% of all hysterectomies performed.

In general, the ovulatory type of bleeding has the poorest response to replacement hormonal therapy and the highest incidence of recurrence. Although hysterectomy can be considered an admission of therapeutic defeat, it is frequently an expedient method of resolving this refractory and recurrent type of DUB. When bleeding persists after repeated curettage and cyclic hormonal therapy, hysterecopy may be required. If other conditions are present that should be corrected surgically, such as a relaxed vaginal outlet, rectocele, cystocele, or uterine descensus, we recommend vaginal hysterectomy with support of the vaginal vault and repair of the vaginal wall relaxation. When hysterectomy is indicated in premenopausal women younger than 50 years of age, normal ovarian tissue is conserved. In a patient younger than 30 years of age, radical surgical treatment should be strongly avoided; one can almost always control uterine bleeding by repeated curettage or by increasing amounts of cyclic hormone therapy. Today, the availability and use of estrogen and progesterone have changed the need for hysterectomy to treat DUB. Hysterecopy is not indicated in young women but may be indicated in older women when hormonal therapy and repeated curettage have failed.

Blood transfusions are seldom required when DUB is associated with anemia, but they may be given if the anemia is so severe that symptoms are present. Oral iron therapy should be started at the first sign of heavy menstruation to prevent depletion of iron stores, and it should be given for 3 to 6 months after normal hemoglobin and hematocrit levels have been restored in patients with iron-deficiency anemia.

**PERIMENOPAUSAL AND POSTMENOPAUSAL BLEEDING**

When uterine bleeding occurs more than 12 months after the last regular menstrual period, it is defined as postmenopausal bleeding. For a period varying from months to years before menopause, the individual patient may experience irregular patterns of bleeding. Often the first sign is a shortening of the menstrual interval secondary to premature elevation in FSH, followed by intermittent periods of amenorrhea.
altering with heavy bleeding consistent with oligoovulation or anovulation. With this clinical picture, special consideration must be given to ruling out a neoplastic process as the source of the bleeding. The first diagnostic consideration is to ensure that the bleeding originates from the uterus. In elderly women especially, bleeding from the urethra or rectum may be reported as vaginal bleeding. Vaginal or cervical lesions causing the bleeding should be diagnosed readily with careful inspection or biopsy. Cancers of the vagina or cervix or cervical polyps can also be readily diagnosed and appropriate treatment rendered.

When the source of the bleeding is determined to be the uterine cavity, sampling of the endometrium for pathology examination is usually considered to be mandatory. Although D&C continues to be a commonly performed procedure for both its diagnostic and therapeutic benefits, office endometrial biopsy can often expedite appropriate evaluation and therapy. Many instruments have been devised for the sampling of endometrial tissue and evaluation of the endometrial cavity. The standard instrument used for many years has been the Novak curet. Although this curet was initially devised to obtain a sample of the endometrium by suction and aspiration, it is most commonly used as a miniature curet that contains a serrated edge surrounding its biopsy aperture. The curet is about 5 mm in diameter and can usually be passed without dilatation through a small cervical canal, even in nulliparous women. Occasionally, the postmenopausal cervical canal is stenotic and difficult to penetrate. Because of the discomfort associated with passage of the Novak curet, newer plastic curets have been developed. These have a smaller diameter (3 mm), are flexible, and are often better tolerated by patients. They can be difficult to pass through a truly stenotic cervix because of their pliability. Often there is an accompanying syringe that attaches and develops effective vacuum pressure to improve the size of the sample obtained (Fig. 26.5). A four-quadrant endometrial biopsy with passes along the anterior and posterior and both lateral walls of the endometrial cavity is recommended for diagnosis of abnormal bleeding. Another potentially useful device not requiring a syringe to develop negative pressure is a disposable plastic tube with a 3.1-mm outer diameter, an aspiration port, and solid plastic obturator at its tip. The obturator fits so closely that its slow withdrawal from the uterine cavity causes sufficient suction to obtain an adequate endometrial specimen in most cases (Fig. 26.6). However, the endometrial surface area sampled is small (5%) and can easily miss polyps, submucous myomas, and endometrial carcinoma that occupies only a small portion of the endometrial cavity (Guido et al.). Because of the small aperture of this device and its almost total reliance on suction to obtain a specimen, the architecture of the obtained biopsy may be somewhat distorted.

Vacuum suction curettage has gained some popularity as an office procedure for endometrial sampling that does not require general anesthesia. A small metal or plastic cannula with an outside diameter of 3 mm that has a slightly curved tip and an opening on the concave surface for easier insertion through a small endocervical canal is connected to a plastic collection chamber, which in newer models is a large syringe rather than the old pumps or faucets. Several studies have compared the results of suction curettage with those of regular curettage under anesthesia in the same patient. Cohen and colleagues...
studied 98 patients; in 93, they found identical histologic patterns with both methods. In five patients, there was no correlation between the results of the two techniques, and none of these had cancer. At the Medical University of South Carolina, Luttz and colleagues found suction curettage to be 98% accurate in evaluating high-risk women with abnormal bleeding for endometrial malignant disease.

These new agents, or no cervical dilatation and permit almost painless endometrial sampling. A quick-acting, nonsteroidal antinflammatory drug (e.g., 320 mg naproxen sodium, administered 15 to 30 minutes before curettage provides satisfactory anesthesia for most patients. If dilatation of the cervix is required, paracervical block anesthesia can be initiated by injecting 4 to 5 ml of 1% lidocaine at the 3-o’clock and 9-o’clock positions in the paracervical tissues, exercising care to avoid intravascular injection. The principal value of an endometrial biopsy is that it provides a firm diagnosis. Under anesthesia has been avoided if the removed tissue contains adenocarcinoma. If the cause of postmenopausal bleeding is not identified in a screening endometrial biopsy, however, then a standard curettage is obligatory. In office biopsies of the endometria of more than 20,000 patients of all ages, Hofmenseh detected 273 cases of endometrial carcinoma, 32 of which (14.2%) were totally asymptomatic. The endometrial carcinoma detection rate was 1.76% of the total group of 23,202 patients. Hofmeister’s routine office endometrial biopsies using a modification of the Novak and Randall curet provide one of the largest clinical experiences of this instrument to date. Unfortunately, only patients who had continued uterine bleeding or who demonstrated an atypical pattern in the office biopsy were subjected to a complete curettage. Therefore, the true-negative and false-negative rate for the Novak type of curet in the detection of endometrial cancer has not been documented accurately. In a series of 100 patients, summarized by Cohen and colleagues, the accuracy of detection of endometrial cancer by endometrial curettage varied from 76% to 92%. However, a thorough endometrial curettage under anesthesia is also not infallible in the detection of endometrial cancer. Bettiocchi and colleagues evaluated the diagnostic accuracy of endometrial curettage in 397 patients. D&C failed to detect intrauterine pathology in 62.5% of patients, including four cases of complex hyperplasia and five cases of endometrial adenocarcinoma as well as many endometrial polyps and submucous myomas. Vaginal ultrasound has been investigated as a screening tool in patients with postmenopausal bleeding. The average thickness of the postmenopausal endometrial stripe has been reported as 2.3 ± 1.8 mm, with a range of 0 to 10 mm, in a series of 300 asymptomatic women. Twenty-two had endometrial stripes of 3 mm or larger, and all had benign pathology. In a series of 51 cases of postmenopausal bleeding, Naar and colleagues reported that if the endometrial thickness was less than 3 mm, the pathology would show either inactive or no endometrial tissue. Karlsson and associates reported on 1,168 women with postmenopausal bleeding. Patients with an endometrial echo of less than 4 mm had a sensitivity of 96% and a specificity of 68% for detecting endometrial pathology. If a 5-mm cutoff was used, two endometrial carcinomas would have been missed. In another study by Gull and colleagues, 198 women screened for postmenopausal bleeding had an endometrial thickness of 5 mm or greater. Endometrial sampling diagnosed 36 primary endometrial cancers, one metastatic breast cancer, and three cases of atypical endometrial hyperplasia. Of the 5-mm cutoff was used, two endometrial carcinomas would have been missed. In another study by Gull and colleagues, 198 women screened for postmenopausal bleeding had an endometrial thickness of 5 mm or greater. Endometrial sampling diagnosed 36 primary endometrial cancers, one metastatic breast cancer, and three cases of atypical endometrial hyperplasia. Of the patients older than 40 years of age in the absence of specific contraindications, such as hypertension, hyperlipidemia, and smoking. They provide excellent cycle control with a monthly withdrawal bleed and suppression of the endometrium. Oral
contraceptives can be continued until an FSH level greater than 40 IU/L during the week of placebo pills confirms ovarian failure. Standard postmenopausal hormone replacement can then be used. A sequential program of 12 days of progesterin, 5 to 10 mg medroxyprogesterone acetate, or 5 mg norethindrone acetate on a monthly basis is an alternative and is continued until failure of withdrawal bleeding occurs, indicating the need for further hormone replacement. Recent studies indicate that perimenopausal patients are relatively hypoestrogenic and can be at risk for accelerated bone loss before the actual onset of menopause, some clinicians recommend concurrent estrogen replacement even in the perimenopausal patient.

Endometrial hyperplasia requires more aggressive progesterone treatment. Atypical adenomatous endometrial hyperplasia is considered by most to be the equivalent of an intraepithelial malignancy, and hysterectomy is often advised. Management of several types of endometrial hyperplasia other than atypical adenomatous hyperplasia can generally be accomplished by monthly administration of a progestin such as medroxyprogesterone acetate, 10 mg per day for 12 days, or norethindrone acetate, 3 mg per day for 12 days. Another endometrial biopsy should be obtained within 3 to 6 months to assess for resolution of the hyperplasia. A more aggressive hormonal regimen uses continuous high-dose progestin for 3 to 6 months (i.e., megestrol, 20 to 160 mg per day).

Any of the regimens currently in use for postmenopausal hormonal replacement therapy can cause uterine bleeding. Unopposed estrogen is no longer recommended for postmenopausal hormonal replacement in the case of an intact uterus because hyperplasia develops in 18% to 32% of cases and because unopposed estrogen has an up to sevenfold increased risk of endometrial carcinoma. Cyclic estrogen-progestin regimens significantly decrease this risk to less than 1% to 3.5% during 10 to 12 days of progestin. There are numerous dosage regimens for the use of conjugated estrogens, 0.625 to 1.25 mg, micronized E2, 1 to 2 mg, esterified estrogens, 0.625 to 1.25 mg, and E2 patches. Although estrogen replacement therapy can cause uterine bleeding. Continuous estrogen and low-dose progestin replacement therapy (i.e., conjugated estrogen, 0.625 mg, and medroxyprogesterone acetate, 2.5 mg) are commonly accompanied by irregular bleeding patterns for at least 4 to 6 months after initiation of the regimen. They are used with the anticipation that over months of use, the proportion of women becoming completely amenorrheic will increase, and for most women, the long-term benefits with these regimens will outweigh those of the conventional cyclic regimen, in which most women bleed regularly at the conclusion of the progestin phase of the cycle for at least 6 to 24 months. As a general rule, just as intermenstrual bleeding during the regular menstruating years dictates investigation and management, so do patterns of postmenopausal bleeding not following an anticipated schedule require investigation and management. Thus, the most important point about postmenopausal bleeding is its frequent association with gynecologic malignancy, particularly endometrial carcinoma. Although the incidence of malignancy to explain postmenopausal bleeding has decreased in recent decades, diagnostic efforts must carefully consider and rule out possible malignancy by use of appropriate diagnostic procedures, especially careful pelvic examination and uterine curettage. An endometrial biopsy is helpful for the diagnosis of suspected endometrial carcinoma only if the biopsy is positive. The definitive method for obtaining adequate histology for diagnosis is D&C.

**DILATATION OF THE CERVIX**

Recamier invented the curet in 1943. Since then, dilatation of the cervix with curettage of the endometrial cavity has become the second most frequently performed gynecologic procedure in the United States. Curettage is used to diagnose uterine malignancy, to complete an incomplete or missed abortion, to evaluate the causes of infertility, to relieve dysmenorrhea, and to control DUB. Improved medical therapies for DUB and dysmenorrhea have made dilatation of the cervix and curettage of the uterus less necessary for these two problems, especially in young women.

Dilatation of the cervix is performed as a preliminary step to curettage of the uterine cavity. As a therapeutic measure, it is used for acquired or congenital cervical stenosis, for dysmenorrhea, for introduction of intracervical and intrauterine radium or cesium, occasionally for insertion of an intrauterine contraceptive device, or for allowing drainage of the uterine cavity in the presence of pyometra, as well as a part of other operations on the cervix.

Most indications for cervical dilatation are obvious. In connection with primary dysmenorrhea, however, there is room for controversy. It is a recognized fact that many cases of primary dysmenorrhea are not cured by cervical dilatation. Because of frequent failures, some gynecologists have almost abandoned it as a therapeutic technique. We do not subscribe totally to this pessimistic point of view. Unfortunately, in most instances, it is impossible to detect those cases of dysmenorrhea that will be relieved by cervical dilatation. Often the operation must be performed as a therapeutic test, but it is fortunately such a minor procedure that its performance is justified on that basis.

In nulliparous women in whom pain is greatest just before or during the early part of the menstrual flow, there is a possibility of relief from the pain by cervical dilatation. The result is unpredictable, however, and we advise permitting the patient to decide whether menstrual pain is sufficiently severe to justify an operation that is of limited or possibly no benefit.

Ibuprofen, naproxen sodium, and mefenamic acid have proved to be so effective in the management of dysmenorrhea that a thorough trial of these agents is indicated. It is now evident that endometriosis can occur much earlier than was once believed; dysmenorrhea unrelied by these nonsteroidal antiinflammatory drugs or oral contraceptives should be considered an indication for laparoscopy.

**Postmenopausal Cervical Stenosis**

In cases of postmenopausal cervical stenosis, pyometra may be discovered by uterine sounding. The pus should be cultured for anaerobic and aerobic organisms, and the cervix should be dilated. A short, soft, rubber or plastic tube can be sutured in place to keep the cervical canal open while the uterine cavity is draining. Although antibiotics may not be strictly necessary in all cases, fever and pelvic pain and tenderness herald the onset of spreading pelvic infection.
Curetting a pyometra can produce parametritis or wider pelvic cellulitis. Because the risk of perforation, with the potential for development of serious peritonitis, is increased during curettage, it should be delayed until adequate drainage has occurred (3 to 10 days, depending on the magnitude of the pyometra), and antibiotic therapy should be used. Curettage is mandatory to exclude the endocervical or endometrial malignancies frequently associated with pyometra.

**Technique of Cervical Dilatation**

The patient is placed on the table in the lithotomy position. A careful pelvic examination locates the position of the uterine corpus, and the vagina and the perineum are cleaned with the usual vaginal preparation of povidone-iodine (Betadine). The cervix is grasped with a four-pronged tenaculum (Fig. 26.7A) and gently drawn toward the vaginal outlet. I favor the straight Jacobs clamp, especially when difficult dilatation is anticipated or encountered. It is much less likely to cause cervical laceration than is the single-tooth tenaculum. A sound (Fig. 26.7B) is passed carefully through the cervical canal into the uterine cavity to avoid creating a false passage. Resistance is greatest at the internal cervical os. Occasionally, a fine silver probe is needed for finding the proper passage if the canal is stenotic. Passing the uterine sound provides confirmatory information about the position of the uterus, the length of the uterine cavity, and the angulation between the cervical canal and the uterine cavity. The degree of stenosis of the cervical canal can be detected in this manner. Sounding the uterus is contraindicated in the presence of a pregnancy because of the increased risk of perforating the soft myometrium.

The cervical canal is dilated with a small Hegar dilator (Fig. 26.8). The uterine wall can be perforated by improper passage of the dilator; the cause usually is lack of knowledge or disregard of the position of the uterus. When acute anteflexion is present, the dilator can perforate posteriorly (Fig. 26.9). When retrodisplacement exists, the perforation usually occurs anteriorly (Fig. 26.10). These two complications can be avoided by sounding the uterine cavity before dilating the cervix and by following the direction of the endocervical canal and uterine cavity indicated by the sound. The dilator rarely perforates the fundus except when there is an atrophic postmenopausal uterus or when an invasive tumor or pregnancy has softened the uterine wall. After either the 3- or 4-mm Hegar dilator is passed, successively larger ones are used. For ordinary curettage, dilatation to 8 or 9 mm suffices. When the dilatation is for dysmenorrhea, we prefer to carry the dilatation up to 10 mm. Be aware of concerns that excessive dilatation can be associated with an incompetent cervix in a subsequent pregnancy. If cervical dilatation is difficult, half-size Hegar dilators with incremental diameters of 0.5 mm are useful (Fig. 26.8).
FIGURE 26.9. Perforation of the acutely anteflexed uterus. The uterus was thought to be in retroposition, and the Hegar dilator was erroneously directed posteriorly.

The Hank-Bradley dilator has the shape and contour of the Hegar dilator but has a more tapered shank (Fig. 26.11), with the advantage of a hollow center, which prevents any piston effect that might force air into the uterine cavity during progressive dilatation of the cervix. The positive pressure created within the uterine cavity by passing a Hegar dilator can cause blood, endometrium, fragments of neoplastic tissue, or infected material to be forced into the fallopian tubes or peritoneal cavity. Beyth and colleagues have demonstrated that significant numbers of patients have endometrial tissue in their peritoneal fluid after curettage, and there is a possibility of reflux of endometrial carcinoma cells into the peritoneal cavity with forceful dilatation of a postmenopausal cervix harboring endometrial carcinoma. In the small postmenopausal uterus, however, it is quite easy for the tip of the Hank-Bradley dilator to perforate the uterine fundus when one is attempting to achieve the maximum dilating effect from the widest portion of the instrument.

The Hank-Bradley dilator is used more commonly during curettage for an incomplete abortion because it permits the release of blood through the dilator while the cervix is being dilated. When dilatation is for removal of placental tissue, dilatation up to no. 19 or 20 Hank-Bradley (the equivalent of a 9- or 10-mm Hegar dilator) is often necessary to permit the introduction of a large blunt curet and placental forceps. The cervix is most resistant to dilatation at about 8 mm. Cervical injury is a potential problem when the cervix is forcefully dilated to a larger diameter. The cervical tenaculum can lacerate the cervix, or the internal cervical os can be damaged. Tapered Pratt dilators require less force than blunt Hegar dilators.

The incidence of cervical incompetence can be related to the degree of cervical dilatation. Insertion of laminaria into the cervical canal several hours before cervical dilatation can make the procedure less difficult and traumatic, as suggested by Manabe and Manabe.

CURETTAGE OF THE UTERUS

Indications and Contraindications

It is important that D&C be performed for the proper indications, be performed correctly to obtain the most useful information, and be performed safely. A curetage performed properly and with aseptic technique involves little risk, but if precautions are disregarded, complications and even death can result.

The chief purpose of curettage of the uterus is the removal of endometrial or endocervical tissue for histologic study of cases of abnormal uterine bleeding. Although classical curettage of the uterus continues to be a useful procedure, new practices...
and instrumentation permit the procurement of endometrium as a screening diagnostic test under many circumstances. Appropriate use of such procedures can reduce significantly the need for operating room curettage. Careful pelvic examination under relaxation anesthesia has been an important adjunctive diagnostic aid to conventional D&C, but the precision and availability of ultrasound and other imaging techniques have brought them to the forefront of importance in diagnosis.

**Outpatient Curettage**

Over the years, there have been efforts to lower the cost of D&C by making it an outpatient procedure. In 1957, Vermeer and associates presented a series of 10,000 minor gynecologic operations performed on an outpatient basis on the gynecologic service at the Johns Hopkins Hospital. The results were more than satisfactory. These women were usually operated on under general anesthesia and were discharged after recovery from anesthesia. D&C was the operation most frequently performed. The success and safety of such a program depend, of course, on the careful selection of patients and the willingness of the practitioner to admit a patient for observation should complications occur. Today, D&C is often performed satisfactorily on an outpatient basis or in an ambulatory surgery center. Reports by Sandmire and Austin and by Martin and Rast are among many that record favorable experiences with this procedure.

As mentioned earlier, endometrial sampling today is often performed by biopsy, suction, or D&C as an office procedure. Although these relatively easy outpatient techniques for evaluating endometrium histology can often provide a correct diagnosis, they do not fulfill the requirement of a thorough curettage for absolute determination of the etiology of uterine bleeding. One can have total confidence in the biopsy or office curettage findings only if they show frank adenocarcinoma. If the histology of the office procedures is negative, one cannot rule out this serious condition. Even in the most experienced hands, endometrial carcinoma can be quite elusive. A further note of caution is that none of the office endometrial sampling methods can ensure the removal of an endometrial polyp. Therefore, endometrial carcinoma in a polyp could be missed, as could a polyp that is a source of benign bleeding. Office sampling techniques are used only as screening procedures; if the results are negative, a more thorough D&C under general anesthesia is indicated. Office hysteroscopy can sometimes be an alternative to D&C to identify missed pathologies, such as a polyp or a submucous myoma, or to allow directed biopsy of a suspicious endometrium.

Indications for obtaining endometrial histology by one or more of the aforementioned methods include the following:

- Abnormal bleeding at any premenopausal age, especially when not corrected promptly by medical management, in women older than 35 years of age, or if a submucous myoma is suspected (include hysteroscopy or hysterosalpingography)
- Postmenopausal bleeding of any amount, regardless of a finding of atrophic vaginitis, polyp, or uterine curettage
- Prehysterectomy in the postmenopausal woman to exclude endocervical or endometrial carcinoma
- Postmenopausal vaginal surgery without hysterectomy

When office procedures fail to establish the diagnosis, it is preferable to use a general anesthetic during D&C. The procedure is more comfortable for the patient and easier to perform with the patient fully relaxed, and most patients will opt for a general anesthetic for this procedure. A D&C, under general anesthesia also provides an ideal opportunity for thorough examination of the pelvic organs. Before the examination, the bladder should be empty and the cervix should have been given and expelled. The pelvic examination should be performed after the anterior abdominal wall is relaxed from the anesthesia and before the patient is draped. Occasionally, new and important pelvic findings will be discovered. In a study of 2,666 women requiring curettage, McKlin and colleagues found unanticipated adnexal masses in 30 women during pelvic examination under anesthesia before D&C. Twenty-eight masses were benign, and two were malignant. When women who are serious medical risks require curettage for postmenopausal bleeding, the operation is performed without anesthesia other than hypodermic or intravenous administration of a sedative combined with paracervical nerve block.

A single curettage will not remove all of the surface endometrium completely from the uterine cavity. Repeated studies have demonstrated the inability of a thorough curettage to remove more than 50% to 60% of the endometrium when the procedure has been performed by experienced gynecologists immediately before a planned hysterectomy. Stock and Kanbour, from McGee Hospital in Pittsburgh, observed that in 60% of hysterectomy specimens studied, less than 50% of the endometrial surface had been removed by a prehysterectomy curettage. They also found 26 cases of endometrial carcinoma that had been classified as clinically normal-appearing tissue on prehysterectomy curettage; six of these carcinomas were reported as benign on frozen section. These facts and other similar experiences indicate that it is difficult to be certain of the histology of the endometrium by gross examination of the curetted. If the symptoms warrant a curettage, then the endometrium deserves a full histologic diagnosis.

Curettage is also performed for bleeding from a cervical stump and is frequently performed as part of a cervical conization to rule out extension of cervical carcinoma into the endometrium. Helmkamp and associates found no evidence of endometrial abnormalities in any of 114 curettage specimens removed at the time of 114 cervical conizations. These investigators recommend that curettage at the time of cervical conization should not be performed routinely but should be performed selectively in postmenopausal and perimenopausal patients when the cytology smear shows abnormal glandular cells or when an intrauterine abnormality is suspected.

The chief contraindication to curettage is infection. Acute endometritis and salpingitis are conditions under which curettage should be avoided. If curettage is necessary for removal of infected placental tissue, it should be preceded by a period of parenteral antibiotic therapy adequate to achieve therapeutic tissue levels of antibiotics. Endometriums associated with retained products of conception will remain unresolved until the infected necrotic material is cast off spontaneously or until it is removed by the curet. Curettage is also contraindicated when pyometra is present.

**Technique of Curettage of the Uterus**

After the patient is anesthetized and placed in the lithotomy position, the bladder is emptied with a catheter. The pelvic organs are examined thoroughly before the patient is prepped and draped. The procedure includes a bimanual recto-abdominal examination. The examination under anesthesia is one of the most informative features of this operation because it can provide anatomic details of the reproductive tract that are

unrecognizable without anesthesia. The vagina and perineum are cleaned with the usual technique.

Fractional curettage is an attempt to remove tissue samples from the endocervical canal apart from tissue removed from the endometrial cavity. The cervical canal should be curetted before dilatation of the cervical canal and curettage of the endometrial cavity. The special shape of the small Gusberg curet makes it particularly useful for curettling the endocervix. Differential curettage of the endocervix, separate from the endometrium, is important for diagnosis of endometrial carcinoma that may have extended to the endocervix. All cases of perimenopausal bleeding should be fractionally curetted; this procedure is too often neglected. If the endocervical curettage is not performed, a second fractional curettage is required to determine the anatomic boundaries of endometrial carcinoma. The value of fractional curettage has been questioned, but Chen and Lee and others have emphasized the importance of cervical stromal invasion, rather than the finding of tumor tissue, as the crucial criterion in endocervical curettage affecting staging and prognosis.

The uterine cavity is then sounded to determine its size and to confirm the position determined from examination under anesthesia. The cervical canal is dilated with the Hegar or Hank-Bradley dilator. A dilatation to 8 or 9 mm by a Hegar dilator is sufficient for the usual diagnostic curettage. A gauze is placed in the posterior vaginal fornix along the posterior retractor so that the blood and the endometrium removed from the uterus can fall on it (Fig. 26.12). Before the curettage is performed, the uterine cavity is explored for endometrial polyps by use of a narrow stone forceps (Fig. 26.13). This forceps can be opened and closed as the tip of the forceps is moved systematically across the dome of the uterus and the anterior and posterior walls. An endometrial polyp can be easily missed with an ordinary curet, and unnecessary hysterectomies have been performed because of supposed persistent or recurrent dysfunctional bleeding after a curettage (Fig. 26.14). If polyp forceps are routinely used, such operations can be avoided. It is easier to identify and remove an endometrial polyp if the uterine cavity is explored with the stone forceps before the uterus is curetted. In a 28-month period during which forceps were used routinely at the Johns Hopkins Hospital, Josey found that endometrial polyp was diagnosed 130 times. In 83 of these cases, the polyp was removed by forceps. Although the sessile form of a submucous myoma is diagnosed easily by noting an irregularity of the uterine wall with the curet, the pedunculated variety, like the endometrial polyp, can escape detection because of its narrow stalk. Often, such a leiomyoma can be grasped with the polyp forceps. A uterine septum can also be detected with the forceps. Alternatively, hysteroscopy can be used to evaluate the cavity before curettage.

A small-sized or medium-sized, malleable, bluntly serrated curet (Fig. 26.15) is then introduced into the uterus, and the entire uterine cavity is systematically curetted. The anterior, lateral, and posterior walls are scraped gently but firmly, and finally, the top of the cavity is scraped with a side-to-side movement (Fig. 26.16). The handle of the curet should never be held against the palm of the hand. Instead, it should be held gently, as one would hold a pencil. The instrument is held loosely as it is inserted for the full distance. Pressure is then exerted...
against the uterine wall as the curet is drawn in an outward direction. Because the instrument is malleable, its curvature can be changed to conform to the contour of the uterine cavity. A uterine "cry," vibrations felt in the hand holding the curet, is often used as a sign that adequate tissue has been removed.

The unclotted blood is absorbed quickly by the gauze sponge, leaving the relatively clean endometrium to be placed in a prepared container with appropriate fixative. Again, the curettings should never be mashed or scraped but should be picked carefully from the sponge with a smooth-tip forceps and placed immediately in the fixative. The curettings should be examined carefully at this time for fatty tissue or other unusual tissue. Fragments of hyperplastic endometrium sometimes appear tan or yellow.

When curettage is performed as a curative measure for removal of placental tissue, a large, blunt, smooth curet is used to lessen the possibilities of perforation and endometrial sclerosis. The larger and softer the uterus, the larger the curet should be and the more care one should exercise to avoid these complications. When large masses of placental tissue are present, ovum forceps are most useful when used in conjunction with the curet. High vacuum suction is now used almost routinely for placental tissue removal.

Routine blind biopsy of the cervix is usually unrewarding if a negative cytologic smear has been obtained and there is no suspicious cervical lesion. We no longer do a blind biopsy of the cervix at the time of curettage unless an abnormal lesion is present. If a patient’s recent cytologic results are normal and she has a profuse, recurrent, mucous discharge associated with cervicitis and nabothian cysts, cervical cauterization or laser vaporization can be done at the time of curettage, but biopsy confirmation to exclude occult malignancy should be obtained.

Complications of Cervical Dilatation and Uterine Curettage

If the position and the consistency of the uterus are carefully observed on bimanual examination under anesthesia before curettage is begun, perforation will rarely occur. When the position of the uterus is not known to the operator, perforation occurs with remarkable ease. Special care should be exercised with a uterus that is acutely anteverted or retroverted. With cervical stenosis, pregnancy, or intrauterine malignancy, perforation is more likely. The postmenopausal atrophic uterus can be perforated with only slight force applied to the uterine sound or the curet. Perforation is discovered when the sound or the curet fails to encounter resistance where it normally should, as judged by the palpated size of the uterus. Abdominal ultrasound visualization of the uterus, cervix, and endocervical canal, which may require a distended bladder, can be useful in guiding the passage of either a dilator or a curette through the endocervical canal into the endometrial cavity.
Perforation by the uterine sound or cervical dilator causes less damage than perforation by the sharp curet or suction cannula. Sharp curettage for legally induced abortion has a major complication rate that is two to three times higher than that for suction curettage, according to Grimes and Cates. The two principal dangers of uterine perforation are bleeding and trauma to the abdominal viscera. Lateral perforation through the uterine vessels is especially dangerous from the standpoint of intraperitoneal hemorrhage and broad ligament hematoma formation. Damage can occur to the bowel, omentum, mesentery, ureter, and fallopian tube. Perforation of the anterior or posterior wall of the uterus by a small curet in performing a diagnostic curettage is usually not a serious accident. However, it is usually necessary to discontinuous curettage. One must watch carefully for signs of hemorrhage or infection. If signs of hemorrhage develop, the abdomen should be opened and the uterine wound sutured. If signs of infection occur, broad-spectrum antibiotics should be given. If a pelvic abscess develops, the abscess should be drained if possible. Serious hemorrhage or infection occurs only rarely. When serious damage from perforation is suspected, laparoscopy can be performed to assess the extent of the damage and the needed repair. According to MacKenzie and Bibby, complications occurred in 1.7% of cases of D&C. McElin and colleagues reported that 0.5% of cases had postoperative febrile morbidity after D&C. Uterine perforation occurred in 0.63% of cases.

Perforation by the uterine sound or cervical dilator causes less damage than perforation by the sharp curet or suction cannula. Sharp curettage for legally induced abortion has a major complication rate that is two to three times higher than that for suction curettage, according to Grimes and Cates. The two principal dangers of uterine perforation are bleeding and trauma to the abdominal viscera. Lateral perforation through the uterine vessels is especially dangerous from the standpoint of intraperitoneal hemorrhage and broad ligament hematoma formation. Damage can occur to the bowel, omentum, mesentery, ureter, and fallopian tube. Perforation of the anterior or posterior wall of the uterus by a small curet in performing a diagnostic curettage is usually not a serious accident. However, it is usually necessary to discontinuous curettage. One must watch carefully for signs of hemorrhage or infection. If signs of hemorrhage develop, the abdomen should be opened and the uterine wound sutured. If signs of infection occur, broad-spectrum antibiotics should be given. If a pelvic abscess develops, the abscess should be drained if possible. Serious hemorrhage or infection occurs only rarely. When serious damage from perforation is suspected, laparoscopy can be performed to assess the extent of the damage and the needed repair. According to MacKenzie and Bibby, complications occurred in 1.7% of cases of D&C. McElin and colleagues reported that 0.5% of cases had postoperative febrile morbidity after D&C. Uterine perforation occurred in 0.63% of cases.

Perforation of the anterior or posterior wall of the uterus by a small curet can be managed conservatively with antibiotics and serial hematocrit determination for 24 to 48 hours. If there is no evidence of continued bleeding or developing infection, the patient can be discharged. During laparoscopy, if there is any evidence of intestinal injury or any suspicion of such injury, or if bleeding is significant, then laparotomy is mandatory. Unfortunately, bowel injury by high-vacuum suction may require bowel resection and anastomosis.

Perforation of a pregnant uterus is a more serious complication than is perforation of the nonpregnant uterus. First, there is the requirement that all remaining pregnancy tissue be completely removed to prevent sepsis. To accomplish this blindly when there is a defect in the uterine wall is unsafe. Second, the pregnant uterus is a much more vascular organ than is the nonpregnant uterus, and intraperitoneal bleeding can be profuse without significant external bleeding. Third, it often is difficult to be certain when the perforation occurred. If a high-vacuum suction curettage has passed through the myometrium and the vacuum has been activated, major bowel injury can be present.

These considerations have led to the following protocol for D&C of the pregnant uterus:

1. Never activate the vacuum suction if there is any question about the safe location of the curet within the uterine cavity.

2. Laparoscope any pregnant uterus that is possibly perforated. With the laparoscope in place, a second operator can evacuate remaining placental tissue while the laparoscopist monitors safety. Many perforations in which no other visceral damage has occurred are fundal. If laparoscopic observation confirms that bleeding is minimal, the perforation can be managed conservatively with antibiotics and serial hematocrit determination for 24 to 48 hours. If there is no evidence of continued bleeding or developing infection, the patient can be discharged.

3. During laparoscopy, if there is any evidence of intestinal injury or any suspicion of such injury, or if bleeding is significant, then laparotomy is mandatory. Unfortunately, bowel injury by high-vacuum suction may require bowel resection and anastomosis.

Figure 26.17 shows a uterus removed immediately after a perforation because of intraperitoneal bleeding. Word analyzed 70 accidental uterine perforations. Among these, an unplanned hysterectomy was performed on seven unprepared patients. In none of these cases did the intraperitoneal findings indicate the need for hysterectomy. In fact, hysterectomy compounded the surgical error. Fifty-five patients were treated conservatively, and only one developed a complication, in the form of a pelvic abscess that was drained by colpotomy. Forty-one of the 70 perforations occurred in postmenopausal women.

When a large, boggy, postabortion or puerperal uterus is perforated by a large curet or placental forceps in removing placental tissue, there is more danger of hemorrhage, infection, or injury to bowel. The treatment protocols and the procedures...

for these serious complications are discussed elsewhere in this textbook.

Asherman syndrome is a pathologic condition of intrauterine adhesions that can cause secondary amenorrhea, other menstrual irregularities, infertility, or recurrent abortion. Numerous investigators have shown a strong association between puerperal D&C and the formation of synechiae that can partially or completely obliterate the endometrial cavity. No incidence figures are available because no prospective studies have been performed, but factors other than pregnancy that increase the risk of endometrial sclerosis after D&C are infection, scant endometrium that exposes the basalis to trauma, and a hypoestrogenic state. Rarely, significant synechiae are seen in the absence of an antecedent curettage. Cases have been reported after severe endometritis, tuberculosis, myomectomy, and cesarean section. Diagnosis is made by clinical history, hysterosalpingography, or hysteroscopy. Therapy requires lysis of adhesions by repeat curettage or, preferably, by hysteroscopic scissors or KTP laser.

Patency of the uterine cavity is maintained with an intrauterine device or balloon catheter, and endometrial regeneration is stimulated by oral estrogen therapy. The prognosis with significant adhesions is poor. Only 40% of patients will become pregnant, and about half of these will undergo spontaneous abortion or premature delivery. Consideration should be given to the risks of adhesions that might be missed on endometrial sampling.

BEST SURGICAL PRACTICES

- Although hysteroscopy is the gold standard for evaluating endometrial cavity pathology, saline infusion sonography (SIS) has comparable sensitivity and is less invasive and less expensive.
- historic data showed higher amenorrhea rates with endometrial ablation using endomyometrial resection. However, newer techniques of hydrothermal ablation, radiofrequency current, and microwaves have comparable amenorrhea rates. Hydrothermal ablation has the advantage of visualization of the endometrial cavity, radiofrequency ablation does not require endometrial pretreatment, and microwave endometrial ablation has been reported to be successful in the presence of small submucous myomata.
- Endometrial sampling can be done by Pipelle, four quadrant endometrial biopsy, or formal dilatation and curettage (D&C). All of these techniques can miss significant lesions, and the concurrent use of vaginal ultrasonography or SIS will improve sensitivity.
- Hysteroscopy is a valuable adjunct to D&C, particularly in the patient at higher risk for focal endometrial pathology that might be missed on endometrial sampling.
- Abdominal ultrasound guidance may reduce the risk of complications such as perforation during difficult cervical D&C, such as in the stenotic postmenopausal patient or in the case of a large uterus.

Surgery for Benign Gynecologic Conditions

CHAPTER 27 ■ TUBAL STERILIZATION
HERBERT B. PETERSON, AMY E. POLLACK, AND JEFFREY S. WARSHA

DEFINITIONS

Air embolism—Potential complication of laparoscopic abdominal insufflation with the Veress needle, associated with “vapour lock” of the right ventricle, which occludes blood flow and results in cardiovascular collapse. A “cog wheel” murmur can sometimes be heard.

Bipolar coagulation—Method of tubal occlusion usually performed via laparoscopy that causes electrocoagulation of the tube when current is applied by grasping forceps; one jaw of the forceps is an active electrode, and the other is a return electrode. There is less chance for unintended thermal injury than with unipolar coagulation, and the chance of unintended thermal injury by capacitive coupling is virtually eliminated. However, less widespread thermal destruction of the tube increases the chance for sterilization failure relative to unipolar coagulation unless the surgeon uses techniques that maximize the likelihood of adequate tubal coagulation.

Capacitive coupling—Unintended consequence of laparoscopic use of unipolar coagulation, which under certain conditions can result in a charge being transferred to the operative laparoscope or conductive laparoscopic sheath. Subsequent occult transferral of this charge to intestines can lead to thermal injury and subsequent infectious morbidity or mortality.

Cumulative failure rates—Contrary to previous beliefs, tubal sterilization failures are not isolated to a narrow window of time after the procedure, but rather increase cumulatively with each passing year following sterilization. Younger women, who are more fecund at sterilization and for years after, have higher failure rates initially and over time.

Irving method—Method of partial salpingectomy that buries the end of the proximal tubal stump in the myometrium of the uterus, in an attempt to reduce the rate of posttubal ligation syndrome. Theoretically may be reduced by leaving a proximal tubal stump of 2 cm and by minimizing ligature-induced necrosis at the site of tubal interruption.

Luteal phase pregnancy—Refers to pregnancies that occurred before sterilization but were detected after sterilization. Such pregnancies may be erroneously attributed to sterilization “failure.”

Open laparoscopy—Laparoscopic procedure begun without prior insufflation by directly visualizing, elevating, and incising the layers of the abdominal wall near the umbilicus. Has the benefit of reducing vascular injuries and, potentially, bowel injuries associated with blind direct Veress needle and trocar insertion.

Parkland method—Method of partial salpingectomy that involves ligation of the tube in two places, followed by excision of the intervening segment of tube. Achieves immediate separation of severed tubal ends.

Pomeroy method—Method of partial salpingectomy that involves ligation, followed by excision, of a loop of tube. No attempt to bury the severed ends of tube.

Poststerilization regret—Regret after the decision to undergo surgical sterilization can be related to several factors, including preexisting patient characteristics, subsequent changes in the patient’s situations or attitudes, and dissatisfaction resulting from adverse side effects caused or perceived to be caused by the procedure. Studies have identified young age at tubal sterilization as a risk factor for later regret.

Posttubal ligation syndrome—Refers to the historic perception that menstrual disturbances could result from tubal sterilization. This term is outdated, as substantial evidence against such a syndrome now exists. Women who undergo sterilization are no more likely than their nonsterilized counterparts to experience a syndrome of menstrual abnormalities.

Silicone rubber banding—Method of tubal occlusion usually performed via laparoscopy in which a silicone rubber band is applied to the isthmic portion of the tube. The technique is most effective when the tube has normal anatomy and the operator is experienced with the technique of application. These methods inflict the narrowest zone of tubal damage and are more likely than other methods to achieve absolute sterilization. This term is outdated, as substantial evidence against such a syndrome now exists. Women who undergo sterilization are no more likely than their nonsterilized counterparts to experience a syndrome of menstrual abnormalities.

Sterilization timing—Sterilization can be performed in relation to pregnancy (following vaginal delivery, cesarean section, or abortion) or remote from pregnancy (interval sterilization).

Tubal clips—Methods of tubal occlusion usually performed via laparoscopy in which a Filshie or Hulka clip is applied to the isthmic portion of the tube. The technique is most effective when the tube has normal anatomy and the operator is experienced with the technique of application. These methods inflict the narrowest zone of tubal damage (3–5 mm), affording a greater chance of sterilization reversal when compared with other methods.

Tuboperitoneal fistula—Poststerilization communication of the proximal tubal stump with the peritoneal cavity, which can result in sterilization failure, including ectopic gestation. Theoretically may be reduced by leaving a proximal tubal stump of 2 cm and by minimizing ligature-induced necrosis at the site of tubal interruption.

Uchida method—Method of partial salpingectomy that buries the end of the proximal tubal stump within the leaves of the mesosalpinx in an attempt to reduce the rate of tuboperitoneal fistula.

Unipolar coagulation—Method of tubal occlusion usually performed via laparoscopy that causes electrocoagulation of the tube when current is applied by grasping forceps; both jaws of the forceps serve as an active electrode. The high effectiveness rates observed with this method are
In proposing the concept of tubal sterilization in 1842, James Blundell suggested the following:

"...the operator...ought to remove a portion, say one line, of the Fallopian tube, right and left, so as to intercept its caliber—the larger blood vessels being avoided. More divisions of the tube might be sufficient to produce sterility, but the further removal of a portion of the tube appears to be quite practice. I recommend this precaution, therefore, as an improvement of the operation."

Samuel Smith Lungren of Toledo, Ohio, is credited with having performed the first tubal sterilization in 1880, after having performed a cesarean section for a woman whose previous child was also born by cesarean section because of a contracted pelvis. During the second cesarean section, Lungren intended to remove the woman's ovaries to prevent future pregnancy, but instead decided that “the risk would be lessened and the same result would be accomplished by tying both Fallopian tubes with strong silk ligatures about one inch from the uterus.” At the time of Lungren’s successful tubal sterilization, laparotomy was a life-threatening procedure; thus, the performance of tubal sterilization at the time of cesarean section to prevent future pregnancy was potentially lifesaving. In 1919, Madlener reported on 85 tubal sterilizations performed at the time of laparotomy for other reasons, including cesarean section; three of the 85 women died postoperatively from infection. Because of the extreme risks, performing a laparotomy for the sole purpose of tubal sterilization remained an unpopular idea until the mid-20th century. Indeed, when three deaths were reported from 1950 to 1959 among 1,022 women who had postpartum Pomeroy sterilization, the investigators concluded that the risk for sterilization was comparable to that for multiparity and that “sterilization because of great multiparity alone cannot be justified on medical grounds” (Prystowsky and Eastman).

In addition to concerns about safety, the early history of tubal sterilization included debate about the appropriateness of tubal sterilization for fertility control. At the 21st Annual Meeting of the American Gynecological Society in 1886, participants debated a woman’s right to undergo surgical sterilization. During this debate, Edward P. Davis said, “I hold it [sterilization] to be the right of a woman who is in a condition to which natural delivery is impossible...” H.J. Garrigue objected by saying,

“...we must leave that to Nature or to God... I do not think that the woman has a right of that kind... The mere fact that she does not want to have more children should not decide the question.” (Speert)

The availability and acceptability of tubal sterilization as a method of fertility control remained limited until the mid-20th century, and, accordingly, tubal sterilization remained uncommon in the United States and around the world until the 1960s. In the 1970s, the worldwide popularity of tubal sterilization increased dramatically. Between 1970 and 1980, the estimated number of tubal sterilizations increased markedly in Europe, China, India, other parts of Asia, and Latin America. In the United States, the number of tubal sterilizations increased nearly fourfold—from about 200,000 in 1970 to about 700,000 in 1977. Among the factors affecting this increase were the availability and acceptability of two new surgical approaches—minilaparotomy and laparoscopy. In contrast to laparotomy for sterilization, these approaches were safer, allowed for surgery without hospitalization, reduced recovery time, and gave a better cosmetic result. Minilaparotomy has been used in many developing countries, and laparoscopy has been used in many developed countries, as well as in the United States.

Minilaparotomy for interval sterilization (i.e., sterilization at a time unrelated to pregnancy) requires a 2.5- to 3.0-cm suprapubic incision. The technique was first described by Anderson (1937) and later described by Power and Barnes (1941). The use of laparoscopy in Europe was encouraged by the work of Palmer (France), Steptoe (Britain), and Frangenheim (Germany), and use of the technique rapidly gained popularity in the 1970s, particularly in Europe and the United States.

In the United States, the increased use of tubal sterilization in the 1970s occurred concurrently with the widespread availability and acceptability of laparoscopy. In 1970, less than 1% of sterilizations were performed with a laparoscope, but by 1973, more than one third of the 550,000 women who had tubal sterilization had the procedure performed laparoscopically. This transition was associated with a marked reduction in length of hospital stay for tubal sterilization—from 6.5 nights in 1970 to 4 nights in the years 1975 to 1978. By 1987, one third of tubal sterilizations in the United States required no overnight hospital stay, and 79% of these were performed by way of laparoscopy. Sterilization is now the method of family planning most commonly used in the world. In 1995, about 223 million couples used sterilization (of themselves or their spouses) for contraception; 180 million were women using tubal sterilization and 43 million were men using vasectomy.

Thus, the developing world accounts for most of the use of sterilization. Nearly half of all users are in China, and more than one fourth are in India. Vasectomy accounts for only a small percentage of sterilization procedures in developing countries except for China, India, and South Korea. In nearly all countries, the prevalence of tubal sterilization exceeds that of vasectomy. Worldwide, the ratio of female-to-male sterilization is 4 to 1.

In the United States, more than 3 million tubal sterilizations were performed in 1994–1996. Approximately one-half were postpartum procedures; of these, 58% were performed after vaginal delivery and 42% were concurrent with cesarean section. Of the approximately one-half of tubal sterilizations performed as interval procedures, 96% were performed on an outpatient basis. Among interval sterilizations, laparoscopy was used as the surgical approach in 89% of procedures performed in outpatient settings and 53% of those performed in inpatient settings.

In the United States, sterilization has also become the most commonly used method of contraception among married couples. The proportion of couples who used contraception that chose sterilization more than doubled from 1973 (16%) to 2002 (36%). Most of this increase was in female sterilization—from 3% in 1973 to 27% in 2002; there was little to no increase in male sterilization over this period (8% in 1973 and 9% in 2002). Among U.S. women using contraception in 2002, 10% 25 to 29 years old, 15% to 34 years old, 25% to 39 years old, and 35% to 44 years old had undergone tubal sterilization.
TIMING OF STERILIZATION

Tubal sterilization can be performed at the time of cesarean section, shortly after delivery or induced abortion, or at a time unrelated to pregnancy. About one half of tubal sterilizations in the United States are performed at a time unrelated to pregnancy. The timing of tubal sterilization can influence the choice of anesthetic, surgical approach, and method of tubal occlusion. For example, most sterilizations performed concurrently with cesarean section require no separate anesthesia and involve partial salpingectomy as the method of tubal occlusion. Most tubal sterilizations performed after vaginal delivery are done by minilaparotomy with subumbilical incisions and partial salpingectomy. Tubal sterilization not associated with birth usually is performed by laparoscopy (with use of coagulation, silicone rubber band application, or clip application) or minilaparotomy (with use of partial salpingectomy).

PREOPERATIVE EVALUATION

The candidate for sterilization should be extensively counseled. The intended permanence of the procedure, alternatives to sterilization, and risks of surgery should be discussed. For couples desiring sterilization, no such discussion is complete without consideration of vasectomy as an alternative. Women also should be made aware that sterilization failure can occur and that the relative likelihood of ectopic pregnancy is increased when sterilization failure does occur.

The workup of women who are to undergo tubal sterilization includes a history and physical examination and a laboratory evaluation, as indicated. Consideration should be given to whether the woman might be pregnant at the time of sterilization, and pregnancy testing should be ordered as necessary.

A careful gynecologic history and examination also are necessary before sterilization. Women with gynecologic disease or symptoms may require additional diagnostic or therapeutic measures. Some ultimately may be better served by other surgical procedures, either instead of or in addition to sterilization. For example, some women with enlarged and symptomatic uterine leiomyomata and women with symptomatic pelvic relaxation may benefit more from hysterectomy than from tubal sterilization. Others, such as women with abnormal cervical cytology, need careful evaluation before a decision can be made about preventing or treating invasive cervical cancer.

ANESTHESIA

Complications of general anesthesia are the leading cause of death attributed to sterilization in the United States. The risks inherent in general anesthesia are exacerbated by its use postpartum and during laparoscopy. The special requirements of general anesthesia for laparoscopy have been well described.

Except for the use of conduction anesthesia postpartum, general anesthesia is the technique most often used for female sterilization in the United States. A 1988 survey of members of the American Association of Gynecologic Laparoscopists revealed that the number of providers of tubal sterilization who used local anesthesia for laparoscopic sterilization had increased from 4% in the 1982 survey to 7%. Worldwide, more than 75% of tubal sterilization procedures are performed under local anesthesia. A discussion of the technology and regimen for administering general or conduction anesthesia is beyond the scope of this chapter. Instead, we focus on local anesthesia because of its increasing use in outpatient settings for many types of surgery.

Sterilization by laparoscopy or minilaparotomy can be performed safely under local anesthesia. The patient avoids the risks associated with general anesthesia, spends less time sedated or anesthetized, and has a more rapid recovery. Nausea and vomiting are less likely to occur, and the patient is awake to report symptoms that can indicate the occurrence of a complication. Television technology has made it possible for the patient to observe the procedure if she desires. Furthermore, the overall expense of the procedure is reduced compared with procedures done under general anesthesia.

In the United States, the overall morbidity rate for female sterilization is so low that it is difficult to obtain a sample large enough to demonstrate a comparative safety advantage for local versus general anesthesia. One U.S. study randomly assigned 100 women to either local or general anesthesia for laparoscopic sterilization. Serious or life-threatening events did not occur in either group. However, women who had general anesthesia were more likely to have intraoperative hypotension, hypertension, or tachycardia, which suggests that these women were hemodynamically less stable and may have been at increased risk for cardiovascular complications. In another study, 125 women were randomly allocated to the use of local or general anesthesia for laparoscopic sterilization. Women who had general anesthesia were more likely to develop hypotension; hypertension was more common in the local anesthesia group. No women in either group had tachycardia.

Operating under local anesthesia incurs several possible disadvantages. The patient’s anxiety may be increased; therefore, the surgeon must use a decisive and gentle surgical technique while talking with the patient to the patient may feel a lack of control; thus, the physician must have a thorough understanding of the use of sedative and analgesic drugs. Although obesity can complicate the use of local anesthesia, several studies indicate that local anesthesia can be used successfully for obese women. Women with a history of multiple abdominal or pelvic surgical procedures or peritonitis may need additional anesthesia if the procedure is difficult or prolonged. Additional anesthesia also may be required during minilaparotomy if the abdominal incision needs to be extended. One U.S.-based retrospective study reviewed 2,827 outpatient laparoscopic sterilizations performed under local anesthesia and mild sedation from 1980 to 1988. The mean operating time was 10.0 ± 5.1 minutes, and the mean anesthesia time was 23.3 ± 6.9 minutes. The hospital cost to the patient was reduced 65% to 85%. Another U.S. study reported on 358 minilaparotomies for interval sterilization performed under local anesthesia. The average operating time was 21 minutes, and no complications were reported.

In both series, the local anesthetics were 0.5% bupivacaine hydrochloride used alone or in combination with lidocaine. In one series, midazolam hydrochloride and fentanyl citrate were used for mild intravenous sedation; in the other series, meperidine hydrochloride and diazepam were used. For local infiltration and paracervical block, agents of intermediate intrinsic potency (defined as the minimum concentration required to produce a block within 5 to 10 minutes), such as lidocaine or mepipvacaine, have been found suitable. Both are amides with good stability and low toxicity. Onset of analgesic effects is rapid, even when a low concentration of medication is used, and the duration of effect is sufficient for the procedure but not prolonged (about 1.5 hours when the medication is given in plain solution). Bupivacaine, a more potent

Tubal Sterilization
SURGICAL APPROACH

Minilaparotomy

The minilaparotomy approach to tubal occlusion can be used in the interval or postpartum period. Although interval sterilization by minilaparotomy is the sterilization procedure most frequently performed in many countries, it is not a common procedure in the United States. Minilaparotomy in the United States often is used preferentially among women considered to be at increased risk for laparoscopy.

Interval minilaparotomy is performed with use of a 2- to 3-cm midline vertical or transverse suprapubic incision. In patients with an enlarged uterus resulting from uterine leiomyomata or other benign conditions, the minilaparotomy incision should be made at the level of the uterine fundus to ensure access to the fallopian tubes and to allow visualization of the fundus and movement along the uterus. The fallopian tube is identified first by the fimbriated end, and then the midpoint of the fallopian tube is grasped with a small Babcock clamp and elevated through the abdominal incision. Tubal occlusion most often is performed by use of the modified Pomeroy or Parkland technique. However, clips or rings can be applied through the minilaparotomy incision with modified instruments originally developed for use through the operating laparoscope.

Postpartum minilaparotomy is performed in a manner similar to that of interval minilaparotomy. It is ideally performed before the onset of postpartum uterine involution while the uterine fundus is high in the abdomen (within 48 hours of delivery). A 2- to 3-cm subumbilical vertical or semicircular incision is made in the midline where the abdominal wall is thin. Because of the proximity of the enlarged uterus to the incision, access to the fallopian tubes is easier than it is with an interval approach. A uterine manipulator is unnecessary when minilaparotomy is performed in the postpartum period.

Laparoscopy

The magic is in the magician, not in the wand... Entering the abdomen is the most dangerous part of the laparoscopic procedure. (Hulka and Reich)

The laparoscopic instrumentation, including laparoscope, light cables and light source, insufflator and tubing, and video camera and television, if used, should be set up and tested for proper functioning before any incisions are made. If a Veress needle is to be used, it is good practice to attach it to the insufflation tubing and test that gas flows freely through it. High line pressures (3 mm Hg or higher) during low-flow insufflation (1 L/min) through a Veress needle that has yet to be inserted into the abdominal cavity suggest that the needle has some occlusion. Checking for occlusion before inserting the needle can avoid the multiple attempts at needle placement that might occur in the belief that incorrect placement, rather than needle occlusion, is the cause of resistance to flow. It is convenient, while waiting for surgery, to have the end of the laparoscope bathing in warm sterile fluid to prevent it from fogging when it is inserted into the abdominal cavity.

A no. 11 scalpel blade is used to make a single vertical incision in the lower rim of the umbilicus. This must be done carefully because the aorta can lie just a few centimeters beneath the abdominal wall, particularly in a thin patient. The abdominal wall is lifted away from the aorta by pinching the skin beneath the umbilicus between thumb and index finger. The umbilicus is elevated with one hand while the surgeon’s other hand makes the controlled incision.

A Veress needle is disconnected from the insufflation tubing before insertion. The stopcock on the needle then is placed in the open position, and the spring action of the needle is tested for smooth operation. Elevating the abdominal wall and using the Veress needle with the stopcock open allows air to rush into the previously gas-free abdominal cavity when the end of the needle penetrates the peritoneal layer. The in-rushing air, if heard, is one of the first indicators that successful abdominal entry has occurred. Outflow of blood likewise can serve as an immediate indicator of vessel injury. Allowing air to rush in also can cause the bowel to fall away from the abdominal wall.

The terminal aorta is palpated, even in a moderately obese patient, through the abdominal wall in the midline, just above or at the umbilicus. The pulsations of the aorta are lost in the midline just beneath the umbilicus, corresponding to the sacral hollow. The aorta bifurcates at the level of L4, which corresponds to the umbilicus. This is a more constant landmark for bifurcation of the aorta than the umbilicus. The Veress needle is placed through the umbilical incision and is directed at an angle toward the sacral hollow or uterine fundus (to avoid the aorta) and in the midline (to avoid the iliac vessels). Elevating the abdominal wall during this process increases the distance between the Veress needle and major vessels. While placing the Veress needle, the surgeon should hold the needle like a dart, being careful not to impede the action of the spring mechanism. Resistance at the tip of the needle causes the blunt cannula inside the needle to be pushed back, and the spring mechanism at the hub of the needle extends. When resistance at the tip of the advancing needle is lost, as occurs with successful penetration of the peritoneal cavity, the blunt cannula inside the needle advances back out to the tip, and the spring mechanism at the hub of the needle snaps back in. Observing the spring mechanism for this snap can serve as a sign to test for successful placement. Often there are two snaps—the first when the fascia is penetrated and the second with peritoneal penetration. Continuing to advance the needle tip much beyond the point of penetration of the parietal peritoneum risks placing the needle tip between loops of bowel or under the omental apron, both of which can cause resistance to flow and can result in reinsertion of the needle. Continued advancement of the Veress needle also risks vascular injury. The needle tip should not be moved laterally once the tip is inserted in the abdomen; any simple vascular puncture could be transformed into a major laceration if the needle tip is moved from side to side. Once abdominal penetration is made with the Veress needle, the needle should be stabilized carefully until safety checks have been completed. The needle should not be moved, and a laparotomy should be performed immediately if major vascular injury is suspected.
The distance between skin and fascia can increase with increasing patient obesity. A given angle of entry of the Veress needle that successfully penetrates the peritoneal cavity in a thin patient might fall far short of the peritoneum in an obese patient. To bring the peritoneal cavity within the physical length of the Veress needle, it is often necessary to pursue entry with a trajectory closer to the vertical. However, this also directs the Veress needle toward the aorta and therefore should be attempted only by experienced surgeons, and with extreme care. Alternatively, open laparoscopy can be performed.

Several safety checks for correct intraabdominal placement can be performed while the Veress needle is held steady. The insufflation of 5 to 10 mL of sterile saline through the needle, followed immediately by aspiration, can be helpful. The fluid should meet little resistance, and, more important, scant fluid should return on respiration. Resorption of fluid suggests that the needle tip is in a small enclosed space that does not allow immediate dispersion of the instilled fluid. Resorption of essentially fluid or bloody fluid suggests bowel or vascular penetration, respectively. Simple penetration of the bowel with a Veress needle does not mandate immediate exploratory laparotomy. Depending on the setting and the skill level of the surgeon, remerit of the needle or open laparoscopy, followed by laparoscopic visualization of the intestine, can be pursued.

A second safety check consists of attaching a filled 10-mL syringe to the hub of the Veress needle and then removing the plunger. Elevation of the abdominal wall at this point should cause an increased negative intraperitoneal pressure, which allows the fluid in the syringe to drain passively into the abdominal cavity through an open stopcock. Alternatively, a drop of saline (drip test) can be placed on the hub of the Veress needle, and, with the stopcock open, elevation of the abdominal wall should result in the drop flowing downward freely.

Once these safety checks are performed, insufflation is begun at 1 L/min or less. Initial insufflation pressures often are 5 mm Hg or less in thin patients and, even with correct needle placement, can be 10 mm Hg or more in obese patients. An intraabdominal pressure greater than 15 mm Hg during insufflation generally is avoided to prevent respiratory compromise and decreased venous return secondary to vena caval compression. Abdominal distention increases the distance between the abdominal wall and major pelvic vessels, and this increases the safety buffer when the trocar is inserted. However, the abdomen should not be distended so that it is difficult to manually elevate it for trocar insertion.

During insufflation, a shift from dullness to tympany with percussion over the liver is indicative of pneumoperitoneum formation. It is also prudent for the surgeon to pay attention to the electrocardiogram rhythm during insufflation, because the sudden appearance of premature ventricular contractions can be an indicator of intravascular insufflation. Sudden vascular collapse, during insufflation can be caused by a gas embolism into the right side of the heart, and at times this life-threatening event can be signaled by a new “cog wheel” or “mill wheel” murmur. Rapidly tilting the patient into Trendelenburg position and onto her left side and advancing a Swan-Ganz catheter into the right heart for aspiration can be life-saving.

Once insufflation is complete, the Veress needle is removed, and the umbilical incision is widened to accommodate the trocar and sleeve. An incision that is too large can result in leakage of gas around the sleeve. An incision that is too small can restrict access. The trocar should be checked before insertion to ensure that it is sharp; a dull trocar potentially is dangerous because it requires increased force for abdominal entry. The trocar is grasped as shown in Figure 27.1. The middle finger serves as a stopper, preventing the forward momentum following fascial puncture from carrying the trocar deep into the pelvis. The precautions for insertion of the Veress needle pertain even more to insertion of the trocar; the abdominal wall is elevated, and the trocar is directed toward the hollow of the sacrum or the uterine fundus, and a midline trajectory is followed.

Open laparoscopy is performed without previous creation of a pneumoperitoneum. The skin beneath the umbilicus is incised sufficiently with a scalpel in either a vertical or transverse direction to adequately visualize the underlying fascia. The skin is released, and the fascia is grasped and elevated. The fascia is then incised in the midline, and the opening is stretched with a hemostat or incised to a length just sufficient to visualize the underlying peritoneum, which in turn is elevated and incised. Each angle of the fascial incision is sutured with a no. 0 absorbable stitch but not tied. The Hasson blunt cannula and sleeve are then placed through the opening of the peritoneum. The blunt cannula then is removed, and the abdomen is insufflated through the port found on the sleeve.

**FIGURE 27.1.** Trocar entry. When inserting the trocar through the abdominal wall, the trocar is “palmed” in the surgeon’s dominant hand, with the extended middle finger serving as a stopper to deep abdominal penetration. If the surgeon’s hand is too small to accomplish this, open laparoscopy should be considered.

**METHOD OF TUBAL OCCLUSION**

All tubal sterilization methods rely on correct identification of the fallopian tube for success. With any of the methods, the tube should be followed out to its fimbriated end to confirm that the correct structure has been identified. Theoretically, the risk of tuboperitoneal fistula formation can be reduced by preserving a proximal tubal segment 1 to 2 cm in length. It is possible that the proximal tubal stump serves as a distensible reservoir for the small amount of uterine fluid that is normally forced through the interstitial portion of
the tube by uterine contractions. The capacitance of the proximal stump might serve to dissipate the fluid pressure emanating from the uterus. Otherwise, this direct fluid pressure on the cut end of the tube might prevent complete closure of the tubal lumen during the healing process.

**Irving Procedure**

In 1924, and later, in 1950, Irving reported on his method of achieving tubal sterilization. He attempted to reduce the risk of tuboperitoneal fistulae by extensively dissecting the ligated ends of the tubes and burying the proximal tubal segment. Although the extra dissection in this technique likely enhances effectiveness, it also carries the potential for greater blood loss, as well as increases the difficulty of performing the technique through a minilaparotomy incision. The procedure also takes slightly longer to perform than simpler methods.

The Irving technique is accomplished by first using a hemostat or scissors to create a window in the mesosalpinx just beneath the tube, about 4 cm from the uterotubal junction (Fig. 27.2A). Then the tube is twice ligated (no. 1 chromic) and divided between the ties at this location. The free ends of the proximal stump ligature are held long. A 1-cm incision is made in the serosa of the posterior uterine wall near the uterotubal junction. A hemostat, or similar pointed instrument, is then used to bluntly deepen the incision, creating a pocket in the uterine musculature about 1 to 2 cm deep (Fig. 27.2B). The two free ends of the proximal stump ligature, previously held long, are then individually threaded onto a curved needle and brought deep into the myometrial tunnel and out through the uterine serosa (Fig. 27.2C). Traction on the sutures then draws the ligated proximal stump deep into the myometrial tunnel, and tying the free sutures fix the tube in this buried location (Fig. 27.2D). Often this can be accomplished without incising the mesosalpinx, but if extra mobilization of the proximal stump is needed, or if the proximal stump mesosalpinx appears in danger of being torn when traction is applied, then the mesosalpinx under the proximal tubal segment can be incised partly back toward the uterus. The serosal opening of the myometrial tunnel is then plicated closed around the tube with use of a fine absorbable suture, but great care should be exercised to avoid compromising the tube as it enters the tunnel. Strangulation or damage to the tube with this stitch could cause necrosis and fistula formation in the extramyometrial portion of the proximal tube. No treatment of the distal tubal stump is necessary, but some surgeons choose to bury that segment in the mesosalpinx.

**Modified Pomeroy Procedure**

Bishop and Nelms, colleagues of Pomeroy, reported on the Pomeroy technique for tubal occlusion in 1930. They
careful to point out the importance of using absorbable suture as opposed to permanent suture.

In this method, the tube is grasped in its midportion, usually with a smallatraumatic clamp such as the Babcock, and a loop of tube is elevated (Fig. 27.3A). The base of the loop is ligated with no. 1 plain catgut, leaving a 2- to 3-cm proximal stump of isthmus, and the sutures are held long. A 2- to 3-cm portion of tube in the ligated loop is transected and removed with scissors (Fig. 27.3B). Bishop and Nelms, in the original report on this method, pointed out that ligation was performed with a double strand of absorbable chromic catgut suture to allow the cut tubal ends to quickly separate after surgery. It was their belief that this would allow the ends to naturally fibrose and peritonealize without fistulization or communication. This also is the rationale for the common modification of the Pomeroy technique, in which the original chromic suture is replaced by plain catgut because of the more rapid degradation of the latter. Surgeons have a tendency to strenuously tighten the catgut ligature around the tube (as though the tighter the ligature, the better the occlusion), but this appears to go against the very principles of the procedure. This tightening can result in greater strangulation and necrosis of the adjoining tubal segments, potentially increasing the risk of fistula formation and greater strangulation and necrosis of the adjoining tubal segments. The Pomeroy method minimizes bleeding by compressing and sealing the vascular mesosalpinx before tubal transection.

When a Pomeroy ligature is performed through a minilaparotomy incision, the ligature sutures are held while the tube is reinset in the peritoneal cavity before they can be adequately examined and before hemostasis can be ensured. After examination is complete, the sutures are cut, and the tubal stumps are allowed to retract into the abdomen.

The Pomeroy method minimizes bleeding by compressing and sealing the vascular mesosalpinx before tubal transection. It is not unusual when performing tubal sterilization at the time of cesarean section to find the mesosalpinx greatly engorged with distended veins. Elevation of the uterus through the abdominal incision often facilitates tubal occlusion by allowing the vessels to drain and decompress. It is important when replacing the uterus into the peritoneal cavity to lead with one adnexa at a time while protecting the tubal ligation site on that side. Otherwise, when the uterus is replaced, a tight fit can cause the adnexa to be squeezed against the incision, with resultant avulsion of the ligature and postoperative bleeding.

The Pomeroy method is performed as a laparoscopic interval procedure. In this technique, a laparoscope with an operating channel is placed through the umbilical port, and a 5-mm midline suprapubic cannula is introduced under direct vision. A plain gut Roeder loop (endoscopic slip knot) is introduced through the 5-mm port. A grasper is introduced through the operative channel of the laparoscope, advanced through the suture loop, and the appropriate portion of tube is grasped and retracted back through the loop. The slip knot of the loop is then tightened, ligating a knuckle of the tube. Scissors are then introduced through the operative scope, and the suture is cut. With use of a grasper through the 5-mm port, the loop of tube is held on tension while the scissors are used through the operative channel to transect the tube above the ligature. When the procedure is complete and the tubal segment has been resected, the grasper is used through the operative channel to hold the specimen while the operative scope and grasper are removed together through the abdominal incision.
Surgery for Benign Gynecologic Conditions

umbilical sleeve. In contrast to most other methods of laparo-
sscopic sterilization, this technique has the advantage of pro-
ducing a surgical specimen for evaluation.

Uchida Method

Originally reported on in 1961, and reported on in revised form
in 1975, the Uchida method, like the Irving procedure before
it, recognized the role of fistula formation in tubal sterilization
failures and included steps to prevent this complication.

This method begins by having the surgeon grasp the tube in
its midportion, about 6 to 7 cm from the uterotubal junction.
A 1:1,000 epinephrine in saline solution is injected subsero-
sally, creating a bleb over the tube that is then incised (Fig.
27.4A). The muscular tube, which often can be seen springing
up through the serosal incision, then is divided between two
hemostats. The serosa over the proximal tubal segment is dis-
sected bluntly toward the uterus, exposing about 5 cm of the
proximal tubal segment (Fig. 27.4B). The tube then is ligated
with no. 0 chromic suture near the uterotubal junction, and
this 5-cm segment of exposed tube is resected. The shortened
proximal stump is allowed to retract into the mesosalpinx (Fig.
27.4C). The serosa around the opening in the mesosalpinx is
sutured in a pursestring fashion with a fine absorbable stitch.
Simultaneous ligation of the distal tube and gathering of the
mesosalpinx around the distal stump are accomplished when
the pursestring suture is tied (Fig. 27.4D). This step also fixes
the distal stump in a position open to the peritoneal cavity while
burying the proximal stump within the leaves of the meso-
salpinx.

Uchida added fimbriectomy to the procedure in 1975 to en-
hance effectiveness. Some surgeons omit this step, and in addi-
tion excise only 1 to 2 cm of tube (rather than the recommended
5 cm) to permit future tubal anastomosis.

Parkland Method

In this method, made popular during the 1960s at Parkland
Memorial Hospital, the tube is grasped in its midportion with
a Babcock clamp, and a hemostat or scissors is used to create

---

**FIGURE 27.4.** Uchida method. A: An injection of vasoconstricting solution is given beneath the serosa
of the tube about 6 cm from the uterotubal junction. The serosa is then incised (dashed line). B: The
antimesenteric edge of the mesosalpinx is pulled back toward the uterus, exposing about 5 cm of the tube.
C: The tube is ligated proximally and cut, and the tied stump is allowed to retract into the mesosalpinx.
The hemostat on the distal stump remains attached to facilitate exteriorization of this portion of the tube.
D: The mesosalpinx is closed. A pursestring stitch of the mesosalpinx around the exteriorized tubal stump
secures it in a position open to the abdomen, whereas the ligated proximal stump is buried within the
mesosalpinx. Once the pursestring suture is tied, the hemostat can be removed.
Tubal Sterilization

A window in an avascular area of the mesosalpinx just beneath the isthmic portion of the tube (Fig. 27.5A). The window is stretched to about 2.5 cm in length by opening the hemostat. Two ligatures of no. 0 chromic material are passed through the window, and the tube is ligated proximally and distally, leaving a 2-cm proximal stump of isthmic tube (Fig. 27.5B). The intervening segment of tube between the ties then is resected (Fig. 27.5C). In contrast to the Pomeroy method, in which the resected portions of the tubes are ligated together and later separate when the suture weakens, immediate separation of the tubal ends is accomplished with the Parkland method. Care should be taken to avoid undue traction on the ligatures while resecting the tubal segments, because this could result in tearing of the mesosalpinx and excessive bleeding.

Unipolar Coagulation

Unipolar coagulation was the first method of laparoscopic tubal occlusion to achieve widespread use. However, reports of electrical complications, particularly thermal bowel injury, resulted in a significant decline in this method’s popularity as soon as alternative methods of laparoscopic tubal occlusion became available in the mid-1970s. In unipolar coagulation, a specially designed insulated grasping forceps is introduced through the operating channel of the laparoscope or independently through a 5-mm second puncture port. As a safety precaution, attachment of the electric cable to the grasping forceps should be delayed until the surgeon is ready to coagulate the fallopian tube.

With unipolar coagulation, as much as 3 to 5 cm of tube can be destroyed with a single burn, with occult damage occurring beyond the visual zone of desiccation. For this reason, the isthmic–ampullary portion of the tube should be carefully identified and grasped about 5 cm from the uterus to preserve some length of proximal tube. The jaws of the grasping forceps should completely encircle the fallopian tube and include a portion of the mesosalpinx as well. The tube should be elevated away from adjacent structures, such as bowel and bladder, before current is applied for about 5 seconds. If a second burn is required, it should be applied to the proximal rather than the distal portion of the tube. The current should be turned off before the tube is released and the grasping forceps are retracted into the laparoscope. Both jaws of the grasping forceps serve as active electrodes and will burn any structure they touch while current is applied.

The thermal injuries to abdominal viscera that are seen with unipolar coagulation are, in some cases, likely attributable to the phenomenon of capacitive coupling. The current flowing down the unipolar probe creates an electromagnetic field that can transfer an electric charge to any conductor surrounding the probe. The greater the voltage being used with the probe, the greater this capacitive effect. In the case of laparoscopic unipolar coagulation for sterilization, the conductor...
surrounding the insulated unipolar probe is the operative laparoscope itself. As long as the operative laparoscope is safely grounded (usually by contact with a metal trocar sleeve that, in turn, is in contact with the abdominal wall over a large surface area), then the capacitive charge that builds up on the scope discharges when and wherever any portion of that instrument touches the patient’s tissues. Depending on the surface area of contact, the discharging current from the scope into the patient’s tissues has either a high current density (small contact surface) or a low current density (large contact surface), resulting in either a large thermal effect or a minimal thermal effect, respectively. In the case of contact with bowel, this thermal effect easily can result in delayed necrosis and peritonitis. If the unipolar probe is brought into the abdomen by way of a second puncture trocar sheath, then it is the sheath itself that is capacitively charged (if it is made of a conducting material). If the contact on the trocar sheath is prevented from grounding through the abdominal wall (as could occur if a plastic collar with threads is being used around the trocar sleeve), then any bowel or other grounded tissue touching the trocar sleeve again has capacitive current flowing into it.

If thermal injury to the intestine is noticed during the laparoscopic procedure, then it is important to recognize that the injury can extend well beyond the visibly damaged area. Small burns of the bowel serosa may not require repair, but hospitalization for 5 to 7 days is recommended so the patient can be observed for delayed peritonitis. A laparotomy is required if peritonitis occurs. A large area of superficial thermal bowel injury, or one that is thought to extend beyond the serosa, requires resection of that portion of intestine with a 5-cm margin on either side of the lesion. Owing to the damaged area can result in stitches being placed in bowel that appears healthy virtually but in reality is destined to necrose from occult thermal or electrical injury.

Bipolar Coagulation

The use of bipolar coagulation for tubal sterilization was reported by Roux and Cloutier in 1974. With bipolar coagulation, current flows from one jaw of the grasper to the other, requiring only the intervening tissue of the patient within the jaws of the instrument to complete the circuit. This eliminates the need for a distant ground plate. Compared with unipolar coagulation, which uses the patient’s body to complete the circuit, bipolar coagulation applies current in a more discrete manner (1.5- to 3-cm zone of thermal injury) and with an increased element of safety. Capacitive coupling does not occur with bipolar forceps because the field effects from the equal but opposite currents that flow in both directions along the shaft of the instrument cancel out one another.

Once the fallopian tube is carefully identified, it is grasped in the distal isthmic section with the bipolar forceps in such a way that the tube is completely encircled, including a portion of the mesosalpinx (Fig. 27.6). The tube then is elevated away from any adjacent structures, and current is applied. Two additional contiguous areas similarly are coagulated to ensure at least a 3-cm area of desiccation. As with unipolar coagulation, an effort should be made to leave the proximal 2 cm of tube undisturbed to reduce the risk of tuboperitoneal fistula formation.

The visual end points of tubal blanching and swelling noted with bipolar coagulation cannot be used to ensure destruction of the endosalpinx. Desiccation of the outer one third of the fallopian tube can occur without desiccation of the inner one third. The use of an optical flow meter has been recommended to evaluate cessation of current flow through the tube as an end point. Presumably, when complete desiccation occurs, there will be no further electrolytes in solution to carry current through the dehydrated tissue. Soderstrom and coworkers have demonstrated that complete desiccation of the fallopian tube with bipolar systems is more likely when a cutting waveform, as opposed to a coagulation or blended waveform, is used and when the power output is at least 25 W against a 100-V load.

Silicone Rubber Bands

High complication rates with the use of unipolar coagulation led to the pursuit of safer, nonthermal methods that could be applied laparoscopically. The first of these methods to gain popularity was the silicone rubber band, developed by Yoon and coworkers in the early 1970s.

The band is introduced with a specially designed endoscopic applicator that can be delivered either through the operating channel of a laparoscope or a separate second puncture port. The band is first stretched over the distal end of the applicator, which closes both arms of the tongs around the channel of a laparoscope or a separate second puncture port. The band is first stretched over the distal end of the applicator barrel (immediately before use to avoid extended deformation of the band). A transcervical uterine manipulator can be used to help achieve proper exposure. After the device is introduced into the abdominal cavity, grasping tongs are extended from within the applicator barrel. One of the tongs is used to gently hook and elevate the isthmic portion of the tube about 3 cm from the uterus. The tongs then are retracted into the applicator, which closes both arms of the tongs around the grasped tube while pulling the hoop of tube up into the barrel (Fig. 27.7). The surgeon must take care in ensuring that the tube is completely encircled by the tongs as they are retracted into the applicator. Failure to do this can result in a band that is only tangentially applied to the tube (failing to occlude its lumen) or applied only to the mesosalpinx.

It is important to avoid excessive traction on the tube during retraction of the tongs. The surgeon should slowly advance the entire applicator toward the tube while gradually retracting the tongs and tube up into the applicator. Failure to do this...
FIGURE 27.7. Silicone band method. The isthmic portion of the tube is retracted into the applicator barrel using grasping tongs, which should completely surround the tube. The applicator barrel is advanced toward the tube during this retraction process to avoid excessive traction on the tube and its mesentery.

can result in mesosalpingeal hemorrhage and tubal laceration. Once the loop is fully retracted into the device, the band is slid off the applicator barrel and onto the base of the loop. About 1.5 to 2 cm of tube is contained in the constricted loop. After devascularization, this portion of tube becomes anoxic and resorbs over time. Eventually, the band no longer encircles any tube, and later it is often found in the mesosalpinx. Apart from the 2-cm loop of encircled tube, very little destruction is caused by the band, and 2 mm lateral to the area of constriction of the tube is relatively undisturbed.

It is difficult to apply a band to edematous or thickened fallopian tubes successfully. Tubal adhesions can reduce the mobility of the tube and preclude pulling an adequate loop of tube into the applicator. Additional rings can be applied to the cut edges if transection of the mesosalpinx or tube with accompanying hemorrhage occurs. Bipolar or unipolar coagulation can be used if this is unsuccessful.

Spring Clip

The use of a spring clip for tubal sterilization was reported by Hulka and colleagues in 1973. The introducer for the clip can be delivered into the abdomen through the operative channel of the laparoscope or a second puncture cannula (Fig. 27.8). Because the clip must be applied exactly perpendicular to the long axis of the fallopian tube, it is helpful at times to use the two-puncture method—placing the tube on stretch by use of a transcervical uterine manipulator and a grasping forceps inserted through the operating channel of the laparoscope, and introducing the applicator through the second puncture port. The clip is held in a cradle by the applicator and can be closed and opened on the tube multiple times until an acceptable application is achieved. At this point, further pressure on the thumb device of the applicator drives the spring mechanism over the jaws of the clip, locking it closed. If improper application is determined at this point, the clip cannot be removed, and another clip has to be placed. To be effective, the clip must be applied to the isthmic portion of the tube, about 2 cm from the uterus and exactly at right angles to the long axis of the tube. It must be applied fully advanced over the tube, with the hinge of the clip pressing against the tube and with the tips of the jaws of the clip extending beyond the tube onto the mesosalpinx, creating a characteristic fold in the mesosalpinx when the clip is closed. The tube is not elevated when applying the clip, in contrast to the techniques used in coagulation and band application.

The clip, like the silicone rubber band, is most likely to be successful when applied to a normal tube. Tubal distortion, thickening, and adhesions make correct application difficult and often impossible.

A considerable advantage to the clip method of sterilization is that only 3 mm of tube is compressed by the clip, and minimal collateral damage occurs in the adjacent tissue. As a result, anastomosis procedures after clip sterilization often are highly successful.

Filshie Clip

The Filshie clip was first introduced in Europe in 1975, and the hinged Mark VI model was approved for use in the United States by the U.S. Food and Drug Administration (FDA) in 1996. The device has titanium jaws lined with silicone rubber and is used with specially designed applicators that are available in both single- and double-puncture versions for use with laparoscopy or minilaparotomy. The Filshie clip has a hinge on one end and a small curve on the other and is designed to be placed on the isthmic portion of the fallopian tube approximately 1 to 2 cm from the cornuca (Fig. 27.9).

To be effective, the jaws of this clip, as with the spring clip, must include the entire circumference of the tube. Only one properly applied clip needs to be applied to each fallopian tube. Once the tube is occluded, both the tube and the silicone rubber lining of the clip are compressed. Over time, about 3 to 5 mm of the compressed tissue undergoes avascular necrosis, and the compressed silicone rubber expands. Eventually, placal attenuation and fibrosis of the adjacent tubal segments occurs, and the clips are peritonealized.
FIGURE 27.9. Filshie clip method. The clip is applied to the midisth- 
mus (about 1 to 2 cm from the cornua) with the lower jaw of the clip
being visible in the mesosalpinx to assure that the entire circumference
of the tube is included.

The clip is placed into the applicator, and the applicator and
clip then are introduced through the cannula with the jaws of the clip
in place to manipulate the fallopian tube into proper position. The clip may close prematurely if too
much pressure is placed on the handle of the applicator. The
lower jaw of the clip, with its small curve at the tip, should
be seen through the mesosalpinx to assure that the clip in-
cludes the entire circumference of the isthmic portion of the
tube before the clip is applied. Because of the clip’s hinge and
the silicone lining of the jaws, the tubes can be manipulated
and released several times for better positioning of the clip.
Gentle pressure is placed on the applicator handle once desired
placement is obtained, which causes the upper jaw of the clip
to flatten and lock under the curved tip of the lower jaw. The
clip should be closed slowly to avoid transection of the fallop-
ian tube, which is more likely with edematous tubes. A clip can
be placed on each transected end if transection occurs. Many
surgeons recommend the use of a double-puncture technique
to assure proper placement.

Essure\textsuperscript{TM}

The Essure\textsuperscript{TM} microinsert was approved by the FDA for use as
an interval tubal sterilization device in late 2002. The device is
inserted transcervically via hysteroscopy and thus avoids both
entry into the abdominal cavity and the need for general or
regional anesthesia. It is available as part of a disposable system
that includes the microinsert, a delivery system, and a split
introducer. The microinsert is comprised of a stainless steel
inner coil, a nickel titanium alloy outer coil, and a layer of
polyethylene terephthalate (PET) fibers around the inner coil.
The microinserts are 4 cm in length and 0.8 mm in diameter before
release from the insertion catheter; following release, it expands
to 1.5 to 2.0 mm in diameter as it attaches to the fallopian tube
(Fig. 27.10).

The Essure\textsuperscript{TM} microinsert can be placed in an outpatient or
office surgery setting using a paracervical block with or with-
out intravenous sedation. Using a sterile standard 5-mm hys-
teroscope with a minimum 5 French operating channel and a 12-
to 30-degree angled lens, the uterine cavity is distended ade-
quately with 2 to 3 L of warmed physiologic saline to al-
low accurate identification of both tubal ostia. The procedure
should be terminated if both tubal ostia are not accessible and
considered likely to be patent. The manufacturer’s package in-
sert recommends that the risk of hypervolemia be reduced by
immediately terminating the procedure if the fluid deficit of the
physiologic saline distension medium exceeds 1500 cc and by
limiting the time of the hysteroscopic procedure to a maximum
of 20 minutes.

The Essure\textsuperscript{TM} microinsert is designed to be placed in the fal-
lopian tube across the uterotubal junction where the tube exits
the uterine wall but with 5 to 10 mm (the equivalent of 3–8
coils) still trailing into the uterus. This is achieved by insert-
ing the delivery catheter with the microinsert into the proximal
tubal lumen to the level indicated by the black position marker
on the catheter. When the device is correctly placed, the deliv-
ery catheter is withdrawn, and the delivery wire is separated
from the microinsert. The trailing end of the coils aids in an-
choring the device to decrease the risk of expulsion. The device
is also anchored as it expands in the tube at placement, but
occlusion is not considered adequate without tissue ingrowth
from the tubal wall into the coils that occurs as a result of
an inflammatory and fibrotic response to the PET fibers in the
inner coil. A hysterosalpingogram (HSG) must be performed
3 months postinsertion to assure complete bilateral tubal oc-
cclusion. Alternate contraception should be used until occlusion
is documented.

FIGURE 27.10. Essure method. The Essure microinsert is designed to
be placed in the fallopian tube across the uterotubal junction where
the tube exits the uterine wall but with 5 to 10 mm (the equivalent of
3–8 coils) still trailing into the uterus.
IMMEDIATE COMPLICATIONS

Mortality

In early studies, 14% of microinsert attempts failed on one or both sides, with the first attempt using the braided catheter. Although the rate of failed attempts was reduced as training improved, the insertion failure rate remained considerable at 10%. A newly designed coil catheter system has replaced the original one; initial tests suggest an improved rate of successful single-attempt bilateral placements, but these encouraging findings require confirmation in the general population.

The Essure™ microinsert is indicated, as for other methods of sterilization, only for women who are certain about their desire to terminate future fertility. The microinserts are not removable, and several coils project into the uterine cavity, making it extra fertilization less feasible. Thus, this method has less potential for a desired subsequent pregnancy than laparoscopic or minilaparotomy tubal sterilization should regret occur.

Women with a known hypersensitivity to nickel should not have the Essure™ microinsert inserted because the outer coil is made of nickel-titanium alloy.

In an international study of 41,834 sterilizations performed from 1971 to 1979 in 28 countries, the estimated case-fatality rate was 13.4 per 100,000 interval tubal sterilization procedures, 3.3 per 100,000 postabortion sterilization procedures, and 43.4 per 100,000 sterilizations after vaginal delivery. At least some of the differences in case-fatality rates between interval tubal sterilization and sterilization associated with pregnancy were likely attributable to complications of pregnancy termination or delivery rather than tubal sterilization per se.

The potential health impact of tubal sterilization in countries that have a high rate of maternal mortality can be assessed by analyzing sterilization-attributable deaths in Bangladesh. In the first of two epidemiologic investigations, 24 deaths were attributed to tubal sterilization in two geographic areas; the case-fatality rate was 19 deaths per 100,000 tubal sterilizations. In the second investigation, 19 deaths were identified nationwide, for a case-fatality rate of 12.4 deaths per 100,000 procedures. Anesthesia overdose, tetanus, and hemorrhage were the leading causes of death in both investigations. On the basis of an estimated maternal mortality rate of 570 per 100,000 live births, more than 1,000 maternal deaths for each 100,000 tubal sterilizations performed would have been averted during the reproductive years of the cohort.

In the United States, deaths attributable to tubal sterilization are rare. Based on an assessment of tubal sterilizations performed in U.S. hospitals in 1979 and 1980, the estimated case-fatality rate for tubal sterilization is one to two per 100,000 procedures. Complications of general anesthesia are the leading cause of sterilization-attributable death. In a survey of deaths attributable to tubal sterilization in the United States from 1977 to 1981, 29 deaths were identified; 11 followed complications of general anesthesia, seven were caused by sepsis, four were caused by hemorrhage, three were caused by myocardial infarction, and four were related to other causes.

At least some of these deaths are preventable. Safer use of unipolar coagulation or alternative methods of tubal occlusion reduces the risk of thermal bowel injury. Three of the four deaths attributable to hemorrhage occurred after major vessel laceration during abdominal entry for laparoscopy. Safer insertion of the Veress needle and trocar or use of alternative techniques, such as open laparoscopy or minilaparotomy, should reduce the risk of such laceration.

Morbidity

Morbidity attributable to tubal sterilization is uncommon but not rare. The risks for and type of morbidity vary somewhat by surgical approach and method of tubal occlusion. Direct comparisons of minilaparotomy and laparoscopy for tubal sterilization are limited, but studies suggest several differences. In a nonrandomized study in 23 countries, 7,033 women who had silicone rubber band application by way of laparoscopy were compared with 3,033 women who had silicone rubber band application by minilaparotomy and 5,081 women who had modified Pomeroy ligation by minilaparotomy. The surgical complication rates were 2.04%, 1.45%, and 0.79% for the three groups, respectively. In a smaller but randomized study in eight centers, 791 women who had modified Pomeroy occlusion by minilaparotomy were compared with 819 women who had occlusion from electrocoagulation (technique not specified) by way of laparoscopy. Major complications occurred in 1.5% of the women in the minilaparotomy group and 0.9% of the women in the laparoscopy group. Minor complications, which are more common, occurred in 11.6% of women in the former group and 6.0% in the latter group.

In a U.S. multicenter, collaborative study, major complications were more common among women who had minilaparotomy (3.5%) than among those who had interval laparoscopic sterilization (1.6%). However, women in the study were not randomly assigned to groups, and the sterilization procedures were performed in institutions where most interval tubal sterilizations were done by way of laparoscopy. Thus, minilaparotomy sterilizations may have been performed selectively for women at increased risk for complications.

Although the overall complication rates are similar for minilaparotomy and laparoscopy, the types of complications appear to vary. Complications of minilaparotomy usually are not serious and typically include minor wound infection, longer operating time, slightly longer postoperative convalescence, and greater postoperative pain. Laparoscopic complications are more likely to include rare but life-threatening hemorrhage and vascus perforations during abdominal entry, and thermal bowel injury during electrocoagulation. A study of 100,000 laparoscopies in France suggests that major vessel laceration occurs in three of 10,000 procedures. In a study conducted in the United Kingdom, major vessel laceration occurred in nine of 10,000 laparoscopies.

Some of the most serious complications of both interval minilaparotomy and laparoscopy occur during abdominal entry. Bladder laceration during suprapubic minilaparotomy can occur, but usually it is recognized during surgery and is repaired easily. Major vessel and bowel laceration during needle or trocar insertion for laparoscopy are more difficult to recognize or repair, and delayed treatment of these injuries can be fatal. Metritis is required to reduce the risks of abdominal entry. Comparative studies of open versus conventional laparoscopy are limited and have shown no significant advantage in reducing the risk of life-threatening complications, but use of open laparoscopy should markedly reduce the risk of major vessel laceration and should reduce, to a lesser extent, the risk of bowel injury.
laceration. The use of open laparoscopy can be particularly advantageous for women known or strongly suspected to have multiple abdominal or pelvic adhesions. However, even open laparoscopy can result in bowel injury if the bowel is adherent to the anterior abdominal wall.

The method of tubal occlusion chosen influences the risk for and type of complications during laparoscopy. Thermal bowel injury, thermal bowel adhesions, and thermal bowel injury during coagulation, but it can occur during the latter if the bowel is grasped and coagulated. Transsection of the fallopian tube can occur with any technique, particularly when an attempt is made to mobilize the fallopian tube in the presence of thick peritubal adhesions. Tubal transection is most likely to occur when silicone rubber bands are used, but any resultant bleeding usually can be managed by the application of a second ring or by the use of coagulation.

DETERMINANTS OF COMPLICATIONS

Sterilization, a multicenter, prospective, cohort study, 10,685 women undergoing tubal sterilization in medical centers in nine U.S. cities from 1978 to 1987 were followed for up to 8 to 14 years (20%). The pregnancies that occurred in the tenth year (20%) through tenth years after sterilization (61%) than in the first 3 years (20%). The proportion of pregnancies that were ectopic was three times greater in the fourth through tenth years after sterilization (61%) than in the first 3 years (20%). The pregnancies that occurred in the tenth year after unilateral and bipolar coagulation, silicone rubber band application, and spring clip application were all ectopic. All but one (an ovarian pregnancy after bipolar coagulation) of the 47 ectopic pregnancies identified in the study were tubal pregnancies. The index of suspicion for ectopic pregnancy should be high when pregnancy is suspected after tubal sterilization. Pregnancy should be confirmed by use of a highly sensitive pregnancy test as soon as feasible.

A woman’s individual risk for ectopic pregnancy can be considered in both absolute and relative terms. Her absolute risk is determined by the likelihood that the sterilization procedure can fail to prevent pregnancy and the likelihood that a resulting ectopic pregnancy will be ectopic. Risk is also relative to the risk for ectopic pregnancy that a woman had before tubal sterilization. Depending on the method of contraception used before sterilization, some women may be at greater risk for ectopic pregnancy after sterilization. In a report from a case-control study in Seattle, both postpartum sterilization and interval sterilization were associated with a lower risk of ectopic pregnancy than was use of no contraception. However, women who had interval tubal sterilization had a higher risk of ectopic pregnancy than did women who were using oral contraceptives or barrier methods of contraception. For example, the risk of ectopic pregnancy was similar between women who had postpartum tubal sterilization and those who used oral contraceptives or barrier contraception.
Menstrual Changes

After nearly a half century of debate, questions regarding the existence of a posttubal ligation syndrome of menstrual abnormalities appear to be largely resolved. Questions arose initially when Williams and colleagues reported in 1951 that sterilized women had a higher-than-expected occurrence of menorrhagia and metrorrhagia. Studies in the 1970s appeared to support the existence of a poststerilization syndrome, but most of those studies had major methodologic shortcomings, including failure to account for factors other than sterilization per se that might have influenced poststerilization menstrual changes. One such factor was the use of oral contraceptives; in the United States, as many as 30% of women may use oral contraceptives immediately after tubal sterilization. A commonality of these women have menstrual changes after sterilization attributable solely to cessation of oral contraceptive use. Although one well-controlled study (Shain et al., 1989) in the 1980s identified poststerilization menstrual changes, nearly all other studies reported in the 1980s that controlled for factors such as cessation of oral contraceptive use found little or no evidence of a poststerilization syndrome at 1 to 2 years after sterilization.

Until the 1990s, questions remained about whether menstrual changes attributable to sterilization may occur several years after the procedure. Two U.S. multicenter, prospective, cohort studies argue strongly for a long-term risk. In the first, reported in 1993, 500 women were evaluated at 6 to 10 months and 3 to 4.5 years after sterilization. When women who were taking oral contraceptives were excluded, no significant differences in seven menstrual parameters were found between sterilized women and two groups of nonsterilized women.

In the second, reported in 2000, 9,514 sterilized women enrolled in the U.S. Collaborative Review of Sterilization were compared with 5,737 women whose husbands underwent vasectomy. All women were asked the same questions about six menstrual parameters before tubal sterilization or the husband's vasectomy and again at annual follow-up interviews for up to 5 years. The sterilized women were no more likely than the nonsterilized women to report changes in intermenstrual bleeding or cycle length. The sterilized women were more likely than the nonsterilized women to have decreases in the number of days of bleeding and the amount of bleeding and menstrual pain; they were also more likely to have an increase in cycle irregularity. When the risk of menstrual abnormalities was evaluated by method of tubal occlusion, there were no significant differences between the women sterilized by any of six methods and the women whose husbands underwent vasectomy in amount or duration of menstrual bleeding, intermenstrual bleeding, or menstrual pain. Women undergoing three methods of sterilization (silicone rubber band application, interval partial salpingectomy, and thermo coagulation) were more likely than nonsterilized women to have an increase in cycle irregularity, whereas women undergoing two other methods (unipolar and bipolar coagulation) were more likely to have decreases in cycle irregularity. This latter observation suggests strongly that the differences between sterilized and nonsterilized women in the likelihood of cycle irregularity and other menstrual features were attributable to chance or unmeasured differences between the study groups. Finally, sterilized women were compared with nonsterilized women for risk of endometriosis consisting of persistent increases in either amount of bleeding, days of bleeding, or intermenstrual bleeding; no significant differences were identified.

Although sterilization procedures have been hypothesized to adversely affect ovarian function, laboratory studies have identified no consistent abnormalities that reflect ovarian dysfunction. Further, the biological plausibility of such an occurrence is uncertain. The tubal branch of the uterine artery, which often is occluded during sterilization, connects with the ovarian branch of the uterine artery; thus, interrupting the tubal branch could affect the blood supply to the ovary. However, blood also is supplied to the ovary by the ovarian artery, which branches directly off the aorta and is remote from the site of tubal occlusion. The possibility has been raised that tubal occlusion could damage the ovary by acutely increasing pressure in the uterine ovarian arterial loop. However, as noted, neither laboratory nor epidemiologic studies find changes consistent with acute injury to the ovary, and there is now strong evidence against the occurrence of sterilization-attributable menstrual abnormalities within 5 years of the procedure. Some women who have two groups of nonsterilized women.
latter group is considered to have an opposing syndrome. Although menstrual abnormalities are common among sterilized women, they also are common among nonsterilized women of similar ages. The balance of the evidence to date suggests strongly that sterilized women are no more likely than comparable nonsterilized women to have menstrual abnormalities.

**Hysterectomy**

Tubal sterilization and hysterectomy are common procedures in the United States, and any relation between the two has important consequences. Tubal sterilization could increase the risk for hysterectomy by increasing either the reality or the perception that a poststerilization syndrome occurs. As noted, the evidence against such a syndrome is now strong; thus, it should not be an indication for hysterectomy. Alternatively, the fact that a woman has had tubal sterilization could affect decision making about further surgery. At least three studies suggest that this effect can occur. Cohen studied 4,374 women 25 to 44 years old who had tubal sterilization in 1974 while enrolled in a universal health insurance plan in Canada. Women 25 to 29 years old at the time of sterilization were 1.6 times more likely than nonsterilized women to have a hysterectomy at a later time. However, women 30 years or older at the time of sterilization were no more likely than nonsterilized women to have a hysterectomy subsequently. Goldhaber and colleagues, who studied 39,302 women sterilized from 1971 to 1984, found that women sterilized at 20 to 24 years old were 2.4 times more likely than nonsterilized women to have a hysterectomy subsequently. For other sterilized women, the risk for hysterectomy steadily decreased with increasing age; women sterilized at 40 to 49 years old had no increased risk. Stengachis and associates studied 7,414 women sterilized from 1968 to 1983 and found that women sterilized at 20 to 29 years old were 3.4 times more likely than nonsterilized women to subsequently have a hysterectomy. Women sterilized at 30 years old or older had no increased risk for hysterectomy.

The fact that the increased risk for hysterectomy was concentrated among women sterilized at a young age in the noted studies suggests that any increased risk for hysterectomy after tubal sterilization is not biologic in etiology but attributable to other factors, such as removal of fertility preservation as a factor in decision making. In the U.S. Collaborative Review of Sterilization, women sterilized at 34 years old and younger were four to five times more likely to undergo hysterectomy than women the same age whose husbands underwent vasectomy. However, women sterilized at 35 years old and older were also four to five times more likely to undergo hysterectomy than women whose husbands underwent vasectomy, suggesting that fertility preservation does not explain all differences in decision making between sterilized and nonsterilized women.

In the U.S. Collaborative Review of Sterilization, the cumulative probability of undergoing hysterectomy within 14 years after sterilization was 17%. Although women with gynecologic disorders at the time of sterilization were at greater risk of hysterectomy, most women who reported gynecologic disorders at sterilization did not undergo hysterectomy within the follow-up period. For example, women who reported having a history of endometriosis at sterilization were more likely to undergo hysterectomy than women without a history of endometriosis; the probability of women reporting endometriosis under- going hysterectomy within 14 years was 35%, versus 15% for women without endometriosis. Similarly, women who reported having a history of uterine leiomyomata at sterilization were more likely to undergo hysterectomy than women without a history of leiomyomata; the 14-year cumulative probability of hysterectomy among women reporting leiomyomata was 27% versus 14% for women without leiomyomata.

**Regret**

The decision to undergo sterilization is serious to both men and women because the intent is to permanently terminate fertility. Although microsurgical methods of reversal are available, these methods require special skill, the procedures are complicated and lengthy, the costs are high, and none of the methods guarantees success. Findings from studies of poststerilization regret provide useful information for presterilization counseling. Sterilization regret is a complex condition that is often causally linked to unpredictable life events. The risk factors for regret described here should not be used as reasons for restricting access to sterilization. Instead, they should be used to identify persons who may need extended counseling. Presterilization counseling has been shown to correlate with poststerilization satisfaction.

Poststerilization regret can arise from several factors, including preexisting patient characteristics, subsequent changes in the patient's social situations or attitudes, and dissatisfaction resulting from adverse side effects caused or perceived to be caused by the procedure. Estimates of the prevalence of sterilization regret vary widely by measure of indication of regret and geographic region. During the last two decades, U.S.-based studies have reported rates of poststerilization regret ranging from 0.9% to 26.0%. The wide range reflects, in part, differences in study design and questions asked of respondents. In general, the likelihood of a woman expressing regret after sterilization appears to be increased from 1% at 7 years and 13% at 14 years. The 5-year cumulative probability of regret following tubal sterilization (7%) was similar to that for women whose husbands underwent vasectomy (6%).

In the 1982 National Survey of Family Growth, about 10% of women who had been sterilized reported that they would have the sterilization reversed if it were safe to do so. In the U.S. Collaborative Review of Sterilization, 14% of sterilized women reported that they had sought information about tubal reanastomosis at least once within 14 years of sterilization; only 1% actually obtained a reversal. At least five studies have identified young age at sterilization as the strongest predictor of later regret of sterilization. In the U.S. Collaborative Review of Sterilization, young age at sterilization also was a strong predictor of regret, regardless of parity or marital status. After adjusting for other risk factors, women 30 years of age or younger at sterilization were about twice as likely as older women to express regret within 14 years of sterilization. Similarly, the cumulative probability of expressing regret within 14 years was 20% for women 30 years old or younger versus 6% for women older than 30 years at sterilization. Likewise, the 14-year cumulative probability of requesting information about reversal was 49%; among women sterilized at 18 to 24 years old and, after adjustment for other risk factors, women 18 to 24 years old were almost four times as likely as women 30 years old or older to request information about reversal. Although low parity has been identified as a risk factor for regret in some studies, it was not an independent risk factor in other studies after control for factors such as young age at the time of sterilization.
Review of Sterilization also found that women identifying tubal substantial conflict with their husbands or partners before sterilization were more than three times as likely to regret their decision and more that five times as likely to request sterilization reversal.

Timing of the procedure in relation to pregnancy has been reported as a risk factor for regret. Several studies found that women who had tubal sterilization concurrent with cesarean section or following vaginal delivery or abortion were more likely to regret sterilization, but studies have been inconsistent in this regard. In the U.S. Collaborative Review of Sterilization, the 14-year cumulative probability of regret was nearly identical for women whose sterilizations were concurrent with cesarean section (16%), after vaginal delivery (18%), and within 1 year of pregnancy (18%). The probability of regret decreased with time since the birth of the youngest child; women with 8 or more years since the birth of the youngest child had a probability of only 5%, a rate similar to that for women with no previous births (6%).

In summary, indicators of regret can vary significantly by cultural and individual circumstances. Most studies have found that age younger than 30 years is an independent risk factor for regret. The presterilization counseling for women in this age group should place special emphasis on the risk for regret. Other risk factors, such as time in relation to an obstetric event, ambivalence, or unstable life circumstances, should be assessed with each patient on an individual basis.

### Sexual Function

In the U.S. Collaborative Review of Sterilization, approximately 80% of women undergoing interval sterilization reported a moderate sexual interest or pleasure in the first 2 years after the procedure. Of women reporting a consistent change, women were 10 and 15 times more likely to report positive changes in sexual interest or pleasure than negative ones.

### Cancer

Although there is no evidence that tubal sterilization increases the risk for cancer at any site, studies are inconsistent regarding a possible reduction in risk of breast cancer after sterilization. One large prospective study by the American Cancer Society found that tubal sterilization reduced the risk of breast cancer mortality but only among women sterilized before 1973. It is unclear whether women who were sterilized had rates of screening mammography similar to those of non-sterilized women; thus, women who underwent tubal sterilization may have had greater access to screening services. A retrospective cohort study using data from the Ontario Cancer Registry found a reduced risk of breast cancer incidence among sterilized women, but that study was unable to control for potentially confounding variables. Two population-based case-control studies supported by NIH that did control for confounding found no effect of sterilization on breast cancer risk. Thus, at this point, it is unclear whether there is any biologic relationship between tubal sterilization and reduction in risk of subsequent breast cancer.

Several studies have identified a reduced risk of ovarian cancer among women whose sterizations were concurrent with cesarean section after tubal sterilization. Hankinson and colleagues reported no consistent change in either sexual interest or pleasure with each patient on an individual basis.

### VASECTOMY AS A SURGICAL ALTERNATIVE

Some couples who have chosen surgical sterilization for permanent contraception have difficulty in deciding whether vasectomy or tubal sterilization is most appropriate. Although numerous individual- or couple-related concerns can influence the decision, many couples include considerations about safety and effectiveness in their decision making. To assist such couples, we provide a brief overview of the health effects of vasectomy.

In regard to immediate surgical complications, vasectomy is a remarkably safe procedure. Serious morbidity and death are extremely rare. Fairly minor complications, such as scrotal swelling, ecchymosis, and pain, occur in up to 50% of men who have a vasectomy, but these symptoms usually resolve spontaneously within 1 to 2 weeks. Vasectomy generally has been performed through two incisions in the scrotum, one overlying each vas. Hematoma formation usually occurs in about 2% of such procedures; infections usually occur in less than 2%. In 1985, a new vasectomy technique was introduced, referred to as no-scalpel vasectomy. It reduced the already low-rate of minor complications. In most reports, the rate of hematoma formation with no-scalpel vasectomy are less than 1%. Unlike tubal sterilization, vasectomy is not immediately effective. Three months are required to flush the vas of viable sperm. This should be confirmed by a postvasectomy semen analysis at 3 months or more after the procedure.

In 1978, questions about the long-term health effects of vasectomy were raised when an increased risk for atherosclerosis was found among monkeys that had had a vasectomy. At least nine subsequent epidemiologic studies in men found no such increased risk, and later findings in monkeys did not support an increased risk. Thus, vasectomy does not affect the risk for subsequent cardiovascular disease. These studies also provided strong evidence that vasectomy does not increase overall mortality. More recently, questions were raised about the risk of prostate cancer after vasectomy. A 1998 metaanalysis of 14 observational studies concluded that the evidence for an association between vasectomy and prostate cancer was of low quality because of biases that overestimate the effect of vasectomy, and that any association is likely not a causal one. Subsequently, a large population-based study in New Zealand found no relation between vasectomy and risk of prostate cancer. Thus, the evidence to date argues strongly against any causal relationship.

Questions remain regarding a potential syndrome of postvasectomy pain. The purported syndrome has been variously defined as chronic testicular, epidydymal, or scrotal pain, and the proposed causes include epidydymal congestion, nerve entrapment, and sperm granulomas. Although a few small, uncontrolled surveys found rates of such pain as high as 2% to 15%, the largest and best study found the incidence of epidymitis-orchitis more than 12 months after vasectomy.
to be 24.7 per 10,000 person-years versus 13.6 per 10,000 person-years among men who did not undergo vasectomy. Although uncertainties remain, it is likely that a small percentage of men will indeed experience chronic pain after vasectomy. It appears, based on limited information, that many such men will respond to conservative measures and that surgical management, including vasectomy reversal, may help others.

**BEST SURGICAL PRACTICES**

- Preprocedure assessment and counseling are essential elements in a successful sterilization procedure. Counseling regarding failure rates, risks, and risk factors for later regret should be performed. Preprocedure cytologic screening and day-of-surgery pregnancy testing are encouraged if indicated.

- General anesthesia is the leading cause of death of tubal sterilizations in the United States. Although tubal sterilizations can usually be performed safely under local anesthesia, general anesthesia is used more often in the United States. One of the reasons that vasectomy is safer than tubal sterilization is that general anesthesia is rarely required.

- A major portion of morbidity and mortality associated with laparoscopic methods of sterilization is related to entry into the abdominal cavity. Open laparoscopy can reduce the incidence of major vascular injury at entry. In closed laparoscopy technique, meticulous attention to details of entry can help reduce injury.

- Safety measures with insertion of the Veress needle include directing it in the midline, toward the hollow of the sacrum or uterine fundus, and away from the major vessels, while simultaneously elevating the abdominal wall away from the dorsal vascular structures. The aortic bifurcation occurs at the level of the summits of the iliac crests and should be avoided. The Veress needle should be inserted with the port open and held in a manner to avoid occluding the spring mechanism of the inner safety obturator. Infiltration followed by aspiration of 5 to 10 cc of sterile fluid through the port can help identify malposition of the tip of the needle. Negative intraperitoneal pressure induced by elevation of the abdominal wall can be used in a variety of fluid tests at the hub of the Veress needle to confirm proper needle placement (e.g., drip test). Return of blood through the Veress needle should prompt immediate laparotomy, and the Veress needle should be left in place until the site of injury is identified, as is also the case with trocar/sleeve insertion. Insufflation should proceed at a rate no greater than 1 L/min, and the starting insufflation pressure should be less than 10 mm Hg. Intravascular insufflation can manifest as an irregular heart rhythm, “cog wheel” heart murmur, and then result in vascular collapse. Immediate Trendelenberg and left lateral positioning can be lifesaving. Insufflation to greater than 15 mm Hg pressure should be attempted with only the greatest of care and with close monitoring of possible compromise of cardiac venous return and respiratory function. When inserting the umbilical or accessory trocar, “palming” the trocar with the surgeon’s middle finger along the shaft of the instrument can serve as a safety stopper to sudden uncontrolled deep advancement of the sharp trocar tip when fascial bursting pressure is finally exceeded. Accessory trocars, if used, should be advanced under direct visualization.

- With all the techniques of tubal sterilization, success is dependent on correct identification of the tube, and hasty tubal identification, without taking the time to follow the tubes out to their fimbriated ends (or not distorted by adhesions), can result in procedural failure.

- Nearly all the techniques of tubal sterilization involve the isthmic portion of the fallopian tube, which is the narrowest and most uniform caliber portion of the extramural tube. However, it is suggested that 2 cm of the isthmic portion of the tube be left at the cornu, proximal to the site of tubal interruption, to theoretically reduce the incidence of tuboperitoneal fistula. Aggressive overstringing of ligatures, just as avoided in surgical technique elsewhere in the body, should likewise be avoided at time of tubal interruption, as strangulation and necrosis of the tube can lead to fistulization and failure rather than success. Ligatures applied during partial salpingectomy methods of sterilization (e.g., Pomeroy, Parkland) at the time of cesarean delivery are at risk of dislodge- ment by shearing forces when the uterus is restrung into the abdominal cavity at the end of the procedure. Care should be exerted to protect the ligated areas as one and then the other adnexa is replaced into the abdomen.

- Laparoscopic unilateral coagulation of the fallopian tube is one of the most successful methods of sterilization, likely attributed to the approximately 3-cm zone of thermal destruction that results. However, the risk for thermal injuries is also highest with this method, unless the safe application of unipolar energy at laparoscopy and the concept of capacitive coupling is understood by the surgeon. Greater tubal destruction and sterilization success with this method go hand in hand with least likelihood that reversal could ever be achieved.

- Laparoscopic bipolar coagulation creates a smaller zone of thermal injury (approximately 0.5 cm) than unipolar and is also not likely to result in indirect thermal injury by capacitive coupling. Three contiguous burns over a 3-cm length of tube, beginning approximately 3 cm from the cornu and moving toward the fimbriated end, is recommended. Also recommended is use of the cutting waveform, delivering at least 25 W of bipolar energy (continuous waveform by default) and the use of an optical flow meter to estimate when coagulation (and flow of current) is complete.

- Silastic band application requires familiarity with the applicator and the tendency of its grasping tongs to transect the fallopian tube when trying to retract a knuckle of tube into the hollow applicator cannula. Tethered or thickened tubes are at greatest risk of transaction and should be avoided. A complete encirclement of the tube by the grasping tongs is necessary if a partial or tangential application of the ligating band is to be avoided.

- Hulka and Fishe clips are reliable methods of tubal interruption but require strict adherence to surgical technique to be successful. Application at right angles to the tube, 2 cm from the uterus, without excessive tubal elevation, and with the tips of the clips advanced onto the mesosalpinx are the key points of the application. Clips are associated with minimal tubal destruction (3 mm) and are therefore the most amenable to tubal reversal.

- Essure microinserts are placed transcervically via hysteroscopy. Care should be taken to identify both tubal ostia and to insert the device into the proximal lumen to the level marked on the catheter. Hypervolemia should be avoided, and a follow-up HSG must be performed at 3 months postinsertion. Alternate contraception should be used until occlusion is documented.

DEFINITIONS

Accessory ovary—An additional ovarian mass close to the normally placed ovary and connected to it by the uteroovarian or infundibulopelvic ligament.

Fimbria ovarica—The structure attaching the infundibulum of the fallopian tube to the distal pole of the ovary. It is vitally important to the fimbrial ovum capture mechanism.

Gore-Tex surgical membrane—A permanent, nonporous material of expanded polytetrafluoroethylene. It may be used as a peritoneal substitute to prevent adhesions.

Interceed—An absorbable material consisting of oxidized regenerated cellulose. It functions as a temporary barrier to prevent adherence of serosal surfaces and has demonstrated efficacy in the peritoneal cavity.

Malpositioned ovary—An ovary located above the pelvic brim because of a lack of normal descent into the pelvis. It may be elongated, but it remains attached to the uterus by the uteroovarian ligament and to the fallopian tube by the fimbria ovarica.

Ovarian cortex—The outer layer of the ovary consisting of an outer zone, which is mainly collagenous (tunica albuginea), and an inner zone, which is less fibrous and more cellular and contains the germ cells (primordial follicles).

Ovarian medulla—The inner region surrounding the hilum of the ovary. It contains no follicles, only blood vessels and the remnants of the tubular structures that are homologous to the male testis (rete testis).

Ovarian remnant—Persistent ovarian tissue unintentionally left behind following oophorectomy.

Paradoxic oophorectomy—A concept suggesting that removing an ovary on the side of unilateral obstruction or absence of a fallopian tube may improve fertility. Removal of one ovary supposedly promotes repeated ovulations from the ovary opposite the remaining patent fallopian tube.

Residual ovary—Symptomatic ovarian tissue following removal of the ovary.

Supernumerary ovary—An additional ovary that has no direct or ligamentous connection with a normally placed ovary. It is located at some distance from the normally placed ovaries.

Tumor markers—Substances identified in higher than normal amounts in blood, urine, or body tissues of patients with specific malignancies. They are produced directly by the tumor or as a response to the presence of cancer, i.e., indirect marker.

Tunica albuginea—Condensed ovarian stroma that forms a fibrous capsule.

Management of benign disease of the ovary continues to unfold with new and challenging clinical alternatives. Progress has occurred with regard to ovarian reconstruction. The population is living longer, and cancer survivors are increasing exponentially. All of this leads us to focus on enhancing our understanding of preservation of ovarian function, determining treatment related to decreased adhesion formation, and addressing a host of other aspects related to ovarian activity.

It has been established that the ovaries and fallopian tubes are sensitive to ischemia from surgical trauma; adhesions may develop as a result; and the normal anatomic relationship between fallopian tubes, ovaries, and uterus may be altered. Knowledge regarding anatomy and embryology of the ovaries and other reproductive organs complemented by mastery of the principles and skills of microsurgery are the prerequisites for excellent results following ovarian reconstructive surgery. Embryology and anatomy are addressed in this chapter with emphasis on the importance of the anatomic relations of the ovary to other pelvic organs in the section on the evaluation and management of an adnexal mass. State-of-the-art surgical procedures—both via minimally invasive as well as laparotomic approaches and techniques devised for the reconstruction of the ovary—for restoration of normal pelvic anatomy are presented in the context of specific pathology or other abnormal conditions that require surgical intervention. This chapter also focuses on pediatric and adolescent surgical procedures that are performed when ovarian pathology is identified.

EMBRYOLOGY

The reproductive system is derived from mesoderm. The primordium of the urogenital ridge, it is divided into two segments. One is the nephrogenic ridge, i.e., metanephric derivatives, the renal system; the other is the gonadal ridge for development of the reproductive tract. Gonads are a reflection of three origins: mesothelium, mesenchyme, and primordial germ cells. The paramesonephros gives rise to the fallopian tubes and the uterus. Two gonadal ridges arise early in gestation (4 to 5 weeks) in the developing embryo as thickening on the medial aspect of the coelomic cavity adjacent to the mesonephros. These gonadal outgrowths are composed of coelomic epithelium and underlying mesenchyme projecting into the future peritoneal cavity. The epithelial and mesenchymal cells of the gonadal primordia are of mesodermal origin (large, spherical ovoid germ cells that originate extragonadally in the wall of the yolk sac and migrate to the developing gonads). Until the 6th week of gestation, the gonads of the two sexes remain morphologically indistinguishable. The presumptive ovaries remain undifferentiated until the onset of meiosis at the end of the first trimester. The ovarian cortex is a single germinal epithelium.
The mechanisms responsible for gonadal sex differentiation are largely unknown. Investigators have theorized the presence of a testicular determining factor (H-Y cell-surface antigen) on the short arm of the Y chromosome that is elaborated by a specific gene. Meiosis-inducing and -preventing substances, both of which are produced by cells derived from mesonephric structures adjacent to the gonad, are the agents of regulation of ovarian and testicular germ cell differentiation. The balance between these two substances varies between the two sexes and at different stages of development. The meiosis-inducing substance predominates in the fetal ovary. Maternal ovarian hormone production is not required for differentiation of the germ cells or, apparently, for later development of the fetal reproductive tract. Various ultrastructural studies have shown no specific changes in fetal granulosa cells that can be definitely associated with steroid hormone secretion such as is identified in the fetal Leydig cells. Thecal cells play an essential role in steroid synthesis in the adult ovary, but they do not appear until later in gestation and even then retain a relatively undifferentiated appearance. Fetal pituitary gonadotropin production begins as early as 10 weeks’ gestation and reaches peak levels at midgestation. Gonadotropins have a major influence on follicular development in the adult ovary, but evidence for a follicular determination in the fetus is lacking.

**GENE EXPRESSION**

Specific follicular cell receptors bind growth factors, which are locally synthesized with the ultimate effect of intracellular signaling and protein kinase activation. This activity affects transcription of targeted genes. Gene expression is involved in follicle development, ovulation, and corpus luteum and corpus albicans formation. Transcription factors include protooncogenes, C-myc, and CCAAT/enhancer binding protein.

**FEMALE FETAL DEVELOPMENT**

The ovarian surface cortex, during the early prefollicular stage, is characterized by germ cells and graafian follicles organized in cords and sheets, but the cortex lacks specific conformation. The final distinctive change to occur in the fetal ovary is the onset of meiosis at the 11th or 12th week of gestation. Meiosis is preceded by differentiation of primitive germ cells into actively dividing mitotic cells called oogonia. The mitotic divisions of the oogonia are associated with complete separation at telophase, leaving the daughter cells connected by intracellular bridges. After a series of mitotic divisions, there is progressive entry of cells into meiosis, beginning in the innermost cortex and gradually extending to the periphery. These cells passing through the various stages of the first meiotic prophase are then designated oocytes. By late gestation, all surviving oocytes have advanced to the diplophase stage. Further differentiation of the oocyte is arrested at this stage and does not resume until ovulation begins at menarche, about 12 years later. Follicular formation begins at 18 to 20 weeks’ gestation and continues throughout the remaining weeks of fetal development. All the surviving oocytes are surrounded by adjacent granulosa cells; oocyte and follicular growth are well established by the late fetal and early neonatal period. The constant degeneration and loss of oocytes before their incorporation into the follicles reduces their numbers to only 1 to 2 million (follicles) in the newborn ovary.

**ANATOMY**

The dimensions of the adult ovary vary from individual to individual but average 3 to 5 cm in length, 2 to 3 cm in width, and 1 to 2 cm in diameter, with a weight of 3 to 8g. The ovarian capsule is smooth in childhood, but its surface becomes pitted from follicular maturation and atresia.

The size, shape, and position of the ovary in the pelvis are somewhat variable, and both the consistency and the follicular changes taking place within the ovary vary with stage of the menstrual cycle. The ovary typically is anchored to the side wall of the pelvis in the shallow peritoneal fossa of Waldrein formed between the angle of proximity of the ovary to the ureter. This knowledge is important before dissecting the ovary off the pelvic side wall.

The ovary is connected to the uterus by the uteroovarian ligament, to the posterior aspect of the broad ligament by the mesovarium ligament, and to the lateral pelvic sidewall by the infundibulopelvic ligament (Fig. 28.1). The mesovarium ligament attaches to the mesentery of the ovary. The other two ligaments are attached at the hilum of the ovary. The ovary migrates downward from high in the abdomen during embryonic life. The infundibulum of the fallopian tube extends onto the ovary and is attached to it at its most distal pole by the fimbria ovarica. The relation of the ovary to the fimbria ovarica and to the uteroovarian ligament is crucial, and they should be carefully maintained during ovarian reconstruction.

During embryogenesis, the ovary may assume an unusual appearance (i.e., it may be septate) or assume an unusual position (Fig. 28.2). An accessory ovary (Fig. 28.2A) usually is close to or is connected to a normally placed ovary. An accessory ovary also may be attached to the adjacent, broad, uteroovarian or infundibulopelvic ligaments. Unlike the accessory ovary, a supernumerary ovary (Fig. 28.2B) must have an independent embryologic origin. It may develop from a primordium such as arrested migrating gonadocytes. A supernumerary ovary consists of typical ovarian tissue but has no direct or ligamentous connection with a normally placed ovary. A supernumerary ovary is thus a true third ovary that has independent function and is located at a point that is distant to a normally placed ovary. Ovarian malposition (Fig. 28.2C) also may occur when the ovary fails to descend into the pelvis to assume its normal position. In ovarian malposition, the ovary is attached as it should be to the uterus by the uteroovarian ligament and to the fallopian tube by the fimbria ovarica, but it may lie adjacent to the liver or spleen. The ovary is elongated and may measure up to 15 cm in length. The fallopian tube attaching to such a malpositioned ovary may be 20 to 26 cm in length, almost twice its normal length.

The normal ovary has a surface covering composed of a single layer of flattened, germinal epithelial cells. This layer is contiguous at the ovarian hilum, with the peritoneal epithelium...
FIGURE 28.1. Normal anatomy of the ovary. A: Anatomic relations of the uterus, tube, and ovary. B: The infundibulum of the oviduct extends onto the ovary and is attached at its most distal pole (ovarian fimbria). The mesovarian is the mesentery of the ovary. Each ovary is attached at the hilum.

of the posterior leaf of the broad ligament. Beneath the germi-
nal epithelium is a second layer of condensed ovarian stroma
that forms a fibrous capsule, i.e., the tunica albuginea. The
area through which the vessels and nerves enter and exit is
called the hilum of the ovary. Immediately around the hilum
and extending into the substance of the ovary is an area known
as the medulla, which is covered by the cortex. The medulla is
composed of fibrous tissue unlike the condensed stroma of the
ovarian cortex. The medulla contains no follicles; it has only
blood vessels and the remnants of the tubular structure that
would have developed into a testis (i.e., the rete ovarii) had the
fetus been male.

The ovarian artery arises on each side of the abdominal
aorta just below the renal arteries. The artery descends from the
aorta and crosses the ureter obliquely to enter the infundibu-
lopelvic ligament on its course to the ovary. When it reaches
the broad ligament, the ovarian artery branches to supply the
fallopian tube and ovary before it finally anastomoses directly
with the uterine artery to form a continuous arcade in the broad
ligament. The ovarian veins are situated mainly in the meso-
salpinx, where they give rise to the pampiniform plexus. At the
outer end of the broad ligament, this plexus coalesces to form
a single, large ovarian vein. The ovarian veins accompany the
ovarian artery to terminate in the inferior vena cava on the
right and the renal vein on the left.

The lymphatic vessels of the ovary drain in three directions.
The main group accompanies the ovarian vessels in the in-
fundibulopelvic ligament and eventually reaches the periaortic
nodes in the vicinity of the kidney. Other lymphatic channels
communicate with channels of the opposite ovary by crossing
the fundus of the uterus through the ovarian ligament. Some
channels drain through the ovarian and round ligaments into
the superficial inguinal lymph nodes in the groin. The ovary is
supplied by both motor and sensory parasympathetic and sym-
pathetic nerves, which accompany the ovarian vessels from the
abdomen as they pass into the infundibulopelvic ligament to
reach the hilum of the ovary. The segmented nerves supply the
ovary from T10 and T11.

**ADNEXAL MASS**

The uterine adnexa (gynecologic origin) consist of the ovaries,
the fallopian tubes, and the uterine ligaments. Although ad-
nexal pathology often involves one of these structures, contigu-
ous tissue of nongynecologic origin also may be involved. The
bimanual examination is the most practical method of screen-
ing for an adnexal mass. When such a mass is found, its initial
characteristics should be carefully described so that any subse-
quent change can be appreciated and the nature of the mass can
be better ascertained. The description should include location,
size (in centimeters), consistency, shape, mobility, tenderness,
bilaterality, and associated findings (e.g., fever, ascites).

Adjunctive diagnostic techniques such as sonography, mag-
netic resonance imaging (MRI), and computed tomography
(CT) may help delineate the nature of adnexal enlargement.
Pelvic ultrasonography, especially three dimensional, is an ac-
curate means of determining the location, size, extent, and con-
sistency of pelvic masses and is also useful for detecting obstruc-
tive uterine leiomyomas, and malignancy. Other more specialized
diagnostic procedures also may be necessary for the evalua-
tion of an adnexal mass (Table 28.1).

CT scanning has been particularly useful in gynecologic on-
ology because it helps define the extent of paracervical and
parametral involvement and allows a reasonable determina-
tion of the resectability of malignant neoplasms. MRI has sur-
passed CT in the precision of measurement of adnexal masses.
MRI also allows a clear definition of the relationship of adja-
cent organs.

In a study conducted by Timmerman and coworkers, assess-
ment was made of the use of both ultrasound and circulating
levels of CA-125 antigen. Multivariate logistic regression anal-
ysis algorithms were used to distinguish benign adnexal masses
from a malignant process. Transvaginal ultrasonography with
color Doppler imaging was recorded in the 191 patients eval-
uated, ages 18 to 93 years. Of interest, 26.7% of the cohort of
patients studied had malignant tumors. The authors believed
that regression analysis could be used to accurately discrimi-
nate malignant from benign adnexal masses preoperatively.

An intriguing aspect of ultrasound assessment is the predic-
tion of malignancy in adnexal masses using an artificial neural
network. Taylor and colleagues reported generating a neural
network algorithm that enabled computing of a probability of
malignancy score for preoperative discrimination between
malignant and benign adnexal masses. A retrospective anal-
ysis that included training in artificial neural network assess-
ing transvaginal B-mode ultrasonography and color Doppler
imaging was determined. The variables that were put into the
artificial neural network included age, menopausal status, max-
imum diameter of the neoplasm, tumor volume, and papillary
projections. The results identified four primary variables that
were most effective in distinguishing benign versus malignant
processes. These variables included age, time-average maxi-
mum velocity, papillary projection score, and maximum tumor
diameter. The authors concluded that artificial neural networks
are a useful clinical parameter to distinguish benign from ma-
lignant ovarian masses.

Surgical intervention ultimately may be necessary to de-
terminate the nature of the adnexal mass. Minimally invasive
surgery is useful to exclude benign ovarian or nonovarian neo-
plasms. Indications for visualization of an adnexal mass with
surgery is useful to exclude benign ovarian or nonovarian neo-
plasms. Indications for visualization of an adnexal mass with

Any solid mass first developing after menopause
Failure to discover the nature of the mass (e.g., leiomyoma) with radiologic or sonographic imaging techniques

One of the major goals of the evaluation of the adnexal mass is to rule out malignancy. There is an age-dependent risk for a malignant adnexal mass. The incidence of malignant neoplasm increases significantly after age 50 years. Increased size of the adnexal mass is associated with an increased risk of malignancy.

Granberg and colleagues found that less than 1% of masses smaller than 5 cm were malignant, less than 11% of masses 5 to 10 cm were malignant, and 72% of masses larger than 10 cm were malignant. Sassone and associates, in an evaluation of women of all ages (mean age, 41 years) by transvaginal sonography, found that 3% of masses smaller than 5 cm and 7% of masses 5 to 10 cm were malignant; the incidence of malignancy for masses larger than 10 cm was 13%.

Endometriosis is a common cause of an adnexal mass. An endometrial cyst of the ovary may develop into an endometrioma. Leakage of blood from the cyst may cause peritoneal irritation, pelvic adhesions, and pelvic organ fixation.

Tuboovarian inflammatory complex usually is the result of incompletely treated or unresolved subacute, chronic pelvic inflammatory disease (PID) in the walled-off area surrounding the pelvic structure. Uterine leiomyomata cause nodularity and consequent irregular conformation of the uterus. The uterus may become enlarged and may present as an abdominal mass. The inability to distinguish a leiomyoma from an ovarian tumor on pelvic examination is an indication for further diagnostic evaluation.

Adnexal enlargement may be the result of carcinoma of the rectum, appendix, or bladder. Patients present with a variety of symptoms according to the organ involved. A complete and thorough evaluation is necessary to delineate the etiology of a neoplasm.

An adnexal mass may be noted in cases of acute abdomen. The differential diagnosis should include adnexal torsion, ruptured hemorrhagic cyst, degenerating leiomyomata, ectopic pregnancy, unruptured tuboovarian abscess, acute appendicitis with or without abscess formation, and diverticular disease of the sigmoid colon. A careful history, pelvic examination, and appropriate imaging studies often allow a prompt diagnosis.

Although every adnexal mass requires individual evaluation and management, it is possible to make a number of useful general recommendations. Expectant management is justified only when an asymptomatic physiologic cyst is suspected. Most cysts greater than 6 cm in diameter require a thorough evaluation. Imaging techniques are invaluable for characterizing the nature of the adnexal enlargement, but these procedures do not replace a careful medical history and thorough physical and pelvic examination.

ADNEXAL MALIGN DURING PREGNANCY

The incidence of adnexal mass in pregnancy requiring surgical intervention has been reported to occur in 1 in 81 to 2,500 pregnancies. When an adnexal mass is noted incidentally on ultrasound during pregnancy, the majority of small, simple cysts do not pose a risk to the pregnancy. Furthermore, most large or sonographically complex masses spontaneously resolve, as reported by Bernhard and colleagues. This study evaluated 18,391 ultrasound studies done in an obstetric population for which 412 women were identified with an adnexal mass. The incidence of adnexal masses was 2.3% in the pregnant population evaluated. In addition, the rate of torsion of the adnexal mass was 1%, and the rate of malignancy was also reported as 1%.

Before operative intervention, a complete assessment of the fetus—including ultrasound to rule out a lethal anomaly and to document cardiac activity—is in order. The optimal time for elective surgery is during the second trimester. The patient should be informed of the increased risk of preterm labor and delivery. The patient should be placed in the left lateral tilt position to avoid inferior vena cava compression and associated uteroplacental insufficiency. Postoperatively, the fetus should be placed on continuous fetal heart rate monitoring.

The most effective approach in management of adnexal masses during pregnancy remains a point of controversy (i.e., laparoscopy versus laparotomy). In a series of 88 pregnant women who underwent 93 surgical procedures for suspected adnexal pathology, laparoscopy was performed during the first trimester in 39 patients. The remaining 54 patients underwent laparotomy, 25 during the first trimester and 29 during the second trimester. Neither intraoperative nor postoperative intrauterine complications were reported in the series. Five of 39 women undergoing the first-trimester surgery had a spontaneous abortion. Neither intraoperative nor postoperative intrauterine complications were reported in the series. Five of 39 women undergoing the first-trimester surgery had a spontaneous abortion. Neither intraoperative nor postoperative intrauterine complications were reported in the series.

ULTRASOUND

Ultrasound is useful in predicting malignancy (Table 28.2): Characteristic features of benign versus malignant neoplasms have been reported. Collated data from studies of ultrasound accuracy in the prediction of malignancy have an average positive predictive value of 74% and an average sensitivity of 88% (Table 28.3).

Weiner and coworkers have used transvaginal color flow imaging before exploratory surgery to study the impedance to blood flow in women with an adnexal mass. Intramural blood vessels consistently demonstrated low impedance to flow with

disease. Many (tumor markers) are not specific for a particular patient with malignancy, especially in the early stages of the benign conditions. Tumor markers are not elevated in every case, are not unique to malignant processes and can be elevated with the tumor per se or as a response to the presence of cancer. They are produced by normal amounts in blood, urine, or body tissues of patients with specific malignancies. The tumor marker is produced by the tumor itself and can be elevated with specific malignancies. The tumor marker is produced by the tumor per se or as a response to the presence of cancer. They are produced by normal amounts in blood, urine, or body tissues of patients with specific malignancies. The tumor marker is produced by the tumor itself and can be elevated with specific malignancies.

The pelvic (adnexal) mass may be of gynecologic or nongynecologic origin (Table 28.5). Specific clinical findings are helpful in differentiating a malignant from a benign neoplasm. The clinical findings listed in Tables 28.3 through 28.6 are often helpful in differentiating a malignant from a benign neoplasm. All ovarian neoplasms larger than 6 cm in diameter with a solid component should undergo investigation. The postmenopausal ovary is usually small and nonpalpable. Enlargement of the postmenopausal ovary requires immediate investigation. Symptoms of ovarian neoplasms usually depend on their size, rate of growth, and position in the pelvis or abdomen. Symptoms may include vague lower abdominal fullness or pressure discomfort. Larger masses rise out of the true pelvis and may cause abdominal enlargement with varicosities and edema of the lower extremities. Most ovarian neoplasms are asymptomatic until they enlarge or involve adjacent organs and structures.

A pulsatility index less than 1:16 in women with malignant tumors. The sensitivity and specificity of the preoperative pulsatility index in detecting malignant ovarian tumors were 94% and 97%, respectively. Kurjak and colleagues found that vessels with a low-resistance index near the center of the mass or within papules or septa were highly correlated with malignancy. Therefore, transvaginal color flow imaging may be a useful clinical tool in the preoperative evaluation of ovarian masses.

Doppler resistance index has been used as a “vascular” scoring system. Color Doppler ultrasonography appears to be a reliable method in presurgically evaluating ovarian neoplasms. Transvaginal color Doppler sonography has identified the following parameters as useful in determining malignant versus benign ovarian masses: number of vessels detected in each tumor, tumor vessel location (central versus peripheral), peak systolic velocity, lowest resistance index, mean resistance index, and pulsatility index. Color Doppler signals were detected in 100% of malignant masses and 73% of benign masses, with the difference being statistically significant as reported by Alcazar and associates. Tumor vessel location appears to be central in virtually all malignant masses. Overall, the investigator operating characteristic curves generated can be used to predict malignant processes. The lowest resistance index was associated with the majority of malignant tumors.

Three-dimensional ultrasonographic technology has been used to evaluate adnexal masses. Images are dissected in XYZ planes and can be focused especially on areas suggestive of malignancy. Three-dimensional ultrasound facilitates real-time analysis of acquired image data and allows reassessment of the findings at the time of the original ultrasound. Three-dimensional transvaginal ultrasonographic technology appears to enhance and facilitate morphologic assessment of benign as well as malignant ovarian masses.

**TUMOR MARKERS**

Tumor markers are substances that are identified in higher than normal amounts in blood, urine, or body tissues of patients with specific malignancies. The tumor marker is produced by the tumor per se or as a response to the presence of cancer. They are not unique to malignant processes and can be elevated with benign conditions. Tumor markers are not elevated in every patient with malignancy, especially in the early stages of the disease. Many (tumor markers) are not specific for a particular type of cancer; therefore, there are limitations to the use of tumor markers.

CA-125 is a tumor-associated antigen to an antibody expressed by about 80% of patients with epithelial ovarian cancer. It can be increased by nongynecologic malignancies with involvement of the pleura or peritoneum and by benign conditions that result in ascites. Because of the many medical diagnoses that give false-positive CA-125 results, CA-125 cannot be used for general population screening for ovarian cancer in either premenopausal or postmenopausal women. However, in menopausal women who present with a pelvic mass, CA-125 can help differentiate benign from malignant masses.

Because menopausal women have fewer gynecologic diseases that give false elevation of CA-125, the test is more sensitive and specific in this age group. Several authors have demonstrated that a panel of assays can improve both sensitivity and specificity in the detection of ovarian malignancies. For example, Soper and associates demonstrated 100% specificity and predictive value for CA-125 with TAG 72 or CA-15-3. Table 28.4 provides specific markers and their clinical application.

The clinical findings listed in Tables 28.3 through 28.6 are often helpful in differentiating a malignant from a benign neoplasm. All ovarian neoplasms larger than 6 cm in diameter with a solid component should undergo investigation. The postmenopausal ovary is usually small and nonpalpable. Enlargement of the postmenopausal ovary requires immediate investigation. Symptoms of ovarian neoplasms usually depend on their size, rate of growth, and position in the pelvis or abdomen. Symptoms may include vague lower abdominal fullness or pressure discomfort. Larger masses rise out of the true pelvis and may cause abdominal enlargement with varicosities and edema of the lower extremities. Most ovarian neoplasms are asymptomatic until they enlarge or involve adjacent organs and structures.

**LAPAROSCOPIC MANAGEMENT OF AN OVARIAN MASS**

The pelvic (adnexal) mass may be of gynecologic or nongynecologic origin (Table 28.5). Specific clinical findings are helpful in differentiating a malignant from a benign neoplasm (Table 28.6). It is important to establish whether the mass is of ovarian origin and to understand that a mass causing an ovary to enlarge to >6 cm in diameter should be considered potentially malignant until proven otherwise. The most common ovarian mass is the physiologic ovarian cyst, which is caused by failure

of a follicle to rupture or to regress. Physiologic ovarian cysts normally are <6 cm in diameter, smooth, mobile, and slightly tender to palpation. They usually contain straw-colored fluid and may be associated with menstrual irregularity. Physiologic ovarian cysts smaller than 6 cm usually regress by absorption of the fluid or spontaneous rupture. The premenopausal patient may be managed conservatively over two menstrual cycles. If regression fails to occur over two periods of observation or if enlargement is noted, reassessment is indicated.

Oral contraceptives have been suggested as an alternative treatment for functional cysts. The combination-type oral contraceptives send negative feedback to the pituitary gland to decrease gonadotropin stimulation of the ovary, which causes regression of the cyst. Steinkampf and colleagues noted that the rate of disappearance of functional ovarian cysts was not affected by estrogen-progestin treatment; nevertheless, a patient taking oral contraceptives with an adnexal mass should be thoroughly investigated.

Failure of the corpus luteum to regress (in the nonpregnant patient) may cause development of a corpus luteum cyst. The size of the corpus luteum cyst varies according to the amount of blood contained within the cyst. A large corpus luteum may rupture and cause intraperitoneal hemorrhage. Amenorrhea or irregular uterine bleeding may accompany the development of a corpus luteum cyst. A sensitive pregnancy test, ultrasonography, and laparoscopy can be used to differentiate an ectopic pregnancy from a persistent corpus luteum.

A theca-lutein cyst, which may be associated with gestational trophoblastic disease or pregnancy, is the result of luteinization of the ovary by human chorionic gonadotropin (hCG). Many of these cysts are bilateral and multicystic. A reduction in hCG levels usually leads to their spontaneous regression.

Polycystic ovarian disease (PCOD) is associated with bilaterally enlarged ovaries with a smooth surface. The ovaries contain multiple follicular cysts; many patients are obese and hypertensive and have accompanying anovulation (see Ovarian Surgery for Polycystic Ovarian Disease).

Congenital anomalies of the Müllerian system and vestigial remnants of the wolffian system are of gynecologic, if not strictly ovarian, origin. Müllerian anomalies should be considered in the differential diagnosis of an adnexal mass. Uterine anomalies often are associated with cyclic pain from degeneration of ovarian remnant to surrounding structures.

Ovarian remnant syndrome follows attempted oophorectomy. Minke and associates demonstrated that devascularization of ovarian tissue can occur with reimplanting on intact or abraded peritoneal surfaces, where it may resume endocrine function. Thus, the authors suggest that great care should be exercised to remove all ovarian tissue, particularly when oophorectomy is performed through the laparoscope.

Ultrasonography remains a valuable tool in establishing the diagnosis of ovarian remnant syndrome. The use of both transabdominal sonography and transvaginal sonography with use of color Doppler identification of the mass acquires information with respect to both arterial and venous flow. This facilitates identification of ovarian tissue. With respect to diagnosis, use of gonadotropin-releasing hormone (GnRH) agonist stimulation test allows identification of the presence of functioning ovarian tissue in association with ovarian remnant syndrome. Associated chronic pelvic pain frequently responds to suppressive therapy. Initially, the gonadotropin flare results in increased production of estradiol and allows confirmation of the diagnosis. As treatment is continued, the GnRH agonist often proves efficacious in relief of pelvic pain.

Symmonds and Petit identified three major factors that may complicate the initial surgery and make it difficult or impossible for the surgeon to ascertain whether all ovarian tissue has been removed: increased pelvic vascularity, which renders hemostasis difficult; adhesions, which distort the anatomy and make dissection difficult; and neoplasms, which also distort the anatomy. The most common preexisting disease is endometriosis, followed in frequency by pelvic inflammatory disease. Patients with ovarian remnant syndrome often present with both pelvic pain and a mass. The quality of the pain varies, often cyclically, and ranges from a sensation of pressure or dull aching to a severe stabbing pain.

The clinical diagnosis of ovarian remnant syndrome can be difficult. A finding of premenopausal levels of follicle-stimulating hormone (FSH) may facilitate the diagnosis. Sonography (especially vaginal) may be of some value, and a CT scan or MRI may be useful for defining the physical relation of the ovarian remnant to surrounding structures.

The treatment of choice is adequate excision of the ovarian remnant with removal of contiguous adherent tissue such as pelvic peritoneum, bowel serosa, the underlying involved ligament, and alveolar and vascular tissues (Fig. 28.3). Excision of ovarian tissue may require a retroperitoneal dissection to define the relation of the ureter to the bowel and ovary. Special care should be taken to carefully define all anatomic relations before extirpation of the remnant.

Magtibay and colleagues addressed the surgical management of patients with ovarian remnant syndrome at the Mayo Clinic. All operations for residual ovarian syndrome were performed by laparotomy. Of 138 patients who underwent a wide dissection and removal of the remnant, a moderate risk of bowel, bladder, or ureteral injury was noted; however, 90% of patients had complete resolution or marked improvement of symptoms after surgery.

The laparoscopic excision of ovarian remnant ovaries is feasible. A laparoscopic retroperitoneal approach that allows dissection of the course of the ureters with coagulation and dissection of the infundibulopelvic ligament and the uterine vessels can be accomplished. Surgeons with appropriate laparoscopic skills can consider this surgical approach. There is potential for ureteral injury as well as cystotomy and bowel injury.

RESIDUAL OVARY

Based on the clinical circumstance, the gynecologic surgeon should consider the value of ovarian conservation at the time of hysterectomy for benign disease. Some authors have noted the incidence of malignant neoplasm in retained ovaries as a reason for prophylactic oophorectomy, and others have noted the presence of “residual ovary syndrome,” characterized by either recurrent pelvic pain or a persistent pelvic mass (Fig. 28.4). However, Funt followed up 992 patients after conservation of one or both ovaries at the time of hysterectomy and reported that none developed ovarian malignancy, and only 1.4% required subsequent surgical intervention for adnexal pathology. The benefits of preserved ovarian function thus appear to substantially outweigh the risk of subsequent ovarian pathology requiring further surgery. Before surgery, the gynecologic surgeon should discuss the various risks and benefits of castration and should encourage the patient to participate in any decision concerning the fate of her ovaries.

GnRH agonists have been used to assess response of residual ovaries with chronic pelvic pain followed by surgical intervention to remove the residual ovarian tissue. Resolution of pelvic pain in six treated patients occurred with the analog (GnRH agonist) and persisted with surgical extirpation of the ovarian tissue. Suppression of ovarian function by GnRH agonists allows differentiation of pelvic pain caused by residual ovarian tissue from other sources and thus should be a prerequisite to surgical intervention.

In a retrospective report of 20 years’ experience with residual ovary syndrome in which 2,561 hysterectomies were performed, the incidence of residual ovary syndrome was 2.85%. Thus, 1 in 35 women who undergo hysterectomy with ovarian preservation become symptomatic—that is, they experience pelvic pain often with the presence of a benign cyst. Patients should be counseled preoperatively with respect to the potential for residual ovary syndrome when the initial surgical intervention is anticipated. In addition to chronic pelvic pain, a pelvic mass and dyspareunia include the “cluster of symptoms” that can occur in patients who have undergone previous hysterectomy.
A Not infrequently, the ovarian remnant may adhere to the bowel and the pelvic sidewall peritoneum. B The ureter must be visualized and its relation to the bowel and ovarian remnant established. This may require development of the pararectal and rectovaginal spaces.

FIGURE 28.3. A: Not infrequently, the ovarian remnant may adhere to the bowel and the pelvic sidewall peritoneum. B: The ureter must be visualized and its relation to the bowel and ovarian remnant established. This may require development of the pararectal and rectovaginal spaces.

ADNEXAL TORSION

Torsion of the adnexa is an infrequent cause of pain in the lower abdomen. However, torsion is a common gynecologic surgical emergency, with a prevalence of 2.7%. Treatment of adnexal torsion is considered an emergency because peritonitis and death can result. Any portion of the adnexa (tube or ovary) may undergo torsion. It may occur in neoplastic ovaries or as a consequence of hyperstimulation.

The clinical findings of torsion are nonspecific. For this reason, delay in diagnosis and surgical intervention is common. The classic presentation is the acute onset of abdominal pain with clinical evidence of peritonitis and an adnexal mass. However, according to Bayer and Wiskind, the presenting findings in most patients are nonspecific and unimpressive. Torsion is more likely to occur during ovulation or as a premenstrual event associated with increased pelvic congestion; the authors found no correlation between the phase of the cycle and the onset of the symptoms.

Historically, the adnexa usually were removed because some authors suggested that untwisting the adnexa could increase
Surgery for Benign Gynecologic Conditions

The risk of thromboembolism. This has not been well substantiated. There is growing evidence that unwinding the involved adnexa to observe for tissue reperfusion and viability is safe. Nevertheless, a significant delay in surgical intervention may result in irreversible necrosis, requiring removal of the tube, ovary, or both.

The minimally invasive surgical management of adnexal torsion has been increasing in efficacy. Mage and colleagues found that unwinding the adnexa was possible in most patients in their series, and no further intervention was required. Likewise, Shalev and Pelleg demonstrated that laparoscopic detorsion of the adnexa is safe and reliable as a primary treatment of this condition. Thus, the weight of evidence warrants conservation of the adnexa, if there is evidence of reperfusion and if significant delay has not resulted in irreversible tissue necrosis. In most instances, detorsion may be accomplished through the laparoscope.

SURGERY OF THE OVARIAN SURFACE

Surgery to remove adhesions or endometriosis from the ovarian surface is not unusual and primarily accomplished via laparoscopy. De novo adhesions or adhesions between the medial surface of the ovary and the broad ligament may be filmy and vascular (Fig. 28.5A), and may be excised by fine electrocautery or vaporized with the use of a laser (Fig. 28.5B). More extensive adhesions that completely cover the ovarian surface may be thick and avascular (Fig. 28.5C and D). The plane of dissection between the broad ligament or pelvic sidewall and the adherent ovarian surface must be developed with care so as not to remove or damage the peritoneum while excising the adhesion (Fig. 28.3D). Multiple, small adhesions distributed over the ovarian surface, once coagulated, can be gently removed from the ovary without trauma to the ovarian cortex.

If the lateral aspect of the ovary is densely adherent to the broad ligament, it may be necessary to dissect the ovary free. Some cases require that a large area of the sidewall or the broad ligament be denuded; reperitonealization can be accomplished with 7-0 fine, nonreactive suture material.

Small endometrial implants can be fulgurated or vaporized. The resulting small ovarian defect usually does not require closure. Care should be taken to ensure that the endometriosis is superficial and that the implant is not actually the tip of a large endometrioma within the substance of the ovary.

RECONSTRUCTION OF THE OVARY

Before ovarian reconstruction is begun, it is important that proper mobilization of the ovary be accomplished for reestablishment of normal anatomic relations. Once complete

FIGURE 28.5. Ovarian adhesions. A: Filmy adhesions between the medial aspect of the ovary and the pelvic sidewall. B: These may be removed with laser or fine electrocautery with use of a quartz or glass rod, respectively, as a backstop. C: The ovary may be enveloped by adhesions. D: Care should be taken to tent up the adhesions so that the peritoneum is not damaged or incised.
The approach to resection of an ovarian cyst should be planned so as to minimize adhesion formation. The incidence of de novo adhesion formation appears to be decreased when the initial approach is through laparoscopy. The Operative Laparoscopy Study Group assessed the issue of frequency and severity of adhesion reformation and of de novo adhesions after operative laparoscopy. In a multicenter collaborative approach that included early second-look intervention, 68 patients underwent operative laparoscopic procedures, including adhesiolyis as well as ovarian cysectomy. The scoring of adhesions noted during the second-look laparoscopy occurred at nine sites (each ovary, each fallopian tube, omentum, cul-de-sac, pelvic sidewall, and large and small bowel). The study concluded that adhesion reformation is a frequent occurrence and that de novo adhesion formation occurred less frequently after initial operative laparoscopy.

A number of agents have been advocated for preventing adhesions, including oxidized regenerated cellulose [Interceed (TC7), Johnson & Johnson Medical, Arlington, TX], which is an absorbable barrier that promotes reepithelialization of the affected area. Pagidas and Tulandi compared Interceed with Ringer lactate solution for adhesion prevention. Ringer lactate solution was as effective as Interceed in decreasing adhesion formation. Haney and colleagues compared oxidized regenerated cellulose with expanded polytetrafluoroethylene (Goretex surgical membrane). The results indicated that expanded polytetrafluoroethylene was associated with fewer post-surgical adhesions. Other agents include sodium hyaluronate carboxymethyl cellulose (Seprafilm).

Functional Ovarian Cysts

Physiologic cyst enlargement of the ovary may occur as a sequela of failure of either follicular rupture or corpus luteum regression. The latter is termed Halban syndrome. The former has been associated with luteinized unruptured follicle syndrome, in which “intraovarian ovulation” is thought to occur; this is a diagnosis usually established with ultrasound. In general, functional ovarian cysts regress spontaneously; however, they may persist and become symptomatic, reaching dimensions of several centimeters. The most important aspect of ovarian cysts is observation, because most such cysts are self-limited. The cyst, however, may prove to be a source of continued pelvic pain or may adhere to the posterior broad ligament, producing persistent symptoms. The potential for adnexal torsion always exists with an ovarian cyst.

RESECTION OF BENIGN CYSTS

Surgical intervention often is initiated with a laparoscopic approach, which permits evaluation of any neoplastic ovarian cyst. The cyst lining is stripped from the remaining “normal ovary,” and ovarian reconstruction takes place. In several series of laparoscopic management of ovarian cysts, a simple follicular or luteal cyst was identified in most patients evaluated for pelvic pain. In a series by Kleppinger, 31 of 64 ovarian cysts were noted to fall into this category.

Surgical Techniques

Laparotomy

An elliptic incision is made through the thin ovarian cortex of a benign cyst (Fig. 28.6). The end of the knife handle is then inserted and a plane developed over the cyst wall. Alternatively, fine-needle electrocautery can be used to develop a plane, and microsurgical scissors can be used to separate the cyst wall from the ovarian cortex. Low-power magnification (i.e., surgical loupes) often assists the surgeon in identifying the correct plane between the cyst wall and the ovarian parenchyma. After the cyst wall has been completely separated from its adherent attachments to the thin ovarian cortex, it can be shelled out without rupture. However, even with the gentlest technique, rupture can occur because of the friability of the cyst wall. Before the cyst is shelled out, it is important to pack the cul-de-sac with moist, lint-free pads so that, if rupture does occur, spillage does not contaminate the pelvic cavity. After the cyst has been removed, the dead space can be obliterated with a pursestring suture of fine gauge 7-0 nonreactive material. Alternatively, 5-0 nonreactive vertical mattress sutures or figure-of-eight, or both, can be placed to approximate the lateral walls of the ovary. The ovarian surface is then neatly reapproximated with subcortical running suture of 7-0 fine-gauge nonreactive material. If the cyst is quite friable, it may be necessary to place interrupted 7-0 sutures to achieve adequate approximation. Some authors advocate leaving the ovary open after cysectomy. To date, there have been no controlled trials evaluating postoperative adhesion formation when the incised ovarian surface is or is not reapproximated.

In some instances, there is excessive redundant thin cortex, which may present a special problem in ovarian reconstruction. The amount of cortex removed depends on the position of the cyst as well as its overall size. Careful assessment of the ovary is necessary before the initial incision is made. The incision in the ovarian cortex facilitates symmetric reconstruction. The redundant cortex can be removed and the dead space obliterated with an internal closure, with care taken that suture material does not penetrate the ovarian cortex. This prevents ischemia and adhesion formation. The infolding technique recommended by Kistner and Patton may result in anatomic distortion and puckering of the ovarian cortex. The “baseball” closure allows careful approximation of cortical edges when redundancy is noted (Fig. 28.7).

Concern over ovarian surgery via laparotomy has been reported. In an older reference of 36 young women operated on for an ovarian cyst, 45% were noted subsequently to be infertile. The author, Van der Watt, conveyed the importance of not interfering with functional cysts in “normal ovaries.”
Surgery for Benign Gynecologic Conditions

FIGURE 28.6. Resection of benign cyst. A: Thin-walled ovarian cyst. B: An incision is made through the cortex. C: A plane is developed by the use of blunt dissection. The inner ovarian stroma may be approximated with a pursestring suture of 5–0 nonreactive material. D: The ovarian cortex is approximated with 7–0 nonreactive suture material.

because resulting adhesion formation could compromise fertility. It was advocated that benign ovarian cysts should not be removed at the time of surgery for other indications unless they are sufficiently large to interfere with tubal function or cause discomfort to the patient.

Minimally Invasive Surgery

Specific skill levels reflecting both the degree of operator expertise and appropriate instrumentation provide clinicians with four levels of training. Level I stands for equipment needs and potential surgical procedures for basic operative laparoscopy, including such entities as diagnostic laparoscopy, tubal sterilization, lysis of filmy adhesions, and biopsy. Level II reflects the clinician's ability to perform linear salpingostomy for ectopic pregnancy, salpingectomy, lysis of vascular adhesions, and elimination of endometriotic implants. Level III includes the ability to perform salpingo-oophorectomy, lysis of extensive adhesions (including bowel adhesions), ovarian cystectomy, appendectomy, myomectomy, laparoscopic-assisted hysterectomy, and neosalpingostomy, as well as the ability to treat tuboovarian abscess and uterine suspension. Level IV includes bowel resection, anastomosis, pelvic lymphadenectomy, presacral neurectomy, tubal reanastomosis, and excision of deep, infiltrating vaginal, paravaginal, and rectal endometrioses.

A number of principles should be followed as surgeons proceed with the correction of pelvic abnormalities that are
Surgery for Benign Disease of the Ovary

amenable to a laparoscopic approach. The first is to restore normal anatomy. Once the ovary is stabilized, ideally with an atraumatic forceps, an appropriately planned ovarian incision can be made to correct the pathology encountered. Every effort should be made not to spill the contents.

Large amounts of irrigation solution should be used. In some instances, the cyst wall can be stripped (Fig. 28.8), electrocoagulated, or vaporized. The ovarian incision can then be either left open to heal by primary intention or reapproximated with sutures with either extracorporeal or intracorporeal suturing techniques. When this procedure is completed, the pelvis is irrigated with large amounts of irrigation solution (Ringer lactate), and the patient is taken out of the Trendelenburg position to facilitate removal of any blood products that remain in the peritoneal cavity.

One alternative to suturing is to reapproximate incised segments of ovarian cortex with the use of bipolar coagulation to provide coaptation of the incised segment of the ovary. There is continued debate regarding the use of adhesion prevention materials.

A number of potential pitfalls continue to be of concern in the laparoscopic approach to ovarian lesions. These have been addressed by Seltzer and colleagues and include the following:

- The potential for disruption of an ovarian malignancy
- Whether observation-recommended surgical intervention would be the most feasible alternative
- Potential for increased duration of the surgical procedure if done endoscopically
- Total cost
- Potential for incomplete resection of an ovarian lesion laparoscopically

One can view laparoscopic approach to the adnexal mass based on age. Specifically, in the pediatric patient, problems such as torsion, hemorrhagic cysts, benign neoplasm (e.g., teratomas), as well as oophorectomy have been reportedly addressed via the laparoscope. One advantage over laparotomy is the ability to better visualize the entire lower abdomen and pelvis, including the opposite ovary. In the adult, depending on the clinical circumstance, cyst aspiration, cystectomy, or oophorectomy can be accomplished laparoscopically.

Predictors of clinical outcomes in the laparoscopic management of adnexal mass has been addressed by Havrilesky and coauthors. The authors noted that adnexal mass thought to be benign preoperatively were successfully managed laparoscopically in three fourths of the patients. Adverse events were attributable to concurrent hysterectomy rather than removal of the adnexal mass. Malignancy occurred in 2.6%, and laparoscopic management was not associated with adverse outcomes.

Concern is expressed for an ovarian neoplasm subsequently noted to be malignant. In a countrywide survey in Austria, Wenzl and colleagues reported on 54,198 laparoscopies; 16,601 were performed for adnexal masses, and 108 cases of ovarian tumors were subsequently found to be malignant. Of the 108 cases, 20 were managed laparoscopically, 22 by immediate laparotomy, and the rest by delayed laparotomy (3 to 1,415 days). The authors concluded that laparoscopic surgery with the finding of an ovarian malignancy is rare: 0.65% of all endoscopic surgical procedures. If a malignancy is identified, laparotomy is recommended for optimal staging and treatment.

The extent of damage to ovarian reserve associated with laparoscopic excision of endometriomas was studied by Ragni and coauthors. A reduced number of dominate follicles, oocytes, embryos, and high-quality embryos was observed in the operated gonad. Fertilization rate and rate of good-quality

FIGURE 28.8. Removal of a small ovarian endometrial cyst through the laparoscope. A: After incision of the ovarian cortex, the contents of the endometrioma are removed with suction and irrigation. B: The plane between the ovary and the cyst wall is developed by using traction and twisting the forceps clockwise. C: The endometrial cyst wall is grasped with forceps. D: The cyst wall separates from the ovarian tissue by use of a twisting motion. The ovarian defect may be left open to heal by secondary intention or may be closed with vertical mattress sutures. E: The cyst wall is removed.
Oligoamenorrhea
Clinical and or biochemical evidence for hyperandrogenemia, allowing normalization of the luteinizing level of 17 alpha-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, and testosterone, as well as a transitory decrease in estradiol. This reduction in the steroidogenesis of androgens, allowing normalization of the luteinizing hormone (LH): follicle stimulating hormone (LH-FSH) ratio, results in the resumption of ovulatory cycles. Ovarian renin-angiotensin activity is enhanced with PCO. This system—renin-angiotensin—remains unaltered following ovarian electrocautery (i.e., ovarian drilling), even though serum levels of LH, testosterone, and androstenedione decline.

Sex hormone-binding globulin (SHBG) concentrations following electrocautery with PCO have been evaluated. Whereas there were significant decreases in serum androgens and gonadotropins, the concentration of SHBG increased in the serum. Gjonnaess has reported that there is no change with respect to dehydroepiandrosterone sulfate (DHEAS) with ovarian drilling. This is indicative of neural alteration in the pituitary-adrenal axis in comparison to the pituitary-ovarian axis.

A more recent consensus (2007) regarding PCOS focused on treatment. The results noted better pregnancy rates with use of clomiphene citrate or clomiphene citrate plus the insulin sensitizer metformin in comparison to metformin alone. They also felt that there is a role for ovarian drilling.

There is some debate as to the amount of ovarian mass that should be removed at the time of wedge resection. Halbe and coworkers attempted to clarify this question by removing different amounts of ovarian cortex and medulla from a random selection of patients with polycystic ovarian disease. Thirty-eight of 62 patients were interested in conception. The 38 patients were divided into three groups, the first of which underwent removal of not more than one fifth of the original ovarian size. The second group had one third of the ovarian mass removed, and the third group had one half to three fourths of the original ovarian size reduced. The resumption of ovulatory cycles was recorded at 53%, 71%, and 91%, respectively.

The authors concluded that the best ovulatory rate and the best pregnancy rate resulted after removal of at least half of the ovarian medulla.

OVARIAN SURGERY FOR POLYCYSTIC OVARIAN DISEASE

Signs and symptoms of polycystic ovarian (PCO) syndrome begin at puberty. PCO is a sign, not a diagnosis. In a consensus meeting held in Rotterdam, the American Society for Reproductive Medicine and the European Society for Human Reproduction and Embryology agreed that two of the following criteria must be met once other endocrinopathies have been ruled out (i.e., Cushing, adrenal hyperplasia):
- Oligoamenorrhea
- Clinical and or biochemical evidence for hyperandrogenemia
- Polycystic-appearing ovaries on ultrasound

The polycystic ovary may result from a virilizing ovarian or adrenal neoplasm or from congenital adrenal hyperplasia, or it may result from suboptimal hypothalamic-pituitary function at puberty. The exact mechanism for the development of ovulatory failure has been attributed to androgen overproduction and its effect on the hypothalamic-pituitary ovarian axis. Stein and Leventhal, during the period 1902 to 1935, noted that a group of women had evidence for what is currently called polycystic ovaries at the time of laparotomy. Specifically, in 1935, Stein and Leventhal reported seven patients with the hallmark of PCO.

The histologic findings in a polycystic ovary cover a broad spectrum, ranging from the originally described typical “Stein-Leventhal” type of polycystic ovary with a large number of follicular cysts and few atretic cysts in which there is marked stromal hyperplasia and hyperthecosis, to a smaller ovary with a few follicular cysts and atretic follicles. The polycystic ovary may exhibit microscopic islands of luteinized thecal cells, i.e., hyperthecosis, scattered in the stroma, but usually there is a thickened, fibrosed tunica with a large number of cystic follicles beneath this thickened capsule.

There are several hypotheses regarding the mechanism by which ovarian drilling (wedge resection) of the polycystic ovary resolves ovulatory failure. The theory stating that the fibrous capsule acts as a mechanical barrier to the ovulatory follicle has been refuted. Evidence against this theory consists of the observation that if one ovary is removed, ovulation occurs from the other ovary. In addition, the use of clomiphene citrate results in ovulation through an intact capsule. Some have stated that neonatal androgens may cause an abnormal hypothalamic-pituitary axis, resulting in abnormal gonadotropin production. This theory is not widely accepted. Neonatal androgen treatment in rats is associated with masculinization of the hypothalamus and with ovulatory failure with polycystic ovaries.

The most popular theory explaining how ovarian drilling results in the resumption of ovulatory cycles notes that the removal of androgen-secreting stroma and theca reduces the amount of abnormal steroid production in the ovary. After wedge resection, there is usually a decrease in the mean level of 17a-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, and testosterone, as well as a transitory decrease in estradiol. This reduction in the steroidogenesis of androgens, allowing normalization of the luteinizing hormone (LH): follicle stimulating hormone (LH-FSH) ratio, Antidiabetic agents have been advocated to reduce insulin resistance with PCO. Metformin has been shown to decrease insulin levels with resultant diminishing of circulating androgens. Hirsutism often improves. Metformin may enhance the efficacy of clomiphene and gonadotropin therapy with PCO. Metformin may also promote weight loss. Baseline and periodic liver function tests are recommended. Metformin is contraindicated with renal or hepatic disease. Patients have shown a response at dosages of 500 mg three times per day.

Surgical Technique of Laparoscopic Treatment of Polycystic Ovaries

The laparoscopic approach incorporates the use of monopolar cautery with a needlepoint applicator or bipolar cautery to

| Indications
---|

The introduction of clomiphene citrate and the oral antihyperglycemic drug and insulin sensitizer metformin has changed the management of PCOS in patients who desire pregnancy. Depending on the clinical circumstance, the conception rate with clomiphene citrate has been reported at 50% to 60%. The incidence of post-clomiphene citrate birth defects (3.1%) is not increased over commonly quoted rates for populations at large. Some patients may not want to accept the risks of multiple births or hyperstimulation with pure FSH or FSH and LH ovulation induction. The need for wedge resection of the polycystic ovary is much lower with the development of the newer reproductive technologies. Antidiabetic agents have been advocated to reduce insulin resistance with PCO. Metformin has been shown to decrease insulin levels with resultant diminishing of circulating androgens. Hirsutism often improves. Metformin may enhance the efficacy of clomiphene and gonadotropin therapy with PCO. Metformin may also promote weight loss. Baseline and periodic liver function tests are recommended. Metformin is contraindicated with renal or hepatic disease. Patients have shown a response at dosages of 500 mg three times per day.

Surgical Technique of Laparoscopic Treatment of Polycystic Ovaries

The laparoscopic approach incorporates the use of monopolar cautery with a needlepoint applicator or bipolar cautery to

laser drilling of ovary for surgical treatment of polycystic ovarian disease (Fig. 28.9). Care should be exercised to avoid the hilum because bleeding could result if it is penetrated. It is important to achieve hemostasis over the drilled areas.

The ovarian drilling technique includes a 5-mm second puncture placed suprapubically, through which suction irrigation or grasping of tissues can be performed. All visible subcapsular follicles are vaporized, and a 2- to 4-mm-diameter crater is made randomly in the ovarian stroma. Hemostasis is accomplished with bipolar forceps.

Ovarian coagulation can be accomplished with unipolar punch biopsy forceps or a needle electrode. The power setting is 20 to 30 W in a cutting mode. The cortex is usually penetrated at 10 to 15 sites for a depth of 3 to 5 mm. Caution is exercised to minimize thermal damage. Smaller ovaries may require fewer cauteryization sites.

There are no randomized controlled studies addressing the efficacy of the laparoscopic approach to ovarian drilling. Twenty-seven studies were evaluated by Donesky and Adashi and involved a total of 729 patients. The ovulation rate was 84.2%, and the pregnancy rate was 55.7%. These authors emphasized that well-designed studies are needed in this area, which would encompass the PCO population proposed for laparoscopic drilling. This cohort of patients would require a well-documented clinical and biochemical finding of PCO, documented long-standing infertility (2 years or more), evidence for failure of clomiphene citrate, absence of correction of other infertility factors, randomization into a treatment group, and standardized documented follow-up, with particular attention to postovulatory patterns.

Complications

The major concern is that of adhesion formation after either wedge resection or laparoscopic drilling. Taaffe and associates noted extensive peritubular and periovarian adhesions in a small series (seven) of patients who did not conceive after bilateral wedge resection or laparoscopic drilling. This cohort of patients would require a well-documented clinical and biochemical finding of PCO, documented long-standing infertility (2 years or more), evidence for failure of clomiphene citrate, absence of correction of other infertility factors, randomization into a treatment group, and standardized documented follow-up, with particular attention to postovulatory patterns.

PARADOXICAL OOPHORECTOMY

Paradoxical oophorectomy is the removal of severely pathologic adnexa to improve fertility in patients with strictly unilateral tubal disease. Consideration of removal of the contralateral ovary when there is single tubal patency (i.e., paradoxical oophorectomy) has perhaps taken on a new perspective with the advent of assisted reproductive technology (ART). From a historical point of view, it has been advocated that a patient with one functional tube would benefit from paradoxical oophorectomy, thus ensuring that ovulation would occur repeatedly on the appropriate side. Scott and coworkers reported a series of 24 patients with unilateral tubal patency diagnosed by retrograde injection at laparotomy. Contralateral oophorectomy or salpingo-oophorectomy was performed on all patients, and 16 women subsequently had 21 pregnancies, for a pregnancy rate of 67%. The authors suggested that the frequency with which transperitoneal migration occurs may be a factor. Hallet noted that one in five tubal ectopic pregnancies has a corpus luteum. On the contralateral side, Jansen noted an intrauterine pregnancy rate of 18.7% (n = 91), contrasted with bilateral salpingostomy for hydrosalpinges in the presence of only one ovary wherein the pregnancy rate was 43.8% (n = 16). With unilateral salpingostomy or bilateral division of adhesions, pregnancy rates were comparable to those after bilateral salpingolysis. The mean surgery-pregnancy interval was longer after unilateral salpingostomy (104 weeks) than after bilateral salpingolysis (45 weeks). The author suggested that salpingo-oophorectomy may be preferable to salpingostomy for unilateral hydrosalpinx.

Perhaps the major concern is for the patient who presents with tubal ectopic gestation in which the opposite (i.e., normal-appearing) adnexa appears to be unaffected. The paradoxical salpingo-oophorectomy approach has been advocated with this circumstance by Scott and coworkers. It has been advocated to wait at least 2 years after diagnostic laparoscopy reveals extensive unilateral disease before proceeding with paradoxical oophorectomy.

Randomized, carefully controlled clinical trials are necessary to further evaluate the efficacy of paradoxical oophorectomy. The risks and benefits must be carefully considered both preoperatively and intraoperatively, especially if the patient is a candidate for ART. There is clear evidence that increased numbers of ova can be recovered when both ovaries are in situ. Increased pregnancy success after superovulation is a reflection of the number of ovaries (one versus two)—the total number of follicles available for stimulation.

Laparoscopic Oophorectomy

The general principles of laparoscopic oophorectomy include placing the patient in the Trendelenburg position, with appropriate planning of ports for the proposed procedure, and planning for removal of the affected adnexa. Pelvic washings and the use of frozen section may be germane to the task at hand. After restoration of normal anatomy and adhesiolysis as indicated, the adnexa are gently placed on stretch. They are
approached from either the infundibulopelvic ligament or the insertion of the round ligament. Regardless of the approach chosen, identification of the ureter is of paramount importance. The infundibulopelvic ligament is identified and coagulated. The broad ligament is incised, beginning at the round ligament, and further dissection is performed with an irrigation dissection probe into the retroperitoneal space. Every effort must be made to completely remove all ovarian tissue to prevent ovarian remnant syndrome.

### Tissue Removal

Once the adnexa have been completely freed, if benign disease is extremely likely, desiccation of the tissue and thus segmental removal is appropriate. However, if there is concern for the pathology, use of an endoscopic pouch is appropriate. In this circumstance, every effort is made to remove the ovary intact. Careful inspection of the operative site and a check for any bleeding are recommended. In addition, the end-point pressure of CO₂ insufflation should be reduced with suctioning of some of the CO₂ to check for any tamponade effect. As with all laparoscopic procedures, the patient should be monitored carefully after surgery for any signs of intraperitoneal bleeding.

### FERTILITY PRESERVATION WITH CANCER

As response to both medical and surgical therapies continue to result in increasing numbers of survivors, gynecologic surgeons must be kept abreast of current thinking in this field. Cryopreservation of ovarian tissue, nonfertilized, immature germ cells in oocytes, has received increased attention including in prepubertal girls. Medical agents, including letrozole and tamoxifen, have been used as ovarian stimulants for cryopreservation in women with breast cancer. Tamoxifen resulted in two to five times higher embryo yield than natural cycle in vitro fertilization (IVF). The best prognosis for fertility appears to preserve gametes before initiation of chemotherapy for cancer. Ovarian transplantation with subsequent embryo generation has been reported after restoration of ovarian function by heterotopic transplantation. Ovarian transplantation remains an experimental technique at this point in time. Ovarian cortical tissue strip retrieval is amenable to a laparoscopic approach. Autologous, orthotopic transplantation after cryopreservation has been successfully used to restore fertility. Ovarian tissue banking and autografting of ovarian cortex are promising therapies for patients with ovarian failure. Kim and coauthors have reported similar recommendations. Bisharah and Tulandi have recommended transsection of the ovarian ligament and transposition of the ovaries without affecting the fallopian tubes. This is associated with positioning of the ovaries laterally and anteriorly at the level of the anterior superior iliac spines (Fig. 28.10).

Cytotoxic drugs are classified as follows:

- **High risk:** Cyclophosphamide, ifosfamide, chloroethylnitrosourea, busulfan, procarbazine, and chlorambucil
- **Moderate risk:** Cisplatin, carboplatin, and doxorubicin
- **Low risk:** Vincristine, methotrexate, Daunomycin, bleomycin, melphalan, procarbazine, and vinblastine

Attempts have been made to assess ovarian function and “ovarian reserve.” This has included evaluation of ovarian volume; serum inhibin B, secreted by antral developing follicles; and antimüllerian hormone, a glycoprotein expressed in fetal tissue and preantral and small antral follicles, but in the adult, when levels are lowered (i.e., in cancer survivors), the ovarian reserve is decreased.

One alternative to oophorexy is oocyte retrieval, fertilization, and cryopreservation—i.e., ART/IVF. Preserving unfertilized oocytes remains an area of research as prognosis for fertility overall is poor.

A number of factors may affect fertility. Factors that may adversely affect uterine function. It is estimated that the sensitivity of oocytes to radiation is an LD50 of 2 Gy (the lethal dose required to eliminate 50% of the oocytes).

Fertility outcome following ovarian transposition and pelvic irradiation for pelvic cancer has been addressed in a total of 37 consecutive cases by Morice and colleagues. Patients were treated for clear cell adenocarcinoma of the vagina or cervix, ovarian dysgerminoma, and sarcoma. The pregnancy rate was 15% (4/27) in patients attempting pregnancy with clear cell ovarian disease.

Lemevel and coworkers reported laparoscopic transposition in a patient being treated for Hodgkin disease before receiving radiotherapy. The ovaries were laparoscopically suspended out of the field of radiation. Iatrogenic menopause did not occur in the four patients for which this was reported. Other authors have reported similar recommendations. Bisharah and Tulandi have recommended transsection of the ovarian ligament and transposition of the ovaries without affecting the fallopian tubes. This is associated with positioning of the ovaries laterally and anteriorly at the level of the anterior superior iliac spines (Fig. 28.10).

### OVARIAN TRANSPOSITION BEFORE RADIOTHERAPY

Lemevel and coworkers reported laparoscopic transposition in a patient being treated for Hodgkin disease before receiving radiotherapy. The ovaries were laparoscopically suspended out of the field of radiation. Iatrogenic menopause did not occur in the four patients for which this was reported. Other authors have reported similar recommendations. Bisharah and Tulandi have recommended transsection of the ovarian ligament and transposition of the ovaries without affecting the fallopian tubes. This is associated with positioning of the ovaries laterally and anteriorly at the level of the anterior superior iliac spines (Fig. 28.10).

Gonads are sensitive to irradiation. Whole-body, abdominal, or pelvic irradiation can cause ovarian damage and adversely affect uterine function. It is estimated that the sensitivity of oocytes to radiation is an LD50 of 2 Gy (the lethal dose required to eliminate 50% of the oocytes).

Cytotoxic drugs are classified as follows:

- **High risk:** Cyclophosphamide, ifosfamide, chloroethylnitrosourea, busulfan, procarbazine, and chlorambucil
- **Moderate risk:** Cisplatin, carboplatin, and doxorubicin
- **Low risk:** Vincristine, methotrexate, Daunomycin, bleomycin, melphalan, procarbazine, and vinblastine

The pregnancy rate was 15% (4/27) in patients attempting pregnancy with clear cell ovarian disease.
OVARIAN CYSTS IN NEONATE AND PREPUBERTAL CHILD

In a retrospective study of 65 fetal ovarian cysts noted by ultrasonography, 37% were located on the left, 36% were on the right, and 7% were bilateral. In 17 patients, intervention was required after delivery because of persistence and/or enlargement. The histologic results included follicular cysts in 12 cases, a lymphangioma, and one teratoma; the remaining were amenable to aspiration. The authors, Mittermayer and colleagues, conclude that lack of regression requires intervention in the neonatal period. Ovarian cysts in the neonate ≥ 5 cm in diameter have an increased chance of torsion.

Ovarian surgery in the premenarchal girl has been evaluated in a study from the University of Michigan in 52 patients, 50% of whom were less than 1 year and 31% between 1 and 8 years old. The most common presentation was abdominal/pelvic mass (n = 24), and the postoperative diagnoses included torsion in 18 and malignancy in 5 patients. Histopathologic evaluation included hemorrhagic infarction, dysgerminomatous growth, simple cysts, teratoma, theca lutein cyst, fibroma, neorhabdostroma, germ cell tumor, gonadoblastoma, and metastatic Wilms tumor.

LAPAROSCOPIC OVARIAN SURGERY IN THE PEDIATRIC OR ADOLESCENT PATIENT

A number of gynecologic problems from the neonatal period through adolescence can be addressed laparoscopically. Entities such as ovarian torsion, acute PID (diagnosis and treatment complementing antimicrobial therapy), torsion, and benign neoplasms must be considered in this age group. In addition, gonadectomy for problems such as male pseudohermaphroditism is amenable to the laparoscopic approach.

Follicular cysts appear to be of particular concern in both the pediatric and adolescent patient because they present with abdominal pain. An abdominal or pelvic mass can be identified on physical examination. The clinician must always keep in mind the importance of appropriate preoperative assessment (with the use of ultrasound and other clinical parameters) in deciding which patients are candidates for operative intervention. Depending on the clinical circumstance, a conservative approach in this age group is advocated; appropriate concern must be given (especially in the pediatric patient) to the potential for malignancy with ovarian masses, particularly if a solid component is identified.

The literature attests to operative intervention of ovarian cysts that appear to be nonfunctional. One of these was reported in a 1.5-month-old infant in whom ultrasound showed evidence of an ovarian mass. At laparotomy, the mass proved to be consistent with right ovarian torsion and necrosis, and it required adnexitomy. In one other reported case, a follicular-appearing cyst seen on ultrasound was associated with rapidly progressive virilization and a markedly elevated plasma testosterone level (289 ng/dL); histologic evaluation identified a granulosa cell tumor with mild luteinization.

The feasibility of adnexal tissue resection continues to be controversial. In two case reports, laparoscopic puncture and aspiration of a malignant ovarian cyst was performed. Preoperative ultrasound indicated that the involved adnexal mass had a benign nature. Cytologically negative fluid was obtained from the aspirate. Eight weeks after operation, extensive disseminated ovarian carcinoma was noted at laparotomy.

Endoscopic surgery continues to broaden its horizon with expansion into laparoscopic surgical care beginning with the neonate. The use of 2-mm laparoscopes with the addition of 2- to 3-mm instrumentation has facilitated the diagnostic and therapeutic aspects of laparoscopy in this age group. Miniaturized video camera systems are necessary when one uses the 2-mm laparoscopic telescope. When a decision is made to proceed with laparoscopy in a neonate or infant, general endotracheal anesthesia is used. Ideally, prophylactic antibiotics are administered preoperatively. The stomach is emptied with a suction catheter when the patient is asleep, and the bladder is emptied by use of the Credé maneuver. The abdominal wall is thinner and more elastic in the child than in the adolescent or adult. One must take this into consideration when introducing instrumentation, because it may be easier to insufflate in the subcutaneous space of the child than in the subcutaneous space of an adult. A Veress needle can be used with insufflation of carbon dioxide at 0.5 L/min. In infants, the end point of peritoneal distending pressure should be set at 6 to 8 mm Hg; in the pediatric patient, 6 to 10 mm Hg; in the older child or adolescent, 10 to 12 mm Hg.

After surgery, the trocar sites can be sutured in children, whereas in neonates and infants, the use of Steri-Strips (3M, St. Paul, MN) or other wound-closure bandages is usually adequate for reapproximation of the incised skin edges. Waldschmidt and Schier reported a series of 136 laparoscopic surgical procedures in neonates and infants. The most frequent indications were lysis of adhesions, abdominal cysts and neoplasms, gonadectomy, appendectomy, and cholecystectomy. A 1,400 g premature infant was the only one in the series who suffered a complication (hemia at the incision site). Thus, adnexal pathology in this age group appears to be amenable to a laparoscopic approach.

Procedures such as transposition of an ovary before radiotherapy, bilateral gonadal excision in a male pseudohermaphrodite (i.e., Y-bearing chromosomal analysis), adnexal torsion, suspected salpingitis, and endometriosis all have been identified in this age group. The authors concluded that because the morbidity is low and recovery is likely, the laparoscopic approach should be considered.

Although certain procedures in the child do not differ significantly from those in the adult, the early diagnosis of ovarian pathology (e.g., adnexal torsion) can result in a significant advantage in terms of managing the patient and preserving ovarian tissue.

BEST SURGICAL PRACTICES

- Minimally invasive surgery can be used to evaluate and manage ovarian masses ≥ 6 cm and adnexal masses ≥ 10 cm.
Before operative intervention in a pregnant patient with a symptomatic adnexal mass, complete assessment of the fetus—including ultrasound to rule out any fetal anomalies—is recommended. The optimal time for elective intervention is during the second trimester. The patient should be informed regarding preterm labor and delivery. The surgical procedure ideally is performed in the left lateral decubitus position.

Transvaginal color Doppler sonographic assessment of ovarian malignant masses includes number of vessels detected, location of tumor vessels (central vs. peripheral), determined nation of peak systolic velocity, low-resistance index, mean-resistance index, and low pulsatility index.

The major goal of the evaluation of a pelvic mass is to rule out malignancy. All ovarian neoplasms >6 cm with a solid component should undergo a thorough evaluation to try to rule out cancer.

In management of ovarian remnant syndrome, treatment of choice is adequate excision of the remnant ovarian tissue and contiguous adherent tissues, i.e., pelvic peritoneum, bowel serosa, and underlying involved alveolar and/or vasculat tissues. Retroperitoneal dissection may be required.

CHAPTER 29 ■ PERSISTENT OR CHRONIC PELVIC PAIN
JOHN F. STEEGE

DEFINITIONS

Alldynia—Pain resulting from a nonnoxious stimulus.

Hyperalgesia—Painful sensation of abnormal severity following noxious stimulation.

Neuropathic pain—Pain persisting after healing of disease or trauma-induced tissue damage.

Neuroplasticity—The malleability of central pain perception mechanisms in response to chronic pain states.

Nociceptor—A nerve receptor for pain.

Chronic pelvic pain (CPP) is defined as pain present either intermittently or continuously for 6 months or more. Although much work remains to be done concerning the epidemiology of the disorder, preliminary surveys suggest that it may affect 5% to 15% of women at some time in their lives, predominately during their reproductive years. The gynecologist confronts this problem on a regular basis. Many organic and functional disorders of the reproductive, gastrointestinal, urinary tract, and musculoskeletal systems may contribute nociceptive stimuli to the problem. Dysfunction or organic disease in one organ system may induce nociception in an adjacent system in the manner of “cross-talk.” In addition, by dysregulation of neurologic pathways, pain can become an illness in itself when it lasts longer than 4 to 6 months. This chapter reviews the common structural and functional components of CPP, describes the criteria for a chronic pain syndrome (CPS), and offers a theoretical model to explain the evolution of chronic pain over time.

Many pain disorders are deemed “chronic” by virtue of their duration—that is, 6 months or longer. In practice, this usually connotes decreased function (perhaps even disability) as well as progressive behavioral and affective changes. Although this definition is useful as a benchmark, some victims of chronic pain may develop these characteristics sooner than 6 months into the problem, and others may endure severe pain for years while remaining surprisingly functional and well adjusted. As suggested later, it is therefore perhaps useful to use additional behavioral and psychometric criteria to the chronologic definition of “chronic” to focus diagnostic and treatment efforts.

HISTORY

Over the past 50 years, the study of CPP has gone through significant changes in approach. Investigations undertaken before the development of laparoscopy focused on correlations between pelvic pain and psychologic distress. This approach was prompted by the fact that the two most common organic contributors to CPP—endometriosis and adhesions—can be difficult to diagnose by history and physical examination alone. In the absence of palpable pathology, the gynecologist of the 1950s and 1960s was understandably reluctant to subject a patient to laparotomy to investigate pain. During this era, the prevailing cartesian theory of pain perception suggested that pain should be somewhat proportional to the degree of tissue damage found. (If the pathology was not big enough to palpate, it was seldom operated on.) Although this was sufficient to explain most acute pain, the cartesian model fails to explain the majority of chronic pain disorders, in gynecology as well as other areas of medicine. The gate control theory, promulgated by Melzack and Wall in 1965, allowed integration of physical and psychologic parameters, and explained how chronic pain can be quite different from acute pain. The model also suggests that information flows in two directions regarding pain: (i) nociceptive signals from peripheral tissue ascend through the spinal cord to higher centers, and (ii) central centers can modulate, via descending signals altering spinal cord neurotransmitter and interneuron activity, the transmission of these nociceptive signals from the periphery. Deterioration of these regulatory processes were thought to potentially account for development of chronic pain states by allowing too many peripheral signals through the spinal cord “gates.”

While these changes in pain theory were stimulating the field of pain research, gynecologists were busy developing laparoscopy. Previously cherished myths soon fell by the wayside: for example, endometriosis is seldom found in adolescents or African Americans. With these observations came the hope that laparoscopic and medical treatment of this pathology would fix CPP. Reports of CPP from that era focused on “laparoscopy-negative” patients; indeed, some pelvic pain clinics required a negative laparoscopy as an entry criterion, implying that if some pathology were found, it must be a “real” cause for pain. Subsequent experience has shown that even though treatment of laparoscopically diagnosed pathology is often helpful, the clinical reality is more complex:

1. In many instances, the organic pathology found at laparoscopy may be incidental and not related to the pain.
2. In those with pathology that does contribute to nociception, the pain experienced by the patient may be the sum of this contribution plus signals from some or all of the disorders listed in Table 29.1.

Consider the research of the 1980s that documented a distressingly high prevalence of physical and sexual abuse. Epidemiologic surveys of community samples revealed that as many as 25% to 50% of adult women reported having experienced sexual abuse during childhood. Studies of women attending pelvic pain clinics, especially those based in psychiatric settings, showed that up to 60% of these women had been abused. These observations led to the speculation that the experience of abuse may make a person more vulnerable to the
When nociception has been emanating from one organ system ing end of peripheral nociceptive stimuli for prolonged periods. have become pain generators as a result of being on the receiv-or the result of sensitization of spinal cord interneurons that understood (e.g., the mechanism of pain from endometriosis) but it may also be the result of nociceptive mechanisms not yet for the patient, as well as past or present emotional trauma, found. This may reflect the emotional meaning of the problem whose pain responses seem out of proportion to the pathology (hyperalgesia). Every practicing gynecologist has seen patients lodynia), as well as exaggerated responses to painful stimuli to the neurophysiologic behavior of the central nervous system includes the notion of neuroplasticity, among other elements. The matrix theory, described by Melzack, is an expansion that in-quate to explain clinical manifestations of pain. The neuro-activity theory, described by Melzack, is an expansion that in-cludes the notion of neuroplasticity, among other elements. The concept of neuroplasticity suggests that experience can change the neurophysiologic behavior of the central nervous system in a manner that influences the subsequent processing of no-ceptive stimuli. It may explain the apparent development of pain responses to stimuli usually thought of as nonpainful (al-odynia), as well as exaggerated responses to painful stimuli (hyperalgesia). Every practicing gynecologist has seen patients whose pain responses seem out of proportion to the pathology found. This may reflect the emotional meaning of the problem for the patient, as well as past or present emotional trauma, but it may also be the result of nociceptive mechanisms not yet understood (e.g., the mechanism of pain from endometriosis) or the result of sensitization of spinal cord interneurons that have become pain generators as a result of being on the receiv-ing end of peripheral nociceptive stimuli for prolonged periods. When nociception has been emanating from one organ system for a period of time, adjacent organs may join the chorus. A common example is the finding that pain from endometriosis and bladder symptoms coexist more than one might expect. Vulvar vestibulitis overlaps with interstitial cystitis in a simi-lar manner. On occasion, one is confronted with the unfortu-nate patient with multiple somatosensory disorders—e.g., she might have IBS, endometriosis, interstitial cystitis, fibromyal-gia, chronic fatigue syndrome, etc., all at the same time. Such observations have led some investigators to pursue potential genetic variations in central neurotransmitter networks that might predispose to the development of multiple such disor-ders. The above is the negative side of neuroplasticity. The posi-tive side of the neuroplasticity concept is that, perhaps, given enough time and the right treatment, even seemingly intractable chronic pain problems may ameliorate to the point of allow-ing substantially improved function. This chapter reviews the various organic, psychologic, and physiologic factors that con-tribute to CPP, outlines methods of evaluation, gives sugges-tions for treatment, and finishes with a discussion of an inte-grated model of the development of CPP.

*From Stowe JF, Jones AL, Somkuti SG. Chronic pelvis pain: toward an integrative model. Obstet Gynecol Surv. 1993;48:93, with permission.*

A recent review summarized laparoscopic findings from 2,615 patients in 13 studies (nine retrospective, six prospective). En-dometriosis was found in 2% to 51% of patients, suggesting that referral biases lead to very skewed samples. Clearly, not ev-ery woman with pain has endometriosis, not does every woman with endometriosis have pain, although women with the dis-ease had pain more often than those without it. A number of previous studies of CPP either described only patients with-out organic laparoscopic findings or stratified patients accord-ing to the presence or absence of physical pathology. The de-scription of atypical (nonpigmented) endometriosis by Jansen and Russell in 1986 calls these classifications into question. Laparoscopy studies published before that time reported that 11% of women with CPP had endometriosis, whereas three similarly conducted studies published since 1986 reported a 41% prevalence of endometriosis in women undergoing lap-aroscopy for CPP. The pre-1986 literature on pelvic pain must be reevaluated with this information in mind. Many studies may have included women with endometriosis in the anatom-ically normal group, thus generating erroneous conclusions about the entirely psychogenic nature of their pain. The first symptom of significant endometriosis is often in-creased dysmenorrhea alone, but other pain often develops, and its duration and severity often progress as the disease ad-ances, to the point that it can be present almost constantly. Again, the severity of the pain correlates poorly with the amount of diffuse periendometrial disease, but may vary more di-rectly with deep infiltrative cul-de-sac disease. Fear of wors-ened pain, impaired fertility, or recurrent disease after treat-ment can increase pain levels. Of the many women we perform laparoscopy for recurrent pain following complete hysterectomy and adnexectomy for endometriosis, only a small minority (3% to 5%) proved to have recurrent dis-ease. Most cases of postoperative pain have been attributable to a combination of postoperative adhesions, fear of recurrent disease, and functional problems such as levator spasm and IBS.
Surgery for Benign Gynecologic Conditions

When endometriosis is strongly suspected, and initial treatment with oral contraceptives has failed, diagnostic laparoscopy should be the next step. One widely discussed study (Ling et al. 1999) concluded that a careful clinical history and physical examination can predict the presence of endometriosis in about 80% of cases. However, this was done in the setting of a strict research protocol; the diagnostic sensitivity of this approach in general clinical practice is likely much lower. Unfortunately, the study is often misinterpreted as implying that reliance on pain following GnRH treatment is also specific, i.e., makes the diagnosis of endometriosis. Careful reading of the data reveals that this is not the case: the frequency of relief following GnRH treatment was the same in women with and without endometriosis. In addition, pain sensitivity is known to increase perimenstrually even in women without gynecologic pain problems. This may mean that nociceptive from pain disorders outside the reproductive tract may also improve when menstrual cyclicity is eliminated. For example, symptoms from IBS have been shown to be reduced in women taking a GnRH agonist. Hence, although failure to relieve pain with a GnRH agonist would appear to strongly support the notion that the reproductive organs are not involved, relief of pain with these medications does not prove that they are to blame.

Pelvic Adhesions

Pelvic relaxation usually leads to reports of heaviness, pressure, dropping sensations, or aching. In attempting to hold in prolapsing organs, the patient may be tending the levator plate and contributing to tenderness during daily activities and intercourse. Fear of (or actual) loss of urinary control during coitus can add to the discomfort by impairing physiologic sexual response.

Excess mobility of the pelvic organs (universal joint or Allen-Masters syndrome) attributed to childbirth or other traumatic causes of ligament (especially broad ligament) tears in uterine supports has been implicated in CPP. Such highly subjective physical examination findings are difficult to document rigorously, and because surgery has been the traditional primary treatment, controlled studies of the association of pain with ligamentous tears have not been possible.

Uterine retroversion is another controversial potential etiology for CPP, particularly in the form of deep dyspareunia. Uncontrolled clinical series of uterine suspension procedures for pelvic pain suggest that the most frequent scenario involves a combination of uterine retroversion (most often innocent by itself) with new intrinsic uterine pathology (e.g., adenomyosis, myomas) or nearby cul-de-sac or adnexal pathology (e.g., endometriosis, adhesions, ovary prolapsed into the cul-de-sac). On occasion, these anatomic circumstances, combined with a new partner of more generous penile dimensions, produce new deep dyspareunia.

Generally speaking, uterine suspension procedures have earned a mixed reputation at best, as many versions yield short-term benefit at best. A recently developed laparoscopic procedure uses permanent suture that is woven through almost the entire length of the round ligament on each side. As support is dependent on the suture and less on shortening an intrinsically weak round ligament, maintenance of postoperative relief appears to be better and may even persist following pregnancy in some cases.

Pelvic Congestion

Overfilling (congestion) of the pelvic venous system has been implicated as a cause of dull chronic aching pain that usually is worse at the end of the day after prolonged standing, premenstrually, and after cotonus not accompanied by orgasm. The pain is occasionally unilateral, is usually present in multiparous women, and is likely due to anatomic causes, at least in part. The high comorbidity with psychologic distress indicates that psychophysologic factors may also contribute. Medroxyprogesterone can help (by eliminating the menstrual cycle), but the best long-term results have followed psychotherapy in conjunction with this medication. In any case, good radiologic studies in women who are awake during the procedure have documented increased pelvic venous diameter in those affected. Veins cannot be reliably evaluated during laparoscopy because of confounding effects such as position and fluid load.

Pelvic Support

Although problems with pelvic relaxation are common in women in their sixth or seventh decade of life, most patients at pain clinics are in their third or fourth decade. The implication is that cases of pain associated with pelvic support problems constitute the minority of pelvic pain problems.

Residual Ovary

When the uterus has been removed, with or without removal of one ovary, the remaining ovary or ovaries can become symptomatic in 1% to 4% of women. In many instances, benign functional ovarian cysts can form and can be transiently symptomatic. Pain from the ovary can be increased by confinement of the ovary within postoperative adhesions, rupture or leakage of a cyst prompting additional adhesion formation, or attachment of the ovary to the sigmoid colon or vaginal apex by postoperative adhesions. In the case of attachment to the vaginal apex, deep dyspareunia can result when the vaginal apex is struck. When this pain causes diminished sexual response, loss of the normal vaginal apex expansion and elongation that is part of sexual response can leave the ovary or ovaries closer to the introitus, thus aggravating the deep dyspareunia.
Ovarian Remnant

A more difficult situation can develop if a small fragment of ovarian tissue is left behind during attempted oophorectomy. In most instances, this happens when extensive pelvic adhesive disease or endometriosis made the dissection difficult. Within 1 to 3 years of the attempted oophorectomy, continued follicle-stimulating hormone (FSH) stimulation will result in growth of the ovarian fragment, often producing an intermittently symptomatic pelvic mass located along the course of the ovarian vascular supply. This problem is uncommon, but not rare, as implied by early case series. The prevalence of asymptomatic ovarian remnants is unknown. As in the case of the residual ovary, the remnant can produce dyspareunia if it is located close to the vaginal apex.

Vaginal Apex Pain

Following hysterectomy, pain may persist or recur because of intrinsic sensitivity of the vaginal apex. Although the cuff may appear to have healed perfectly well, gentle examination with a cotton-tipped applicator may reveal focal sensitivity of moderate to severe degree, often located in one lateral fornix or the other, and often replicating the reported pain of dyspareunia. When this is not done, the unwary examiner may then, noting pain upon traditional bimanual examination, mistakenly conclude that the source of nociception lies cephalad, for example, in a remaining ovary, pelvic scarring, or bowel adhesions.

The diagnosis may be confirmed by noting elimination of the pain following injection of local anesthesia. The pain appears to be neuropathic in nature, by virtue of the typical descriptors used (burning, stinging, sharp), and by virtue of the treatments that seem to be of benefit to some patients (overnight applications of 5% lidocaine ointment, low doses of nortriptyline, and medications such as gabapentin, lamotrigine, and Lamictal). Surgical revision of the vaginal apex, often done laparoscopically, may give good initial relief in about two thirds of patients, but pain tends to recur to a degree over the subsequent 2 to 3 years.

Musculoskeletal Problems

Musculoskeletal changes can become involved with CPP; either as the primary problem or as a secondary reaction to the pelvic pain. Dysmenorrhea can be referred to the midline of the low back, especially when the uterus is retroverted. Pain can also be referred to the midline of the low back in the presence of cul-de-sac endometriosis. An ovary fixed to the pelvic sidewall can refer pain to the ischiolateral low back and lower quadrant.

The muscular problem that most often produces pelvic pain is pelvic floor muscle spasm. Pain referable to the levator plate can be present as a primary myofascial trigger point and can persist after transcutaneous electrical nerve stimulation (TENS) or coitus. Slocumb has advanced the theory that myofascial trigger points account for a large fraction of CPP. In my experience, abdominal wall components may be the primary cause for pain in some cases, but are more often a later reaction to the long duration of pain from some other source. Rester and Gambone reported that 14% of 122 laparoscopy-negative women had myofascial pain probably related to a previous surgical incision.

Persistent or Chronic Pelvic Pain 651

Myofascial Pain

Focal lower quadrant abdominal wall pain can be produced by entrapment of the genitofemoral and ilioinguinal nerves, as described by Applegate. Such entrapment appears most often after Pfannenstiel abdominal incisions. Slocumb has advanced the theory that myofascial trigger points account for a large fraction of CPP. In my experience, abdominal wall components may be the primary cause for pain in some cases, but are more often a later reaction to the long duration of pain from some other source. Rester and Gambone reported that 14% of 122 laparoscopy-negative women had myofascial pain probably related to a previous surgical incision.

Medical Comorbidity

The cause of chronic lower abdominal or pelvic pain often involves nongynecologic systems (Table 29.1). A careful history and physical examination returns the patient to gynecologic disorders, are perhaps second in terms of prevalence. The urethral syndrome (frequency, urgency, and dysuria in the absence of bacteriuria), interstitial cystitis, and bladder spasms are all accompanied by significant anxiety and depression symptoms. The symptoms of these three disorders are very similar to those in a population of gynecologic CPP patients. Structured questionnaires (e.g., the Pain, Urgency, Frequency [PUF] scale) help detect symptoms possibly emanating from the bladder, but in some patients, a “positive” score can be achieved on the basis of other components of pelvic pain alone, without specific bladder symptoms, hence making this measure perhaps too sensitive, and hence insufficiently specific. A history (whether pain occurs during micturition, daily activities, or coitus) does not always reveal the involved system, but careful pelvic examination with stepwise gentle palpation of the urethra, bladder base, and bladder may help the physician identify from the patient’s response the site of the pain she is experiencing.

Many patients do not experience the problems described here in pure form, but rather in varying degrees of intensity,
with varying contributions to an individual's total discomfort. Indeed, we suspect that shared innervation of pelvic organs may often lead to sub syndromal symptoms in an organ system that neighbors one with organic pathology. Such patients may have a multifaceted somatosensory disorder, as opposed to being the unfortunate victim of multiple unrelated organ-specific disease processes. Close attention to such nuances of detail is warranted both in clinical management and in published reports.

**PSYCHOLOGIC FACTORS**

**Personality**

The links between chronic pain and individual psychology and personality style have been sought after and discussed in the psychiatric literature for many years. Some early reports implied that women who reported CPP had a high prevalence of feminine identity problems related to conflicts about adult sexuality, psychiatric disturbance characterized by mixed character disorder with predominant schizoid features, high neuroticism, and unsatisfactory relationships. Although these initial studies were an important beginning, the high prevalence of psychopathology in some reported samples did not seem applicable to significant numbers of CPP patients seen in practice. The findings are difficult to interpret, partly because there is a lack of clarity concerning the operational definition of CPP that was used. Bases in patient selection and interviewer information, inadequate control groups, and the absence of diagnostic laparoscopy also contribute to the confusion. Despite these shortcomings, it seems apparent that disorders of personality, especially borderline personality, are overrepresented both in the general population of severe chronic pain patients and in the population of pelvic pain patients. In primary care, such patients usually are seen less often. In any case, a label of personality disorder should not be applied indiscriminately to every angry patient by her frustrated physician. People who have difficulties maintaining satisfactory relationships and function in life, even when these difficulties are caused in part by sub syndromal personality problems, can be more vulnerable to nociceptive signals from tissue damaged by endometriosis, infection, or surgery. Unmet dependency needs may lead them to seek external solutions such as medications and further surgery, rather than to rely on their own impaired coping skills.

**Depression**

Focusing specifically on a CPP sample that had been evaluated by diagnostic laparoscopy, Walker and associates found that women with CPP (with and without positive laparoscopic findings) met criteria for lifetime major depression, current major depression, lifetime substance abuse, adult sexual dysfunction, and somatization more often than did control subjects. Stout and Steege found that 39% of 294 women seeking evaluation at a pelvic pain clinic scored in the depressed range (greater than 16) on the Center for Epidemiologic Studies Depression Scale at the time of their initial visit. Slomcumb and colleagues reported that patients with an abdominal pelvic pain syndrome scored higher as a group on scales of anxiety, depression, anger, hostility, and somatization on the Hopkins Symptom Checklist; however, 56% of the total sample scored within the normal range on all scales.

Because no study of CPP has assessed its association with depression over time, no statement can be made as to whether depressive symptoms are a predisposing factor leading to, or a reaction to, the pain condition. There seem to be two distinct groups of CPP patients: one in which pain and depression are common final presentations reached by a number of pathways and another in which depression develops in reaction to pain, as is the case with many other acute and chronic medical diseases.

**History of Sexual Abuse**

Women seeking treatment for CPP have a high prevalence of sexual trauma in their personal histories. In Reiter's study of 106 women with CPP, 48% had a history of major psychosocial trauma (molestation, incest, or rape) compared with 6.5% of 92 pain-free control subjects presenting for annual routine gynecologic examination (p < .001). The high prevalence of reports of psychosexual trauma elicited from pelvic pain patients supports the hypothesis that pelvic pain is specifically and psychodynamically related to sexual abuse. However, Rajkin and colleagues did not find a higher prevalence of childhood or adult sexual abuse in a group of women with CPP compared with women with chronic pain in other locations, although women with CPP reported a higher incidence of childhood or adult sexual abuse in a group of women with CPP compared with women with chronic pain in other locations, although women with CPP reported a higher incidence of childhood sexual abuse. These findings argue against a unique relation between sexual abuse and CPP and suggest that abusive experiences promote the chronicity of many different painful conditions. Morrison also reported an association between sexual abuse and a wide variety of pathologic conditions. Jamieason and Steege, in a survey of 581 women seen in primary care practices, found that 28% of women reported having been sexually abused as children and 26% as adults. In this study, those abused only in childhood did not have an increased prevalence of CPP or other pain disorders, whereas those who had suffered abuse both as children and adults did.

When such a history is documented, the clinician and patient together must judge whether the feelings surrounding these events are intense enough to intrude upon the present. If so, psychotherapeutic help may be indicated. If not, although the memories may be painful, further emotional work on this area may not be beneficial. The treatment literature on the sequelae of abuse (and their treatment) is disappointing, especially when the abuse occurred in the distant past. In either case, it is difficult to judge whether these events are directly relevant to the present pain and hence demand attention, or whether they contribute to a psychologically vulnerable substrate acted upon by subsequent physical and emotional events. In these circumstances, it may be worthwhile to suggest further mental health evaluation as an exploratory measure, being careful not to imply that the patient is being referred because the physician is certain that the abuse is related to the development of the pain.

**Sexual Dysfunction**

In clinical practice, women presenting with CPP often report a high incidence of marital distress and sexual dysfunction, particularly dyspareunia. Stout and Steege found that 56% of 220 married women scored in the maritaly distressed range (less than 100) on the Locke-Wallace Marital Adjustment Scale at the time of initial visit. A high level of marital distress has also been reported in other chronic pain patients and their spouses. Although some women report satisfactory sexual functioning before the onset of pain symptoms, others appear to have
long-standing impairments in sexual response. In our experience, sexual difficulties are often the problem that makes a person seek help for her pain.

**DIAGNOSTIC STRATEGIES**

**Recognizing a Chronic Pain Syndrome**

Many women can experience pain for longer than 6 months without becoming debilitated; although their pain is chronic, such women are not described as having a CPS. The following are the common clinical hallmarks of true CPSs:

1. **Duration of 6 months or longer**
2. **Incomplete relief by most previous treatments**
3. **Significantly impaired physical function at home or at work**
4. **Signs of depression (sleep disturbance, weight loss, loss of appetite)**
5. **Pain out of proportion to pathology**
6. **Altered family roles**

Of the signs of depression, sleep disturbances are usually the first to appear. Careful questioning is needed to distinguish the patient's self-esteem and progressively reduce her family's interactions with her to little more than checking on her pain. Over time, this covertly reinforces the symptom of pain and imparts it unintended value as a major means of maintaining communication within the family.

**Simultaneous Medical and Psychosocial Evaluation**

When the aforementioned markers of CPS are present, one should surrender the need to immediately discover how much of the pain problem is physical and how much is psychologic. Rather than guess, it is useful to ask two separate questions: Is there a physical disease that requires medical or surgical treatment? Is there an emotional or psychological distress that requires treatment?

It is useful to directly state that the precise connection between these two cannot be measured; this can help diminish the patient's fear that she will be told “it's all in her head.” The patient can then be more open to sharing her personal and emotional concerns. If this statement is made early in the evaluation, before all physical evaluations have been carried out, the patient is likely to be less defensive. At this stage, a mental health consultant has a better chance of developing rapport with the patient and will be more helpful collaborator when needed.

**History Taking**

The site, duration, pattern during activities, relation to position changes, and association with bodily functions are all important elements of pain. For example, pain that is focal and positional is more often associated with adhesive disease; pain that is absent in the morning but worsens progressively during the day may be associated with pelvic congestion or pelvic floor muscle dysfunction. The patterns of pain associated with endometriosis are discussed earlier.

The chronology of the pain is critical. As CPS develops, pain can be present over a progressively larger area despite stable organic pathology. Interpreting this as the breakdown or wearing out of physiologic systems that deal with pain signals has some biologic validity and may make sense to the patient.

From a cognitive perspective, it is invaluable to discern the patient's and her family's ideas about the causes of and future for her pain. Fears of cancer can be discovered even if this diagnosis was never even remotely considered by the clinician. Less dramatic, but equally powerful, attributions of cause can emerge, such as pelvic infection that is due to sexual acts remote in time, arguments with a spouse, divine retribution, and so forth.

**Physical Examination**

The exam begins with single finger palpation of the abdominal wall, with and without having the patient flex the rectus muscles. A positive Carnett sign (persistent increase in tenderness when palpation is done in the presence of abdominal wall flexion) implies at least a contribution to the pain from abdominal wall myofascial sources. On occasion, gentle fingertip palpation of the abdominal wall can detect such trigger points in the musculature.

Pelvic exam then begins with external review of the vulva and vestibule. Gentle palpation with a cotton swab can detect areas of sensitivity compatible with vestibulitis in the introitus or trigger points higher in the vagina.

Guiding a patient through contraction-relaxation sequences of the abdominal, thigh, and vaginal introital muscles can reduce the discomfort of the examination and can indicate the patient's degree of control over muscle tension. Single-digit palpation of the levator plate, perineum, and obturator muscles can elicit tenderness compatible with the label of pelvic floor myalgia. This condition is often present as a sequel to some other pelvic pain, but it can become a problem in itself. Discomfort is usually felt as pelvic pressure and radiation pain to the sacrum, near the insertions of the levator plate muscles.

Single-digit palpation should also be used to discover areas of tenderness in the cervix, uterus, and adnexa as well. Premature addition of the abdominal hand to the exam adds nociceptive signals from abdominal wall myofascial components that may lead the examiner to overattribute pain to the viscera. Finally, the abdominal hand is added to assess size, shape, and mobility of pelvic structures. Adnexal thickening and mobility, pelvic relaxation, coccygeal tenderness, and focal pain that reproduce dyspareunia should be noted.

**Laboratory Tests**

**Imaging Studies**

In the case of CPS, it has already been established that intensity of pain does not correlate well with extent of organic pathology. It follows that if the physical examination is relatively benign and is not severely limited by body habitus, extensive imaging usually adds little to the database needed before laparoscopy is performed. This is especially true in the case of organ-specific studies (intravenous pyelography, barium enema, colonoscopy) in the absence of symptoms or signs pointing to a specific organ.
system (e.g., blood in the stools). If the patient has had multiple previous surgeries, high-resolution studies such as MRI and computed tomography scans are often misleading because of postoperative artifact. “Cystic masses” seen on such studies often prove to be nothing more than pockets of adhesions or peritoneal inclusion cysts.

Blood Studies
Relatively few hematologic or chemical measures are of use in diagnosing CPP. An elevated leukocyte count and erythrocyte sedimentation rate may make the clinician suspect chronic pelvic inflammation. However, even when cervical cultures are negative for the most common sexually transmitted diseases. The cancer antigen-125 test is positive in advanced endometriosis but is not sufficiently sensitive to detect early-stage disease or reliably monitor its response to treatment. If any remnant ovarian tissue is present, FSH and estradiol levels remain in premenopausal ranges in almost all instances. Replacement estrogen therapy should be withdrawn 3 weeks before these levels are measured.

Anesthetic Blocks
Injection of small volumes of a local anesthetic, 1 to 5 ml of 1% lidocaine or 0.5% bupivacaine, blocks pain from either an entrapped segmental nerve (e.g., ilioinguinal) or an abdominal wall trigger point. In the latter case, such blocks can be therapeutic as well as diagnostic. Many anesthesia pain clinicians administer epidural or spinal anesthetics to distinguish pain arising from peripheral organs from pain that has become completely central in origin.

In some instances, it is useful to attempt transvaginal blocks with the same local anesthetics for vaginal apex pain, as discussed above. Local blocks can be therapeutic as well as diagnostic. A series of three or four blocks administered 1 to 2 weeks apart may give relief for months to years in some instances. In most cases, a history and careful routine physical examination distinguishes central from lateral sources of pelvic pain. When this discrimination is difficult, it may be useful to administer a transvaginal uterosacral block (blocking most uterine innervation) and then repeat the pelvic examination. When this relieves the pain, the pain can be assumed to arise from the uterus, but if the pain is not relieved, one cannot distinguish a failed block from pain of nonuterine origin.

Psychologic Tests and Interviews
To distinguish physical from psychogenic causes for pain, many studies of CPP have used traditional psychologic instruments that were developed to measure general psychopathology or personality factors. In some studies, more abnormalities are detected in women without physical pathology at laparoscopy. In other papers, women with organic disease who have had pain for a long time appear equally distressed in their questionnaire responses. These psychometric instruments generally have little face value for chronic pain patients, and their use often confirms the physician’s fears that the health care provider thinks she is “crazy” or that the pain is “all in her head.” Once again, the question of whether the emotional distress identified by these instruments is an antecedent to or a consequence of persistent pain remains unanswered. A more complete review of the psychometric instruments that have been used to study CPP is presented elsewhere.

Psychometric tests are most useful when they are interpreted by a psychologist who has interviewed the patient, and they serve best as a means to better understand the patient’s strengths and weaknesses, rather than as a means to decide who needs surgery.

Laparoscopy
Great strides have been made in operative laparoscopy in the past two decades. New techniques and new terminology (e.g., pelviscopy) imply new “magic” to the physician and public alike. Laparoscopy should be liberally performed for diagnostic purposes, and ablation/excision of endometriosis and lysis of adhesions are no doubt useful procedures. However, the premature surgical procedure errs in the notion that pain is “hardwired” to pelvic pathology. The available evidence clearly argues against this. When a CPS is clinically evident, results of laparoscopic treatment alone, despite comparable pathology, are much less impressive. For a patient with the clinical markers of CPS listed earlier, the complete workup as described should be performed before laparoscopy.

In some puzzling cases, we have performed laparoscopy under local anesthesia to “pain map” the pelvis. A 2-mm laparoscope and a small suprapubic probe are placed with the use of short-acting intravenous analgesia (remifentanil) and local lidocaine 1%. Having been oriented to the procedure beforehand, as each organ is touched, she is asked (i) “Does this give you the pain you get?” and (ii) “Please rate the pain.” She responds with a number picked from a scale of 1 to 10, with 10 signifying the “worst pain you could imagine.” This technique may make it possible to determine whether visualized pathology is causing nociceptive signals or to discriminate visceral from somatic pain. It is possible in some cases to block the superior hypogastric plexus during pain mapping to better predict benefit from presacral neuroectomy. In this approach, mapping is done before and after injecting 10 ml of 1% lidocaine just underneath the peritoneum over the sacrum, using a 7-inch, 22-gauge spinal needle.

MANAGEMENT
Physicians use specific treatments in chronic pain depending on the model of pain perception that they follow. The surgically oriented gynecologist often tacitly follows the cartesian model, attempting to eliminate organic tissue damage to diminish pain proportionately. The behaviorist, cognitive therapist, and insight-oriented psychotherapist use approaches consistent with each one’s basic therapeutic orientation, whereas advocates of the gate control theory use medications and other treatments that make sense based on that theory. The following represents an eclectic treatment approach. The treatment literature is considerably sparser than is the literature exploring the etiology of CPP.

General Principles
A complete evaluation of CPS often reveals a number of contributing factors, such as bladder irritability, irregular bowel function, poor posture, and emotional and relationship stresses, in addition to laparoscopically visualized pathology. Treating each component sequentially is common practice but often ends in frustration because each treatment addresses only
a part of the problem. Simultaneous treatments often begin with disquieting multiple drug therapy but allow better relief. Close follow-up at regularly scheduled visits allows gradual tapering of medications over time. Planned visits also provide support and a coping mechanism for the patient. When the patient is essentially required to feel worse to be seen again, the pain may be tacitly reinforced.

**Medication Use**

**Analgesics**

Advocates of the operant conditioning model suggest that analgesics be taken continuously, in a non-pain-contingent fashion. This eliminates the need to demonstrate pain behaviors or voice pain symptoms to justify the use of medication, thus eliminating the tendency of medication to act as a reinforcer of pain behaviors. This approach is benign enough when relatively nontoxic and nonaddicting medications such as acetaminophen are used, but it presents potential hazards when drugs such as the following are used: nonsteroidal antiinflammatory drugs (NSAIDs; gastric irritation, renal damage); aspirin or NSAIDs in combination with the milder narcotics, such as codeine, oxycodeone, and pentazocine (constipation, sedation, habituation); and pure narcotics (addiction, diminished analgesic potency over time). When well tolerated, all three types of drugs can serve well in appropriate patients (without histories of substance abuse). Indeed, contrary to common perception, there is support for the notion that chronic low-dose opiate therapy may allow good return of function without adverse side effects in those who have failed intensive pain clinic treatments.

**Antidepressants**

This class of drugs, particularly the tricyclic antidepressants, can potentiate the effects of analgesics in CPS, even when given at doses less than those usually used in the treatment of depression. Agents such as fluoxetine (Prozac) show promise and have a low level of side effects. Few controlled trials of antidepressants have been carried out in CPP patients.

**Anxiolytics**

Anxiolytic drugs are certainly widely prescribed by gynecologists, although it is uncertain how often they are given for pain. In one study, alprazolam, a trazodobenzodiazepine with mixed anxiolytic and antidepressant effects, had a surprising degree of analgesic effect in moderate to high doses in patients with chronic pain of malignant origin and concomitant mood changes or anxiety. These patients were already receiving narcotics, which may suggest that alprazolam potentiates the analgesic effect of narcotics. Their role in conjunction with non-narcotic analgesics is uncertain, and the addiction potential is obvious.

**Other Medications**

Nonanalgesic and nonpsychotropic drugs also have potential roles in the treatment of specific pelvic conditions. For example, medroxyprogesterone acetate treatment sufficient to suppress ovarian function may reduce the diameter of engorged pelvic veins and thus reduce the discomfort of pelvic congestion. However, the longest-lasting relief was observed when psychotherapy was used as well. The use of GnRH agonists has been recommended to distinguish gynecologic from nongynecologic sources of pain; however, these agents also relieve the symptoms of IBS, probably by reducing serum relaxin levels. When the differential diagnosis includes ovarian remnant syndrome, residual ovary syndrome, or any other disorder influenced by the menstrual cycle, the impact of GnRH agonists on pelvic pain must be interpreted with caution in anyone with symptoms at all compatible with bowel dysfunction. In addition, pain threshold has been shown to be lower premenstrually, even in asymptomatic patients. The impact of the menstrual cycle itself in chronic pain patients has not been well explored, but it seems likely that it may impart some cyclicity even to conditions unrelated to the reproductive tract. Cyclicity of symptoms must therefore be interpreted with caution, and the obliteration of symptoms or of their cyclicity by pharmacologically obliterating the menstrual cycle does not demonstrate a gynecologic cause. To address the most common clinical circumstance: relieving pain with a GnRH agonist does not prove that the pain is due to endometriosis, nor does it prove that pain comes from the reproductive tract, as discussed above.

**Surgery**

Two basic surgical approaches have been used to treat CPP: removing pelvic organs and treating visible disease while leaving the pelvic organs in place. Only the former approach has been evaluated for efficacy to any degree.

In the United States, about 12% of hysterectomies are performed with pelvic pain as the primary indication. An additional 6.1% are performed for endometriosis or adenomyosis, and 5.1% are performed for pelvic inflammatory disease; no doubt many in these two categories also involve symptoms of pain. In about one third of hysterectomies performed for pain, no pathology is found. Despite the frequency of unrevealed pathology, no as an indication for this procedure, data regarding efficacy are surprisingly sparse. One report notes relief in 78% of women after hysterectomy for pelvic pain of uterine etiology (women with adnexal or other pelvic disease were excluded). However, the presence or absence of uterine pathology (adenomyosis or leiomyomata) had no bearing on whether pain was relieved. It cannot be determined from the report (Table 29.1) whether failure to obtain relief was due to the presence of other pelvic conditions, postoperative adhesion formation, or psychologic reasons. Symptom substitution was not evaluated in the report. Relief of pain by removal of the normal uterus is even more puzzling; apparently this was not accounted for by concomitant procedures performed for deficient pelvic support. Some of these cases may have involved pelvic congestion or perhaps other mechanisms even less well understood. A 22% failure rate emphasizes the need for careful preoperative evaluation of all potentially contributing factors, both physical and emotional.

According to two recent reports, hysterectomy performed in primary care settings was very effective for the treatment of CPP. In a prospective observational study of private practices in Maine, Carlson and associates reported that at a 1-year follow-up, satisfaction with the outcome of surgical treatment was much higher than satisfaction with the outcome of medical therapy. However, about one third of women improved substantially on medical therapy, and perhaps women were more likely to undergo operation when organic pathology was demonstrable. In the Maryland Women’s Health Study, 1,299 women were interviewed at length before hysterectomy for pelvic pain, bowel dysfunction and at 3, 6, 12, and 24 months after surgery. In more than 90% of cases, the procedure was well tolerated and did not result in postoperative depression or a decline in
sexual functioning. In the subset of women with pain as the primary indication for surgery, relief of pain occurred in more than 80%, indicating that the clinicians involved generally used good judgment and technique. In general, women with preop-

erative depression or sexual dysfunction did not fare as well as their less symptomatic counterparts, although even when hys-
terectomy is performed in women with both depression and chronic pelvic pain, slightly more than 80% are improved emo-
tionally and in terms of pain at 2-year follow-up.

Adnexal and other intrapelvic diseases, usually endometri-
sis or adhesions that are due to either postoperative changes or chronic pelvic inflammatory disease, have been treated by both laparotomy and laparoscopy. Use of the CO2 laser during lap-
arotomies does not improve the results of standard infertility surgical techniques as evaluated by second-look laparoscopy and by pregnancy rate.

Laparoscopy is probably superior to laparotomy for treat-
ing adhesive disease. In the rabbit model, infliction of injuries with the laser by way of laparotomy resulted in adhesion for-
mation, but no adhesions formed when identical damage was caused by laparoscopy. In the rabbit and the human, adhesio-
lysis is more effective with laparoscopy than with laparotomy. However, none of the large clinical trials of laparoscopic adhe-
siolysis evaluate the effects of the procedures on pain. Although second-look verification of effective adhesiolysis is lacking, results of several studies on the treatment of pelvic adhesions for the relief of pain are encouraging. Even when treated by laparotomy, with the use of infertility techniques, 28 of 42 (65%) patients reported cure or improvement of pain. In a sample of mostly primary care patients, 84% of 65 patients had relief of pain after laser laparoscopic adhesiolysis with follow-up intervals of 1 to 5 years. In Sutton’s large series, 85% had pain relief at 1 year. Streege and Stout reported that 13 of 20 (65%) patients who had laparoscopic laser adhesiolysis had good relief of pain at a follow-up of 6 to 12 months after surgery. However, if a CPS was present, only 4 of 10 (40%) patients with equivalent adhesive disease obtained relief. The greater the emotional and behavioral dis-

ability, the greater the chance for combined medical, surgical, and mental health management.

Several studies support an association between pelvic pain and endometriosis, although a strict quantitative relationship is lacking. In terms of surgical treatment of pain from en-
dometriosis, laser ablation results in relief of pain in about 60% of women at 1 year follow-up, compared with 96% treated by laparoscopic excision of the disease. A randomized trial comparing these two methods has not been done. The benefits of surgical excision may be prolonged by subsequent medi-
cal therapy. Numerous studies have been done of postsurgi-
cal treatment with hormonal medications. Oral contraceptives, Danocrine, progestins, and GnRH agonists (with or without add-back estrogen/progestin) have all been shown to be effec-
tive. Although the GnRH agonists have become perhaps the most widely used of these, definitive evidence for their superior-
ity is lacking. The more economical and less physiologically in-
trusive approach would seem to favor sex steroids over GnRH agonists. Most troublesome in reviewing all of these studies is the observation that dyspareunia is the symptom that is most refractory to treatment, testifying to its multifactorial nature.

Presacral neurectomy, as an adjunct to surgical excision of endometriosis, has been evaluated for its effect on pelvic pain. In a retrospective sample of 71 women undergoing con-

servative resection of endometriosis by way of laparotomy, 35 (50%) who also had presacral neurectomy enjoyed signifi-

antly greater improvement in both dysmenorrhea and dys-
pareunia, with 75% to 95% obtaining improvement. Two sub-
sequent retrospective reports noted that similar percentages (about 75%) of women obtained pain relief after endometriosis-
surgery that included presacral neurectomy, compared with about 25% who obtained relief without neurectomy.

Two studies on the treatment of presacral neurectomy as adjunctive therapy along with conservative resection for stage III–IV endometriosis reached different conclusions about the additive value of presacral neurectomy. Tjaden and associates performed conservative resection by way of laparotomy and randomized eight women to receive or not receive presacral neurectomy. All the neurectomized women improved dramati-
cally, whereas the others did not. The institutional review board mandated stopping the study because statistical significance had been reached. The authors then reported an open clinical-
sical series in which 13 of 17 women improved substantially af-
ter conservative resection with presacral neurectomy. Candas and colleagues reached a different conclusion after randomiz-
ing 71 women to receive or not receive presacral neurectomy along with conservative resection of advanced endometrio-
sis. They found that central dysmenorrhea improved slightly more in neurectomized women, but daily pain and dyspareu-
nia were not improved by adding presacral neurectomy to the procedure. The literature is therefore inconclusive regarding the value of the neurectomy procedure.

Laparoscopic treatment of even severe endometriosis has a growing number of advocates. Again, the focus has been on fertility rates, but one prospective report notes prolonged pain relief in two thirds of patients. The ability to perform pre-
sacral neurectomy by way of laparoscopy should not provoke wide adoption of the procedure without careful consideration of these data.

An ovarian remnant should be removed if it is persistently symptomatic despite all reasonable attempts at medical sup-
pression and if a menopause is desired in the patient’s near future. Whether performed by laparoscopy or laparotomy, the dissection should be detailed and should include all the peri-
toneum surrounding the mass. The ureter and pelvic sidewall vessels should be exposed and carefully freed from the speci-
men. When a GnRH agonist has been used preoperatively for symptom control or to distinguish the relative contributions made by the remnant and other pelvic pathology, such as ad-
hesions, the remnant tissue may become so small as to make it difficult to identify. Hence, if a palpable (or ultrasonically visible) mass disappears after GnRH agonist treatment, it may be wise to allow time for it to regrow before pursuing surgical excision. When the remnant is small, some surgeons have stim-
ulated the remnant with clomiphene citrate to make it easier to find.

Finally, the peritoneal windows syndrome must be men-
tioned. Openings in the peritoneum covering the posterior broad ligament and the cul-de-sac of Douglas, or peritoneal “windows,” have been noted since the 1950s and were associ-
ated with endometriosis by Chatman. Excision and closure of the windows have been anecdotally reported, but the value of these operations in treating pain associated with the disease remains to be demonstrated. It is my practice to excise the peri-
toneal involved with the window, but not to stitch the area closed. Microscopic endometriosis is found in many cases.

Alternative Treatments

Biofeedback, transcutaneous electric nerve stimulation units, relaxation training, and individual and couples counseling all have their appropriate roles in individual cases, but none is so clearly applicable or effective that its automatic use is
supported in cases of CPP. In keeping with the approach outlined in the earlier discussion of medications, problems requiring counseling should be addressed but should be treated as issues separate from the discussion of appropriate surgical approaches. Cause-and-effect relations are difficult to demonstrate even in retrospect when psychologic assistance works.

Management Overview

The most effective clinical approach requires simultaneous treatment of as many factors as possible: anatomic, muscularkeletal, functional bowel and bladder, psychologic, and so forth. Patient and physician must contract for the long term and work from a rehabilitation perspective, rather than hope that the latest single addition to the treatment will prove to be the answer. The physician, to prevent frustration and feelings of defeat, must often play the role of helping to manage and relieve the pain while helping to maximize function, even when pain persists. To the surgically trained gynecologist who prefers a clear-cut single answer to a clinical problem, this can be the most difficult part of dealing with the problem of CPP.

THE EVOLUTION OF A CHRONIC PAIN SYNDROME

As is apparent from this discussion, CPP is a heterogeneous problem, not a single diagnosis, and no single etiologic hypothesis is clearly supported. Most of the hypotheses reviewed here have some credible evidence supporting them; none have been sufficiently validated.

Some patients appear to have a pure version of one or the other of the syndromes described, whereas many others present with several or many simultaneously. Psychologic and neurologic mechanisms are proposed here to explain how the evolution of chronic pain may occur, regardless of the particular tissue damage or functional disorder that may first have provided nociceptive stimuli. We suggest the following elements (Fig. 29.1): biologic events sufficient to initiate nociception, alterations of lifestyles and relations over time, recruitment of neighboring organ systems, anxiety and affective disorders, and a circular interaction (vicious cycle) among these elements.

Biologic Events Sufficient to Initiate Nociception

Sexually transmitted diseases, endometriosis, recurrent bladder and vaginal infections, primary or secondary functional dyspareunia, alterations of bowel habit, muscular dysfunction, pelvic congestion, and gynecologic or other abdominal surgeries (Table 29.1) may contribute individually or in combination.

Alteration of Lifestyle and Relations

Physical activities at home and recreational pursuits can suffer. Believing that rest usually helps in the treatment of most causes of acute pain, the patient may assume that the same applies to chronic pain and may thus restrict herself more than actual discomfort dictates. Family members start to regard the patient as sick and leave her out of many activities, thus reducing her roles within the family structure. With time, concern for and discussion of her pain can become the family’s major pattern of communication with the pain victim. If sexual intimacy has been the major means of emotional sharing and smoothing over of differences, and if this intimacy is reduced, then the altered pattern of interactions may take hold more quickly.

Anxiety and Affective Disorders

Depression can occur as a cumulative result of the disability suffered, or the pain can bring on an episode of depression in a patient already biologically vulnerable. The observation most relevant here is that pain patients with a family history of depression can derive the most benefit from tricyclic antidepressants.

The Vicious Cycle

Diminished activity, altered family roles and social supports, anxiety, and affective disturbances can influence nociception by a variety of central pathways, ultimately altering spinal cord “gating” of nociceptive signals. Cognitions about the pain can play an additional role.

Several important modifying influences can be present in addition to these major pathways (Fig. 29.2). Incest and other forms of sexual abuse have attracted the most attention as possible forerunners of CPP. However, CPP is clearly not a unique or specific sequel to sexual abuse, and a large proportion of CPP patients have not been abused in this manner. Victims of sexual abuse have many negative emotional sequelae; pain problems often occur after abuse, but they are not necessarily directly caused by the abuse.

Sexual abuse perpetrated by a family member is a clear indication of a psychologically detrimental environment of rearing that might have led to disturbances in character and personality.
An integrative model for chronic pelvic pain, including elements of gate control theory, cognitive-behavioral theory, and the operant conditioning model.

development perhaps equal in importance to the terrible trauma of the abuse itself. Learning more about the factors that can mitigate the impact of sexual abuse in general will facilitate our understanding of the psychologic vulnerabilities that can make a particular person more susceptible to development of CPP or other chronic pain disorders.

A genetic predisposition to depression also allows the vicious cycle to become easily established and strengthened over time. Antidepressant medications play an important role in the overall therapeutic plan in such cases. A relatively new area of research in pain is dealing with possible genetically determined variations in central neurotransmitter processes that may predispose to the development of pain syndromes.

Several authors have suggested that the concept of perceived control best explains the development of affective changes accompanying chronic pain, regardless of the location of the pain.

The individual who sees herself as having little control over the physical and emotional events affecting her may be most vulnerable to development of a CPP. It may be reasonable to consider this variable as a culmination of the effects of affective change, activity, family roles, sexual dysfunction, and previous victimization experiences.

The longer that pain has been a part of the person's life, and the more psychologic vulnerabilities she carries forward to the present, the less likely it is that any treatment of the tissue damage itself will be effective in relieving pain and restoring physical and emotional function. However, as treatment studies show, the organic contribution to chronic pain can seldom be dismissed entirely. The more difficult task is the selection of an efficient and cost-effective combination of treatment approaches aimed at the most important factors acting in the present.

Bibliography

CHAPTER 30 ■ PELVIC INFLAMMATORY DISEASE
MARK G. MARTENS

DEFINITIONS

Bacterial vaginosis (BV)—A vaginal condition demonstrated by a replacement of the normal lactobacillus predominant vaginal flora with a mixture of facultative and obligate anaerobes, mycoplasma, and other species, resulting in a malodorous discharge. The presence of Gardnerella vaginalis without symptoms is not synonymous with BV.

Colpostomy—Incision into and through the vaginal epithelium into a cavity (often abscess or pelvic/abdominal cavity).

Pelvic morbidity—Temperature equal to or greater than 100.4 °F or 38 °C on two separate occasions (greater than 4 hours apart), starting 24 hours after the initiating event.

Fever—Temperature equal to or greater than 99.6 °F or 37.5 °C.

Lower genital tract infection (LGTI)—An alternative term used to describe infection limited to the cervix and/or vulva and vagina.

Mollicutes—Class of organisms that includes Chlamydia, Mycoplasma, Ureaplasma, and other species.

Outpatient therapy—Previously synonymous with oral therapy; however, the term now includes oral, ambulatory intravenous, or intermittent injectable therapies.

Parenteral therapy—Usually denotes intravenous (antibiotic) therapy, but not necessarily given while hospitalized.

Pelvic inflammatory disease (PID)—A general term used to refer to infection and inflammation of the upper genital tract in women.

Pneumonia—A massive infiltration of inflammatory cells into infected soft tissue resulting not in an abscess, but a “woody induration” sensation upon examination/palpation.

Prevotella—Newly named genus that now includes several species formerly called Bacteroides (e.g., Bacteroides fragilis).

Salpingitis—Infection/inflammation of one or both of the fallopian tubes (often incorrectly used as an equivalent to all PID).

Tuboovarian abscess (TOA)—A term used to describe an abscess incorporating the fallopian tube and ovary.

Upper genital tract infection (UGTI)—A more descriptive term used alternatively to PID.

Pelvic inflammatory disease (PID) is one of the most serious infections facing women today. According to Velebil and colleagues, it is the most common gynecologic reason for hospitalization and emergency department visits in the United States each year. Untreated or unsuccessfully treated women may suffer life-threatening consequences, and even adequately treated women are at much higher risk for potentially serious sequelae. PID is a spectrum of diseases initially involving the cervix, uterus, and fallopian tubes. Acute PID, the acute clinical syndrome, is most often attributed to an ascending spread of microorganisms from the vagina and endocervix to the endometrium, fallopian tubes, and contiguous structures. The terms acute PID and acute salpingitis are often used interchangeably, but PID is not limited to tubal infection only. A more descriptive term to differentiate the severity and extent of various forms of PID was introduced by Hemsell and colleagues: upper genital tract infection (UGTI). This is differentiated from lower genital tract infection (LGTI) because response to treatment appears to be different in these two entities. PID was previously categorized as inpatient or outpatient treatment groups, which sometimes did not accurately reflect the severity of illness.

Sexually transmitted diseases (STDs) have been reported at epidemic proportions in the United States, with the Centers for Disease Control and Prevention (CDC) estimating 19 million new infections each year. The incidence of chlamydia infections increased almost 6%, with 929,000 cases reported and 2.8 million new cases suspected annually. Gonorrhea incidence has decreased 70% since 1975, but is still estimated to occur in more than 60,000 women each year in the United States. For women, acute PID is the most common and important complication of STDs. Bell and Holmes in the 1980s estimated that 1 million women a year were treated for acute salpingitis in the United States, but recent estimates by Sutton and colleagues estimated a decrease in cases of PID to less than 800,000 per year and a 68% decrease in hospitalized PID from 1995 to 2001. About 230,000 to 300,000 women are hospitalized each year with a diagnosis of salpingitis or PID. The disease generates nearly 2.5 million visits to physicians, and an estimated 150,000 surgical procedures are performed for complications every year. According to Sutton and colleagues, the direct and indirect costs of PID and its sequelae now total $2 billion and $10 billion in the United States, respectively. In terms of overall incidence, acute PID occurs in about 1% to 2% of young, sexually active women each year. PID is the most common serious bacterial infection in women age 16 to 25 years, and the resultant morbidity exceeds that produced by all other infections combined for this age group.

ETIOLOGY

Within certain geographic areas or populations, Neisseria gonorrhoeae is a common cause of PID; however, most cases of acute PID are the result of a polymicrobial infection caused by organisms ascending from the vagina and cervix to infect the lining of the endometrium and fallopian tube. Approximately 85% of cases are natural, nonantigenic occurring infections in sexually active women of reproductive age. The remaining 15% of infections occur after procedures that break the cervical mucous barrier, such as placement of an intrauterine device (IUD), endometrial biopsy, or uterine curettage, which allow vaginal flora to infect the upper genital tract.
In the United States, non-tuberculous acute PID was traditionally separated into gonococcal and nongonococcal disease, depending on the isolation of N. gonorrhoeae from the endocervix. A variety of organisms can be isolated from the endocervix; therefore, it is difficult to determine which of these organisms cause PID and which are normal cervicovaginal flora and only present as colonizers in the upper genital tract at time of infection. Whether these organisms are prob-ably more indicative of the causative organisms, they are often difficult to obtain without suspecting endocervical contamination during the diagnostic procedure. Bacterial organisms cultured directly from tubal fluid may commonly include N. gonorrhoeae, Chlamydia trachomatis, endogenous aerobic and anaerobic bacteria, and genital Mycoplasma species. Laparoscopic studies have demonstrated a correlation of no more than 50% between endocervical and tubal cultures, but the presence of N. gonorrhoeae is usually considered an important causative factor. However, endocervical gonorrhea does not necessarily indicate its sole pathogenic nature in all cases. Direct fallopian tube cultures have demonstrated that tubal infections are often polymicrobial. The type and number of species vary depending on the stage of the disease. Gonorrhea, for example, is often cultured from the cervix during the first 24 to 48 hours of the disease but is often absent later. Similarly, fewer organisms are cultured late in the disease, and anaerobic bacteria such as Prevotella, Bacteroides, Peptococcus, and Peptostreptococcus appear to predominate. Whether these anaerobes play a causative role or increase in number and frequency as a result of the inflammatory response is uncertain. Sweet has summarized the literature by stating that in approximately one third of women with PID, N. gonorrhoeae is the only organism recovered by direct tubal or cul-de-sac culture. One third have a culture positive for N. gonorrhoeae plus a mixture of endogenous aerobic and anaerobic bacteria, such as retaining one third have only aerobic and anaerobic organisms. Chow and colleagues and Monif and colleagues have postulated that the gonococcus may initiate acute PID and produce tissue damage. This damage changes the local environment, which in turn allows anaerobic and aerobic organisms from the vaginal and cervical flora to invade the upper genital tract. Both Eichenbach and Sweet have suggested that not all PID follows gonococcal infection and that aerobic flora may also have a polymicrobial etiology.

According to Sweet and Gibbs, about 20% of all women with salpingitis have tubal cultures positive for C. trachomatis. N. gonorrhoeae and C. trachomatis are found in the same individual 25% to 40% of the time. Scandinavian studies by Eilard and coworkers have reported the recovery of C. trachomatis from the cervix in 22% to 47% of women with acute PID. C. trachomatis by itself produces a mild form of salpingitis with an insidious onset. In contrast to gonorrhea, Chlamydia can remain in the fallopian tubes for months or years after initial colonization of the upper genital tract. Svensson and colleagues found that women with C. trachomatis infection at laparoscopy had the most severe fallopian tube involvement, probably because of its clinically silent or minimally symptomatic nature, which results in difficult or delayed diagnosis and therefore delayed or absent treatment. The two major sequelae of acute PID are tubal infertility and ectopic pregnancy. These have been strongly associated with prior chlamydial infection as a consequence of intratubal and peritubal adhesions.

Although C. trachomatis is generally believed to be one of the more common causes of PID, along with N. gonorrhoeae, its etiologic role is very different. N. gonorrhoeae is a Gram-negative diplococcus with rapid growth that is due to a rapid cycle of about 20 to 40 minutes to divide. This results in a logarithmic increase in the number of organisms once N. gonorrhoeae reaches an area such as the endometrium or fallopian tube, where growth is relatively unimpeded. This rapid increase in the number of Gram-negative bacteria usually results in a rapid and intense inflammatory response by the woman’s host defenses. The response to this rapid bacterial growth is proliferation and aggregation of white blood cells and their inflammatory mediators. Mycoplasma, Gardnerella, Mycoplasma hominis, and Ureaplasma urealyticum have also been suggested as causal agents in acute salpingitis by Ness and colleagues (2005). However, although success was evident with short-term follow-up, long-term follow-up demonstrated that treatment of C. trachomatis was necessary. PID regimens without Chlamydia coverage resulted in an increased incidence of long-term complications such as abscesses and chronic pelvic pain, with resultant increased surgical intervention. Therefore, modern treatment of PID includes C. trachomatis coverage, even though this organism may not be the cause of the acute symptoms.

Nongonococcal infections are believed to be the result of acute bacterial infections or possibly a preceding or previously treated C. trachomatis UCT. This is confirmed by the high incidence of Chlamydia antibodies in patients with acute PID, ectopic pregnancy, and infertility.

In addition to N. gonorrhoeae, Chlamydia, and aerobic and anaerobic bacteria, other microorganisms have been implicated as etiologic agents in acute salpingitis. Bacterial vaginosis-related organisms such as Gardnerella, Mycoplasma hominis, and Ureaplasma urealyticum have also been suggested as causal agents in acute salpingitis by Ness and colleagues (2005). However, their role remains controversial, and this study contradicts in a study from the previous group of investigators. Cervical cultures positive for both M. hominis and U. urealyticum have been recovered from women with PID. However, the rate of isolation can be as high as 75%, which
is not statistically different from that of women who are sex-
ually active but without PID (baseline rate of about 50%), as
found by Lemeke and Losel. However, evidence is recently
accumulating that Mycoplasma genitalium may play a role in
PID, with Ross of Great Britain calling for the development of
reliable tests for its identification and susceptibility.

RISK FACTORS

Several factors that predispose to the development of acute
PID have been identified. Risk factors are important consid-
erations in both the clinical management and prevention of
UGTIs. There is a strong correlation between exposure to STDs
and PID. In the United States, recent studies have confirmed
this association with thevey of N. gonorrhoeae and C. trachomatis in about 50% of patients hospitalized with acute
PID. Age at first intercourse, frequency of intercourse, number
of sexual partners, and marital status are all associated with
the frequency of exposure to STDS and thus are associated with
PID. Women with multiple partners have an increased
risk (four to six times normal) for development of acute sal-
ingitis, compared with women who have monogamous sex-
ual relations. Recently, Ness and colleagues have demonstrated
the validity of a Chlamydia risk factor scoring system for the
prediction of 74% of PID. Significant factors included age at
first sex, cervicitis, history of PID, family income, smoking, me-
droxyprogesterone use, and sex with menes.

The incidence of acute PID decreases with advancing age.
Adolescent girls are at significant risk for development of acute
salpingitis. Westrom reported that nearly 70% of women with
PID were younger than 25 years of age, 33% experienced
their first infection before the age of 19, and 75% were nul-
aripous. The risk for development of acute PID in a sexually
active adolescent female patient was 1:8, whereas the risk was
1:80 for a sexually active woman 24 years of age or older.
Several reasons have been suggested for this increased risk.
The two microorganisms most commonly considered to be
risks are Chlamydia and N. gonorrhoeae. The incidence of acute
PID was increased in about 50% of patients hospitalized with acute
PID. The pill’s ability to inhibit ovulation presumably helps from
providing a nidus for tuboovarian abscess formation.

Surgical procedures of the female genital tract also place
the patient at risk for PID. About 15% of pelvic infections
occur after procedures that break the cervical mucous barrier,
allowing for colonization of the upper genital tract. Eichen-
bach and Holmes reported that these procedures include en-
dometrial biopsy, curettage, IUD insertion, hysteroscopy, and
hysterosalpingography. The incidence of UGTI associated with
first-trimester abortions is about 1 in 200 cases. Recent practice
has emphasized the use of microorganisms associated with high
risk to attempt to decrease the incidence of intravenous acute
PID. Two randomized trials have indicated that the treatment
of bacterial vaginosis (BV) with metronidazole substantially
reduced postabortion PID (Jackson and Luton and Dunstable
Hospital).

Acute salpingitis occurring in a woman with a previous
tubal ligation was once believed to be rare. Phillips and
D’Abling reported that acute PID developed in the proximal
stump of previously ligated fallopian tubes in 1 of 450 women
hospitalized for acute salpingitis. However, many cases may be
undiagnosed because of the absence of peritoneal signs.

Prevalent acute PID is also a risk factor for future episodes
of the disease. Another acute tubal infection develops in about
25% of women who have had acute PID. The exact mechanism
for this increased susceptibility has not been determined, but
it may be loss of the natural protective mechanisms of the fal-
lopian tube lining against microorganisms. This increased risk
may be related to the sexual habits of the woman involved. Acute
salpingitis occurring in a woman with previous
PID, with Ross of Great Britain calling for the development of
reliable tests for its identification and susceptibility.

Acute PID presents with a broad spectrum of clinical symp-
toms. The differential diagnosis of acute PID includes acute
appendicitis, endometritis, torsion or rupture of an adnexal
mass, ectopic pregnancy, and IUGTIs. Common clinical manifesta-
tions include lower abdominal pain, cervical motion tenderness, and adnexal tenderness
and may include fever, cervical discharge, and leukocytosis. Histor-
ically, the diagnosis of acute PID was not established unless the
patient had the triad of lower abdominal and pelvic pain, fever,
and leukocytosis.

Jacobson and Westrom have shown that all three are present
in only 15% to 30% of actual PID cases. In addition, about
50% of patients initially present with a normal temperature
and white blood cell (WBC) count. Pain in the lower abdomen
and pelvis is by far the most common symptom of acute PID.
It occurs in more than 90% of patients at initial presentation.
The pain is usually described as constant and dull and is ac-
centuated by motion and sexual activity. Generally, the pain
is of recent onset, usually less than 7 days. About 75% of pa-
tients with PID have an associated endovascular infection and
coevertent purulent vaginal discharge. Nausea and vomiting are comparable late symptoms in the course of the disease.
Normal vaginal bleeding, especially menorrhagia, or spotting,
is noted in about 40% of patients. The CDC has established the
criteria for making the diagnosis of gonorrhea based on clinical
grounds. The most recent update includes that only signs
of pelvic and abdominal pain are required for a diagnosis of PID and eliminates leukocytosis and fever as essential criteria (Table 30.1). Perihepatic inflammation and adhesions, more commonly known as the Fitz-Hugh-Curtis syndrome, develop in 1% to 10% of patients with acute PID. Signs and symptoms include right upper quadrant pain, pleuritic pain, and tenderness in the right upper quadrant when the liver is palpated. Usually the symptoms and signs of this syndrome are preceded by the clinical onset of acute PID. The condition is often mistakenly diagnosed as either acute cholecystitis or pneumonia. Fitz-Hugh-Curtis syndrome is believed to develop from vascular or transperitoneal dissemination of either N. gonorrhoeae or C. trachomatis. The majority of women with PID have either mucopurulent cervical discharge or evidence of WBC on a microscopic evaluation of vaginal fluid. If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated. A wet prep of vaginal fluid offers the ability to detect the presence of concomitant infections (e.g., bacterial vaginosis and trichomoniasis). The most specific criteria for diagnosing PID include the following:

- Endometrial biopsy with histopathologic evidence of endometritis
- Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tuboovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)
- Laparoscopic abnormalities consistent with PID

A diagnostic evaluation that includes some of these more extensive studies might be warranted in certain cases. Endometrial biopsy is warranted in women undergoing laparoscopy who do not have visual evidence of salpingitis, as some women with PID have endometritis alone.

Despite these shortcomings of early diagnosis, laparoscopic visualization of the pelvis is still the most accurate method of confirming the diagnosis of acute PID. However, it is logistically and economically impractical for all patients suspected of having acute PID to undergo diagnostic laparoscopy in the United States. Therefore, the diagnosis of most episodes of acute PID is often made on the basis of clinical history and physical examination. Although it is suggested that laparoscopy be offered to all patients with an uncertain diagnosis, it is strongly indicated for patients who are not responding to therapy in an effort to confirm the diagnosis, obtain cultures from the cul-de-sac or fallopian tubes, and drain pus if necessary. In summary, laparoscopic studies have shown the following:

1. The clinical diagnosis of acute PID may be inaccurate.
2. Acute PID is sometimes found in patients undergoing laparoscopy for other causes of pelvic pain.
3. Laparoscopy is a relatively safe method for making the visual diagnosis of the latter stages of PID, and thus assessing future fertility prognosis and planning.
4. Laparoscopy is an excellent means of obtaining cultures directly from the tube.

The appearance of the pelvic organs can vary from erythematous, indurated, edematous ovaries, to pockets of purulent material, to a large pyosalpinx or tuboovarian abscess. However, although no disease may be evident in early stages, it is imperative to render treatment to all stages to avoid long-term sequelae.
Other less invasive methods of diagnosis have been suggested for verifying a clinical diagnosis of acute PID. Endometrial biopsy is one alternative to laparoscopy. Paavonen and associates reported a 90% correlation between histologic endometritis and laparoscopically confirmed salpingitis. However, results may be delayed up to 2 to 3 days, making its clinical applicability limited. Ultrasonography is of limited value for patients with mild or moderate pelvic PID. Thus, the routine use of sonography in patients with acute salpingitis does not appear to be indicated. Ultrasound is helpful in distinguishing an adnexal mass, especially in patients who demonstrate a lack of response to antimicrobial therapy in the initial 48 to 72 hours of therapy. Sonohysterography, an ultrasonic examination using the instillation of saline to better define pelvic structures, is not indicated at this time for patients suspected of having PID because no studies have been performed to demonstrate its safety in the event that pathogens are dispersed into the upper genital tract in the process of instilling the saline. Culdocentesis, with evidence of purulent peritoneal fluid, is helpful in the diagnosis of acute PID. With acute PID, the WBC count of peritoneal fluid is greater than 30,000 cells/mL, compared with a WBC count of 1,000 cells/mL in women without peritoneal inflammation. However, other infections, such as appendicitis and diverticulitis, among others, can also cause purulent pelvic fluid and a false diagnosis of PID.

Laboratory tests can be obtained, but their results lack sufficient sensitivity and specificity to make them an important factor in establishing the diagnosis. Leukocytosis is not a reliable indicator of acute PID, nor does it accurately correlate with the severity of tubal inflammation or need for hospitalization. Less than 50% of women with acute PID have a WBC count greater than 10,000 cells/mL. Similarly, the erythrocyte sedimentation rate (ESR), which for years was a routine laboratory test for the diagnosis of PID, is nonspecific and is a crude indicator of severity of disease. The ESR is elevated higher than 50 mm/hr in about 75% of women with laparoscopically confirmed acute salpingitis. However, 55% of women with pelvic pain and normal-appearing pelvic organs also have an elevated ESR. Plasma proteins, such as C-reactive protein and antichymotrypsin, have been studied to determine whether they help in the diagnosis of acute PID. They have been found to be more sensitive than the ESR. Other investigators have found that decreased or absent isoenzyme activity in peritoneal fluid in cases of acute PID is the best nonculture laboratory test for the disease. The major disadvantages of this test are that it requires several hours to complete and that peritoneal fluid must be obtained. Other evaluation has revealed various inflammatory cytokines to be associated with pelvic infections; however, these tests are not commercially available to a useful extent. Because most cases of UGTIs are associated with, and preceded by, lower genital tract infection, examination of the endocervix for inflammation, Gram stain, and culture for both N. gonorrhoeae and C. trachomatis are important for proper evaluation. A negative Gram-stained smear of the endocervix does not rule out upper tract infection. However, most studies have found that acute PID is rare without a concomitant increase in inflammatory cells in the vagina and the cervix.

**SEQUELAE**

**Infertility**

One fourth of all women who have had acute salpingitis experience one or more long-term sequelae. The most common is involuntary infertility, which occurs in about 20% of patients. PID ranks as one of the major causes of infertility. Before antibiotic therapy, 50% to 70% of women who had experienced UGTIs became sterile. The sequelae of infections vary from a patent oviduct, to peritubal and periovarian adhesions that may interfere with ovum pickup, to complete tubal obstruction. The infertility rate increases directly with the number of episodes of acute pelvic infection. Also, women with mild disease are seven times less likely to suffer tubal obstruction than women with severe PID.

**Ectopic Pregnancy**

The chance of ectopic pregnancy is increased 6- to 10-fold in patients with a previous episode of acute salpingitis. Pathologic studies estimate that at least 50% of ectopic pregnancies occur in fallopian tubes damaged by previous salpingitis. The mechanism for the increased rate is believed to be interference of ovum transport through the tube or entrapment of the ovum secondary to microscopic tubal damage.

**Chronic Pelvic Pain**

The chance that chronic pelvic pain will develop in a woman after acute salpingitis is four times that of control subjects without pelvic infection (20% vs. 5%). Chronic pelvic pain can be caused by a hydrosalpinx. A hydrosalpinx is presumably the end-stage development of a pyosalpinx. The pain can also be related to adhesions surrounding the ovary. All patients with chronic pelvic pain believed to be caused by acute PID should undergo laparoscopy or laparotomy to establish the cause of the chronic pain and rule out other diseases such as endometriosis, which require different treatment, or the presence of pelvic adhesions, which can often be directly resolved. A tuboovarian complex is a collection of pus within an anatomic space created by adherence to adjacent organs. The incidence of true adnexal abscess is about 10% in women with acute PID. Landers and Sweet noted a 20% rate of early treatment failure (after 48 to 72 hours) of antibiotic therapy as a result of persistent pain or enlargement of a tuboovarian abscess or complex. In addition, according to Landers and Sweet, 31% required an operation several weeks to months after their acute infections for persistent disease or pain.

**MORTALITY**

Before antibiotic therapy, the mortality rate associated with acute PID was 1%. Most of these deaths resulted from rupture of tuboovarian abscesses. Today, death associated with PID is rare, but the mortality rate can still be as high as 5% to 10% for ruptured tuboovarian abscesses, even with modern medical and operative therapy. This is mostly the result of subsequent development of adult respiratory distress syndrome (ARDS), a condition often associated with serious infection or delayed treatment.

**TREATMENT**

The therapeutic goals in the management of acute PID include both elimination of the acute infection and symptoms and prevention of long-term sequelae such as infertility, ectopic pregnancy, chronic pelvic pain, and the residue of
Pelvic Inflammatory Disease

Infection. Antibiotic treatment should be started as soon as cultures have been obtained and diagnosis is confirmed or strongly suspected. Treatment is based on the consensus that PID is polymicrobial in cause. Empirical antibiotic protocols should cover a wide range of bacteria, including *N. gonorrhoeae*, *C. trachomatis*, anaerobic rods and cocci, Gram-negative aerobic rods, Gram-positive aerobes, and *Mycoplasma* species. Despite general agreement that broad-spectrum therapy is appropriate, questions persist regarding optimal therapeutic regimens. Controversy has arisen over the issue of outpatient treatment with oral antibiotics versus inpatient treatment with parenteral antibiotics. There are no data available to evaluate the efficacy of hospital versus ambulatory management of acute PID. In the United States, three of four women with acute pelvic infection are treated as outpatients for their disease. In Scandinavia, which has a different health care system, most women are treated as inpatients. In 2006, the CDC published recommended treatment guidelines for outpatient management of acute PID (Table 30.2). Some of the treatment regimens are:

<sup>a</sup>Quinolones should not be used in persons with a history of recent foreign travel or partners’ travel, infections acquired in California or Hawaii, or in other areas with increased QRNG (quinolone-resistant *Neisseria gonorrhoeae*) prevalence.
Surgical emergencies (such as appendicitis) cannot be ruled out. Patients with serious illness, patients with nausea and vomiting, patients who are unable to follow or tolerate outpatient therapy, and patients with a previously failed outpatient regimen also should be hospitalized and given parenteral antibiotics. A recent trial by Ness and colleagues investigating the outcomes in patients randomized to inpatient or outpatient did not find differences in short-term outcomes, but difficulties in patient selection and randomization may not permit these results to be applicable to all PID patients.

The 2006 CDC guidelines for inpatient treatment of acute PID describe two regimens (Table 30.4). Regimen A is a combination of oral or parenteral doxycycline plus intravenous cefoxitin or cefotetan. Other broad-spectrum cephalosporins can be substituted, such as ceftriaxone (Claforan) or cefotaxime (Claforan). All of these agents are effective against penicillinase-producing N. gonorrhoeae, Peptostreptococcus, and other anaerobic species, as well as E. coli and other aerobic (facultative) species. Ceftriaxone is recommended by the CDC; however, its poor anaerobic activity and lack of trials do not make it an acceptable alternative for several investigators. Doxycycline can be given intravenously if the patient is unable to tolerate oral therapy, but it must be infused very slowly to prevent pain and sclerosis of the vein. Oral doxycycline has been demonstrated to be equally effective because of the slow growth cycle of Chlamydia and the requirement of prolonged treatment. A recent study by Viberga and colleagues investigating the microbiology of IUD-related infection found an increased recovery of Peptostreptococcus species, which generally are covered by both cephalosporin and clindamycin. A possible disadvantage of the cephalosporin-doxycycline combination is that these two antibiotics may be less than ideal for anaerobic infections or for a pelvic abscess.

Regimen B is a combination of clindamycin and an aminoglycoside (gentamicin). This combination provides excellent activity against anaerobes, Gram-negative aerobes, and Gram-positive aerobes. Historically, it has been the preferred regimen for patients with an abscess, IUD-related infections, or pelvic infections after a diagnostic or operative procedure. However, there are few data to prove that it is significantly more effective than the cephalosporin regimens. A possible disadvantage of regimen B is that it may not provide optimal activity against C. trachomatis and N. gonorrhoeae. Clindamycin in high doses (900 mg in 8 hours) has good activity against Chlamydia, and in vitro studies by Martens and colleagues have demonstrated effectiveness against 90% of C. trachomatis strains. Doxycycline is believed to be the most effective chlamydial agent according to in vitro testing and is often used for at least 7 days to complete treatment when the patient is switched from parenteral to posthospitalization therapy. Also, the CDC recommends treatment of once-daily dosing for gentamicin is not based on any data on PID patients and should be used only if indicated for renal considerations.

Each regimen stresses two concepts: the polymicrobial etiology of acute pelvic infection and the necessity of protecting against C. trachomatis and N. gonorrhoeae. With both protocols, the CDC recommends a minimum of at least 24 hours of intravenous treatment after clinical improvement. Both protocols also require completion of a 14-day course of oral antibiotics (doxycycline or clindamycin) to eradicate slow-growing organisms such as C. trachomatis.

Alternative inpatient parenteral regimens are included in the 2006 CDC PID guidelines (Table 30.4). The CDC recommends the β-lactamase inhibitor combination ampicillin-sulbactam (Unasyn), but piperacillin-tazobactam has been demonstrated by Hensell and colleagues, Sweet and colleagues, and others based on the controversial premise that it may be adequate to cover just a few of the major etiologic agents (N. gonorrhoeae and C. trachomatis) involved in acute salpingitis. As a result, studies have documented a 10% to 20% treatment failure rate for women receiving oral antibiotics as outpatients compared with a 5% to 10% failure rate for women without an abscess receiving intravenous antibiotics as inpatients, where broader coverage is used. The inclusion of the quinolone arm, ofloxacin, and levofloxacin in the outpatient treatment regimen does permit broader oral coverage of probable pathogens, but this still may not be adequate for serious disease. It is important to reevaluate patients within 48 to 72 hours of initiating outpatient therapy to determine the response of the disease. If a poor response has been obtained, the patient should be hospitalized with parenteral antibiotics and possible laparoscopic evaluation in the hope of preventing or limiting the sequelae of PID.

Every woman with acute PID should be hospitalized for the first few days for parenteral antibiotic treatment. Because this may not be practical because of limited economic or physical facility resources, the clinician who diagnoses acute salpingitis in the office or emergency department is faced with the question of which patient to hospitalize. Indications for the hospitalization of patients with acute salpingitis are also defined by the CDC in the 2006 guidelines (Table 30.3). In the past, the CDC has suggested that all adolescents with salpingitis be hospitalized because of their high noncompliance rate and to optimize treatment to prevent damage to the reproductive tract, which could affect future fertility and result in chronic pelvic pain. Recently, Kelly and colleagues found a high incidence and recurrence in adolescents, perhaps related to poor compliance. However, the CDC’s new policy is to use the same criteria for hospitalization as for older women. This recommendation is not agreed upon by all infectious disease groups because of the seriousness of inadequately treated PID in the younger, often noncompliant population.

Another indication for hospitalization is the presence of an abscess or pelvic abscess. Outpatient therapy may not provide adequate antibiotic levels high enough to penetrate an abscess, and these should be inadequately treated PID in the younger, often noncompliant women. This recommendation is not agreed upon by all infectious disease groups because of the seriousness of inadequately treated PID in the younger, often noncompliant population.

Indicated for hospitalization is the presence of an abscess or pelvic abscess. Outpatient therapy may not provide antibiotic levels high enough to penetrate an abscess, and rupture of the abscess may have serious consequences. Women in whom the definitive diagnosis of acute PID is in question should also be hospitalized, and additional diagnostic measures should be instituted. As previously stated, at least 10% of all patients have other serious diagnoses, such as acute appendicitis, ectopic pregnancy, or adnexal torsion, and these should be included.

The following criteria for hospitalization are suggested:

- Surgical emergencies (such as appendicitis) cannot be excluded.
- The patient is pregnant.
- The patient does not respond clinically to oral antibiotics.
- The patient is unable to follow or tolerate an outpatient regimen.
- The patient has severe illness, nausea and vomiting, or high fever.
- The patient has a tuboovarian abscess.

TABLE 30.4

CDC-RECOMMENDED TREATMENT REGIMENS FOR PARENTERAL THERAPY OF ACUTE PELVIC
INFLAMMATORY DISEASE

| Regimen A | Cefotetan 2 g IV every 12 hours  
OR  
Cefoxitin 2 g IV every 6 hours  
PLUS  
Doxycycline 100 mg orally or IV every 12 hours  
Because of pain associated with infusion, doxycycline should be administered orally when possible, even when the patient is hospitalized. Both oral and IV administration of doxycycline provide similar bioavailability. Parenteral therapy may be discontinued 24 hours after a patient improves clinically, and oral therapy with doxycycline (100 mg twice a day) should continue to complete 14 days of therapy. When tuboovarian abscess is present, many health care providers use clindamycin or metronidazole with doxycycline for continued therapy rather than doxycycline alone, because it provides more effective anaerobic coverage. Clinical data are limited regarding the use of other second- or third-generation cephalosporins (e.g., ceftizoxime, cefotaxime, and ceftriaxone), which also may be effective therapy for PID and may replace cefotetan or cefoxitin. However, these cephalosporins are less active than cefotetan or cefoxitin against anaerobic bacteria. |
|---|---|
| Regimen B | Clindamycin 900 mg IV every 8 hours  
PLUS  
Gentamicin loading dose IV or IM (2 mg/kg of body weight) followed by a maintenance dose (1.5 mg/kg) every 8 hours. Single daily dosing may be substituted. Although use of a single daily dose of gentamicin has not been evaluated for the treatment of PID, it is efficacious in other analogous situations. Parenteral therapy can be discontinued 24 hours after a patient improves clinically; continuing oral therapy should consist of doxycycline 100 mg orally twice a day or clindamycin 450 mg orally four times a day to complete a total of 14 days of therapy. When tuboovarian abscess is present, many health care providers use clindamycin for continued therapy rather than doxycycline, because clindamycin provides more effective anaerobic coverage. |
| Alternative Parenteral Regimens | Limited data support the use of other parenteral regimens, but the following three regimens have been investigated in at least one clinical trial, and they have broad-spectrum coverage. Levofloxacin 500 mg IV once daily WITH OR WITHOUT Metronidazole 500 mg IV every 8 hours  
OR  
Ofloxacin 400 mg IV every 12 hours WITH OR WITHOUT Metronidazole 500 mg IV every 8 hours  
OR  
Ampicillin/sulbactam 3 g IV every 6 hours  
PLUS  
Doxycycline 100 mg orally or IV every 12 hours  
IV ofloxacin has been investigated as a single agent; however, because of concerns regarding its spectrum, metronidazole may be included in the regimen. Levofloxacin is as effective as ofloxacin and may be substituted; its single daily dosing makes it advantageous from a compliance perspective. One trial demonstrated high short-term clinical cure rates with azithromycin, either alone for 1 week (at least one IV dose, followed by oral therapy) or with a 12-day course or metronidazole. Ampicillin/sulbactam plus doxycycline is effective coverage against C. trachomatis, N. gonorrhoeae, and anaerobes and for patients who have tuboovarian abscesses. |

CDC, Centers for Disease Control and Prevention; IM, intramuscularly; IV, intravenously; PID, pelvic inflammatory disease.

*Quinolones should not be used in persons with a history of recent foreign travel or partners’ travel, infections acquired in California or Hawaii, or in other areas with increased QNIG (quinolone-resistant Neisseria gonorrhoeae) prevalence.

Pelvic Inflammatory Disease to have excellent in vitro and in vivo activity against PID and its pathogens.

MANAGEMENT OF SEX PARTNERS

Male sex partners of women with PID should be examined and treated if they had sexual contact with the patient during the 60 days preceding the patient’s onset of symptoms. Evaluation and treatment is imperative because of the risk for reinfection of the patient and the strong likelihood of urethral gonococcal or chlamydial infection in the sex partner. Male partners of women who have PID caused by C. trachomatis and/or N. gonorrhoeae often are asymptomatic. Management of acute PID should include treatment of the male partner and education for the prevention of reinfection, including the use of proper contraception. The importance of treating sexual partners cannot be overstressed. Eschenbach
reported that 23% of gonococcal PID patients were readmitted to the hospital within 10 weeks of the initial treatment. A study of gonococcal PID noted that 13% of male partners screened were asymptomatic urethral carriers and that even higher rates for C. trachomatis were present. These partners should be treated with one of the regimens for uncomplicated gonorrhoeae and chlamydial infection (i.e., ceftriaxone, 125 mg intramuscularly, followed by oral doxycycline, 100 mg twice a day for 7 days, oral azithromycin in 1 g or ofloxacin 300 mg b.i.d. for 7 days orally). Women with acute PID often return to the same social situations they were in before treatment. It is hoped that treating sexual partners and educating patients with regard to contra-prophylaxis would decrease the incidence of recurrent infections and affect the often poor prognosis for future fertility.

HIV INFECTION

Differences in the clinical manifestations of PID between human immunodeficiency virus (HIV)-infected women and HIV-negative women have not been well delineated. In early observational studies, HIV-infected women with PID were more likely to require surgical intervention. In recent, more comprehensive observational and controlled studies, HIV-infected women with PID had similar symptoms when compared with uninfected controls. They were more likely to have a tuboovarian abscess, but responded equally to standard parenteral and oral antibiotic regimens when compared with HIV-negative women. The microbiologic findings for HIV-positive and HIV-negative women were similar, except for (a) higher rates of concurrent M. hominis, candida, streptococci, and HPV infections and (b) HPV-related cytologic abnormalities among those with HIV infection. Whether the management of immunodeficient HIV-infected women with PID requires more aggressive interventions (e.g., hospitalization or parenteral antimicrobial regimens) had not been determined.

SURGICAL MANAGEMENT

Laparotomy should generally be reserved for patients with surgical emergencies such as ruptured abscesses or definitive treatment of failed medical management. Laparoscopy, however, is an underused but usually helpful procedure for diagnosis, prognosis, and possible treatment of PID. Laparoscopic evaluation should be considered in all patients with a differential diagnosis of PID and without laparoscopic surgery contraindications.

Laparoscopy is important not only to diagnose PID but also to rule out surgical emergencies, such as appendicitis and ruptured abscesses. It also prevents inappropriate management of patients with noninfectious problems, such as endometriosis. These patients need additional surgical and medical management, not antibiotic therapy and delayed diagnosis. In addition, evaluation of the extent of the inflammatory process in confirmed PID is helpful in establishing a prognosis and further management plan if initial treatment fails. Patients with evidence of current or previous abscesses have a higher failure rate with antibiotic therapy. Also, treatment of unilateral abscesses may necessitate surgical management to avoid the spread of the infection to the other tube and ovary.

 Cultures obtained from the peritubal region or from the peritoneal cavity can also be helpful in identifying organisms resistant to initial management. This has become increasingly important in light of the increasing rate of clindamycin-resistant anaerobes and the elimination of metronidazole from the CDC-recommended inpatient guidelines. Laparoscopic management of PID that appears helpful includes copious drainage of the pelvis with normal saline or preferably Ringer solution. Antibiotic inclusion in the lavage fluid has not been demonstrated to be helpful to date. Laparoscopic manipulation or drainage of documented pelvic abscesses has been attempted by several investigators.

Henry-Suchet and associates reported the successful use of laparoscopy to diagnose and drain tuboovarian abscesses in 50 women. Adhesions were lysed, and the abscesses were drained through the laparoscope. All patients received intravenous antibiotics. Forty-five of the 50 (90%) patients were cured. Rech and McGlynn had a similar experience in 25 women with pelvic abscesses treated laparoscopically. Four of seven women desiring pregnancy conceived, and two women had unplanned pregnancies. However, the diagnosis of abscesses is not uniform in these studies. Also, it is of concern that similar results will not necessarily be demonstrated in less experienced hands. Anatomically, drainage of abscesses within the pelvic cavity by laparoscopy will not drain the entire abscess contents out of the pelvic cavity, and despite how extensive the lavage or laparoscopic removal is, pus and bacteria will be spilled and exposed to the pelvic cavity. This is contrary to the natural defense mechanism of the body of isolating and containing the inflammation-causing organisms within an abscess. Therefore, laparoscopic drainage of pelvic abscesses should be undertaken only by experienced laparoscopic surgeons and with the patient's full understanding of all other options.

Laparotomy with extensive pelvic surgery was often recommended in the past, before the development of broad-spectrum antibiotics. If a patient has been hospitalized on several occasions for acute exacerbation of PID with bilateral tuboovarian abscesses to the point where the future management increases significantly, definitively, definitive surgical intervention may be indicated. The operation should be done when the infection is quiescent, if possible. The surgery may still be difficult, but there will be fewer complications than when patients are operated on in the acute phase of the infection. The timing of the operative intervention is important. There should be complete absorption of the inflammatory exudate surrounding the focus of the infection, as seen radiologically. Bimanual pelvic examination should be possible without producing a marked or persistent febrile response. It has been suggested that definitive surgery be delayed for 2 to 3 months after the recent exacerbation for more complete resolution of the infection. Ideally, the patient should have a normal ESR, WBC, and hematocrit, and relatively nontender pelvic organs, except possibly with motion. Kaplan and associates recommended more aggressive management in patients who exhibit either no clinical response or only partial response after 24 to 72 hours. Their approach included a total abdominal hysterectomy and bilateral salpingooophorectomy and was thought to reduce the protracted period of intensive medical therapy in a group of patients who would eventually require surgery. They noted that conservative management of their cases usually resulted in protracted periods of intensive care and repeated hospital admissions, and rarely in subsequent pregnancies. However, the early surgical intervention described above was associated with six incidences of injury to the bowel and additional postoperative complications. Unfortunately, patients with acute pelvic abscess are frequently young, and future childbearing is often desired, even though it may be impossible without identifying organisms resistant to initial management. Conservation of ovarian function for these young women is an important benefit of medical management. Some differences in the percentage of patients responding
to conservative management in different studies and different geographic locations might be explained by differences in the predominant microorganisms causing the infection at these locations and their sensitivity to the antibiotics used.

Older studies of the management of patients with pelvic abscess, which emphasized the early use of surgery, are no longer pertinent, because modern antibiotic drugs were not available then. Collins and Jansen in 1959 had an early failure rate of 10% for conservative medical therapy. However, 11% of their 178 patients required later surgery, which corresponds to a late failure rate of 6.5%. Ginsburg and associates reviewed cases of 160 patients treated for tuboovarian abscess during the years 1969 to 1979. The early failure rate with broad-spectrum antibiotics was 31%, whereas the late failure rate was an additional 21%. Thus, with an average follow-up period of 23.5 months, 48% did not require later surgery. Subsequent reports by Hager and colleagues and by Landers and Sweet support conservative management.

When conservative management fails and a pelvic abscess is noted dissecting the rectovaginal septum, drainage by way of colpotomy may be possible.

POSTERIOR COLPOTOMY

In a classic article, Wharton described various techniques of vaginal drainage of pelvic abscess. Today, posterior colpotomy is done to evacuate pus and to establish drainage from a pelvic abscess that presents in the cul-de-sac.

There are three requirements for colpotomy drainage of a pelvic abscess:

1. The abscess must be midline or nearly so.
2. The abscess should be adherent to the cul-de-sac peritoneum and should dissect the rectovaginal septum to assure the surgeon that the drainage will be extraperitoneal and that pus will not be disseminated transperitoneally.
3. The abscess should be cystic or fluctuant to ensure adequate drainage.

Occasionally, a cul-de-sac abscess can be successfully drained without dissecting the septum. However, the serosal surface of the abscess should be adherent to the cul-de-sac peritoneum. Ultrasonography may be helpful in locating the pockets of pus.

After adequate anesthesia, the patient is placed in the lithotomy position. It is essential that a thorough examination of the pelvis be performed under anesthesia so that the operator knows the size and position of the mass that is to be drained.

After preparation and draping in the dorsal lithotomy position, the posterior lip of the cervix is grasped with a tenaculum and drawn down and forward. The vaginal mucosa of the posterior vaginal fornix is incised just below the reflection of the vaginal mucosa onto the cervix, and the transverse incision is widened with a pair of long scissors (Fig. 30.1A). The incision must be large enough to allow adequate exploration and drainage of the abscess cavity with the index finger. The cul-de-sac peritoneum and abscess wall are punctured with a long Kelly clamp (Fig. 30.1B). As the abscess wall is perforated, there is a definite sensation of puncturing a cystic cavity. If blood or pus is present, this is soon seen in the upper vagina. The jaws of the clamp are spread, and the flow of liquid from the cul-de-sac is increased. A sample of the purulent exudate is sent to the pathology laboratory for appropriate culture and sensitivity. Collection of the specimen anaerobically with a capped syringe with rapid transport to the laboratory allows the more fastidious flora to be defined. A direct smear for Gram stain is also made from the pus and examined for predominating organisms.

There may be more than one compartment in an abscess cavity (Fig. 30.2). It is desirable to insert an index finger in the cavity and explore. Fibrous adhesions within the cavity can be gently broken. If another abscess wall is felt, it can often be cautiously and safely punctured under the guidance of a finger. Exploration and manipulation should be done carefully to avoid intraperitoneal rupture of the abscess or perforation of the bowel. To allow adequate drainage, the vaginal incision should be at least 2 cm wide. If pus has been obtained, one or two drains are inserted into the abscess cavity and anchored with fine absorbable suture to permit easy removal. Penrose or closed suction drainage systems can be used. These are left for several days or longer. Wharton has emphasized the importance of prolonged drainage. A suture or two may be required to control bleeding from the vaginal mucosa. However, if a mushroom (Malecot) catheter is used for drainage, it should

![FIGURE 30.1: Posterior colpotomy.](image-url)
FIGURE 30.2. Pus may be contained within the tuboovarian abscess and within other pockets in the pelvic cavity.

Experience with percutaneous drainage of intraabdominal and pelvic abscesses under ultrasonographic or computed tomographic (CT) guidance has been reported by Olak and associates, and by others. Worthen and Gunning used percutaneous catheter drainage of 11 abscesses in nine patients and achieved a cure rate of 77%. Two patients required surgical intervention subsequently. In 19 patients, simple percutaneous aspiration of 23 abscesses was successful, with a 94% cure rate. The attempt at aspiration failed in seven patients (Fig. 30.3). The Grady Memorial Hospital experience, as reported by Tyrrel and associates, is similar. CT-guided percutaneous drainage in eight patients with tuboovarian abscess resulted in recovery without surgery in seven. One patient had marked clinical improvement but still required a posterior colpotomy. No complications occurred. Loy and associates have reported that the simultaneous use of real-time pelvic ultrasonography can facilitate transvaginal drainage of a pelvic abscess. If patients do not respond to intravenous antibiotics and percutaneous drainage or aspiration, surgical intervention is required.

The long-term effects of pus and organisms released into the pelvis from the puncture site are unknown. However, short-term success rates are good, and surgical drainage of acute abscess is a basic principle. Therefore, needle drainage can be considered with proper patient selection and appropriate informed consent, which includes other management options. If exploratory laparotomy is necessary, the patient can be positioned in Allen universal stirrups. A lower abdominal transverse Maylard incision is ideal because it affords good exposure to the lateral adnexal pelvic organs and pelvic side walls. Pelvic adhesions should be released, and the bowel should be packed off before the pelvic dissection commences. During the dissection, free pus is often spilled, and the upper abdomen should be isolated from this, if possible. When a ruptured abscess is encountered, the exudate is collected and sent immediately to the laboratory for Gram stain, anaerobic and aerobic cultures, and antimicrobial sensitivity studies. The easiest way to obtain the material for anaerobic culture is simply to collect

FIGURE 30.3. Transabdominal needle aspiration of a pelvic abscess under guidance of computed tomography. Drainage tube is also placed.
it in an airtight syringe and to submit a small piece of the abscess wall in an airtight container. The easiest place to begin the dissection is in the round ligament, which is the most consistently available and identifiable landmark. Following the round ligament medially always leads to the uterine corpus. Variations in the usual technique for the operation may be required because of extensive disease, dense adhesions, indurated and edema- tous tissue, and distorted anatomy. For example, it is sometimes convenient to perform the central dissection first (i.e., a subtotal hysterectomy). This allows more space and adequate exposure to perform the required adnexal surgery. Tuboovarian inflammatory masses may be found densely adherent in the cul-de-sac to the uterus, to the posterior surface of the broad ligament, and to the lateral pelvic sidewall. There is risk of injury to the ureters, sigmoid, rectum, and small intestines. The method of dissection used depends on the nature of the adhe- sions. Soft, fresh adhesions can be broken gently and easily with finger dissection. Dense fibrotic adhesions must be carefully dis- sected and cut with scissors. The dissection can be especially difficult and risky if pelvic tissues are intensely indurated, as in ligamentous pelvic cellulitis. If the infundibulopelvic ligament can be clamped, cut, and securely ligated, one can gain access to the lateral retroperitoneal space and identify the ureter. This facilit- ates a safe dissection of the abscess wall away from the ureter. In cases with extensive disease involving one or both adnexa, the use of preoperative ureteral catheterization may be helpful in identifying the location of the pelvic ureters. With tuboovarian abscesses, the anatomic limits of the ovary may be difficult to define. If the ovary is to be removed, it should be removed com- pletely to prevent subsequent development of ovarian remnant syndrome.

When both adnexa must be removed, a hysterectomy should be entertained if extensive uterine involvement is suspected. In some cases, only subtotal hysterectomy is feasible. However, if the lower uterine segment can be visualized, the cervix can usually be excised after removal of the adnexa and the uter- ine corpus. The operative field should be copiously irrigated. The vaginal vault should be left open for drainage. A Penrose drain may be inserted and then removed several days later. Sus- pension of the vaginal vault and repositioning of the pelvis are accomplished in the usual manner, if possible. A routine closure of the abdominal incision is performed. Jackson-Pratt suction drains are often placed above the fascia and brought out through a separate incision.

Because the patient has been placed in the Allen universal stirrups for laparotomy, ureteral integrity can be confirmed as discussed elsewhere. Five milliliters of indigo carmine is given intravenously, and a cystoscopy is placed in the bladder. Blue dye can then be seen flowing from each ureteral orifice.

In the past, it was standard practice to do a bilateral salpingo-oophorectomy in almost all patients who had a lap- arotomy for acute pelvic abscess. This practice was based on the belief that the disease is almost always severe in both adnexa. Recent studies have suggested that as many as 25% to 50% of patients will have a relatively normal tube and ovary on one side. This may be especially true of patients whose infection is associated with IUD use. Golde and associates reported that 33 of 153 patients (44%) with tuboovarian abscesses confirmed at operation had unilateral abscesses; 20 were using an IUD. The studies of Lunders, and Swart, Hager and Majnudajad, and Ginsburg and coworkers also found a higher percentage of unilat- eral adnexal disease than was previously reported. In light of the recent findings, subtotal adnexectomy may be possible in some patients. We have no hesitation in leaving a relatively nor- mal tube and ovary at the time of hysterectomy with removal of the opposite adnexa for acute pelvic abscess. When the uterus is removed and the continuity between the conserved tube and the lower genital tract is interrupted, there is little risk of a new infection. If a strictly unilateral pelvic abscess is found at lap- arotomy, removal of the affected tube and ovary only, leaving in the uterus and the opposite adnexa, is acceptable in a patient who wishes to preserve fertility. However, in vitro fertilization techniques may be required to accomplish pregnancy. Such a patient does have a risk of recurrent tuboovarian abscess. It is especially important that her sexual partner be examined and receive treatment when indicated.

In recent years there have been advances in reproductive technology that allow infertile patients to conceive and carry pregnancies to term under the most extraordinary circum- stances. It has been possible, for example, to accomplish a suc- cessful pregnancy in a woman who has a uterus but no ovaries by instillation of a donated fertilized ovum into a suitably pre- pared uterus. Such a sophisticated procedure is not available to a large number of patients. However, in light of the recent find- ings of the risk of estrogen plus progesterone treatment from the Women’s Health Initiative Study, the option of leaving in the uterus when bilateral salpingo-oophorectomy is to be per- formed should be discussed with the patient, especially if she is young and nulliparous.

In summary, patients with an acute pelvic abscess should be hospitalized for treatment with parenteral broad-spectrum antibiotics. Surgery is indicated if the diagnosis is uncertain, if intraperitoneal rupture is diagnosed or suspected, or if the patient fails to respond to medical management.

RUPTURED PELVIC ABSCESS

A tuboovarian or pelvic abscess can rupture spontaneously into the rectum or sigmoid colon usually occurs in a patient whose abscess is too high to drain with a posterior colpotomy. In other words, although the ab- sess is fluctuant and midline, it is not yet dissecting the recto- vaginal septum. While waiting for the abscess to come down, a sudden unexpected improvement in the patient’s condition usu- ally occurs. A posterior colpotomy is not needed and, indeed, is contraindicated because doing so could cause a rectovaginal fistula to form.

Spontaneous drainage through the rectum or sigmoid colon usually occurs in a patient whose abscess is too high to drain with a posterior colpotomy. In other words, although the ab- sess is fluctuant and midline, it is not yet dissecting the recto- vaginal septum. While waiting for the abscess to come down, a sudden unexpected improvement in the patient’s condition usu- ally occurs. A posterior colpotomy is not needed and, indeed, is contraindicated because doing so could cause a rectovaginal fistula to form.

Spontaneous drainage through the bladder is rare. It occurs most commonly in elderly women with chronic abscesses de- veloping from ruptured sigmoid diverticula. Only rarely does a chronic tuboovarian or pelvic abscess rupture and drain through the bladder, causing secondary infection of the bladder. When the abscess is removed with laparotomy, a defect in the bladder wall is noted. The emaciated tissue around the defect should be removed and the defect closed with 3–0 delayed- absorbable suture in two layers. A Foley catheter can be left in place for 10 to 14 days while healing of the bladder wall takes place.

Of all the complications that can result from PID, intraab- dominal rupture of a tuboovarian abscess is the most life- threatening. Mortality from this complication is due to septic shock and the complications of generalized peritonitis, and the
mortality rate can approach up to 10% in patients with warm shock. Abscesses can rupture spontaneously, after bimanual examination or accidental trauma. Bacteriologic study of the contents of the abscess has historically been unrewarding; a specific organism has been isolated in less than 50% of cases. The gonococcus is rarely identified in a pelvic abscess. Careful aerobic and anaerobic cultures often demonstrate the presence of a mixed infection that includes anaerobic organisms. McNamara and Moid reviewed the results of three separate studies that documented 34 positive isolates of anaerobes in 30 patients with a pelvic abscess. Landers and Sweet have also confirmed similar findings in their series.

Diagnosis of Ruptured Tuboovarian Abscess

The major clinical symptom of ruptured tuboovarian abscess is acute, progressive pelvic pain that is usually so severe that the patient can accurately identify the time and place of its occurrence. In a classic series from the Johns Hopkins Hospital reported by Vermeeren and Te Linde, the average age of patients with a ruptured tuboovarian abscess was 33 years, which is at least 10 years older than the average age of patients with acute PID. About 2% of these patients are postmenopausal. To our knowledge, only two cases of ruptured tuboovarian abscess in a pregnant patient have been reported. Often, there is a history of recurrent attacks of PID, with a sudden increase in the severity and extent of abdominal pain during a recent exacerbation of infection. On examination, the patient appears seriously ill and dehydrated, with rapid, shallow respirations. The abdomen is distended and quiet, with diminished or absent bowel sounds. Signs of generalized peritonitis, direct and indirect tenderness, muscle rigidity, and shifting dulness may be noted. A pelvic mass is palpable in more than 50% of cases. Tachycardia is common. Shock can be present or can develop while the patient is under observation. It is due to accumulation of fluids in peripheral tissues and later failure of compensatory mechanisms. The patient’s temperature is usually greater than 101°F, but it can also be normal and even subnormal late in the course. The leukocyte count is likely to be more than 15,000, but it also can be normal. Severe leukopenia is an ominous sign. A culdocentesis is a valuable diagnostic aid and was positive for purulent material in 70% of the cases in the McCaig and Sellmann series. An abdominal radiograph usually shows a paralytic ileus, sometimes evidence of free fluid in the peritoneal cavity, and atelectasis in the lung bases. A CT scan of the pelvis and abdomen is most helpful and will usually confirm the pelvic abscess with free purulent fluid in the upper abdomen. It may also suggest an alternative diagnosis such as a ruptured appendix or acute cholecystitis. Drainage of a pelvic abscess can also be done percutaneously under CT scan or ultrasound guidance.

Treatment of Ruptured Tuboovarian Abscess

The longer the delay in the operative treatment of ruptured tuboovarian abscess, the greater the primary mortality rate. In the series by Vermeeren and Te Linde from the Johns Hopkins Hospital, death occurred less than 90 hours after the time of rupture in 88% of fatal cases, both operative and nonoperative. As time passes after rupture of a tuboovarian abscess, septic peritonitis becomes more severe and generalized. The passage of time allows the development of septic shock from greater absorption of bacteria and bacterial endotoxins, and secretion of great quantities of fluid into the peritoneal cavity across inflamed peritoneal surfaces. Fluid shifts from the intravascular compartment to interstitial spaces as a result of the increased vascular permeability of the inflamed peritoneal membrane. This leads to hypovolemia, decreased cardiac output, decreased central venous pressure, hypotension, vasoconstriction, increased peripheral resistance, decreased tissue perfusion, metabolic acidosis, ARDS, decreased renal glomerular perfusion and filtration with decreased urine flow, severe hypoxemia, multiple organ system failure, and death. The prompt diagnosis and treatment of intraperitoneal rupture of a tuboovarian abscess is essential to minimize the risk of mortality of generalized peritonitis.

The treatment of patients with ruptured tuboovarian abscess can be divided into three phases: preoperative, operative, and postoperative.

Preoperative Phase

Surgery should be undertaken after rapid but adequate preoperative preparation. The patient should be typed and cross-matched with 2 to 4 units of packed red blood cells. Monitoring of central venous pressure is essential for proper evaluation of the hemodynamics of this condition because many patients are dehydrated, in shock, and anemic. Swan-Ganz catheter placement may be preferable because it allows pulmonary capillary wedge pressure and pulmonary artery pressure determinations that are helpful in assessing the adequacy of fluid replacement and in detecting fluid overload. Variable amounts of fluid, sometimes tremendous amounts, are lost into the peritoneal cavity and intestinal tract because of peritonitis. Emergency blood chemistry determinations (e.g., serum electrolytes, creatinine, glucose, bilirubin, and alkaline phosphatase) are obtained, and intravenous fluids, preferably Ringer lactate, are started immediately. Crystalloid solutions for fluid volume resuscitation are preferred for most patients with septic peritonitis. It may be advantageous to use partial colloid resuscitation in some patients with evidence of cardiovascular dysfunction because a smaller total volume is required. An excess of intravenous crystalloid solution may result in fluid overload. Vigorous broad-spectrum intravenous antibiotic therapy should be instituted. An indwelling urethral catheter is used to monitor fluid intake with hourly urine output. Combating shock is a primary concern throughout treatment. Clinical assessment of respiratory function should be made. A distended tender abdomen may cause rapid, shallow respirations and use of accessory muscles for ventilation. Arterial blood gases may indicate mild hypoxemia, in which case oxygen should be administered. If anemia is severe, blood transfusion should be started before surgery. When the patient has been properly prepared, immediate surgery should be undertaken. The results of treatment are better if major metabolic and hemodynamic problems are corrected before operation, but one cannot waste time in treating a critically ill patient with septic peritonitis.

Operative Phase

The anesthetic of choice depends on the preference and experience of the anesthesiologist and the medical condition of the patient. The operation should be performed as rapidly as possible. Because speed as well as access to the upper abdomen may be required, a lower midline incision should be used. It can be quickly extended above the umbilicus if necessary.

Surgery for Benign Gynecologic Conditions
The patient should not be put in the Trendelenburg position until the abdomen is packed off, and no more of a dependent position should be used than is needed to prevent further dissemination of pus into the upper abdomen. When the abdomen is opened, any odor that is present should be noted. An unpleasant, putrid odor is indicative of infection with anaerobic organisms. Pus from the abdomen should be collected carefully for culture and for Gram stain, and be promptly transported to the laboratory. Organisms grown should be tested for sensitivity to various antibiotics.

The operation of choice is removal of the free pus, together with the abscess, the uterus, the tubes, and usually the ovaries. Only occasionally is it possible to leave an ovary in a patient with a ruptured pelvic abscess. If rupture has occurred from a strictly unilateral tuboovarian abscess, with a relatively normal tube and ovary on the opposite side, a unilateral salpingo-oophorectomy can be performed, especially if the patient is young. However, the risk of a recurrent abscess in the opposite tube and ovary is high if the uterus is also left in place. When the uterus is removed along with the tuboovarian abscess, the risk of recurrent abscesses in the opposite adnexa is reduced. When hysterectomy is performed, usually a total hysterectomy can be done. However, even in the best surgical hands, a subtotal hysterectomy is faster than a total one and is sometimes justified. It is probable that the mortality rate would be increased if total hysterectomies were always performed. Although we believe firmly in total hysterectomy, we do not believe in performing it when the danger of total hysterectomy exceeds the danger from a retained cervix. Except in the young patient, it is often better to remove the corpus than to perform a unilateral adnexectomy alone. Furthermore, the opposite adnexa is significantly involved in most patients, and subsequent operation by the surgeon if conservation of one side is practiced, as was required in 35% of Pedowitz and Bloomfield’s cases. This is contrary to what has been described earlier in the surgical treatment of an unruptured abscess, because the risk of incomplete eradication of the immediate infection in an acutely ill patient with rupture, peritonitis, and possibly septic shock is much higher. Therefore, definitive surgical treatment is usually recommended in severely ill patients with ruptured abscesses.

The technical performance of the procedure may be difficult, but is similar to that described earlier for laparotomy followed by failed colpotomy drainage or suspected rupture. Anatomy is distorted, dependable landmarks are obscured, and tissues are thick, edematous, friable, and inflamed. Loops of densely adherent intestine must be separated carefully to avoid injury. Injury to the serosa of distended bowel occurs commonly and often requires repair. Any entry into the lumen of the bowel must be recognized and repaired. Retroperitoneal planes of dissection can be used to advantage in identifying the ureters and removing inflammatory adnexal masses. Otherwise, it is likely that fragments of ovary will be left behind, which can subsequently cause signs and symptoms of the ovarian remnant syndrome. As much of the remaining abcess wall as possible should be removed without causing unnecessary additional bleeding. Borders of the abscess wall can be left adherent to the pelvic sidewall and cul-de-sac. Oozing of blood from all dissected tissue has been likened to “cinder bed burning” and is difficult to control.

The upper abdomen should be carefully explored for collections of pus in the subphrenic and subhepatic regions. If an upper abdominal abscess is found, it may be necessary to place a closed suction drain into the abscess cavity through the upper abdominal wall.

Before the incision is closed, the abdominal cavity should be irrigated with copious quantities of warm sterile saline to remove remaining bacteria and debris. There is always some fear of dissemination of the infection by copious irrigation. However, this disadvantage is far outweighed by the benefit of diluting and removing bacteria and necrotic debris. We do not add antiseptics or antibiotics to the irrigating solution. If hemostasis is poor or if considerable necrotic material is left behind, there may be some benefit from peritoneal drainage with closed suction catheters. Closed suction drains can be placed through a separate stab wound in the abdominal wall, through the cul-de-sac, or through the vaginal vault when a total hysterectomy has been done, but the drainage of free peritoneal exudate in the upper abdomen is of no therapeutic value.

The abdominal incision is closed with a Smead-Jones technique or with a continuous suture taking large bites of tissue. A monofilament suture of polypropylene or nylon should be used. Retention sutures can be placed but are not usually necessary. The incision should be irrigated with warm saline. When there has been gross contamination of the incision, the subcutaneous fat and skin should be left open and packed lightly with gauze soaked in an antibiotic or dilute acetic acid solution. The wound is repacked daily and inspected. In 4 to 5 days, if the tissues are healthy, the incision is closed secondarily with sutures. Alternatively, the edges can be drawn together with sterile adhesive strips.

Postoperative Phase

Postoperative care should consider shock, infection, ileus, and fluid imbalances. Complications of the late postoperative period include pelvic and abdominal abscesses, intestinal obstruction, intestinal fistulas, incontinence with or without fecal soiling, incisional dehiscence, pulmonary embolus, continued sepsis, and disseminated intravascular coagulation. Serious medical diseases such as uncontrolled diabetes or renal or pulmonary failure are contraindications to surgery. Postoperative ileus is a very important feature of postoperative care. A dynamic ileus persists postoperatively for a variable period and is
interested in pregnancy, the uterus and fallopian tubes can be
the uterus and both tubes can also be removed. If the patient is
served. If both ovaries are involved, they should be removed.
and start antibiotic therapy. At operation, only the affected
arotomy after a brief but intense effort to stabilize the patient
supportive care is indicated. A failure to respond or deteriora-
with antibiotics for both anaerobic and aerobic organisms plus
is similar to the management of patients with acute tuboovar-
is usually obvious.
patient appears gravely ill, and the need for immediate surgery
direct and rebound tenderness, ileus, and sometimes shock. The
as in ruptured tuboovarian abscess, with abdominal distention,
and CT can be helpful in identifying an abscess cavity. If an
IUD use, appendicitis, or systemic infection) may be uncovered
an event predisposing to primary ovarian abscess (e.g., surgery,
pathologic lesions found at operation but also to the patient’s
abdomen open. Consideration must be given not only to the
in one of the lower abdominal quadrants; repeated exacerba-
reproductive system. A primary ovarian abscess, on the other hand,
the abscess wall is composed of fallopian tube and ovarian
is usually unilateral. However, its occurrence
primary ovarian abscesses occur because bac-
teria present around the ovary gain access to the parenchyma
through a break in the ovarian capsule. This can occur natu-
ally by ovulation or it can be broken by a surgical procedure.
Bacteria come from the fallopian tube, from the vagina dur-
ing or after hysterec-
omy, from intrauterine infection associ-
ated with an IUD, or from appendicitis, diverticulitis, or any
other condition that is associated with peritonitis. A primary
ovarian abscess is usually unilateral. However, its occurrence
simultaneously in both ovaries and during pregnancy seems
to be associated with the occurrence of generalized or lymphatic spread,
or both. Primary ovarian abscess has been reported secondary
to infections at distant sites (tonsillitis, typhoid, parotitis, and
tuberculosis).
Diagnosis of an unruptured primary ovarian abscess can be
difficult because of the variable clinical presentation. Lower
abdominal pain and fever are usually present. Lower abdomi-
nal and pelvic tenderness and an adnexal mass may be present,
but the pelvic examination is sometimes not helpful. Although
an event predisposing to primary ovarian abscess (e.g., surgery,
IUD use, appendicitis, or systemic infection) may be uncovered
in the history, the event is sometimes remote. Ultrasonography
and CT can be helpful in identifying an abscess cavity. If an
ovarian abscess ruptures, the clinical picture is much the same
as in ruptured tuboovarian abscess, with abdominal distention,
direct and rebound tenderness, ileus, and sometimes shock. The
patient appears gravely ill, and the need for immediate surgery
is usually obvious.
The management of patients with primary ovarian abscess
is similar to the management of patients with acute tuboovar-
ian abscess. If the abscess is not ruptured, medical management
with antibiotics for both anaerobic and aerobic organisms plus
supportive care is indicated. A failure to respond or deteriora-
tion in the patient’s condition suggests alteration in antibiotic
coverage or possible exploratory surgery, or both, to remove
the abscess. Ruptured ovarian abscess requires immediate lapar-
aotomy after a brief but intense effort to stabilize the patient
and start antibiotic therapy. At operation, only the affected
ovary need be removed. The tubes and the uterus can be con-
served. If both ovaries are involved, they should be removed.
For a patient who is not interested in conception in the future,
the uterus and both tubes can also be removed. If the patient
is interested in pregnancy, the uterus and fallopian tubes can be
left in place for possible implantation of a donated egg in the
future.

**SURGERY FOR CHRONIC PELVIC INFLAMMATORY DISEASE**

Although the gonococcus may be responsible for initiating
acute salpingitis, which is short-lived, the residual chronic sal-
ingitis is usually due to secondary invaders, both aerobic and
anaerobic, or perhaps to an initial infection with C. trachoma-
tis. As a result of the initial infection or from subsequent sec-
onder exacerbations, the fimbria can become occluded and
the tubes bound to the ovaries with adhesions. In addition, the
bowel can become adherent to the broad ligament and the ad-
nexal structures, and the fascia and loose connective tissue of
the broad ligament can be converted into an indurated, brawny
structure typical of ligneous induration. This can extend to in-
clude tissues beneath the peritoneum on the lateral pelvic side-
wall, where ligneous pelvic cellulitis can cause ureteral obstruc-
tion. If the chronic infection persists, serious effusion from the
inflammatory process within the endosalpinx produces a hy-
drosalpinx that can ignite periodically with secondary subacute pelvic infection or can progress to produce a pyosalpinx and tuboovarian abscess. If the subacute infection is left untreated
or is treated inadequately, spontaneous intraabdominal rup-
ture or leakage of an old tuboovarian abscess can occur. In a
review of this subject, Heaton and Ledger identified this prob-
lem principally in premenopausal women, with only 1.7% of
patients with a tuboovarian abscess being postmenopausal.
The signs and symptoms of chronic PID that most often re-
quire surgical treatment include severe, persistent, progressive pelvic pain, usually bilateral, although occasionally localized
in one of the lower abdominal quadrants; repeated exacerba-
tions of PID requiring multiple hospitalizations and recurrent
medical treatment; progressive enlargement of a tuboovarian
inflammatory mass, especially if it cannot be distinguished from
a neoplastic tumor of the ovary; severe dyspareunia related to
the chronic pelvic infection; and bilateral ureteral obstruction
from ligneous cellulitis. It was formerly accepted that a his-
tory of previous colpomytomy for drainage of a pelvic abscess
was sufficient reason in itself to justify definitive abdominal surgery later for removal of the uterus and adnexa. We have
seen several patients who have become pregnant after posterior
colpomytomy for drainage of a cul-de-sac abscess and who have
remained relatively free of symptoms for long periods. Today,
previous posterior colpomytomy for pelvic abscess drainage is not
a sufficient indication by itself for definitive abdominal surgery.

**Selection of Operation**
The final decision regarding the proper operation for the sur-
urgical management of chronic PID is usually made with the
abdomen open. Consideration must be given not only to the
pathologic lesions found at operation but also to the patient’s
age, parity, desire for children, previous history of pelvic dis-
ease, and other associated pelvic disease and symptoms. Be-
cause a knowledge of all these is essential to the best surgical
judgment, the operator should be thoroughly familiar with the
patient, her history, and her desires.
In the surgical management of chronic PID, the question
of removal or retention of the ovary at the time of hysterec-
tomy and salpingectomy has been left open to conjecture and
individual surgical opinion in most instances. This question

---

674 Surgery for Benign Gynecologic Conditions
Pelvic Inflammatory Disease

was the subject of a study by Weiner and Wallach of the ovarian histology in ovaries removed from patients with PID. In 40 consecutive women who underwent oophorectomy during surgical treatment of PID, nearly 50% of the removed ovaries were free of inflammatory disease and demonstrated normal follicular activity. The study concluded that ovarian histology was usually normal among patients who gave no history of dysfunctional uterine bleeding. Therefore, the menstrual history of such patients should be helpful in the decision regarding ovarian conservation or ablation. Kirtley and Benigno have reviewed our experience with ovarian conservation at the time of surgery for PID. In this series, 98 (82%) patients who required surgery had a total abdominal hysterectomy and bilateral salpingo-oophorectomy. In 22 patients (18%), either part or all of an ovary was retained. Of the 22 patients, 15 were available for follow-up hormonal assays. The mean follow-up time was 38 months. Cyclic ovarian function was confirmed in all but two patients. No patient suffered a complication as a result of adnexal conservation. We believe that normal ovarian tissue should be conserved at the time of definitive surgery for PID. The release of peritubal adhesions in mild chronic PID is indicated occasionally in women in whom future childbearing is desired, as long as the tubes can be shown to be patent, usually by transluminal chromotubation after the lower uterine isthmus is occluded by a Ziegler clamp. This type of procedure provides the most rewarding pregnancy rate of all types of tubal reconstructive surgery. More often, one tube is hopelessly closed and the opposite tube is patent after release of adhesions. In such a case, unilateral salpingectomy may be required if reconstructive surgery is not possible. Many other procedures are available in the treatment of this disease, including salpingo-oophorectomy with or without hysterectomy (Figs. 30.4 and 30.5).

In most instances of surgery for chronic PID, total abdominal hysterectomy and bilateral salpingo-oophorectomy are necessary to remove the primary tubal pathology because of inflammatory damage of both tubes and ovaries. Total abdominal hysterectomy and bilateral salpingo-oophorectomy (Fig. 30.6) have been performed for severe actinomycosis infection. If the uterus is removed and an ovary is preserved, it may be preferable to leave the entire adnexa in place in the absence of active tubal infection rather than compromise the venous drainage or the arterial blood supply to the ovary with subsequent cystic changes that may require an additional operative procedure later. Once the continuity of the tubal lumen from the uterine cavity is broken, the chronically inflamed tube does not usually produce subsequent symptoms, as shown by Falk in his series of cases with interstitial tubal resection. A small hydrosalpinx on the same side as the normal ovary can also be left in place so that ovarian blood supply is not disturbed during an attempt to remove the tube. When it is considered advisable to remove both adnexa because of the extent of the tuboovarian disease, a total hysterectomy may also be considered unless the uterus is hopelessly encased in pelvic scar tissue and densely adherent to the pelvic viscera. In the optimum case, especially in a young woman who wishes to establish or maintain the possibility of future fertility, conservative surgery may be desirable, with the hope that pregnancy can be accomplished through in vitro fertilization techniques. In this situation, the uterus and one adnexa should be conserved, and the ovary should be positioned in the pelvis so an ovum can be harvested later through the laparoscope or through the vagina. As mentioned earlier, if the patient wishes,
the uterus can be left in place even though both tubes and ovaries have been removed.

**Salpingectomy for Chronic Salpingitis**

At the time of surgery for the treatment of chronic PID, every effort should be made to retain uninvolved organs. Unilateral salpingectomy should be considered when the oviduct is hopelessly destroyed by the disease process and presents as a large hydrosalpinx.

Once the abdomen has been opened and the extent of disease evaluated, the adhesions binding the tube are cut, and the tube is freed. It is held by a Kelly clamp placed on the mesosalpinx just beneath the fimbriated end. The mesosalpinx is then clamped and cut, with a succession of small bites taken as close to the tube as possible (Fig. 30.7A). Removal of a chronic hydrosalpinx can also be done laparoscopically.

Keeping the operative trauma as far as possible from the ovary that is to be retained lessens the danger of impairing its blood supply. Experience has shown that the ovary whose tube has been removed is more apt to become cystic than the ovary whose tube has been left undisturbed. Therefore, it seems logical to interfere as little as possible with the blood supply of the ovary by hugging the tube closely when excising it.

The tube is excised at the uterine cornu in a wedge-shaped manner, as indicated in Figure 30.7B. A wide, figure-of-eight 2-0 delayed-absorbable suture is placed in the cornu before the wedge is excised and is tightened as the interstitial portion of the tube is removed. If there is palpable extension of the inflammation at the uterine cornu (so-called salpingitis isthmica nodosa), the wedge may be large.

The wound in the uterus is closed with one or more 2-0 delayed-absorbable figure-of-eight sutures (Fig. 30.7B). The vessels in the mesosalpinx are ligated with transfixion 3-0 delayed-absorbable sutures. The advantage of the transfixed suture is that it does not slip off the tissue when tied as the clamp is withdrawn (Fig. 30.7C).

A mattress suture of 3-0 delayed-absorbable material is used to bring the broad and round ligaments over the cornual wound (Fig. 30.7D). This suture passes just beneath the round ligament, so that the ligament is not strangulated when the suture is drawn tight. When this suture is tied, the cornual wound is covered with the broad ligament, and the uterus is suspended to some extent in a manner similar to that used in the Coffey suspension. Usually, a second mattress or interrupted suture is necessary to cover the mesosalpinx completely, as shown in Figure 30.7E.

**Salpingo-oophorectomy for Chronic Salpingitis**

As in salpingectomy, the abdomen is entered through a transverse Maylard incision. The chronic tuboovarian inflammatory mass is first dissected free, and the infundibulopelvic ligament is identified. It is doubly clamped with Ochsner clamps, and a third clamp is applied to control back-bleeding (Fig. 30.8A). The uterine end must be identified before the infundibulopelvic ligament is clamped, cut, and ligated.

After the infundibulopelvic ligament is cut and ligated, the remainder of the broad ligament attachment of the tube and the ovary is clamped, cut, and ligated. The uterine end of the tube and the ovarian ligament are excised from the uterus in a wedge-shaped manner. The ascending uterine vessels are ligated just below the cornual wound, and the cornual incision is closed with a 2-0 delayed-absorbable figure-of-eight suture (Fig. 30.8B).

The infundibulopelvic ligament is doubly ligated with 2-0 delayed-absorbable sutures, and the vessels in the broad ligament are ligated with 3-0 delayed-absorbable sutures. The cornual wound is peritonized, and the uterus is suspended to some degree by bringing the round and the broad ligaments over the uterine cornu with a mattress suture of 2-0 delayed-absorbable material, as shown in Figure 30.8C. An attempt should be made to remove the tuboovarian inflammatory complex completely. If a fragment of ovary is left attached to the lateral pelvic peritoneum or the broad ligament, the ovarian remnant syndrome may develop later. To prevent this, a retroperitoneal approach may be required.

Identification of the Ureter

Identification of the course of the ureter in a pelvis in which the anatomy has become obliterated as a result of PID is one of the most important techniques for the gynecologic surgeon. In the surgical treatment of this disease, one may find a tuboovarian inflammatory mass that is located between the leaves of the broad ligament and extends to the lateral pelvic wall. It is not uncommon for the ligatured induration of the thickened parietal peritoneum to obscure completely the location and course of the pelvic ureter so that dissection of the diseased adnexa produces a surgical risk to the urinary tract, requiring great technical skill to avoid ureteral injury. Knowledge of the normal anatomic location of the pelvic ureters is essential so that these vital structures can be identified before an attempt is made to remove the adnexal masses. Division of the round ligament allows access to the lateral pelvic wall beneath the peritoneum. After the round ligament is divided, the peritoneum is incised inferiorly toward the internal cervical os and superiorly just lateral to the infundibulopelvic ligament. The peritoneum is easily reflected medially away from the pelvic sidewall with finger dissection, and the ureter is identified. It remains attached to the peritoneum. If there is difficulty with this procedure, the ureter can usually be identified as it crosses over the common iliac artery just above its bifurcation, and it can be traced downward. Such patients may have a preoperative ureteral catheterization when there is clinical evidence of large, adherent adnexal masses. However, if such an anatomic problem is encountered at the time of laparotomy, an incision can be made in the dome of the bladder that allows the passage of ureteral catheters. If the patient has been positioned in the Allen universal stirrups for operation, intraoperative cystoscopy with passage of ureteral stents is easily accomplished. At the end of the operation, 5 mL of indigo carmine is given intravenously. With a cystoscope in the bladder, the dye can be seen eflusing from both ureteral orifices, confirming that the ureters have not been injured or compromised.

**PELVIC TUBERCULOSIS**

Tuberculosis of the upper genital tract is a rare disease in the United States. However, it is a frequent cause of chronic PID and infertility in other parts of the world. For various reasons, the incidence of tuberculosis is again increasing in the United States. Therefore, cases of tuberculosis-associated PID may also become more evident. It should always be considered in the differential diagnosis of pelvic pain in immigrants, especially those who have had a previous history of tuberculosis.

from Asia, the Middle East, and Latin America, and in patients with HIV. Pelvic tuberculosis is produced primarily by either *Mycobacterium tuberculosis* or *Mycobacterium bovis*. The primary site of infection for tuberculosis is usually the lung, with lymphatic spread from the Ghon complex to regional lymph nodes at the hilum-usually occurring within 1 to 2 years. More rapid dissemination is due to hematogenous spread, which results in miliary disease often within the first year. The fallopian tubes are the predominant site of pelvic tuberculosis, but the bacilli also spread to the endometrium and occasionally the ovaries.

No location in the body is immune to the development of metastatic foci of infection. Tuberculosis of the bone, meninges, kidney, epididymis, fallopian tubes, and other sites can develop. At some sites of miliary spread, the lesions can remain quiescent for long periods before reactivation and further spread of the disease. Direct extension from one organ or system to an adjacent organ or system can also occur. Organs of the female reproductive tract are usually infected by hematogenous miliary spread from a primary pulmonary lesion, by hematogenous spread from a secondary miliary site, by lymphatic spread from a primary pulmonary site to intestinal lymph nodes and then to the pelvis, or by direct extension from adjacent abdominal organs (small intestines, appendix, rectum, bladder) that are the site of tuberculous infection. Fistulas between the intestinal tract and the fallopian tubes have been reported with pelvic tuberculosis.

A venereal transmission of the disease has been reported, with primary genital infection in the woman occurring after coitus with a sexual partner who had tuberculosis of the genitourinary tract. According to Sutherland and MacFarlane, it is not possible to prove conclusively that genitourinary tuberculosis in the man can be transmitted to the woman through sexual intercourse. Because it has been shown that *M. tuberculosis* is present in the sperm of men with urogenital tuberculosis, the possibility of transmission to the pelvic organs of the woman through intercourse must be accepted. Sutherland presents five cases in which sexual transmission of genitourinary tuberculosis from man to woman presumably occurred. However, of 128 husbands of women with genital tuberculosis, only five (3.9%) were found to have active genitourinary tuberculosis. When tuberculosis of the vulva, vagina, and cervix is present without evidence of tuberculous elsewhere in the body, venereal transmission should be suspected.
Pathology of Pelvic Tuberculosis

Both fallopian tubes are involved in almost all patients with pelvic tuberculosis. About one half of patients with tuberculous salpingitis have tuberculous endometritis. Tuberculosis of the cervix is present in 3% of cases. The vagina and vulva are rarely involved. At operation, one may find evidence of generalized tuberculous peritonitis with small, grayish white tubercles covering all peritoneal surfaces of the abdominal and pelvic organs. The mucosa of the fallopian tubes may not be involved in generalized serosal tuberculous infection. At a later stage of infection, tuberculous salpingitis may grossly resemble other forms of PID involving the adnexa. Unless tubercles are seen, the diagnosis may not be apparent until microscopic sections are examined by the pathologist. A large pyosalpinx may contain the caseous material of a tuberculous infection but may also contain the purulent exudate of a secondary infection with other common organisms. Tubercles form in the lining of the tube. Some have caseation at the center, with giant cells and epithelioid cells. A proliferation of the mucosal lining of the fallopian tube may resemble a primary tubal carcinoma microscopically and may be confusing to the pathologist.

Tuberculous peritonitis is commonly associated with tuberculous of the pelvis. Clinically, tuberculous peritonitis can be divided into two groups. In “wet” peritonitis there is an outpouring of straw-colored fluid into the peritoneal cavity, producing ascites. The peritoneum of the parietal wall and viscerum are covered with innumerable small tubercles (Fig. 30.9). The tubes, in addition to being covered with miliary tubercles on the serosal surface, are usually slightly enlarged and distended. In contrast to other forms of salpingitis, the fimbriae may be patent. Within the tubal wall and tubal mucosa, the histology is typical of tuberculosis, with tubercle formation, multinucleated giant cells, and epithelioid reaction (Fig. 30.10). In advanced cases, frank caseation is present. This pattern is usually associated with hematogenous spread of the tuberculous organism to the peritoneal surfaces and the pelvic organs.

Another type of tuberculous peritonitis encountered in women is the “dry” or adhesive type. Bowel adheres to bowel by innumerable dense adhesions that blend with the musculature. The muscle of the bowel is often invaded to some degree by the tuberculous process. Separation of these adhesions is extremely difficult surgically, and accidental injury to the bowel is common. The pelvic organs show evidence of tuberculous
salpingitis with enlargement of the tubes and occasionally pyosalpinges and even tuboovarian abscess formation.

Tuberculous involvement of the myometrium is rare. Tuberculous endometritis, however, is common, occurring in 60% to 70% of women with pelvic tuberculosis. Microscopically, tubercles are seen scattered throughout the endometrium, but they may be scanty. Tubercles are often seen in the endometrium removed by curettage in the premenstrual phase and are usually located in the endometrium adjacent to the tubal ostia. Apparently, the uterine cavity is protected from advanced tuberculous infection by the cyclic shedding of endometrial tissue in the reproductive years. Even in advanced pelvic tuberculosis, evidence of caseation, fibrosis, and calcification are rarely seen in the uterine cavity. Occasionally, the endometrial cavity is obliterated by extensive adhesions. Total destruction of the endometrium can result in amenorrhea. Tuberculous pyometra can also develop, especially in postmenopausal women with an occluded internal cervical os.

Tuberculous lesions of the cervix are rare. They can be either ulcerative or exophytic and can resemble a primary cervical malignancy or granuloma inguinale of the cervix. When there is a tuberculous lesion of the cervix, the cervical biopsy often reveals tubercles.

A tuberculous infection of the ovary usually involves only the surface of the ovary and represents simply an extension of infection from the peritoneal cavity and the adjacent fallopian tubes. The infection is usually limited to a peri-ovarian abscess. Tuberculous caseation can be found within the ovarian parenchyma, although this is uncommon. Presumably, it occurs as a result of hematogenous spread to the ovarian parenchyma rather than by direct extension through the ovarian capsule. However, a breach in the ovary caused by ovulation may also allow the tubercular bacilli to gain access to the ovarian parenchyma. The ovaries are involved in about 25% of cases of pelvic tuberculosis.

It is uncommon for tuberculosis to involve the vulva and vagina. It is seen in only 2% of patients with pelvic tuberculosis. The gross appearance may be ulcerative with multiple sinuses, it may be hypertrophic with elephantiasis, or it may be similar to that of carcinoma.

Throughout the pelvic organs, the microscopic picture is similar, with tubercles of granulomatous inflammation, Langhans' giant cells, epithelioid cells, and central caseation associated with chronic inflammation. With special stains, acid-fast bacilli can be demonstrated on careful microscopic examination of the tubercles.

FIGURE 30.8. (Continued) C: The infundibulopelvic ligament and the rest of the broad ligament vessels have been ligated. The cornual wound is covered with the round and the broad ligament using a mattress suture of 2-0 delayed-absorbable material.
Clinical Features of Pelvic Tuberculosis

Pelvic tuberculosis occurs most often in patients between the ages of 20 and 40 years. The age of patients with gynecologic tuberculosis has changed in recent years; the proportion of patients older than 40 years of age is now much higher than it was in the past. Falk and associates found that the incidence of pelvic tuberculosis in postmenopausal Swedish women is increasing. This was also the opinion of Sutherland, who reported an investigation from Glasgow in which 26 of 701 patients (3.7%) with proven gynecologic tuberculosis were postmenopausal.

The most common clinical symptoms of pelvic tuberculosis include pelvic pain, general malaise, menstrual irregularity, and infertility. Brown and associates found that menstrual irregularity occurred in nearly 50% of patients, whereas amenorrhea or oligomenorrhea was present in 27%. A low-grade fever that on occasion can produce a fulminating septic course is noted in most cases of active or subacute disease. The failure of fever to subside with high doses of broad-spectrum antibiotics is a classic feature of pelvic tuberculosis. A clinical course that is refractory to antibiotic therapy for the usual PID should alert the clinician to the possibility of tuberculosis.

Among patients with pulmonary tuberculosis, the incidence of pelvic tuberculosis generally varies between 10% and 20%. Falk and associates noted that 38% of women with genital tuberculosis had previously had tuberculosis in other organs, usually the lungs. Often, the patient’s clinical course is that of a chronic indolent illness.
Diagnosis of Pelvic Tuberculosis

The clinical symptoms and signs of pelvic tuberculosis should direct the clinician to the diagnosis. However, the disease is so uncommon that it is seldom encountered in the gynecologist’s usual practice; therefore, the clinical index of suspicion is generally low. In many cases, the clinical presentation is obscure and the diagnosis is delayed. Howard Kelly once said that when competent gynecologists disagree about the diagnosis of an obscure pelvic condition, it usually is diagnosed as either an “old ectopic pregnancy or pelvic tuberculosis.”

When the diagnosis of pelvic tuberculosis cannot be made in other ways, laparoscopy has been used. Because numerous adhesions may be present, making the introduction of the trocar hazardous, we believe that laparoscopy should be used with particular care. If possible, biopsy specimens of tubal fimbriae or other suspicious areas should be examined histologically or cultured to confirm the diagnosis. In addition to disclosing numerous adhesions, laparoscopy may reveal widespread military tubercles involving the omentum and peritoneal surfaces. Multiple peritoneal tumors, unrecognized masses may be seen. Microscopic examination of peritoneal fluid shows a predominance of lymphocytes.

Vaginal cytology is of limited value in diagnosing tuberculosis. The cytologist must be familiar with the morphology of epithelial cells in the vaginal smear. Only in cases of tuberculosis of the cervix may cytology be helpful. Patients with pelvic tuberculosis should also have an examination and special diagnostic procedures to rule out tuberculosis infections in the upper genital tract. Chest radiograph, tuberculin skin test, pelvic ultrasonography, intravenous pyelogram, and urine, gastric, and aseptic cultures for M. tuberculosis should be done. In some patients, exploratory laparotomy is needed to make the diagnosis.

Treatment of Pelvic Tuberculosis

Before the advent of antituberculous drug therapy, surgery was often used in the treatment of pelvic tuberculosis. Primary surgical treatment was technically difficult, sometimes ineffective, and associated with a high rate of fistula formation and severe, sometimes fatal, postoperative infections. The most common symptom is infertility, and the second most common symptom is lower abdominal and pelvic pain. More than two thirds of the cases are diagnosed at the time of laparotomy performed for some other indication or at the time of investigation for infertility or abnormal uterine bleeding. The most common symptom is infertility, and the second most common symptom is lower abdominal and pelvic pain. Some patients are completely asymptomatic and are found to have pelvic tuberculosis during examination for other disorders such as infertility. A dilatation and curettage or endometrial biopsy is diagnostic in some cases, especially if performed in the late premenstrual phase of the menstrual cycle. In addition to standard microscopic sections, the specimen can be examined by fluorescent antibody technique. Acid-fast staining of tissue or culture of menstrual blood is effective in detecting the organism in only about 10% of cases, according to Overbeck. The menstrual blood can be collected in a cervical cap. The culture or maceration can be repeated many times before a positive result is obtained. Acid-fast stains of tissue suspected of tuberculous infection are important to confirm the diagnosis. Because some acid-fast bacilli are not tuberculous bacilli, it is important to obtain a positive culture whenever possible. A negative evaluation of the endometrium does not rule out pelvic tuberculosis, because the disease can be present in the fallopian tubes without tuberculous endometritis in 30% to 40% of cases.

On pelvic examination, bilateral adnexal tenderness is the rule. The tenderness is usually less marked than with acute gonococcal or streptococcal infections. Occasionally, a large tuberculous tuboovarian abscess is palpated on pelvic examination and even felt through the abdominal wall. The classic doughy feel of the broad ligament suggests a tuberculous inflammation and even felt through the abdominal wall. The classic tender feel of the broad ligament, adherent bowel, and some ascitic fluid. On occasion, cul-de-sac nodules representing tubercles on the serosal surfaces of pelvic organs can be felt. The clinical detection of tubercles in the strongest evidence obtainable in favor of pelvic tuberculosis. It was present in one fifth of the cases reported by Brown and associates. However, other causes of tuberculous peritonitis must be considered, including ovarian carcinoma and cirrhosis of the liver. In differentiating tuberculous salpingitis from neisserial infections, the finding of a virginal outlet in the fallopian tubes without tuberculous endometritis in 30% to 40% of cases from acute gonococcal or streptococcal infections. Occasionally, a large tuberculous tuboovarian abscess is palpated on pelvic examination and even felt through the abdominal wall. The classic tenderness of the broad ligament, adherent bowel, and some ascitic fluid. On occasion, cul-de-sac nodules representing tubercles on the serosal surfaces of pelvic organs can be felt. The clinical detection of tubercles in the strongest evidence obtainable in favor of pelvic tuberculosis. It was present in one fifth of the cases reported by Brown and associates. However, other causes of tuberculous peritonitis must be considered, including ovarian carcinoma and cirrhosis of the liver. In differentiating tuberculous salpingitis from neisserial infections, the finding of a virginal outlet in the fallopian tubes without tuberculous endometritis in 30% to 40% of cases.
TABLE 30.5

REGIMEN OPTIONS FOR THE INITIAL TREATMENT OF TUBERCULOSIS

<table>
<thead>
<tr>
<th>Option 1</th>
<th>Option 2</th>
<th>Option 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>Administer daily INH, RIF, and PZA for 8 wk, followed by 16 wk of INH and RIF daily or 2–3 times/wk.</td>
<td>Administer daily INH, RIF, PZA, and SM or EMB for 2 wk, then administer the same drugs 2 times/wk for 6 wk (by DOT). Next, administer INH and RIF 2 times/wk for 16 wk (by DOT).</td>
<td>Treat by DOT, 3 times/wk with RIF, PZA, and EMB or SM for 6 mo.</td>
</tr>
<tr>
<td>a In areas where the INH resistance rate is not documented as less than 4%, EMB or SM should be added to the initial regimen until susceptibility to INH and RIF is demonstrated. Continue treatment for at least 6 mo, and 3 mo beyond culture conversion. Consult a tuberculosis medical expert if the patient is symptomatic or smear or culture positive after 3 mo.</td>
<td>b Consult a tuberculosis medical expert if the patient is symptomatic or smear or culture positive after 3 mo.</td>

</table>

INH, isoniazid; RIF, rifampin; PZA, pyrazinamide; EMB, ethambutol hydrochloride; SM, streptomycin sulfate; DOT, directly observed therapy.

a All regimens administered two times a week or three times a week should be monitored by DOT for the duration of therapy.

b The strongest evidence from clinical trials is the effectiveness of all four drugs administered for the full 6 months. There is weaker evidence that SM can be discontinued after 4 months if the isolate is susceptible to all drugs. The evidence for stopping PZA before the end of 6 months is equivocal for the three-times-a-week regimen, and there is no evidence on the effectiveness of this regimen with EMB for less than full 6 months.

Surgical specimens. The experience of Sutherland suggests, however, that the results of treatment may be improved with newer drugs. The patients under treatment must be followed up closely for evidence of regression or remission of the pelvic tuberculosis. Only about 50% of patients with genital tuberculosis have the disease in the endometrial cavity; therefore, repeat endometrial biopses and culture of menstrual egress provides only limited diagnostic information. The progress of the disease can be monitored closely by evaluating the size of adnexal masses with pelvic examinations and ultrasonography, as well as tracking the ESR, WBC count, and temperature response. Prolonged follow-up is probably indicated in all cases, because recurrence of the tuberculosis lesion 5 years and even later after the end of drug treatment has occasionally been found.

Surgery in the management of patients with pelvic tuberculosis should be reserved for specific indications, as outlined by Schaefer and by Sutherland. In general, surgery is reserved for those patients who have failed to respond to an adequate trial of medical therapy. Our indications for the surgical treatment of pelvic tuberculosis include the following:

1. Persistence or enlargement of an adnexal mass after 4 to 6 months of antituberculous antibiotic therapy. The rare possibility of an ovarian tumor must always be considered, even though pelvic tuberculosis is also present. In a 1980 report by Sutherland, the persistence or development of substantial pelvic masses was the indication for surgery in 36 of 91 women with proven tuberculosis of the genital tract treated by surgery. Pelvic ultrasonography should be useful in following the response of adnexal masses to treatment.

2. Persistence of pelvic pain or recurrence of pelvic pain while on medical therapy. In Sutherland’s report, 40 of 94 patients were operated on because of pain.

3. Primary unresponsiveness of the tuberculous infection to antibiotic therapy, as shown by persistent spiking temperature, leukocytosis, elevated ESR, and evidence on biopsy of continued endometrial infection. Of the 91 women in Sutherland’s report, 10 were operated on because of persistence of endometrial tuberculosis.

4. Difficulty in obtaining patient cooperation for continued long-term therapy. In these cases, we are accustomed to giving a brief course of streptomycin, 0.5 g every 12 hours intramuscularly for 1 week before surgery, to perform definitive surgery, and then we give 0.5 g every 24 hours in the postoperative period for 2 weeks. A persistent effort should be made to obtain the patient’s cooperation for continued antituberculous therapy postoperatively. It is advisable to continue treatment for a year or longer. Isoniazid and rifampin should be used if possible. A common reason for failure of treatment is a tendency for the physician to discontinue drugs after only a few months because the patient appears well.

The preferred surgical treatment includes total abdominal hysterectomy and bilateral salpingo-oophorectomy. The nature of this inflammatory disease may make this operative procedure technically difficult, with an increased risk of injury to bowel and bladder. Consequently, in the event of a frozen pelvis from pelvic tuberculosis, it is occasionally necessary to perform only a subtotal abdominal hysterectomy and adnexectomy.

Adhesions, which are invariably present and usually widespread, may make the dissection more difficult and injury more likely. However, it is usually possible to do this operation without a high incidence of bowel fistulas and other significant complications. Sutherland reported the results of surgery in 62 cases while antituberculous therapy was administered. There were no deaths, no fistulas, and few late complications.

For young patients who are eager to attempt future childbearing, conservative adnexectomy should be carried out only if it is possible to do so after the extent of the adnexal disease is carefully evaluated and is found to be minimal. It is unusual for the surgeon to be committed to a specific operative procedure before the time of surgery, because conservative pelvic surgery for tuberculosis may constitute poor surgical judgment once the operative findings are known. The patient should be forewarned that conservative surgery will be performed only if the disease is minimal and such surgery is considered medically advisable.

Conservation of an ovary at the time of operation for pelvic tuberculosis is occasionally possible if the ovary is involved only on its surface. However, if one finds gross evidence of ovarian enlargement or other gross evidence of infection deep in the ovarian parenchyma, the ovary should be removed. Bi-section of ovaries to assess the presence of disease deep in the ovarian parenchyma is not advisable.

Reactivation of silent pelvic tuberculosis after tubal reconstructive surgery has been reported by Ballon and associates and by others. We believe that reconstructive tubal surgery has no place in the management of patients whose infertility is the result of bilateral tubal obstruction from tuberculous salpingitis.

**Pregnancy after Pelvic Tuberculosis**

It is evident from the literature, including the studies of both Schaeffer and Sutherland, that only about 5% of patients with genital tuberculosis are carriers of an active pregnancy (who only 2% carry a pregnancy to term. It is also evident that in the presence of tuberculous tuboovarian abscesses, pregnancy is extremely rare, and conservative surgery for the purpose of preserving fertility is unwarranted. Only when there is minimal pelvic disease without adnexal masses should conservative surgery be considered.

**BEST SURGICAL PRACTICES**

- Laparoscopy should be discussed with all patients suspected of pelvic inflammatory disease to confirm the diagnosis and to rule out other surgical emergencies such as appendicitis, ectopic pregnancy, or ruptured abscess. However, patients at high risk for complications or with contraindications to laparoscopy can be started on antimicrobial therapy and followed for 24 to 48 hours for a response. With the advent of very effective antimicrobial therapy, strong consideration should be given for surgical exploration if the patient fails initial therapy or symptomatology changes suggesting an alternative diagnosis. If laparoscopy is not selected as initial management, an endometrial sampling for detection of inflammatory cells and bacterial culture is usually helpful.

- Sonohysterography is contraindicated in patients suspected of having PID. Culdocentesis with the finding of purulent peritoneal fluid may indicate PID, but does not rule out appendicitis or diverticulitis.

- Posterior colpotomy requires midline abscess, an abscess that is adherent to cul-de-sac peritoneum and dissects the rectovaginal septum, and a cystic or fluctuant abscess.

- Hysterectomy is no longer absolutely necessary if salpingo-oophorectomy is needed for treatment of tuboovarian abscesses. Coupure irrigation with lactated Ringer is essential if an abscess has ruptured or pus is present in the abdomen. Antibiotic irrigation has not demonstrated additional benefit or risk. If hysterectomy is necessary after bilateral salpingo-oophorectomy, the vaginal vault should be left open for drainage (with or without a Penrose drain).

- Swan-Ganz catheter placement is helpful in monitoring central venous pressure in patients undergoing surgery for ruptured tuboovarian abscess.

CHAPTER 31 LEIOMYOMATA UTERI AND MYOMECTOMY

LESLEY L. BREECH AND JOHN A. ROCK

DEFINITIONS

Intravenous leiomyomatosis—Smooth muscle tumor that consists of polypoid intravascular projections into the veins of the parametrium and broad ligaments.

Leiomyomatosis peritonealis disseminata—A benign reparative process in which fibroblasts replace soft peritoneal decidua on subperitoneal surfaces of the uterus and other pelvic and abdominal viscera resulting in nodules with a pseudoleiomyomatous pattern.

Menorrhagia—Prolonged (>7 days) or heavy (>80 mL) menstrual bleeding occurring at regular intervals.

Menometrorrhagia—Prolonged (>7 days) episodes of menstrual bleeding occurring at irregular intervals.

Submucosal—Present within the uterine myometrium just below the basal layer of the endometrial lining.

Subserosal—Present within the uterine myometrium just below the serosal or peritoneal covering of the uterus.

Leiomyomata are the most common tumors of the uterus and the female pelvis. This chapter discusses the pathologic and clinical features of uterine leiomyomata, the choice of treatment, and the indications and techniques for myomectomy.

Hysterectomy is sometimes required for the management of leiomyomata. It is also performed for many other indications, but leiomyomata uteri is the most common indication for hysterectomy. Refer to Chapter 32 for a complete discussion of hysterectomy.

Advances in gynecologic surgery just 100 years ago finally brought this common and sometimes fatal disease of women under reasonable control. Before the 20th century, no effective treatment was available. Uterine leiomyomata often grew to enormous size and caused great suffering from bleeding, pain, and emaciation (Fig. 31.1). Death from this benign disease was not uncommon. Progress in gynecologic surgery and anesthesia finally allowed the safe removal of these tumors by skilled gynecologic surgeons.

No one played a more important role in this endeavor than Drs. Kelly and Cullen. Working together at the Johns Hopkins Hospital, they gradually developed surgical techniques that were successful in preventing and controlling intraoperative hemorrhage. Several illustrations from their magnificent treatise, Myomata of the Uterus, published in 1907, are included in this chapter. In the preface, Cullen wrote:

It was my good fortune to come to Baltimore in 1891, shortly after the hospital opened. At that time many cases of myoma were considered inoperable, and even when hysterectomy was undertaken it was only in the cases in which a stout rubber ligature could be temporarily tied around the cervix and when, as happened in some cases, this ligature slipped, alarming hemorrhage followed. Then came the systematic controlling of each of the cardinal vessels, later the bisection, and finally the transverse severance of the cervix as a preliminary feature of the operation in exceptionally difficult cases, until at present a myomatous uterus that cannot be removed is almost unheard of. I have watched the gradual simplification of the surgical procedures with the greatest interest. Many American surgeons have had much to do with the wonderful advance in this direction, but I know of no other man, either here or abroad, who has done as much toward this advancement as Howard A. Kelly.

The mortality rate for 4,373 operations performed for uterine leiomyomata at the Johns Hopkins Hospital between 1889 and 1906 was 5.75%; it was less than 1% for 238 operations performed between 1906 and 1909. In 53 patients, no operation was attempted because of refusal or the patient’s weakened condition. Among these patients, 21 deaths occurred in the hospital. Death from uterine leiomyomata is a rare occurrence today. The almost total elimination of mortality caused by this tumor represents a major milestone in the health care of women.

During the past century, hysterectomy and myomectomy by the traditional and classic techniques have been the main treatment for women with uterine leiomyomata and significant symptoms, and they continue to be so today. Each year in the United States, more than 200,000 hysterectomies are performed with uterine leiomyomata as the primary indication. However, this traditional management will change in the future for several reasons:

1. Concern regarding the increasing costs of health care has focused on the need to use effective but less expensive methods of management of uterine leiomyomata.

2. Advances in surgical technology now allow certain patients to be treated with new, minimally invasive techniques, including laparoscopic hysterectomy, laparoscopic-assisted vaginal hysterectomy, laparoscopic myomectomy, laparoscopic myoma coagulation (mynalysis), and hysteroscopic resection of submucous myomata. Under proper circumstances, these procedures can be safe, effective, and less costly, but more time is needed before they will be available to a greater number of patients in need.

3. Interest in nonsurgical management also appears to be increasing with more data available regarding minimally invasive procedures, including uterine artery embolization. This procedure has emerged from an investigational realm to common clinical practice. As more long-term data become available, outcomes and prognosis are becoming more clearly defined.

4. A medical approach to the management of patients with leiomyomata is now available. Gonadotropin-releasing hormone (GnRH) analogs, administered for 3 to 6 months, cause most uterine leiomyomata to shrink. However, the...
myomata regain their original size several months after the GnRH analog is discontinued. This medical regimen has been useful as an adjunct to surgical management. Women who become symptomatic with leiomyomata just before menopause can be treated temporarily with GnRH analogs and can possibly avoid surgical therapy.

5. Uterine leiomyomata are a major public health and women's health care problem. Society has a legitimate reason for interest and concern and has questioned the advisability of hysterectomy for the management of most cases of uterine leiomyomata. Many women insist on the preservation of uterine function for future childbearing, and sometimes even when future childbearing is not desired or not likely to occur. There will probably be a greater emphasis on expectant management, medical management, minimally invasive surgical procedures, and conservational management of uterine leiomyomata in the future.

In the future, the traditional and classic techniques of hysterectomy and myomectomy will be required less often for patients with symptomatic leiomyomata. At present, however, these operations are still appropriate in many situations.

ETIOLOGY, PATHOLOGY, AND GROWTH CHARACTERISTICS OF UTERINE LEIOMYOMATA

A leiomyoma is a benign tumor composed mainly of smooth muscle cells but containing varying amounts of fibrous connective tissue. The tumor is well circumscribed but not encapsulated. Various terms are used to refer to the tumor, such as fibromyoma, myofibroma, leiomyofibroma, fibroleiomyoma, myoma, fibroma, and fibroid. The latter designation is the one most commonly used, but it is the least accurate and acceptable. The term leiomyoma is a reasonably accurate one that emphasizes the origin of this tumor from smooth muscle cells and the predominance of the smooth muscle component. The tissue culture work of Miller and Ludovici suggested an origin from smooth muscle cells. The studies of Townsend and associates suggest a unicellular origin for leiomyomata. Leiomyomata are the most common tumors of the uterus and female pelvis. It is impossible to determine their true incidence accurately, although the frequently quoted incidence of 50% found at postmortem examinations seems reasonable. Leiomyomata are responsible for about one third of all hospital admissions to gynecology services. It is well recognized that the incidence is much higher in black women than in white. In a careful study of leiomyomata among women in Augusta, Georgia, Torpin and associates found the incidence among black women to be three and one third times that among white women. There is no explanation for this racial difference. Leiomyomata also are larger and occur at a younger age in black women. In our experience, a large degenerating intramural leiomyoma was removed from a 1-year-old black girl; the tumor had enlarged the uterus to the level of the umbilicus. In black women, leiomyomata are not uncommon before 30 years of age. However, they are uncommon in any women before 20 years of age. Patients with uterine leiomyomata often have a positive family history of uterine leiomyomata. This suggests the presence of a gene encoding for their development.

About 40% to 50% of leiomyomas show karyotypically detectable chromosomal abnormalities that are both nonrandom and tumor specific. Identified chromosomal abnormalities include t(12;14)(q15;q23–24), del(7)(q22q32), rearrangements involving 6p21, 10q, trisomy 12, and deletions of 8q. Interestingly, a recent study of 217 myomas found a positive correlation between the presence of a cytogenetic abnormality and the anatomic location of the myoma. In this study by Brosens and colleagues, submucous myomas were consistently shown to have fewer cytogenetic abnormalities when compared with intramural and subserous lesions (12% vs. 35% and 29%, respectively). An increased prevalence in certain races, twin studies indicating higher correlation with hysterectomy in monzygotic twins, and increased incidence in first-degree relatives all seem to support an inherited predisposition. The true genetic contribution to the development of uterine leiomyomata remains to be defined.

Most of the data concerning the incidence of uterine leiomyomata are based on gross examination of the uterus, routine pathology reports, or the clinical diagnosis of uterine leiomyomata. Cramer and Patel subjected 100 uteri to gross serial sectioning at 2-mm intervals. They found 649 leiomyomata, roughly threefold the number identified by routine pathologic examination. Admittedly, some were only a few millimeters in diameter, but all were grossly visible. In 48 uteri with no
mention of leiomyoma in the routine report, 27 were found to have small tumors. The incidence of leiomyoma was the same in premenopausal and postmenopausal uteri, although the average number of leiomyoma and the average size of the largest leiomyoma were greater in the premenopausal women. This work has important implications for future epidemiologic studies. It also suggests that it is almost never possible to sur-
gically remove all leiomyomas when a myomectomy is per-
formed.

The growth of leiomyoma is dependent on estrogen pro-
duction. The tumors thrive during the years of greatest ovarian ac-

tivity. Continuous estrogen secretion, especially when unun-
terupted, between pregnancy and lactation, is thought to be the most

important underlying risk factor in the development of my-

omata. After menopause, with regression of ovarian estrogen secre-
cion, growth of leiomyomata usually ceases. Actual re-
gression in the tumor size may occur. There are rare instances,

however, of postmenopausal growth of benign leiomyomata,
suggesting the possibility of postmenopausal estrogen produc-
tion either in the ovary or elsewhere. Postmenopausal ovarian
cortical stromal hyperplasia may be associated with an increase in
estrogen secretion by the ovary. The postmenopausal ovarian
stroma in a variety of presumably inactive ovarian tumors, in-
cluding mucinous cysts and Brenner tumors, can also produce
estrogen. When a central pelvic tumor presumed to be uterine
leiomyomata enlarges after menopause, one should think of
the possibility of malignant change in the leiomyoma itself or in
the adjacent myometrium, or of the growth of a new pelvic
tumor of extratrigonal origin.

Older nulliparous women have an increased risk of develop-
ing leiomyomata. However, in multiparous women, the rel-
vative risk decreases with each pregnancy. A woman who has
had five term pregnancies has only one fifth the risk of a nulli-
parity woman of the same age without leiomymata. The risk is reduced
in women who smoke and is increased in obese women; this is possibly related to the conversion of androgens to estrogen by
fat aromatase.

The observation that leiomyomata may show significant en-
largement during pregnancy provides further clinical evidence of
the relation of estrogen and progestrone to the growth of these
tumors. However, a better blood supply during preg-
nancy might also encourage their growth. In a prospective
ultrasonographic study of 29 pregnant patients with uterine
leiomyomata, Ahammer and associates found no evidence of en-
largement of the myomata in 78%. Lew-Toaff and colleagues also confirmed that some leiomyomata do enlarge during preg-
nancy in response to estrogen and progestrone.

In the initial two decades following the introduction of oral
contraceptives containing high-dose estrogen, there was a striking
increase in the occurrence of large leiomyomata among young
women of all racial backgrounds who took these pills. Although the growth of uterine leiomyomata is not invariably stimu-
lated, oral contraceptives containing high-dose estrogen should not be prescribed for women with these tumors. Oral
contraceptives with low-dose estrogen are less likely to stim-
lulate growth. According to Parazzini and associates, there is no significant relation between the occurrence or growth of
leiomyomata and the newer oral contraceptives that contain
much smaller amounts of estrogens and progestins, and some
believe that the risk of developing myomata is reduced with
these low-dose pills.

Scientific investigators have been intrigued by the obser-
vation that leiomyoma develop during the reproductive years, sometimes grow during pregnancy, and regress after
menopause. Nelson, Lipshutz, and others have produced mul-
tiple leiomyoma artificially on the serosal surface of the
uterus and other peritoneal surfaces in guinea pigs given pro-
longed estrogen injections. Spellacy and coworkers found that
levels of plasma estradiol were the same in patients with and
without leiomyomata. However, Wilson and associates found
a significantly higher concentration of estrogen receptors in
leiomyomata than in myometrium. Farber and colleagues re-
ported that these tumors had a 20% more estradiol (17β)
milligram of cytoplasmic protein than does the normal my-
ometrium of the same organ. This observation was not uni-
formly true for all leiomyoma, suggesting that different cel-
lular components with a leiomyoma may be associated with different biologic activity. Onuba and coworkers found the
concentration of estradiol to be significantly higher in leiomy-
omata than in normal myometrium, especially in the prolif-
erative phase of the menstrual cycle. Soules and McCarty re-
ported that leiomyomata had more estrogen receptors than did
normal uterine tissues in the first phase (days 1 through 9)
and in the second phase (days 10 through 18) of the men-
strual cycle. Gabb and Stone found that the ability to con-
vert estradiol to estrone was similar in leiomyomata and
myometrium. However, Follaw and associates found the con-
version of estradiol into estrone to be significantly lower in
leiomyomata than in myometrium. This difference in con-
version rate could result in a relative accumulation ofestro-
gen in a leiomyoma, causing a hyperestrogenic state within
the tumor and surrounding tissues. The enzyme 17β-hydroxy
dehydrogenase accelerates the conversion of estradiol to es-
trone. Leiomyomata have a low concentration of 17β-hydroxy
dehydrogenase, which results in a relative accumulation of
estradiol in leiomyomatous tissue. These findings may explain the
myometrial hypertrophy that is invariably present with
leiomyomata.

Other abnormalities in endocrine function have also been
suggested. Ylikorkala and colleagues found that pituitary func-
tion may be abnormal in women with leiomyomata. Patients
with leiomyomata had a low follicle-stimulating hormone level
and a diminished follicle-stimulating hormone response to pi-

tuitary GnRH. There was an exaggerated prolactin response to thyrotropin-releasing hormone. Spellacy and colleagues found
that the peak levels of human growth hormone reached dur-
ing a hypoglycemic test were twice as high in patients with
leiomyomata as in the control group. Reddy and Rose sug-
gested the possibility that 5α-reduced androgens may play a
role in the pathophysiology of uterine leiomyomata, because a
significant increase in 5α-reductase has been found in leiomy-
omata tissue as compared with myometrium and endometrium.

Influenced by the experimental investigations of Lipschutz and
associates, Goodman in 1946 treated patients with uterine
leiomyomata with progesterone and noted a decrease in tu-
mor size in all patients. However, Segaloff and colleagues re-
ported no effect in their study. Goldracher and coworkers pro-
duced histologic evidence of extensive degenerative changes
in leiomyomata by administering high-dose progestin therapy
(medrogestone in high doses for 21 days). Filscher and asso-
ciates have reported the regression of a uterine leiomyoma after
long-term administration of a long-acting luteinizing hormone
releasing hormone agonist given to suppress ovarian estrogen
secretion. Coutinho successfully used a potent 19-norsteroid
antiestrogen-antiprogesterone to treat excessive uterine bleed-
ing in 16 patients with uterine leiomyomata. A reduction in the
size of the tumors was noted.

Although the exact etiology of uterine leiomyomata is not
known, the puzzle may be solved bit by bit by the research of
Kornay and colleagues, Wilson and coworkers, Tamaya and

Leiomyomata Uteri and Myomectomy 689
Surgery for Benign Gynecologic Conditions

...and occasionally parasitic, receiving its blood supply from anastomotic vessels with the endometrium and myometrium.

The extracellular matrix of leiomyoma is composed mostly of collagen but also contains proteoglycans and fibronectin. According to Fujita, myomata contain 50% more collagen than does normal myometrium, and the ratio of collagen type I to collagen type III is increased in myomata. Fibronectin is a glycoprotein that mediates adhesion between myoma cells and extracellular matrix.

The most common change in leiomyosarcoma is hyaline degeneration. The cut surface of a hyalinized area is smooth and...
Leiomyomata Uteri and Myomectomy

FIGURE 31.2. The uterine corpus is almost completely replaced by small and large myomas in intramural, subserous, and submucous positions. Some are pedunculated. A pedunculated submucous myoma is dilating the endocervical canal. A pedunculated subserous myoma is adjacent to the left ovary and will interfere with its palpation.

homogeneous and does not show the whorl-like arrangement of the rest of the leiomyoma. Almost all leiomyomata, except the smallest, have scattered areas of hyaline degeneration. Eventually these may become liquefied and form cystic cavities filled with clear liquid or gelatinous material (Fig. 31.3). Sometimes the cystic change is so great that the leiomyoma becomes a mere shell and is truly a cystic tumor. Softness of a tumor does not necessarily indicate cystic degeneration. Fleshy leiomyomata may be equally soft.

FIGURE 31.3. Multiple leiomyomata are present. A large subserous myoma has undergone partial cystic degeneration.

Over time, with continued diminished blood supply and ischemic necrosis of tissue, calcium phosphates and carbonates are deposited in myomata. Their presence is evidence of a continuum of degenerative changes. The calcium may be deposited in varying amounts. If it is deposited at the periphery of the tumor, the leiomyoma may resemble a calcified cyst. Other calcified leiomyomata may show an irregular or diffuse distribution throughout with a honeycomb or mulberry appearance. When the degenerative change is advanced, the leiomyoma may become solidly calcified. Such calcified tumors have been called “wombstones.” Calcified leiomyomata are seen most often in elderly women, in black women, and in women who have pedunculated subserous tumors. They are easily seen radiographically (Fig. 31.4).

Leiomyomata may undergo changes as a result of infection. Submucous leiomyomata are most commonly infected when they protrude into the uterine cavity, or especially into the vagina (Fig. 31.5). The pedunculated submucous leiomyoma thins out the endometrium as it grows inward, and eventually the surface becomes ulcerated and infected (Fig. 31.6). An intramural leiomyoma in an involuting puerperal uterus can also become infected when endometritis is present. Microscopic abscesses can be found, and gross abscesses occasionally occur, particularly if the leiomyoma descends as low as the cervical canal. Such infections are usually streptococcal and may be virulent. Bacteroides fragilis infections also occur. Perimetritis, peritonitis, and even septicemia may result.

Necrosis of a leiomyoma is caused by interference with its blood supply. Occasionally a pedunculated subserous leiomyoma twists, and if an operation is not done immediately, infarction results. Necrosis sometimes occurs in the center of a large tumor simply as a result of poor circulation. Necrotic leiomyomata are dark and hemorrhagic in the interior. Eventually the tissue breaks down completely. So-called red or carneous degeneration is seen occasionally, especially in association with pregnancy. This condition is thought to result from poor circulation of blood through a rapidly growing tumor. Thrombosis and extravasation of blood into the myoma tissue are responsible for the reddish discoloration (Fig. 31.7).

A subserous and especially a subserous pedunculated myoma may gradually outgrow its blood supply (Fig. 31.8). To keep the myoma tissue from undergoing complete ischemic...
FIGURE 31.4. An abdominal radiograph shows typical calcification in a leiomyoma.

FIGURE 31.5. A large submucous pedunculated myoma has dilated the cervix and is now located in the vagina. Its pedicle is attached inside the uterine cavity. Morcellation of the myoma performed transvaginally allows clamping and ligation of the pedicle.

FIGURE 31.6. Pedunculated submucous myoma showing necrosis and ulceration.
Leiomyomata Uteri and Myomectomy

FIGURE 31.7. Degenerating leiomyoma showing carneous discoloration caused by thrombosis and extravasation of blood into the myoma tissue. A Dalkon shield can be seen in the endometrial cavity. See color version of figure.

FIGURE 31.8. A subserous pedunculated myoma receives tenuous blood supply through its uterine pedicle. Such a myoma may wander in the upper abdomen and eventually receive its blood supply from other sources. It may also twist on its pedicle and undergo infarction.

necrosis, the omentum becomes adherent to the peritoneal surface of a pedunculated subserous myoma and provides whatever blood supply is needed. Eventually, the pedicle may disappear or twist, and the myoma will become completely free from the uterus, wander in the upper abdomen, and receive its “parasitic” blood supply from the omentum and other sources. On occasion, fat occurs in leiomyomata as true fatty degeneration. The cut surface may have a yellowish discoloration. Infrequently, a deposit of true fat may form a fibrolipoma; however, the presence of fat in a leiomyoma is rare. Indeed, if fat is seen grossly or microscopically in a curettage specimen, one should not assume that it represents fatty degeneration of a leiomyoma. One should assume that the uterus has been perforated and that fragments of fat have been curetted from the mesentery or omentum.

The most important, but rare, change in a leiomyoma is sarcomatous degeneration. There is much variation in the reported incidence of sarcoma in leiomyomata. The incidence given by Novak is 0.7%. However, a review of 13,000 myomata by Montague and associates at the Johns Hopkins Hospital revealed 38 cases of malignant change, the incidence of sarcoma thus being 0.29%. Corscaden and Singh indicated by their study that the true incidence of sarcoma developing within uterine leiomyomata is no higher than 0.13% and is probably as low as 0.04%. It should be remembered that because most women with uterine leiomyomata do not undergo surgical removal, the true incidence of sarcoma in leiomyomata is probably much lower than 1 per 1,000 (0.1%).

After hysterectomy in 1,429 patients with presumed benign leiomyomata, the histologic diagnosis of leiomyosarcoma was made in seven (0.49%), according to a study by Leibsohn and coworkers. There was no evidence of malignancy in the endometrial sampling of any of these seven patients, and the diagnosis was suspected intraoperatively in only three. Uterine weights ranged from 120 to 1,100 g. In a woman between 41 and 50 years of age with presumed symptomatic leiomyomata, there is a 1 in 112 chance of a leiomyosarcoma being present, according to these authors. This information has important implications in the consideration of conservative or delayed treatment for these women. Parker and associates found that the total incidence of uterine sarcomas (leiomyosarcoma, endometrial stromal sarcoma, and mixed mesodermal tumor) among patients operated on for presumed benign uterine leiomyoma is lower (0.23%) than the 0.49% reported by Leibsohn and coworkers.

The difficulty in defining the true incidence of sarcomatous change is understandable if one is familiar with the histology of leiomyomata. Abundantly cellular leiomyomata are relatively common, and at first glance they suggest sarcoma; however, they lack a significant number of mitotic figures, and patients from whom such tumors are removed all remain well. Misinterpretation of the histologic picture of this type of cellular leiomyoma undoubtedly accounts for the increased incidence of leiomyosarcoma reported by some. When cutting into leiomyomata in the operating room, the surgeon finds that sarcomatous areas have a somewhat characteristic appearance, although the histologic diagnosis certainly cannot be made by gross examination. A sarcoma is likely to occur in a rather large leiomyoma and toward the center of the tumor, where the blood supply is poorest. Instead of being firm fibrous tissue that grates when scraped with a knife blade, the tissue is soft and homogenous, and is described as resembling raw pork. Later, as necrosis of the malignant tissue occurs, it becomes more friable and hemorrhagic.

It has been difficult to understand uterine leiomyosarcoma because pathologists do not agree on the criteria necessary for
Surgery for Benign Gynecologic Conditions

There is a lower level of mitotic activity. Although combination therapy (surgery plus radiation therapy or chemotherapy) may not be indicated for a patient with an epithelioid leiomyoma, follow-up should be considered essential, as emphasized by Klunder and colleagues.

An unusual benign form of leiomyomatous uteri, intravenous leiomyomatosis, was first recognized at the turn of the 20th century and has been reported sporadically since then. By 1982, about 50 cases had been reported, according to Bahary and coworkers. Probably at least that many have been reported since. Marshall and Morris presented the first detailed report of this entity in the American literature in 1959. The characteristic feature of this peculiar smooth muscle tumor is the extension of the polyposid intravascular projections into the veins of the parametrium and broad ligaments. Although there may be some difficulty in distinguishing such lesions from low-grade sarcoma, they are distinctly different histologically from stromatous uteri because the intravenous plugs are mainly smooth muscle in origin. In 1966, Edwards and Peacock collected 32 cases of intravenous leiomyomatosis, including two cases of their own, and reviewed the clinical experience with this condition. In approximately 50% of the cases, the intravenous tumor was confined to the parametrium; in 75%, it extended no further than the veins of the broad ligament. The observations of Edwards and Peacock suggest that the severity of intravenous extensions is probably incapable of independent parasitic existence and remain dormant after removal of the uterus. However, the cases presented by Bahary and associates tend to refute this idea. Total surgical excision of the tumor should be attempted for successful therapy. Some patients have survived for many years after incomplete resection of the tumor. A review of 14 cases of this rare uterine tumor from the file of the Armed Forces Institute of Pathology has been reported by Norris and Parmley. In this series, incomplete resection had a recurrence; the recurrent tumor was excised surgically, and the patients were alive and free of disease 3 and 5 years after operation. The authors concluded that this tumor behaves clinically like a benign neoplasm, although its wormlike extensions may involve uterine, vaginal, ovarian, and iliac veins. The uterine veins in the broad ligaments are the most common sites of extension. The mitotic index is quite low, with the most active lesions showing only one mitosis per 10 high-power fields. The material from the Armed Forces Institute of Pathology provides histologic evidence consistent with both theories of origin of intravenous leiomyomatosis, namely, that it may be the result of unusual vascular invasion from a leiomyoma or may arise de novo from the wall of veins within the myometrium.

Extension of benign leiomyomatosis up the vena cava and into the right atrium has been reported in several cases, with a fatal outcome in some. Before 1994, approximately 27 cases of intravenous leiomyomatosis extending to the heart were reported. Several recent cases requiring open-heart surgery to remove the intracardiac tumor thrombosis have been successful and without recurrence. All reported cases occurred in women. Tierney and colleagues reported that substantial quantities of cytoplasmic estradiol and progesterone receptors were found in the right atrial tumor removed from a patient with intravenous leiomyomatosis. Their patient was treated with the antiestrogen tamoxifen because of residual tumor in the vena cava that could be estrogen dependent. Irey and Norris have presented evidence that female reproductive steroids can produce initial proliferation of veins in patients with intravenous leiomyomatosis. The 30 patients with leiomyoma and leiomyosarcomas of the vena cava reviewed by Wray and Dawkins, 80% were female. Both intravenous leiomyomatosis and benign metastasizing

diagnosis. Some pathologists rely on the mitotic count. All tumors with less than five mitotic figures per 10 high-power fields are considered benign. All tumors with more than 10 mitotic figures per 10 high-power fields are called malignant. Those in between can be called smooth muscle tumors of uncertain malignant potential.

Other pathologists believe the mitotic count may have some significance but choose to rely instead on the presence of nuclear hyperchromatism, nuclear pleomorphism, or giant cells and other bizarre cell forms to make the diagnosis. Cascadden and Singh believe that no combination of histologic features is reliable and that only smooth muscle tumors that metastasize or recur are definitively malignant. They believe that all of these features should be taken into consideration for diagnosis and prognosis. When the tumor is confined to the uterus, both mitotic grade and histologic grade are important in the diagnosis and prognosis. A poor prognosis is associated with high mitotic counts and extremely atypical and anaplastic cytologic features. Bell and colleagues at Stanford University Medical Center assessed a variety of histopathologic features of 213 problematic smooth muscle neoplasms for which there were at least 2 years of clinical follow-up data. From the wide variety of light-microscopic features assessed, the important predictors that emerged were mitotic index, the degree of cytologic atypia, and the presence or absence of coagulative tumor cell necrosis. Previously, the mitotic index was relied on exclusively to determine whether a uterine smooth muscle tumor was benign or malignant, but currently an approach is used that incorporates additional histopathologic features. A normal chromosome complement (46,XX) was observed by Meloni and coworkers in about 50% of leiomyoma cases. About 50% showed clonal abnormalities, such as those of chromosomes 1, 7, and 13, and tel(12;14). Interstitial deletions of chromosomes 12, 13, and 17 are most often involved, suggesting that this abnormality may be of primary importance in the cellular proliferation of leiomyomatosa. A relation between more aggressive histology and chromosomal abnormalities was also suggested.

Tumors that show obvious evidence of blood vessel invasion or spread to contiguous organs are rarely cured. The extent of the disease at the time of initial diagnosis is of even greater significance. In other words, when the diagnosis is suspected for the first time by the pathologist when he examines routine sections from a uterine leiomyoma, the patient almost always survives. However, if the diagnosis is made preoperatively by the gynecologist or is suspected during the operative procedure because of invasion of surrounding organs, the prognosis is grave.

An unusual atypical smooth muscle tumor was first described in the stomach by Martin and associates in 1960. Variously called bizarre leiomyoma, leiomyoblastoma, clear-cell leiomyoma, and pleomorphic tumorlet, these atypical smooth muscle tumors probably all belong together. The term epithelioid leiomyoma was adopted by the World Health Organization. Kurman and Norris have proposed that this term be used for all atypical leiomyomas. Histologically, the characteristic feature is the mixture of rounded polygonal cells and multinucleated giant cells present in epithelioid, clear-cell and pleomorphic patterns. Clinically, in the uterus most of these tumors are benign. They may rarely exhibit malignant potential. Malignancy is difficult to predict from histologic criteria because some metastases occurred from tumors that demonstrated very few mitoses. Kurman and Norris believe that epithelioid leiomyomas having more than five mitotic figures per 10 high-power fields should be called epithelioid leiomyosarcoma and that the term epithelioid leiomyoma should be applied when
Leiomyoma uteri and myomectomy

Leiomyoma have been reported to metastasize to the lung. As suggested by Banner and coworkers, by Hoosmann and associates, and by Evans and colleagues, oophorectomy may be indicated in patients with these conditions, again because of the possibility that these tumors may be estrogen dependent or that estrogens may have the ability to stimulate their development, whether in a uterine or extraperitoneal condition. Whether or not tumors develop is not known, but it is possible that these tumors may be estrogen dependent or that estrogens may have the ability to stimulate their development, whether in a uterine or extraperitoneal condition.

The possibility of metastases from a histologically benign uterine leiomyoma has been discussed by Ide1son and Davids and by Clark and Reed. When such a case occurs, it is usually settled by finding a sarcomatous component in the leiomyoma. However, multiple cases have now been reported in which a benign uterine leiomyoma metastasized. Ide1son and Davids’ case showed metastases to the aortic lymph nodes. The patient reported by Cramer and associates had metastatic tumor to the omentum, ovary, peri-aortic lymph node, and lung. In each location, the histology and estrogen receptor content of the tumor resembled those of a benign leiomyoma. The recommended treatment consists of surgical removal with castration and little or no estrogen replacement.

Leiomyomatosis peritonealis disseminata is sometimes confused with intravenous leiomyomatosis. However, only subperitoneal surfaces of the uterus and other pelvic and abdominal viscera are involved with leiomyomatosis peritonealis disseminata, and invasion of the lumen of blood vessels does not occur. Only about 15 cases have been reported, according to the literature. All occurred in patients in the reproductive years who often had large uterine leiomyomata and were usually pregnant or taking oral contraceptives. The condition is likely to be confused with a disseminated intraabdominal malignancy, but it is entirely benign histologically and clinically. Parmley and associates have noted the histologic similarities between this peritoneal lesion and the decidual change of the mesothelium in the pelvis, and they propose that the condition represents a benign reparative process in which fibroblasts replace soft peritoneal decidualia. They suggest that this fibrocystic reaction occurs during pregnancy and especially in the postpartum period, resulting in nodules with a pseudoleiomyomatous pattern. Similar findings have been noted in patients with endometriosis treated with prolonged Enovid therapy. These conditions are pertinent when surgery, especially myomectomy, is contemplated.

According to Vollhoven and associates, the vascularization of leiomyoma was studied by Vasserman and colleagues, and the findings were presented to the World Congress of Gynecology and Obstetrics in 1988. Using femoral arteriography, selective intraoperative angiography, radiography, and injection of surgical specimens, these investigators showed that leiomyomata have a rich vascular supply, including blood lakes within tumors. They found more than one nutrient vessel per myoma. Venous channels were predominantly peripheral, whereas the arterial supply was both internal and peripheral. Farrer-Brown and coworkers, using radiologic methods, demonstrated that myomata in various locations within the myometrium can cause congestion and dilatation of endometrial venous plexuses by obstructing venous return. These obstructions can result in ectasia of endometrial and myometrial veins (Fig. 31.9). The degree of vascularity of leiomyomata was also studied by Karsen and Persson. Vascularity varied from many, to few, to no intrinsic vessels demonstrable. Generally, the sum of the width and number of the uterine arteries increases with the size of the uterus, but the diameter of the two sides sometimes differs markedly. A rich vascularization was found in 22 of 34 uteri with leiomyomata, but with increasing size there is a tendency to less vascularity. In none of five cases with very large (20 cm or more) leiomyomata uteri was the vascularity rich. The intrinsic vessels were few in two cases and absent in three cases.

CLINICAL FEATURES OF UTERINE LEIOMYOMATA

Asymptomatic Leiomyomata

Most leiomyomata are asymptomatic. Untold numbers of such symptomless leiomyomata are removed surgically by either hysterectomy or myomectomy when they would have been better left undisturbed. The incidence of malignancy in leiomyomata is less than 0.1%, which is lower than the operative mortality rate of hysterectomy in the average hospital; therefore, unless there is some reason to suspect malignant change, the risk of the operation for asymptomatic leiomyomata may exceed the danger of malignancy. A history of rapid growth, however, particularly postmenopausal growth, does indicate removal, even when the tumor produces no symptoms. Signs of rapid enlargement are important in all patients but are even more ominous in older patients. In younger patients, the most common reason for rapid enlargement of a uterus with...
leiomyomata is pregnancy. If pregnancy can be ruled out, a leiomyosarcoma may be suspected but is rarely found.

Small leiomyomata that are asymptomatic need only to be observed from time to time, with pelvic examinations perhaps every 6 to 12 months and pelvic ultrasonography when indicated. In the beginning, frequent examination may be indicated to determine the growth rate. Such tumors may remain remarkably constant in size for years. If small leiomyomata are discovered late in menopausal life, it is unusual for symptoms to appear or for surgical treatment to be required. Larger tumors can also be watched safely, but if a policy of watchful waiting is adopted, one should be very sure of the nature of the tumors. If there is uncertainty of the uterine or ovarian origin of a tumor, as may well be the case when the tumor fills the whole pelvis or when a pedunculated tumor is felt in the adnexal region (Fig. 31.10), special diagnostic procedures may be indicated. Pelvic examination by an experienced gynecologist can usually clear up the uncertainty. In difficult cases, an examination under anesthesia may be necessary. Laparoscopy may be of great value in determining the nature of an adnexal mass. Before invasive techniques are used, however, noninvasive diagnostic evaluation should be performed. These include radiographic studies of the abdomen and pelvis, ultrasonography (US), and computed tomography (CT). The characteristic calcification in a leiomyoma may be seen on radiographs. The US and CT features of uterine leiomyomata have been well described. However, mistakes in the interpretation can still be made. Tada and associates reported that 5% of patients given the diagnosis of uterine leiomyomata by CT actually had an ovarian tumor at operation. Therefore, if uncertainty about the diagnosis persists, laparoscopy or laparotomy should still be performed.

When large asymptomatic leiomyomata occur in premenopausal women who have had their families or in whom
future childbearing is not important, a recommendation for removal may be made. It is impossible to predict which patients will become symptomatic in the remaining years before menopause. However, such tumors, with additional years to grow, are likely to require surgical removal eventually. Therefore, it is better to remove them when the patient is a good operative risk and when conservation of normal ovaries with a good blood supply can be easily accomplished. Such tumors should usually be 12 to 14 weeks in gestational size or larger. Depending on a variety of factors, either myomectomy or hysterectomy can be recommended to the patient. GnRH agonists may be useful in women approaching menopause to control symptoms or asymptomatic uterine myoma growth until menopause. The regrowth of tumors after the cessation of treatment limits the usefulness of these agents, however. Nakamura and Yoshimura reported their experience with GnRH agonists in the treatment of uterine leiomyoma in perimenopausal women. One third of patients reached menopause after 16 weeks of treatment, thus avoiding the need for surgery.

Reiter and colleagues studied 93 consecutive patients undergoing hysterectomy for leiomyomata. When the uterus was larger than 12 weeks’ gestational size, there was no increased incidence of surgical complications compared with women with smaller uterus. On the basis of this small series, the authors concluded that hysterectomy need not be recommended to women with large asymptomatic uterine leiomyomata to avoid a possible increased risk of surgical complications.

There is no uniform size of an asymptomatic leiomyoma-tous uterus that can be used as an indication for hysterectomy or myomectomy. When size is the only significant indication for surgery in an asymptomatic patient, the location of the tumors is more important than the total uterine mass. When the leiomyomata are located in the cornual area or in the lateral wall of the uterus and obscure the anatomy of the adnexa and broad ligament, the risk of error in the early recognition of an ovarian tumor is greater. In such cases, one must carefully weigh the advantages and disadvantages of the conservative approach to the management of uterine leiomyomata. When adnexal tumors are present, it is critical that the origin of these tumors be confirmed. The diagnostic studies mentioned earlier should be performed to establish clearly that the tumors are of uterine origin before a decision is made to follow up the patient rather than operate. It is unacceptable to wait to see whether an adnexal tumor enlarges before identifying the site of origin of the mass as either uterine or ovarian. Ovarian carcinoma remains the most lethal disease of the female reproductive tract and the most difficult to diagnose early. Every diagnostic and therapeutic effort must be made to avoid errors in the clinical evaluation of pelvic neoplasms (Fig. 31.10). In women who are approaching menopause, relatively large uterine leiomyomata can be kept under observation with the knowledge that after menopause they will not increase in size and may actually regress somewhat. Still, one must be certain that the entire central pelvic mass is a leiomyomatous uterus. Patient management is largely dependent on knowledge of the exact location and size of leiomyomas. Imaging modalities play an important role in determining patient management, especially when differentiating a benign leiomyoma from other pathologic conditions that may require different therapies.

Uterine size as an indication for surgical intervention in women with leiomyomata has been thoughtfully discussed by Friedman and Haas. These authors point out that many gynecologists advocate surgical removal of leiomyomata when the uterus reaches 12 weeks’ gestational size or greater, regardless of the presence or absence of significant symptoms. Historical reasons given for surgical intervention include the following:

- The inability to accurately assess the ovaries by examination
- The possible malignancy of the pelvic mass
- The potential for compromise of adjacent organ function if the mass continues to enlarge
- The greater risk of surgical complications if the mass grows to a larger size
- The potential for better fertility if myomectomy is performed when the uterus is smaller
- The possibility of continued growth of uterine leiomyomata if hormone replacement therapy is given after menopause

Friedman and Haas find very little in the literature to support these indications for surgical intervention and believe the availability of modern high-resolution US and magnetic resonance imaging (MRI) allows for expectant management in many patients with large asymptomatic uterine leiomyomata. They prefer to give primary consideration to the presence and severity of myoma-related symptoms in deciding whether surgical intervention is indicated. We believe that such a course of expectant management is appropriate only when there is relative certainty regarding the benign nature of the central pelvic mass and all of its components, and when it is possible to get the patient to return for periodic assessment of gynecologic symptoms and findings on pelvic examination. Repeat MRI may also be required occasionally. If one elects to observe a patient with a relatively large asymptomatic uterine leiomyoma, it is a good rule to obtain an excretory urogram or renal ultrasound. Everett and Sturgis showed many years ago that ureteral compression at the pelvic brim may occur so that hydronephrosis and hydroptosis develop (Fig. 31.11). It is usually the symmetrically enlarged
uterus with intramural leiomyomata that extends near or above the umbilicus and rests on the pelvic brim that compresses the ureters, in the same way as a symmetrically enlarged gravid uterus. The process is usually slow and painless even when moderate to severe hydronephrosis has occurred. Pyelographic evidence of kidney damage may be the determining factor in a decision to operate on a patient with an entirely asymptomatic leiomyoma. The irregularly and asymmetrically enlarged uterus with subserous tumors usually does not produce pressure on the ureters.

After menopause, asymptomatic leiomyomata generally should be left undisturbed. Again, the gynecologist must be absolutely certain that an ovarian neoplasm can be ruled out. In the postmenopausal years, shrinkage of myomata and the myometrium occurs. However, the myometrial shrinkage may be disproportionately greater than the myoma shrinkage. Therefore, a myoma in an intramural location before menopause may become a submucous myoma after menopause and then become symptomatic for the first time, usually with postmenopausal bleeding.

In menopausal women, the appearance of even the slightest trace of vaginal bleeding should make one suspect cervical or endometrial malignancy or the possibility of sarcomatous change in the leiomyoma (Figs. 31.12 and 31.13). Careful pelvic examination, Pap test, and evaluation of the cervix by colposcopy or biopsy, pelvic US, fractional curettage, and perhaps hysteroscopy should be done. If the bleeding remains unexplained and the presence of atrophic vaginitis or the use of exogenous estrogens has been excluded, the leiomyomatous uterus should be removed because of the risk of sarcomatous change.

Transabdominal and endovaginal US are the standard imaging modalities for the detection of leiomyomas. Pelvic US by transvaginal and transabdominal techniques is most useful because of good patient tolerance, relatively low cost, availability, and accuracy when performed by well-trained and experienced ultrasonographers (Fig. 31.14). Ultrasonography is the most cost-effective screening mechanism for uterine masses suggestive of myomas. Sonographic criteria for diagnosis have been well described. Generally, abdominal US is unable to detect myomas less than 2 cm in diameter. Endovaginal probes have allowed for improved visualization of both the uterus and adnexa. With higher frequencies, sensitivity in the detection of small myomas has substantially increased. In a series evaluated by Fedele and colleagues using endovaginal ultrasound before hysterectomy, submucous leiomyomas were identified with a sensitivity of 100%. Difficulties may arise, however, if myomas are small or pedunculated, patients are obese, or the uterus is retroverted.

Transvaginal fluid-enhanced vaginal probe sonography (sonohysterography) is a useful technique to assess myomata that distort the endometrial cavity. This technique has little to no complications and is generally well tolerated with only mild cramping described by patients. The limitation of detection of leiomyomas with this modality is 0.5 cm diameter. In a study by Hoetzinger, the majority of intrauterine myomata (14 of 16, or 88%) were detected by sonohysterography. Ultrasound transducing catheters have been suggested as a potential tool.
to supplement abdominal and endovaginal sonography. Three-dimensional data display has recently undergone development and application in sonography; however, the role in evaluation and management of leiomyoma remains unclear (Fig. 31.9).

There is no technique that reliably identifies a leiomyoma. Plain abdominal or pelvic radiographs and hysterosalpingography are older, standard techniques that are still useful in assessing uterine size, calcification in myomata, and uterine filling defects caused by submucous myomata, and tubal pathology. These techniques, combined with US, are the most useful for assessing patients with a central pelvic mass thought to be a leiomyomatous uterus. CA-125 levels may be elevated in women with uterine leiomyomata, but the levels are generally lower than those in patients with ovarian cancer.

Symptomatic Leiomyomata

Less than 50% of patients with uterine leiomyomata have symptoms. Symptoms may be single or multiple and depend on the location, size, and number of tumors present. A clinical and pathologic study of 298 patients with uterine leiomyomata by Perkash and Arjoon revealed no significant relation between the presenting symptoms and the presence of degenerative changes in the tumors. Some form of degeneration was demonstrated in 65.5% of the specimens, with hyaline degeneration accounting for 83% of all types of degeneration. Hyaline degeneration produces no characteristic symptoms. Symptoms, especially pain and fever, may be present in some patients with red degeneration of a leiomyoma during pregnancy, with torsion and infarction of a subserous pedunculated leiomyoma, or with an infected leiomyoma. A discussion of the signs and symptoms caused by uterine leiomyomata follows.

Abnormal Bleeding

It is surprising but not unusual that even patients with large uterine leiomyomata may have a history of normal menstruation. Such patients should be questioned carefully about recent slight increases in the amount, duration, and frequency of menstruation. Some patients with a history of normal menstruation are found to have iron-deficiency anemia from a gradual increase in menstrual blood loss that even the patient has not recognized. If a case of uterine leiomyomata is to be followed, the patient should be asked to monitor her menstrual blood loss carefully and be given instructions to keep a menstrual calendar and monthly record of the number of pads or tampons used each day. A more objective measurement of the amount of menstrual blood loss using the method of Hallberg and Nilsson may be helpful in doubtful cases. Iron depletion may not be evident by laboratory determination unless one performs an iron stain on a uterine curettage specimen. In the early months of increased menstrual blood loss, the hemoglobin and hematocrit values are normal. Heavy menstruation does not cause anemia until iron stores are first depleted.

Abnormal bleeding occurs in about one third of patients with symptomatic uterine leiomyomata and commonly indicates that treatment is necessary. The menstrual flow is usually heavy (menorrhagia), but it can also be prolonged (metrorrhagia) or both heavy and prolonged (menometrorrhagia). Abnormal bleeding may be associated with submucous, intramural, and subserous tumors, but there is a distinct clinical impression that bleeding myomata are associated with the presence of submucous tumors. The submucous leiomyoma bleeds freely at menstruation and may also bleed between periods as a result of passive congestion, necrosis, and ulceration of the endometrial surface over the tumor and ulceration of the contralateral uterine surface. If the submucous myoma is pedunculated, there is usually a constant, thin, blood-tined discharge in addition to the menorrhagia. An intramural tumor that is just beginning to encroach on the uterine cavity can also be responsible for menorrhagia. Intramural leiomyomata near the serosal surface and pedunculated subserous tumors can also be associated with abnormal bleeding. When bleeding is also present with leiomyomata, however, one should search for some other lesion to account for it. The mere presence of leiomyomata in a woman who has abnormal uterine bleeding is not proof that the leiomyomata are causing the bleeding. This fact is important, particularly when there is intermenstrual bleeding. When a patient with leiomyomata has intermenstrual bleeding, it is a rule in our practice to examine and study the cervix carefully with special diagnostic procedures and to sample and evaluate the uterine cavity before we proceed with treatment of the leiomyomata. If an endometrial or cervical malignancy is detected, the treatment of the leiomyomata may need to be altered.

There are several mechanisms by which leiomyomata can cause abnormal bleeding, although a single specific mechanism may not be apparent in a particular patient. According to Sehgal and Haskins, the surface area of the endometrial cavity in a normal uterus is 15 cm². The surface area of the endometrial cavity in the presence of leiomyomata may exceed 200 cm². These authors demonstrated a correlation between the severity of the bleeding and the area of endometrial surface. In addition to an increased surface area from which to bleed, the endometrium may demonstrate local hyperestrogenism in areas immediately adjacent to submucous tumors, and endometrial hyperplasia and endometrial polyps are commonly found.

Degligdish and Loewenthal noted a broad spectrum of histologic abnormalities in the endometrium associated with leiomyomata, ranging from atrophy to hyperplasia. Thinning and ulceration of the endometrial surface may be present over large submucous tumors; smaller ones may show slight thinning without ulceration. The presence of leiomyomata may interfere with myometrial contractility as well as contractility of the spiral arterioles in the basalis portion of the endometrium. Miller and Ludovics suggested that annulation and dysfunctional uterine bleeding are more common in the presence of uterine leiomyomata.

Sampson in 1913 was the first to study the blood supply of uterine leiomyomata and its effect on uterine bleeding. More recent studies have been performed by Faulkner and by Farrer-Brown and associates. The most prominent and important change is the presence of endometrial venule ectasia. Tumors that are strategically located in the myometrium may cause obstruction and proximal congestion of veins in the myometrium and endometrium. Thrombosis and sludging of these large dilated venous channels within the endometrium produce heavy bleeding (Fig. 31.15).

Makarainen and Yliorkinkela have presented evidence that further supports the concept that prostanoids play a role in primary menorrhagia. They found that the production of 6-keto-prostaglandin F₁α (6-keto-PGF₁α), a metabolite of prostacyclin (PGI₂), and thromboxane B₂ (TXB₂), a metabolite of thromboxane A₂ (TXA₂), was normal with menorrhagic endometrium. However, the balance between TXA₂ and PGI₂ shifted to a relative TXA₂ deficiency and was negatively related to blood loss in patients with menorrhagia. Although ibuprofen decreased the blood loss in patients with primary menorrhagia, it failed to reduce myoma-associated menorrhagia. The authors suggest that uterine factors other than prostanoids are more important in causing menorrhagia associated with uterine leiomyomata.
In most cases, when bleeding occurs postmenopausally and leiomyomata are discovered on bimanual examination, the bleeding is due to some other factor, such as cervical or endometrial abnormalities, atrophic vaginitis, or exogenous estrogen, and the leiomyomata are purely incidental. Occasionally, however, the postmenopausal leiomyoma can be responsible for the bleeding. As stated earlier, leiomyomata that do not bleed during the menstrual life of the patient have been found to migrate to a submucous position in later years. This occurs because after menopause the myometrium atrophies and the uterine wall becomes thinner. Leiomyomata also shrink somewhat, but not as much as the surrounding myometrium. Thus, a leiomyoma that was intramural before menopause may work itself into a submucous position after menopause, become ulcerated, and bleed. Postmenopausal growth of uterine leiomyomata may indicate malignant change, especially if associated with postmenopausal bleeding. We have rarely observed postmenopausal growth in a leiomyoma without finding malignancy in the tumor; whenever there is enlargement of the leiomyoma after menopause, one should seriously consider the possibility of sarcomatous change and remove the leiomyoma.

Patients with heavy menstuation and uterine leiomyomata should be evaluated for the presence of submucous myomata. Even patients without palpable evidence of uterine leiomyomata may indicate malignant change, especially if associated with postmenopausal bleeding. We have rarely observed postmenopausal growth in a leiomyoma without finding malignancy in the tumor; whenever there is enlargement of the leiomyoma after menopause, one should seriously consider the possibility of sarcomatous change and remove the leiomyoma.

Pressure

Evidence of pressure on nearby pelvic viscera may be an indication for treatment. The urinary bladder suffers most often from such pressure, giving rise to urgency and frequency of urination and sometimes even urinary incontinence (Fig. 31.16). Although this symptom is common with large leiomyomata, one frequently finds the pelvis filled with leiomyomata when there is no urinary frequency. Occasionally, acute retention of urine or overflow incontinence results from a leiomyoma and necessitates surgical intervention. These effects can occur as a result of rapid interior growth of the leiomyoma with compression of the urethra and bladder neck against the pubic bone. More often, a tumor the size of a 3-month pregnancy may become incarcerated in the cul-de-sac, wedging the cervix forward against the urethra and obstructing the flow of urine through the urethra. A large pedunculated submucous tumor may fill and distend the vagina and press the urethra against the symphysis, causing urinary retention.

As pointed out by Mattingly, one can expect to encounter women who have uterine leiomyomata of significant size and in addition have protrusion of the bladder base and posterior urethra through a widened levator muscle hiatus and a weakened urogenital diaphragm. Both conditions are relatively common. In addition to the usual symptoms produced by the

isotonic saline is slowly injected into the uterine cavity. According to these investigators, this technique provided the most accurate evaluation of the size of submucous myomata, intracavitary and intramural growth, and location within the uterine cavity, with sensitivity, specificity, and predictive values of 100%.

Pressure

Evidence of pressure on nearby pelvic viscera may be an indication for treatment. The urinary bladder suffers most often from such pressure, giving rise to urgency and frequency of urination and sometimes even urinary incontinence (Fig. 31.16). Although this symptom is common with large leiomyomata, one frequently finds the pelvis filled with leiomyomata when there is no urinary frequency. Occasionally, acute retention of urine or overflow incontinence results from a leiomyoma and necessitates surgical intervention. These effects can occur as a result of rapid interior growth of the leiomyoma with compression of the urethra and bladder neck against the pubic bone. More often, a tumor the size of a 3-month pregnancy may become incarcerated in the cul-de-sac, wedging the cervix forward against the urethra and obstructing the flow of urine through the urethra. A large pedunculated submucous tumor may fill and distend the vagina and press the urethra against the symphysis, causing urinary retention.

As pointed out by Mattingly, one can expect to encounter women who have uterine leiomyomata of significant size and in addition have protrusion of the bladder base and posterior urethra through a widened levator muscle hiatus and a weakened urogenital diaphragm. Both conditions are relatively common. In addition to the usual symptoms produced by the
leiomyomata, socially disabling stress urinary incontinence may be present. When the anterior wall of the uterus is greatly distorted by the presence of these tumors, pressure against the bladder can cause urinary frequency. If anatomic pressure equalization incontinence is also present, it may be aggravated by the increased intravesical pressure caused by the leiomyoma. However, the presence of anatomic stress urinary incontinence has no etiologic relation to the uterine enlargement caused by the leiomyomata.

Silent ureteral obstruction from pressure against the pelvic brim is an uncommon complication of uterine enlargement caused by multiple large leiomyomata. Such an asymptomatic anatomic change occurs more often with a symmetrically enlarged leiomyomatosus uterus that becomes large enough to fill the pelvis and compress the ureter against the pelvic sidewalls (Fig. 31.11). Although an infrequent complication, the obstruction can occur in either ureter, depending on the location of the uterine tumors. If there has been no infection or parenchymal damage to the kidney, this anatomic alteration is completely reversible with removal of the uterus and relief of the pressure against the ureter. However, if urinary tract obstruction from leiomyomata has been neglected, ureteric may result. Removal of the tumor and relief of obstruction are necessary to restore kidney function. Chronic bladder neck obstruction from uterine leiomyomata can be so severe as to cause a remarkable increase in the thickness of the bladder wall and enlargement of the bladder resembling that seen in men with urethral obstruction from prostatic enlargement. Indeed, in these neglected cases, the bladder may fill the entire lower abdominal wall so that an incision above the umbilicus is required to enter the peritoneal cavity to remove the tumor without injury to the bladder.

The bowel is less apt to show symptoms from pressure than is the bladder, but constipation can be caused and aggravated by pressure of leiomyomata against the rectum. The small intestines can become entwined with subserous pedunculated tumors, causing intermittent intestinal obstruction.

Pain
Abdominal and pelvic pain or discomfort, a feeling of heaviness in the pelvis, and pressure in the back are present in about one third of patients with symptomatic uterine leiomyomata and may be an appropriate reason for intervention. There are several causes of pain with leiomyomata. However, the usual cause of pain is degeneration of these tumors does not produce symptoms. In rare instances, pedunculated subserous leiomyomata twist and give rise to a clinical picture of acute abdominal pain, much like that seen with a torsed ovarian tumor. These pedunculated tumors, or one may recommend removal of the tumors if the abdominal distortion is of such a magnitude as to be embarrassing to the patient.

Abdominal Distortion
Distortion of the normal abdominal wall contour because of large tumors may justify their removal. Tumors of such size often give rise to other symptoms also, so there is ample reason for surgical interference. However, when no other symptoms are present, one may recommend removal of the tumors if the abdominal distortion is of such a magnitude as to be embarrassing to the patient.

Rapid Growth
Evidence of rapid growth of uterine leiomyomata, as observed by the same examiner over time or as confirmed by US, is an indication for surgical intervention. Such rapid growth in a premenopausal patient is only rarely due to sarcoma. Parker and others reviewed the medical records of 1,332 women admitted for surgical management of uterine leiomyomas. They actually found no correlation between rapid growth and the presence of uterine sarcoma. It may be due to pregnancy or to the use of oral contraceptives containing large amounts of estrogens. In the latter case, these drugs should be discontinued and an alternative method of contraception prescribed. In the postmenopausal patient, however, growth of a uterine leiomyoma is highly suggestive of a malignancy. The malignancy may be a sarcomatous change in the leiomyoma itself, a sarcoma or carcinoma in the endometrium causing uterine enlargement, or an ovarian neoplasm whose estrogen secretion is stimulating enlargement of the leiomyoma or whose growth may be mistaken for rapid enlargement of uterine leiomyomata. Although malignancy is not invariably found, the chances in its favor are so great that one must proceed on the assumption that it exists and should perform dilatation and curettage followed by removal of the enlarged uterus.

Rapid growth of a leiomyomatous uterus is difficult to define in exact terms. Buttram and Reiter have arbitrarily defined it as a gain of 6 weeks or more in gestational size within a year or less. Although this definition could apply in premenopausal women, it might be disastrous to wait for this amount of growth in a postmenopausal woman. It is important to have a definite method of documenting uterine size at periodic intervals. Repeated sounding of the uterine cavity may be of some benefit, although leiomyomatous growth is not always accompanied by concomitant enlargement of the uterine cavity. It is important to document the size of specific leiomyomata or the total uterine size in terms of centimeters or grams of uterine weight rather than in terms of gestational size of the uterus, although the latter method has become quite popular. Changes in a patient’s weight can make evaluation of growth more difficult. Ultrasoundography is a much more objective way of establishing the size of a uterine leiomyoma in the beginning and, when indicated, of evaluating its rate of growth. There is a need for more information about the natural growth patterns of myomata before and after menopause.

Although leiomyomata can increase dramatically in size during pregnancy, usually there is no appreciable growth. Winer-Muram and coworkers studied 99 pregnant women with uterine leiomyomata documented by US examination. In 81 of the patients, there was no demonstrable increase in the size of the leiomyomata. In six patients, there was an increase in size of up to 4 cm. Those myomata that increase in size during

---

Leiomyomata Uteri and Myomectomy 701
pregnancy will decrease in size a few weeks after the pregnancy is over.

**Spontaneous Abortion and Other Pregnancy-Related Problems**

Uterine leiomyomata are associated with a significantly increased risk of spontaneous abortion. In a collected series of patients undergoing myomectomy, Buttram and Reiter reported that 41% had spontaneous abortions. This rate was reduced to 19% after myomectomy. Seoud and colleagues did not demonstrate that in vitro fertilization live birth rates were improved by myomectomy; however, the authors did note a 50% spontaneous abortion rate in patients with leiomyomata compared with 34% after myomectomy. Various mechanisms have been proposed to explain the occurrence of spontaneous abortion from uteri with leiomyomata. These include disturbances in uterine blood flow, alterations in blood supply to the endometrium, uterine irritability, rapid growth or degeneration of leiomyomata during pregnancy, difficulty in enlargement of the uterine cavity to accommodate for the growth of the fetus and placenta, and interference with proper implantation and placental growth by poorly developed endometrium or by subjacent leiomyomata. Implantation in a thin, poorly vascularized endometrium over a submucous leiomyoma is doomed to failure, because proper growth and development of the embryo and placenta are impossible (Fig. 31.17). Matsunaga and Shiota found a twofold increase in the number of malformed embryos recovered from patients with uterine leiomyomata having artificial termination of pregnancy.

Uterine leiomyomata may also be associated with other obstetrical concerns, including premature delivery, stillbirth, and interstitial pregnancy, as in the case reported by Starks. In a retrospective population-based study by Shiejer and colleagues, obstetrical outcomes appeared to be compromised by uterine leiomyoma. Compared with controls, women with myomata during pregnancy had an increase in intrauterine growth restriction (6.8% vs. 1.9%), placental abruption (2.8% vs. 0.7%), abnormal presentation (16.9% vs. 2.4%), cesarean section rate (57.7% vs. 10.8%), premature rupture of membranes (9.6% vs. 5.5%), and likelihood to receive a blood transfusion (4.4% vs. 1.4%). All of these outcomes were statistically significant ($p < 0.001$). Muram and associates have followed patients with leiomyomata through pregnancy with US. When a leiomyoma was in close proximity to the placental site, an increased incidence of pregnancy-related complications was seen. These were mainly bleeding complications, but pain, premature delivery, and postpartum hemorrhage also occurred. Exacoustos and Rosati reviewed the US scans of 12,708 pregnant patients. Four hundred ninety-two patients had myomata. A statistically significant increased incidence of threatened abortion, threatened preterm delivery, abruptio placentae, and pelvic pain was observed in patients with myomata. Abruptio placentae was particularly evident in women with myoma volumes greater than 200 cm$^3$, submucosal location, or superimposition of the placenta. The authors suggest that US findings make it possible to identify women at risk for myoma-related complications of pregnancy. Factors responsible for spontaneous abortion in patients without uterine leiomyomata may also be responsible for spontaneous abortion in patients with leiomyomata.

Occasionally, pregnancy causes a remarkable growth of leiomyomata in the same way that the myometrium undergoes hypertrophy in pregnancy. Red or carneous degeneration of leiomyomata during pregnancy is associated with pain, tenderness over the tumor, low-grade fever, and leukocytosis. Management should be expectant with analgesic medications and bed rest. If premature uterine contractions occur, tocolytics may be given. Pain usually subsides within a few days. Operation is not indicated unless it is necessary to rule out other problems that require surgery for relief, because differentiation from appendicitis, placental abruption, torsed adnexa, and other problems may be difficult. After delivery, leiomyomata involute and generally return to their prepregnancy size by the third postpartum month.

Torsion with infarction of subserous pedunculated leiomyoma is more common in pregnancy. A leiomyoma may interfere with labor and delivery by causing an abnormal presentation, by causing dysfunctional labor, or by obstructing the pelvis. A submucous leiomyoma in the lower uterine segment may entrap the placenta, necessitating manual removal. Indeed, furious postpartum hemorrhage can result if a submucous leiomyoma is disturbed at delivery or during exploration of the uterine cavity. Immediate hysterectomy may be necessary to control the bleeding.

**FIGURE 31.17.** When the placenta is implanted over a myoma in the uterine wall, the blood supply to the fetus may be tenuous.
Most patients with uterine leiomyomata have no difficulty conceiving and carry their pregnancies to term without complications. The only problem encountered may be a difficulty in estimating gestational age from uterine size because of the presence of leiomyomata.

Infertility

When asymptomatic leiomyomata are discovered in young women, the question of how these tumors relate to fertility and pregnancy usually arises. A number of factors may be responsible for infertility in a patient with uterine leiomyomata. Amenorrhea cycles may occur more commonly. There may be interference with sperm transport caused by distortion and an increased surface area within the uterine cavity, impingement of leiomyomata on the endocervical canal or interstitial portion of the fallopian tube, or interference with prostaglandin-induced uterine contractions, which are thought to enhance sperm migration. Endometrial changes (atrophy, ulceration, focal hyperplasia, and polyps), vascular alterations (venous congestion, venule ectasia, impaired blood flow), and enlargement of the uterine cavity may be present. Because uterine leiomyomata occur in later reproductive years, relatively greater difficulty accomplishing conception can be expected in older couples.

The finding of small leiomyomata in sterile women is not an indication for immediate myomectomy. Quite often, an infertile patient with uterine leiomyomata is found to have some other cause of infertility. Tubal inflammatory disease with associated pelvic adhesions is especially common in patients with uterine leiomyomata. Both marital partners should have a complete infertility investigation, and the leiomyomata should be disregarded for a while. The ultimate decision regarding disposal of the tumors depends on their size and location. Usually, small subserous leiomyomata are not considered a factor in infertility. Even if the woman fails to become pregnant, removal of small subserous leiomyomata is not justified. When leiomyomata are intramural or submucous and of significant size, they may well be factors causing the infertility, and a myomectomy may be rewarded with a subsequent pregnancy.

When an unsuspected asymptomatic leiomyomatous uterus of significant size is found in a woman who is planning to become pregnant in the future, great tact is required in describing the problem to the patient. The best surgical and obstetric judgment is needed to make a proper recommendation. Should the patient be discouraged from attempting pregnancy because of the risk of complications may be increased? Should a myomectomy be advised before pregnancy is attempted, with the knowledge that postmyomectomy adhesions may cause infertility? Such questions cannot be answered in a stereotypical manner. Each case presents its own problems, and the answers depend on the patient’s age, her general physical health, her pelvic findings, and, most important, her own desires. All must be considered before a final recommendation can be made. In general terms, under these circumstances, an attempt to become pregnant will be rewarded with a satisfactory outcome in most cases. If pregnancy does not occur or is not successful, a myomectomy may be advised, but one must keep in mind that all causes of infertility, spontaneous abortion, and other pregnancy-related problems must also be investigated in patients with uterine leiomyomata. Uterine leiomyomata represent an infrequent cause of infertility.

Eldar-Geva and colleagues performed a retrospective review of the treatment outcome of 106 assisted reproductive technology cycles in 88 patients with uterine myomata (subserosal, intramuscular without cavity distortion, and submucosal). Patients underwent controlled ovarian hyperstimulation and advanced reproductive technology. Not surprisingly, pregnancy (30.1%) and implantation (15.7%) rates were significantly lower in women with submucosal myomas; however, both pregnancy (16.4%) and implantation (6.4%) rates were also significantly lower in women with intramural myomas. In some advanced assisted reproductive technology patients, this information may influence the decision for surgical intervention regardless of menstrual pattern.

A review of information about infertility and uterine leiomyomata was published by Wallach and Vo, by Vercellini and colleagues, and by Verkauf.

Miscellaneous Signs and Symptoms

A variety of other unusual problems may be associated with uterine leiomyomata and may require treatment. Ascites and uterine inversion have already been mentioned. Sudden intraperitoneal hemorrhage can result from rupture of a dilated vein beneath the serosal surface of a subserous leiomyoma. Although leiomyomata are more often associated with iron-deficiency anemia from chronic uterine blood loss, occasionally patients present with polycythemia. Islands of extramedullary erythropoiesis have been found in leiomyomata. Arteriovenous shunts within the tumors have been found and may be etiologically important in polycythemia. If the tumor obstructs the ureters and causes back pressure on the renal parenchyma, erythropoiesis can be stimulated. Weiss and coworkers and other investigators have found marked erythropoietin activity within uterine leiomyomata. The polycythemia in these cases is cured by hysterectomy.

**CHOICE OF TREATMENT FOR UTERINE LEIOMYOMATA**

Six hundred fifty thousand hysterectomies are performed annually in the United States. Approximately 33% are performed with uterine leiomyomata as the primary indication. Nearly 35,000 myomectomies were reportedly performed annually in 2001, and it is believed that this number is increasing substantially. There are no statistics to indicate the number of hysteroscopic and laparoscopic myomectomies performed each year. Effective medical therapies are available to use as adjuncts to surgical treatment. Additional radiologic procedures may also be desirable in patients who may not be suitable surgical candidates. However, surgery is the preferred method of therapy in many circumstances.

Hysterectomy (abdominal, vaginal, and laparoscopic assisted) is discussed in Chapters 32A, 8, and C. In this chapter, surgical techniques that allow conservation of uterine function are discussed, as are medical therapies that can be used as adjuncts to surgical therapy.

**Medical Management of Uterine Leiomyomatosis**

Most (70%–80%) uterine leiomyomata are asymptomatic and are discovered incidentally during a routine pelvic examination. Such patients require an explanation and reassurance and reexamination at periodic intervals. An initial baseline pelvic US examination or MRI study may be indicated for comparison with future examinations and to evaluate the adnexa if the ovaries cannot be felt on pelvic examination. An experienced pelvic examiner can be fairly certain that a central pelvic mass is a leiomyomatous uterus. However, pelvic US examinations
and repeat pelvic examinations can add to the certainty of the diagnosis. If the diagnosis remains doubtful, however, visual-
ization of the mass, usually by laparoscopy, may be indicated. Patients with an asymptomatic central pelvic mass should be followed up with periodic pelvic examination only when the mass is benign, usually a leiomyomatous uterus. Otherwise, expectant management is not appropriate.

Effective treatment that is likely to result in the permanent cure of uterine leiomyomata is not yet available. Surgical excision by a variety of techniques remains the most effective and widely used method of management for patients with significant symptoms. Medical therapies are available as an adjunct to, or in place of, surgical treatment or as a temporary substitute for definitive surgical treatment. The role of radiologic intervention continues to expand with the development of more effective and less invasive techniques. Among these radiologic approaches is interstitial brachytherapy with radioactive sources (HIFU).

Hormonal therapy for the management of uterine leiomy-
omata has been the subject of investigation for many years. There is no support for the use of danazol or progesterin in the treatment of patients who have continued uterine bleeding. Cyclic administration of progesterin (e.g., medroxyprogesterone acetate) may decrease uterine bleeding and may result in a decrease in the size of the myoma. However, the success rate has been disappointing, and the therapy is variable and unpredictable.

According to the analyses by these investigators, 4% of pa-
tients had an increase in uterine volume ranging from 0.1% to 25%; 24% had decreases in uterine volume ranging from 0.1% to 25%; 51% had decreases in uterine volume ranging from 25.1% to 50%; and 21% had decreases in uterine volume greater than 50%. No factors were found to predict the degree of uterine shrinkage. There were negative correlations with body weight, pretreatment uterine volume, age, height, and serum estradiol concentration.

It is commonly thought that GnRH analogs affect leiomy-
omata by reducing vascularity and the individual cell size within the tumor. The biochemical changes in leiomyomata ob-
tained from women treated with the GnRH agonist leuprolide acetate depot for 3 months were studied by Friedman and colleagues.

The concentrations of amino acids contained in collagen were significantly greater in uterine myomata from treated pa-
tients than in myomata from placebo-treated controls. These investiga-
tors suggest that the reduction in uterine myoma vol-
ume associated with GnRH agonist therapy is due primarily to alterations in the extracellular matrix rather than to a reduction in the number of cells in the myoma. Di Lieto and colleagues evaluated the clinical response, immunohistochemical expression of the angiogenic growth factors βFGF, VEGF, and PDGF, and vascular changes in uterine leiomyomata from women treated with GnRH agonist. They demonstrated that the GnRH agonist therapy caused a reduction in the synthesis of the three considered growth factors in leiomyomatous cells (βFGF, VEGF, and PDGF). The total number of vessels and angiogenic vessels was also decreased after treatment with leuprolide acetate for 3 months.

Many studies have been performed to investigate the treatment of patients with uterine leiomyomata with GnRH analogs. GnRH analogs bind to GnRH receptors, resulting in a biphasic response: a temporary increase in the levels of go-

and steroid mRNAs. The total number of vessels and angiogenic vessels was also decreased after treatment with leuprolide acetate for 3 months.

Because uterine leiomyomas are hormone-sensitive neo-

plasms that can be stimulated to grow by estrogen, some clinicians have been reluctant to prescribe oral contraceptive pills in patients with leiomyomata. However, Friedman and Thomas and others have demonstrated conclusively that oral contraceptives containing 30 to 35 mg of ethinyl estradiol do not cause uterine leiomyomata to increase in size. Therefore, low-dose contraceptives can be used to manage menorrhagia in patients with uterine leiomyomata. Friedman and Thomas demonstrated a significant decrease in the mean duration of menstrual flow and a significant increase in hematocrit values in response to low-dose oral contraceptives in patients with uterine leiomyomata.

When myoma-associated menorrhagia is more severe, GnRH agonist and iron treatment may be more effective than oral contraceptives. In about two thirds of patients, GnRH agonist treatment induces amenorrhea. Most of the remain-
ing patients experience very light, irregular vaginal bleeding or spotting, according to Friedman. A combination of men-

strual suppression and iron therapy allows correction of iron deficien-
cy and iron-deficiency anemia during a 6-month treatment

period. Ovulatory menstrual cycles resume 3 to 24 weeks after the last depot GnRH agonist injection. Stovall and associates reported that a GnRH agonist plus iron was more effective than iron alone in treating anemia in women with uterine leiomyomata. With such effective treatment now available, there is rarely a need to use blood transfusions to cor-
rect anemia caused by myoma-associated menorrhagia. Only

lary bone density of 1% per month occurs in women treated for 6 months. Some of this bone loss may be permanent, but some is reversibly

and repeat pelvic examinations can add to the certainty of the diagnosis. If the diagnosis remains doubtful, however, visual-
ization of the mass, usually by laparoscopy, may be indicated. Patients with an asymptomatic central pelvic mass should be followed up with periodic pelvic examination only when the mass is benign, usually a leiomyomatous uterus. Otherwise, expectant management is not appropriate.

Effective treatment that is likely to result in the permanent cure of uterine leiomyomata is not yet available. will define its use more exactly. For example, it may be pos-
be remains to be seen. Additional information and experience
uterine leiomyomata is an emerging issue. How valuable it will
consistent with previously published studies, as well.

GnRH agonist treatment alone should not be given for pe-
riods longer than 6 months. A prolonged hypotensive state
is undesirable for a number of reasons, the most important be-
ing the loss of trabecular bone. If there are circumstances that
require that GnRH treatment be extended beyond 6 months, con-
ideration should be given to adding low-dose steroies after
3 months of GnRH therapy. The usual postmenopausal
estrogen-progestin replacement regimen can be prescribed
without interfering with the reduction in uterine volume an-
ticipated. Loss of trabecular bone may not be as great. By
adding estrogen-progestin replacement to GnRH agonist ther-
apy, the adverse effects of a prolonged hypotensive state
may be prevented, and treatment with GnRH agonists may be
prolonged. Friedman and colleagues treated 51 premenopausal
women with large, symptomatic myomata with leuprolide ac-
etate depot for 104 weeks. After the first 12 weeks, 0.75 mg of
estrioprate plus 0.7 mg of norethandrene were added on days
1 through 14 each month. Menorrhagia and other symptoms of
uterine leiomymata were controlled successfully. Hemoglobin
and hematocrit levels increased. Symptoms of hypotensive
(hot flashes, vaginal dryness) were decreased significantly. Bone
density decreased in the first 12 weeks, but only a small addi-
tional decrease occurred between weeks 12 and 52.

The use of GnRH analogs in the medical management of
uterine leiomyomata is an emerging issue. How valuable it will
be remains to be seen. Additional information and experience
will define its use more exactly. For example, it may be pos-
sible for patients with symptomatic uterine leiomyomata who
are approaching menopause to be managed medically through
menopause without having a hysterectomy. It may be possible
to improve fertility in some patients with uterine leiomyomata
by treatment with GnRH analogs without myomectomy. With
additional data, these and other questions can be answered.

Vaginal Myomectomy

In 1845, after performed the first successful vaginal myome-
tomy for a patient with a submucous pedunculated myoma.

When a submucous myoma becomes pedunculated within
the uterine cavity, there is a natural tendency for the uterus to
try to expel it through the endocervical canal. Eventually, the
cervix dilates. Even very large submucous pedunculated my-
omata can be delivered through a markedly dilated cervix.
Because adequate blood circulation through a long pedi-
cle is difficult to maintain, the myoma becomes necrotic and
infected (Figs. 31.3 and 31.6).

Patients report cramping lower abdominal pain; pressure
and heaviness in the pelvis; a thin, bloody, foul discharge; diffi-
culty with urination; and other symptoms. Episodes of profuse
vaginal hemorrhage can occur. Such large submucous myomata
may resemble a fetal head.

After satisfactory preoperative preparation, including
broad-spectrum antibiotics and correction of anemia, vagi-
nal myomectomy should be performed. Vercellini and colleagues
performed a multicenter, prospective, randomized, controlled study to as-
ter the treatment course showed that ab-
dominal hysterectomy was no longer indicated in 23 of 33
(47%) patients. No appreciable difference was found between
the groups in postoperative complications. These findings are
consistent with previously published studies, as well.

GnRH agonist treatment alone should not be given for pe-
riods longer than 6 months. A prolonged hypotensive state
is undesirable for a number of reasons, the most important be-
ing the loss of trabecular bone. If there are circumstances that
require that GnRH treatment be extended beyond 6 months, con-
ideration should be given to adding low-dose steroies after
3 months of GnRH therapy. The usual postmenopausal
estrogen-progestin replacement regimen can be prescribed
without interfering with the reduction in uterine volume an-
ticipated. Loss of trabecular bone may not be as great. By
adding estrogen-progestin replacement to GnRH agonist ther-
apy, the adverse effects of a prolonged hypotensive state
may be prevented, and treatment with GnRH agonists may be
prolonged. Friedman and colleagues treated 51 premenopausal
women with large, symptomatic myomata with leuprolide ac-
etate depot for 104 weeks. After the first 12 weeks, 0.75 mg of
estrioprate plus 0.7 mg of norethandrene were added on days
1 through 14 each month. Menorrhagia and other symptoms of
uterine leiomymata were controlled successfully. Hemoglobin
and hematocrit levels increased. Symptoms of hypotensive
(hot flashes, vaginal dryness) were decreased significantly. Bone
density decreased in the first 12 weeks, but only a small addi-
tional decrease occurred between weeks 12 and 52.

The use of GnRH analogs in the medical management of
uterine leiomyomata is an emerging issue. How valuable it will
be remains to be seen. Additional information and experience
will define its use more exactly. For example, it may be pos-
sible for patients with symptomatic uterine leiomyomata who
are approaching menopause to be managed medically through
menopause without having a hysterectomy. It may be possible
to improve fertility in some patients with uterine leiomyomata
by treatment with GnRH analogs without myomectomy. With
additional data, these and other questions can be answered.

Vaginal Myomectomy

In 1845, after performed the first successful vaginal myome-
tomy for a patient with a submucous pedunculated myoma.

When a submucous myoma becomes pedunculated within
the uterine cavity, there is a natural tendency for the uterus to
try to expel it through the endocervical canal. Eventually, the
cervix dilates. Even very large submucous pedunculated my-
omata can be delivered through a markedly dilated cervix.
Because adequate blood circulation through a long pedi-
cle is difficult to maintain, the myoma becomes necrotic and
infected (Figs. 31.3 and 31.6).
FIGURE 31.18. Transvaginal removal of a pedunculated submucous myoma that presents itself at the external cervical os. A: Sagittal view of uterus, demonstrating the location of the myoma originating on the posterior wall of the fundus just above the cervix. B: A transverse incision made anteriorly through the vaginal mucosa at the cervicovaginal junction. C: After the bladder is advanced bluntly, the cervix is incised anteriorly in the midline. D: The myoma and its pedicle are exposed, and the pedicle is suture ligated for hemostasis. E: After the myoma is excised, the cervix is reapproximated with interrupted 0-0 absorbable, nonreactive sutures. F: The overlying vaginal mucosa is sutured with interrupted 3-0 absorbable sutures.
Hysteroscopic Resection of Submucous Myomata

Hysteroscopic resection of submucous myomata was first reported by Neuworth and Amin in 1976 and was reported again by Neuworth in 1978. A uterine resectorcope was used. In 1981, Goldfash and associates used "photocoagulation" of the endometrium with the neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser to treat patients with menorrhagia. Many subsequent reports by Derman and associates, Donnez and colleagues, Goldenberg and coworkers, Corson, Indman, Halle, Baggish and associates, Wamsteker and colleagues, and others have confirmed the advantages of hysteroscopic treatment of menorrhagia in women with and without submucous leiomyomata. The menorrhagia associated with submucous myomata can sometimes be managed with oral contraceptives as long as the bleeding is not too severe. A favorable response can also be expected with GnRH analogs, but the menorrhagia usually reappears when the treatment is discontinued. Friedman has reported on cases of severe menorrhagia with resultant anemia requiring transfusions in women with submucous leiomyomata treated with leuprolide acetate. Both oral contraceptives and GnRH analogs are counterproductive in women who are seeking relief from infertility. The uterine cavity can be curedtted several times, but the benefit of this procedure is temporary at best.

When hysteroscopic resection of submucous myomata is performed, menorrhagia can be controlled in more than 90% of patients. According to Indman, the mean number of pads used during the heaviest day of menses decreased from 17.8 before treatment to 6.8 after treatment in women undergoing myomectomy only, and from 21.4 to 1.7 pads per day in women whose treatment also included endometrial ablation. Dymenorrhea was also reduced significantly; Forty-eight of 51 women (94%) with uterine leiomyomata who were seen with menorrhagia were able to avoid major gynecologic surgery for up to 3 years of follow-up. In the report of 156 patients by Derman and associates, 91.3% of patients received 2 months of intramuscular GnRH analog therapy. Perioperative results were recorded followed by a 24-month follow-up period when recurrent symptoms, myoma recurrence, and the need for repeat surgery were collected. Surgical time for the pretreated group was significantly longer than that of the untreated patients. Although GnRH analog pretreatment may be beneficial in improving anemia in some patients, Campo and colleagues did not demonstrate any improvement in short- or long-term outcomes.

When submucous myomata extend deeply into the myometrium, it may not be possible to perform a complete resection for obvious technical reasons. However, it should be possible to remove most irregularities in the uterine cavity and to restore the contour of the cavity to almost normal in most cases. According to Wamsteker and colleagues, hysteroscopic resection of submucous myomata with more than 50% intramural extension should be performed only in selected cases. Repeat procedures may be needed in cases of initial incomplete resection.

To avoid the possibility of inadvertent uterine perforation or to allow its prompt diagnosis if it occurs, hysteroscopic resection is usually performed under laparoscopic guidance. However, as reported by Sullivan and cowokers, laparoscopy may be insufficient to evaluate fully the possible sequelae of uterine perforation. Laparotomy may be necessary to assess the pelvic viscera fully. Lettieri and Kramer were able to safely substitute intraoperative transabdominal ultrasonographic guidance for laparoscopy. In their opinion, operative hysteroscopy with intraoperative ultrasonographic guidance provide an accurate and precise method to monitor intrauterine surgery, and it can be used to enhance the performance of hysteroscopic myomectomy and endometrial resection. Intraperitoneal US guidance provided sufficient details of the relation between the hysteroscope and the myoma and uterine walls to gauge the depth of resection and prevent uterine perforation.

The success and safety of the procedure depend on the experience and skill of the operating surgeon. During hysteroscopic resection, vascular spaces are opened in the endometrium and myometrium. Large volumes of fluid are instilled into the uterine cavity. Fluid balance must be monitored carefully.
by the surgeon and the anesthesiologist to avoid fluid overload.

All tissue must be submitted for pathologic examination. Among 92 patients undergoing hysteroscopic resection in the series reported by Corson and Brooks, two cases of leiomyosarcoma were diagnosed. Leiomyosarcoma is said to be more common in submucous leiomyomata than in intramural or subserous leiomyomata.

As time passes after hysteroscopic resection of submucous myomata, the possibility of recurrent problems increases because of regrowth of myomata. However, this is no more likely to occur than it is with standard abdominal myomectomy. The experience of many investigators has demonstrated that hysteroscopic management of menorrhagia in patients with submucous leiomyomata is a reasonable alternative to classic surgical hysterectomy or myomectomy. Hysteroscopic resection of a small submucous myoma is illustrated in Figure 31.19. Details of the indications, technique, complications, and results of hysteroscopic resection are also provided in Chapter 18.

**Laparoscopic Myomectomy**

When abdominal myomectomy is indicated, the laparoscopic approach can be offered as an alternative to the standard "open" abdominal myomectomy in selected patients. However, this procedure is appropriate in very few patients for several reasons. First, myomectomy is indicated in infertility patients only if there is significant distortion of the uterine wall or endometrial cavity or if there is obstruction or distortion of the fallopian tubes by myomata. Second, myomectomy is indicated in patients who wish to retain their uterus only if the myomata are significantly symptomatic. In both circumstances, the myomata are likely to be multiple and large, and laparoscopic myomectomy should only be considered if the uterine repair is comparable, or superior, to the uterine closure of an abdominal myomectomy.

There are limitations to laparoscopic myomectomy, and these are mostly technical. Myomata in certain locations are difficult to remove. When myomata are large or multiple, or both, operative time and blood loss may be unacceptable. When myomata are embedded deeply in the myometrium, proper repair of the uterine wall may be difficult or impossible, and uterine rupture may occur in a subsequent pregnancy. Retrieval of the resected myomata from the peritoneal cavity can also pose problems. Large myomata must be morcellated into smaller pieces for retrieval. Retrieval through the posterior vaginal fornix or through the abdominal wall requires separate additional incisions, which somewhat defeats the idea of a minimally invasive procedure. Only very skillful laparoscopists should attempt extensive myomectomy through the laparoscope. According to Mais and colleagues, operation time for myomectomy was significantly longer for laparoscopy than for laparotomy when more than four myomata had to be removed and the largest myoma was greater than 6 cm. Dubuisson and coworkers also reinforce the difficulty of the technique by reporting conversion to laparotomy at a rate of 7.5% (93.7% due to operative difficulties) and a complication rate of 3.8%. These authors echo similar intraoperative concerns: (i) the location of the hysterotomy, (ii) the type of hysterotomy, (iii) the uterine suture, and (iv) removal of the myoma. In addition, they report that one third of patients developed adhesions at the uterine scar.

Several technical innovations have been developed to facilitate laparoscopic myomectomy. Electrosurgical and laser techniques are used in ingenious ways. Special traction devices, including corkscrews of various sizes, are required. The operator must be able to provide hemostasis using monopolar...
cutting current and bipolar forces. The role of the Harmonic Scalpel has also expanded for clean dissection and the potential for less blood loss. Aquadissection can be used to establish planes for dissection between myoma and the surrounding myometrium. Special techniques of approximating myometrium with larger curved needles are used with either intracorporeal or extracorporeal suturing, depending on the surgeon’s expertise. Knowledge of available laparoscopic instrumentation is essential to maximize surgical outcome. Autologous blood donation with intraoperative transfusion when necessary reduces the risk of homologous transfusion. Larger myoma can be removed vaginally with morcellation through a subvaginal or suprapubic incision. In cases of myoma of extreme size, Pelosi and colleagues proposed the use of hand-assisted laparoscopy to avoid a laparotomy. This technique allows the insertion of a hand into the abdomen to assist in dissection. This is accomplished through a glove-sized incision at laparoscopy while preserving the peritoneum. A cylindrical serrated morcellator can also be used to convert smaller myoma to small strips of tissue, which can then be removed abdominally through the trocar sleeve or through a mini-laparotomy incision. Retrieval of all bits and pieces of myoma tissue from the peritoneal cavity can be a tedious challenge. Hirai and colleagues from Japan described a microwave coagulator and electromechanical tissue borer to minimize invasion of the myometrium and abdominal wall. The proposed advantage of this technique is that by morcellating the tissue before removal from the uterus, less myometrial trauma is sustained. Horizontal and perpendicular blades at the tip rotate and hollow out the myoma, allowing large myomas to be removed through a small uterine incision. The authors described the use in five patients with four of five having myomas weighing less than 170 g. The blood loss and operating time were not significantly different with this unconventional abdominal procedure. Long-term data regarding myometrial strength over time and pregnancy outcomes are not yet available. More experience with this procedure is necessary to determine its role in myomectomy.

Another technical innovation called myolysis has been described by Goldfarb and is based on earlier experience in Europe. Either Nd:YAG laser or bipolar needles are used laparoscopically to penetrate the myoma at multiple sites at a 90°-degree angle to the uterus. In response to treatment, the myoma ultimately atrophies. The technique is based on the theory that the coagulating effects of lasers or the bipolar needle can necrose myometrial stroma, denature protein, destroy vasculature, and result in substantial shrinkage of myomas when deprived of their blood supply. Goldfarb advised treatment with GnRH agonists before surgery. The ideal candidates for myolysis are perimenopausal women who have symptomatic leiomyomas measuring 3 to 10 cm or uterine size less than 14 weeks’ gestation. Goldfarb combines myolysis with endometrial ablation in patients with symptomatic myomas with persistent uterine bleeding. The addition of myolysis to endometrial ablation increased the rate of postoperative amenorrhea from 36.5% to 57% and second procedures, including hysterectomy, were reduced from 38% to 12.5%. Goldfarb described significant adhesions at follow-up laparoscopy in patients treated with the Nd:YAG laser technique because of excessive serosal injury from multiple punctures. A circumferential technique was later developed to destroy vasculature instead of the myoma-tous tissue. The devascularized myoma becomes cyanotic, loses viability, and fibrosis. Phillips performed an additional diagnostic laparoscopy to evaluate adhesions associated with previously performed myolysis. Mean adhesion score was only 1.15 ± 0.6 on a scale of 10.

Zreik and colleagues at Yale University modified the myolysis procedure to include cryoetechnology to “freeze” uterine leiomyomas. The technique, cryomyolysis, was described in a prospective pilot study of 14 patients. All patients were pre-treated with GnRH agonist therapy for 3 months. Thirteen of the 14 endoscopic procedures were performed by laparoscopy and the remaining one by hysteroscopic visualization. Cryo-probe placement was achieved and freezing was performed at an internal probe temperature of –180°C until the ice ball encompassed the entire fibroid or reached maximum size. A thaw cycle was then performed, followed by one more freeze-thaw cycle. A hollow track remained within the frozen myoma after removal of the cryoprobes. All myomas were resected uterine and myoma size. The uterus enlarged by 22% after discontinuation of the GnRH therapy. Myoma volume decreased by 6% over 4 months postoperatively, with some patients having a decrease of more than 50%. Four of six women who underwent second-look office laparoscopy had adhesion formation at freezing sites. The authors attributed risk and severity of adhesion formation to the number of punctures with the cryoprobe. The role of this therapy in conservative treatment of uterine myomatla remains to be defined.

Hysteroscopic myomectomy and endometrial resection can be performed simultaneously if submucous myoma are present. In more than 300 myolysis procedures, the authors reported minimal morbidity with a 30% to 50% reduction in myoma size beyond the reduction achieved with GnRH agonist treatment. No regrowth occurred after several years of follow-up, even after estrogen replacement therapy. Bipolar coagulation myolysis may be less likely to cause damage to the uterine serosa and less likely to cause adhesion formation postoperatively. According to Goldfarb, “As a same-day procedure, myoma coagulation appears to be an extremely safe alternative to hysterectomy, allowing the patient to avoid major surgery and its subsequent recovery time, while providing an alternative solution for patients with symptomatic leiomyomas.”

Nizhat and coworkers used a combination of laparoscopy and minilaparotomy to perform myomectomy in 57 women with uteri at 8 to 26 weeks in gestational size. In this laparoscopically assisted myomectomy procedure, the myomata were removed and the uterus repaired through the minilaparotomy incision. It was technically less difficult than laparoscopic myomectomy and allowed better closure of the uterine defects. This technique may be preferable in the case of large myomas in that it is easier to achieve conventional multilayer suturing and easier to extract myomas.

A significant disadvantage of myomectomy is the risk of postoperative pelvic adhesions. The adhesions may adversely affect fertility, give rise to pain, and increase the risk of ectopic pregnancy or even intestinal obstruction. Several studies have demonstrated that the risk of postoperative adhesions decreases when a laparoscopic approach is used in lieu of an open abdominal approach. Literature review demonstrates that the average rate of postoperative adhesions after laparoscopic myomectomy is 41% versus more than 90% after a myomectomy via laparotomy. Dubuisson and colleagues assessed adhesion formation after laparoscopic myomectomy in a prospective manner. Forty-five patients underwent a second look after laparoscopic myomectomy. Seventy-two sites were evaluated. The overall rate of postoperative adhesions was 35.6% per patient. The rate of adhesions per myomectomy site was 16.7%. The rate of adhesions on the adnexa was 24.4%. Associations with the occurrence of adhesions included an additional surgical procedure carried out at the same time, the existence of adhesions before the operation, and posterior location of the myoma. Several factors may increase the risk of...
postoperative adhesion formation owing to a laparoscopic myomectomy. Recognition of these factors may be helpful in limiting adhesion formation.

The use of uterine suture appears to increase the risk of uterine adhesions. In some studies, the frequency doubled after suturing. The suture induces local tissue ischemia with inflammatory changes, which slow the healing process and increase the formation of adhesions. Contradictory data have been published regarding adhesion formation and the use of bipolar coagulation during a laparoscopic procedure.

The location of the myoma also affects adhesion formation. Adhesions are more likely to form when the myomectomy site is located on the posterior uterine wall. During laparoscopy, a uterine incision must be made over each individual myoma. With laparotomy, a single anterior uterine incision may be used for myomectomy, even when posterior myomas are present.

The prior existence of pelvic adhesions significantly increases the risk of postoperative adnexal adhesions, but has not been shown to affect adhesions at the myomectomy site. Two prospective, randomized controlled studies have evaluated the efficacy of adhesion barriers during laparoscopic myomectomy, and both found intervention to be beneficial. Mais and colleagues evaluated the efficacy of oxidized regenerated cellulose, Interceed, on adhesion formation in a prospective, randomized study of 50 women after laparoscopic myomectomy. Interceed was placed over all incisions and suture material with a 1 cm margin, and the barrier was then moistened with saline. During the second-look laparoscopy, 60% of the Interceed group was free of adhesions compared with only 12% of patients in the control group. Interceed appeared to substantially reduce, but not prevent, adhesions after laparoscopic myomectomy. Pellicano and collaborators showed that hyaluronic acid gel reduced adhesions after laparoscopic myomectomy in a prospective randomized study of 36 infertile women. During second look, 72% of patients were adhesion-free, with hyaluronic acid gel treatment versus an adhesion-free barrier such as Interceed. While these studies suggest that laparoscopic myomectomy may be a viable option for women with leiomyomas and infertility. The best prognosis is for young women with otherwise unexplained infertility and myomas that distort the endometrial cavity. Pregnancy rates and spontaneous abortion rates are comparable to abdominal myomectomy. Data is present.

Multiple published studies (Seracchioli et al., Bullietti et al., Stringer et al., and Campo et al.) suggest that laparoscopic myomectomy may be a viable option for women with leiomyomas and infertility. The best prognosis is for young women with otherwise unexplained infertility and myomas that distort the endometrial cavity. Pregnancy rates and spontaneous abortion rates are comparable to abdominal myomectomy. Data is present.

The preoperative hysterosalpingogram is important in predicting fertility. When performed at the same time multiple myomectomy is done. Indeed, tubal reconstruction may not always be necessary to establish tubal patency. In a report by LeV-Toaf and associates, nonfilling of the fallopian tubes was present on the preoperative hysterosalpingogram unilaterally in two patients and bilaterally in another two. In all four patients, tubal patency was shown after myomectomy. In the experience of these authors, hysterosalpingography before myomectomy can assist the gynecologic surgeon in planning the surgical approach by showing the presence, size, and location of submucosal leiomyoma and concomitant tubal disease.

Imaging modalities such as transabdominal, transvaginal US and MRI play an important role in the management of patients with leiomyomatosis, especially those patients who are being prepared for myomectomy. As explained by Mayer and Shipilov, US is the preferred method for screening and initial evaluation of the pelvis. In many cases, it is the only imaging study necessary. There are special cases for which US cannot provide all the diagnostic information required. In a study by Schwartz and colleagues, US results were inconclusive in 20% of cases and did not yield a definitive diagnosis in 59% of cases. MRI was more definitive in all cases (Fig. 31.20). The preoperative diagnosis of submucous leiomyoma by MRI may allow hysterectomy without delay and avoid abdominal myomectomy in some cases. Differentiation between uterine leiomyoma and adenomyosis is more accurate with MRI and thus avoids the need for laparoscopy or laparotomy in some cases (Fig. 31.21). MRI studies can differentiate between uterine leiomyomas, diffuse and localized adenomyosis, and diffuse leiomyomatosis. MRI is the most accurate imaging technique for the detection and localization of leiomyomas (Fig. 31.22). Hricak and coworkers were able to identify accurately by MRI all subserosal (9 of 9), all intramural (23 of 30), and 9 of 11 submucosal leiomyomas. Leiomymatosis as small as 0.3 cm can be detected. Various degrees of cellularity, degeneration, necrosis, and calcification can be identified by MRI, and abnormalities can be suspected. MRI provides imaging planes that are not available on transabdominal or transvaginal US, a feature that permits better visualization of the more lateral and posterior uterus.

Abdominal Myomectomy

The first successful abdominal myomectomy was performed in the United States by the Attle brothers, Washington and John, in 1844.

The first abdominal multiple myomectomy was performed by W. Alexander of Liverpool in 1893. In the early part of the 20th century, the technique of abdominal myomectomy was refined by many notable gynecologic surgeons, including Kelly, Cullen, Mayo, Rubin, Bonney, and others. The procedure did not gain popularity until the middle of the 20th century. The incidence of postoperative intestinal obstruction from adhesions, was considered to be too high. Advances in surgical techniques to control intraoperative bleeding during myomectomy, along with advances in anesthesia, blood transfusion therapy, and GnRH analogs, have made myomectomy a safe alternative to hysterectomy in women with symptomatic leiomyomatosis. The number of myomectomies performed in the United States is decreasing.

Because myomectomy is rarely an emergency, time is available to prepare the patient for surgery. It is important that she be properly informed of the reasons myomectomy has been recommended. She should understand the nature of the procedure so she can know what to expect and what is expected of her. It is especially important that she be informed of the possibility that intraoperative findings may contraindicate myomectomy and that require that hysterectomy be performed instead. For example, myomectomy may not be technically feasible if diffuse leiomyomatosis is found. The technical challenge of removing a large cervical myoma can also preclude myomectomy.

A preoperative hysterosalpingogram may indicate distorsion of the fallopian tubes or uterine cavity, findings that are important in planning the technique of myomectomy. An assessment of fallopian tube patency is helpful in predicting fertility. If the tubes are occluded, however, myomectomy is not necessarily contraindicated. According to Seoud and associates, myomectomy does not interfere with in vitro fertilization performance in relation to overall and ongoing pregnancy rates. The patient whose tubes are occluded should understand that fertility may not be established by myomectomy, and assisted reproductive technologies may still be required after myomectomy.

Tubal reconstruction procedures are uniformly unrewarding when performed at the same time multiple myomectomy is done. Indeed, tubal reconstruction may not always be necessary to establish tubal patency. In a report by LeV-Toaf and associates, nonfilling of the fallopian tubes was present on the preoperative hysterosalpingogram unilaterally in two patients and bilaterally in another two. In all four patients, tubal patency was shown after myomectomy. In the experience of these authors, hysterosalpingography before myomectomy can assist the gynecologic surgeon in planning the surgical approach by showing the presence, size, and location of submucosal leiomyoma and concomitant tubal disease.

...
areas of the pelvis. MRI is the most accurate method for preoperative localization of leiomyomata and surgical planning for myomectomy. Given the greater costs of MRI, it should be used judiciously. However, as noted by Mayer and Shipilov, the effective cost differential between MRI and US is decreasing.

As discussed by Winkind and Thompson, one of the most serious risks of surgical bleeding during myomectomy is the risk associated with homologous blood transfusion. The first rule in reducing or eliminating the need for transfusion is to bring the patient to the operating room with the highest possible hemoglobin and hematocrit level. About 30% of myomectomy patients have associated menorrhagia. These small repeated menstrual hemorrhages deplete the body’s iron stores over time and eventually result in iron-deficiency anemia of various degrees of severity. Patients scheduled for myomectomy benefit from oral iron supplementation. In a study by Thompson, the liberal use of oral iron therapy preoperatively was shown to decrease the number of blood transfusions on the gynecologic surgical service at the Johns Hopkins Hospital. A blood
transfusion is seldom necessary to correct iron-deficiency anemia in a gynecologic patient. Blood transfusions should generally be reserved for patients with hypovolemic shock or agranulocytosis, as anemia is most often corrected by oral iron supplementation.

Occasionally, patients with a myomatous uterus have iron-deficiency anemia. Iron deficiency in these circumstances is often caused by heavy or too continuous menstrual bleeding that is too heavy, or too continuous to allow a response to oral iron therapy. In this situation, it may be beneficial to induce amenorrhea with hormonal therapy to allow the anemia to be corrected more expeditiously. Amenorrhea can be induced with progesterone, such as medroxyprogesterone acetate, with danazol, or with GnRH agonists. Several studies have demonstrated that gonadotropin releasing hormone (GnRH) analogs decrease menstrual blood loss in patients with leiomyomata treated preoperatively for 8 to 24 weeks with GnRH analogs compared with matched control groups. Friedman and colleagues also found a significant increase in serum iron and total iron-binding capacity in a study group treated with the GnRH agonist leuprolide acetate. In some patients, oral iron was also given. In an evaluation of 265 patients, GnRH agonists plus iron were more effective than iron alone in treating the anemia of patients with uterine leiomyomata, according to Stovall and coworkers. In a double-blind, placebo-controlled, multicenter study, Friedman and associates reported a resolution of menorrhagia in 97% of uterine leiomyomata patients treated with GnRH agonists.

Preoperative treatment with GnRH analogs can actually reduce the operative blood loss during myomectomy, according to studies by Friedman and colleagues, Andrekoy and coworkers, Moghissi, and others. In a prospective, randomized study of 30 patients undergoing hysterectomy for symptomatic leiomyomata, Stovall and colleagues found a significant decrease in operative blood loss and intraoperative blood transfusions in patients treated with GnRH agonists who received 2 months of leuprolide acetate treatment preoperatively and matched control subjects. An elegant study by Friedman and associates demonstrated a significant decrease in operative blood loss during myomectomy between patients with pretreatment uterine volumes greater than 600 cm³ who were treated with depot leuprolide acetate for 12 weeks preoperatively and a matched control group. However, there was no significant difference in blood loss between the two groups when patients with smaller uterine volumes (150 to 600 cm³) were included in the analysis. It has been suggested that the hypotensive environment caused by GnRH analog therapy reduces the postoperative blood transfusion requirements of the uterus. How- ever, even in patients not treated with GnRH agonists, blood flow has been observed to be lower in myoma and adjacent tissue.

Intraoperative autotransfusion and normovolemic hemodilution are also discussed. These techniques of reducing or avoiding the risk of homologous blood transfusion are discussed in detail by Wiskind and Thompson.

Perioperative antimicrobial prophylaxis is indicated with myomectomy. It is preferable to perform the operation in the follicular phase of the menstrual cycle. This avoids the chance of encountering an unknown or unsuspected pregnancy and reduces the problems encountered when a fresh corpus luteum is inadvertently traumatized.

After induction of anesthesia, the patient is placed in Allen universal position, the bladder is emptied, and a careful pelvic examination, including a rectovaginal-abdominal bimanual examination, is performed under anesthesia. Preparation and draping are done to allow access to the vagina and cervix in case it is necessary to place an instrument through the cervix and into the endometrial cavity during the procedure. Cervical dilatation should be done to facilitate postoperative drainage from the endometrial cavity, especially for cases in which the endometrial cavity has been entered during the myomectomy.

Many of the general principles of pelvic surgery are applicable to myomectomy. Perhaps the most important of these is optimum exposure at the operative site. This is accomplished primarily by an incision that is long enough to be wide enough to allow proper retraction, good lighting, and able assistants. Although a Pfannenstiel incision is considered adequate for myomectomy on a small uterus, we prefer the Maylard incision for larger uteri, even those that exceed a size equivalent to a 12-week pregnancy. A Maylard incision provides excellent exposure throughout the pelvis. Because it is a transverse incision, it is stronger and provides better cosmesis than a vertical midline incision. A Bockwoldt retractor optimizes exposure of the operative site. A Pfannenstiel incision can be used for removal of a small solitary myoma.

The importance of adequate exposure cannot be overemphasized. With proper exposure, operative time can be shortened and surgical bleeding can be more easily identified and controlled. Limited exposure may lengthen operative time, increase the risk of inadvertent injury to other pelvic structures, and force abandonment of a myomectomy in favor of a hysterectomy in especially difficult cases.

After the peritoneal cavity is entered, the abdomen is explored as usual. Adhesions in the pelvis must be carefully released or excised so that the intestines can be placed in the upper abdomen and held there with packs. The operation is performed according to microsurgical techniques and principles. For example, the laparotomy packs that are used to hold the intestines in the upper abdomen are placed in plastic bags to reduce the microscopic trauma to peritoneal surfaces caused by regular laparotomy packs. It is important to keep the myomatomy packs available. Several laparotomy packs in plastic bags can be used to fill the cul-de-sac, thus elevating and stabilizing the uterus for easier access. Visualization of the operative site can be improved by the liberal use of suction to remove blood from the field. Suction should be used instead of sponges because it allows for a more accurate determination of blood loss and is less traumatic to tissues.

The operative field is kept moist and free of clots with a solution of lactated Ringer solution containing heparin. Very fine instruments and sutures are used when possible, and tissue is handled gently to avoid unnecessary trauma to serosal surfaces. Traumatic instrumentation (e.g., uterine elevators with teeth, Kocher clamps, or any instrument on the uterine serosa) must be avoided. Sutures on serosal surfaces should be of a fine nonreactive material. Running suture lines are preferable to avoid extra knot volume, which may contribute to adhesion formation. If pelvic adhesions develop after myomectomy, future fertility may be adversely affected. Performing the operation in a way that minimizes adhesion formation greatly improves the possibility of a successful result.

At this point in the operative procedure, one should pause and evaluate the size, location, and number of myomata present. Special note should be made of their proximity to the endocervical canal, uterine vessels, and fallopian tubes. One must decide if myomectomy is still feasible, how the leiomyomata will be removed (and in what sequence), and how the uterus will be reconstructed.

The conservation of uterine function with myomectomy requires control of bleeding. Several techniques of controlling bleeding are used. A uterine draping is used to allow access to the vagina and cervix in case it is necessary to place an instrument through the cervix and into the endometrial cavity during the procedure. The importance of adequate exposure cannot be overemphasized. With proper exposure, operative time can be shortened and surgical bleeding can be more easily identified and controlled. Limited exposure may lengthen operative time, increase the risk of inadvertent injury to other pelvic structures, and force abandonment of a myomectomy in favor of a hysterectomy in especially difficult cases.

A uterine draping is used to allow access to the vagina and cervix in case it is necessary to place an instrument through the cervix and into the endometrial cavity during the procedure.
Removing multiple myomata embedded deeply in a vascular myometrium can result in considerable blood loss. Proper application of special techniques to limit blood loss can allow multiple myomectomies even in uteri up to 20 weeks' pregnancy size if satisfactory reconstruction is possible.

Controlled hypotensive anesthesia has become a useful adjunct to decrease surgical bleeding in selected patients. The method of operative field bleeding with hypotensive anesthesia is the reduction of venous tone. This can be accomplished by specific vasoconstricting agents—such as nitroglycerin or sodium nitroprusside, epidual or spinal anesthesia, some inhalation anesthetic agents, and ganglionic blockade—tightly and uniformly around the bowel loops and mesentery encircling the cervix and occluding the uterine vessels during myomectomy. Rubber-shod clamps applied to the broad ligament, myomectomy. Rubber-shod clamps applied to the broad ligament, and the two ends of the tube are then threaded through the holes in the broad ligament. The effect usually lasts for 30 minutes.

As the tourniquets are being placed, controlled hypotension is induced by the anesthesiologist. Before the tourniquets are tightened, the location of the uterine arterial blood flow is identified with a sterile Doptone. When everything is in readiness and the plan of operation has been selected by the surgical team, the tourniquets are snugly tightened and tightened progressively until the uterine arterial flow is no longer audible with the Doppler (Fig. 31.23B). It is very important that the arterial blood flow be occluded. If the venous flow is occluded while the arterial flow remains intact, blood loss could actually be increased with the tourniquets. The mean blood pressure should be reduced to the target hypotensive level (about 60 mm Hg) before the tourniquets are tightened. The higher the blood pressure, the tighter the tourniquets must be to occlude the uterine circulation.

With the combination of properly applied tourniquets and controlled hypotensive anesthesia, the entire circulation to the uterus can be occluded. The myometrium can then be performed in a bloodless field, greatly facilitating complete removal of all tumors and blood pressure. It is critical to control hemorrhage and provide a bloodless operative field. One of the earliest methods was simply to have an assistant grasp the broad ligaments firmly with each hand during myomectomy to impede venous drainage from the lower extremities and pelvis by gravity and may further reduce the blood pressure at the operative site.

Induced hypotension is contraindicated in patients with cerebrovascular disease, myocardial ischemia, peripheral vascular disease, severe renal or hepatic disease, and hypovolemia. None of these contraindications is seen very often in myomectomy patients. An anesthesiologist experienced with the technique is an essential requirement. The decision to use hypotension should be made jointly by the surgeon and the anesthesiologist. It is essential that the blood pressure be returned to normal before closure of the incision to ensure that adequate surgical hemostasis has been established.

Early proponents of myomectomy focused on methods to temporarily occlude uterine blood flow to control hemorrhage and provide a bloodless operative field. One of the earliest methods was simply to have an assistant grasp the broad ligaments firmly with each hand during myomectomy to impede blood flow through the uterine vessels. In the 1920s, Victor Bonney introduced a specially designed clamp that was placed around the uterine vessels and the round ligaments. The ovarian vessels were occluded with ring forceps. Using this technique, he was able on one occasion to remove more than 200 myomata from a single uterus. Rubin, in 1938, was the first to use an elastic rubber tourniquet through the broad ligament, encircling the cervix and occluding the uterine vessels during myomectomy. Rubber-shod clamps applied to the broad ligaments have also been used to occlude the uterine vessels and control bleeding.

Gynecologic surgeons do not often have the opportunity to use tourniquets to control bleeding; however, a myometrium is particularly suited to their use. We prefer to use tourniquets fashioned in the manner of a Rumel-type tourniquet, which is used by vascular, thoracic, and trauma surgeons to occlude the uterine vessels. A 3-French pediatric feeding tube is looped around the upper cervix through the holes in the broad ligament, and the two ends of the tube are then threaded through a 4-inch length of 33-French Malecot catheter and held with a clamp. A loop tourniquet can then be placed around each intramural or intravenous tumor through the same holes in the broad ligaments (Fig. 31.23A).

As the tourniquets are being placed, controlled hypotension is induced by the anesthesiologist staff. Before the tourniquets are tightened, the location of the uterine arterial blood flow is identified with a sterile Doptone. When everything is in readiness and the plan of operation has been selected by the surgical team, the tourniquets are snugly tightened and tightened progressively until the uterine arterial flow is no longer audible with the Doppler (Fig. 31.23B). It is very important that the arterial blood flow be occluded. If the venous flow is occluded while the arterial flow remains intact, blood loss could actually be increased with the tourniquets. The mean blood pressure should be reduced to the target hypotensive level (about 60 mm Hg) before the tourniquets are tightened. The higher the blood pressure, the tighter the tourniquets must be to occlude the uterine circulation.

With the combination of properly applied tourniquets and controlled hypotensive anesthesia, the entire circulation to the uterus can be occluded. The myometrium can then be performed in a bloodless field, greatly facilitating complete removal of all tumors and blood pressure. It is critical to control hemorrhage and provide a bloodless operative field. One of the earliest methods was simply to have an assistant grasp the broad ligaments firmly with each hand during myomectomy to impede venous drainage from the lower extremities and pelvis by gravity and may further reduce the blood pressure at the operative site.

Induced hypotension is contraindicated in patients with cerebrovascular disease, myocardial ischemia, peripheral vascular disease, severe renal or hepatic disease, and hypovolemia. None of these contraindications is seen very often in myomectomy patients. An anesthesiologist experienced with the technique is an essential requirement. The decision to use hypotension should be made jointly by the surgeon and the anesthesiologist. It is essential that the blood pressure be returned to normal before closure of the incision to ensure that adequate surgical hemostasis has been established.

Early proponents of myomectomy focused on methods to temporarily occlude uterine blood flow to control hemorrhage and provide a bloodless operative field. One of the earliest methods was simply to have an assistant grasp the broad ligaments firmly with each hand during myomectomy to impede blood flow through the uterine vessels. In the 1920s, Victor Bonney introduced a specially designed clamp that was placed around the uterine vessels and the round ligaments. The ovarian vessels were occluded with ring forceps. Using this technique, he was able on one occasion to remove more than 200 myomata from a single uterus. Rubin, in 1938, was the first to use an elastic rubber tourniquet through the broad ligament, encircling the cervix and occluding the uterine vessels during myomectomy. Rubber-shod clamps applied to the broad ligaments have also been used to occlude the uterine vessels and control bleeding.

Gynecologic surgeons do not often have the opportunity to use tourniquets to control bleeding; however, a myometrium is particularly suited to their use. We prefer to use tourniquets fashioned in the manner of a Rumel-type tourniquet, which is used by vascular, thoracic, and trauma surgeons to occlude major vessels. Initially, a small hole is made in an avascular space in the broad ligament on either side of the uterine isthmus just lateral to the uterine vessels. A 3-French pediatric feeding tube is looped around the upper cervix through the holes in the broad ligament, and the two ends of the tube are then threaded through a 4-inch length of 33-French Malecot catheter and held with a clamp. A loop tourniquet can then be placed around each intramural or intravenous tumor through the same holes in the broad ligaments (Fig. 31.23A).

As the tourniquets are being placed, controlled hypotension is induced by the anesthesiologist staff. Before the tourniquets are tightened, the location of the uterine arterial blood flow is identified with a sterile Doptone. When everything is in readiness and the plan of operation has been selected by the surgical team, the tourniquets are snugly tightened and tightened progressively until the uterine arterial flow is no longer audible with the Doppler (Fig. 31.23B). It is very important that the arterial blood flow be occluded. If the venous flow is occluded while the arterial flow remains intact, blood loss could actually be increased with the tourniquets. The mean blood pressure should be reduced to the target hypotensive level (about 60 mm Hg) before the tourniquets are tightened. The higher the blood pressure, the tighter the tourniquets must be to occlude the uterine circulation.

With the combination of properly applied tourniquets and controlled hypotensive anesthesia, the entire circulation to the uterus can be occluded. The myometrium can then be performed in a bloodless field, greatly facilitating complete removal of all tumors and blood pressure. It is critical to control hemorrhage and provide a bloodless operative field. One of the earliest methods was simply to have an assistant grasp the broad ligaments firmly with each hand during myomectomy to impede venous drainage from the lower extremities and pelvis by gravity and may further reduce the blood pressure at the operative site.

Induced hypotension is contraindicated in patients with cerebrovascular disease, myocardial ischemia, peripheral vascular disease, severe renal or hepatic disease, and hypovolemia. None of these contraindications is seen very often in myomectomy patients. An anesthesiologist experienced with the technique is an essential requirement. The decision to use hypotension should be made jointly by the surgeon and the anesthesiologist. It is essential that the blood pressure be returned to normal before closure of the incision to ensure that adequate surgical hemostasis has been established.
Dillon reported that with the use of vasopressin, 72% of pa-
tients requiring myomectomy did not need blood replacement
compared with control subjects. Frederick and coworkers
noted significantly less blood loss compared with an untreated
group. Ginsberg and associates compared vasopressin with
mechanical vascular occlusion and found that there were no
demonstrable differences in blood loss, morbidity, or trans-
fusion requirements between the two techniques. A favorable
experience with vasopressin has also been reported by Semm
and Mettler.

The weight of evidence in current clinical investigation in-
dicates that vasopressin is as effective as mechanical vascular
occlusion in controlling blood loss with myomectomy. Nev-
ertheless, careful dissection around myomata and prompt su-
turing with exertion of direct pressure to bleeding vessels by
the operative assistant are necessary to minimize blood loss.
Care should be taken to avoid injecting the solution directly
into a vascular channel, and no more than 30 mL per patient
is recommended because of potential side effects. Vasopressin
should not be used in patients with vascular disease, especially
disease of the coronary arteries. Inadvertent intravascular in-
jection can cause anginal pain; larger doses can cause myocardial
infarction. Water intoxication can also occur as a result of the
antidiuretic effect of vasopressin. This effect is potentiated in
patients taking tricyclic antidepressants.

Although late postoperative bleeding does occur with the
use of vasopressin, it is not a common complication. Arterial
bleeding masked by vasopressin still requires suture ligation.
Because of the short half-life of vasopressin, the hemostatic
effect is observed only for 20 to 30 minutes and should be over
before the incisional closure is started. However, some do claim
that vasopressin simply delays bleeding, gives a false sense of
security, and is not particularly effective for larger myomata
and very extensive myomectomies.

For a variety of reasons, epinephrine as a vasoconstrictive
agent is not recommended for use in gynecologic surgery.
Since its introduction into clinical practice in 1972, the CO₂ laser has been touted as a tool that increases surgical precision and decreases bleeding, tissue injury, and adhesion formation. The laser can be used to make a single uterine incision through which multiple myomata are removed. An elliptical incision can also be made around the base of larger myomata to facilitate their removal. Myomata less than 1 cm in diameter can be vaporized directly with the laser, which destroys tissue by vaporizing cellular water. Despite the favorable results reported by Weather, Reynaek, and Corenthal, McLaughlin, and Starks, we believe that there is no clear advantage in using the CO₂ laser for abdominal myomectomy, especially considering the added cost to the patient.

Although the methods described earlier to control bleeding during myomectomy are helpful, they cannot substitute for good surgical techniques. Adherence to basic principles is essential for good results. Perhaps the most important of these is careful planning of the uterine incisions. Only a minimal number of incisions should be made. If possible, removal of all myomata should be accomplished through a single incision in the anterior uterine corpus, and in the midline when feasible to avoid the vascular areas of the uterus and broad ligaments laterally. Even intramural leiomyoma in the posterior uterine wall can be removed through anterior incisions. Incisions in the posterior uterine wall may be necessary, however, if posterior subserous tumors are being removed. If posterior uterine incisions are made, adhesions are more likely to develop and will likely involve the tubes and ovaries as well.

As many tumors as possible should be removed through a single incision. Methods of removing myomata through a single anterior incision have been described by Bonney. The linear or elliptic incision should usually be over the largest myoma. It should be carried through the superficial myometrium directly into the underlying myoma. The myoma is then grasped with a double-tooth tenaculum or a large Lahey thyroid clamp for traction. The plane of cleavage between the myoma and the surrounding myometrium is easily identified. Sometimes in patients who have been treated with GnRH analogs, the plane of cleavage may seem less distinct. Sharp dissection with the scalpel or Metzenbaum scissors, or blunt dissection with the finger or knife handle, is required to enucleate the myoma from its bed. Sometimes the myoma is larger than expected. It may then be necessary to enlarge the incision or to remove the tumor by morcellation. Other adjacent tumors should be removed through the same incision. Any entry in the endometrial cavity should be noted, and a special attempt should be made to close it with sutures placed in the underlying supporting myometrium. Examples of the step-by-step planning and performance of a multiple myomectomy are illustrated in Figures 31.26 and 31.27.

The muscle fibers and blood vessels surrounding a myoma are compressed by its growth. This compression of surrounding tissue forms a pseudocapsule around the myoma. No large blood vessels enter the myoma, and there is no vascular pedicle. If the dissection can be carried out between the myoma and the pseudocapsule, blood loss can be minimized. If blood vessels are cut or left on the surface of the myoma, it usually means that the dissection has been carried out in an improper plane. Dissection in the proper plane may be more difficult if the patient received GnRH analog therapy preoperatively.

Several ingenious techniques for removing leiomyomata and for repairing defects have been described. For example,
The sequence of steps in a multiple myomectomy is shown in these illustrations. A: Through a transverse Maylard incision, tourniquets are placed to occlude the uterine and ovarian artery flow. Through a single incision in the anterior myometrium, a large anterior myoma is removed first. All other myomas are removed through this incision. B: A smaller intramural myoma is removed through the same incision. C: To avoid making a separate incision in the posterior uterine wall, a large posterior myoma is removed through the uterine cavity. After an incision has been made through the anterior endometrium, an incision is made in the posterior endometrium directly over the posterior myoma. D: The myoma in the posterior uterine wall is dissected from its bed and removed through the uterine cavity. An incision in the posterior uterine serosa is thus avoided. (Continued)

Bonney’s hood can be used to remove a large leiomyoma in the uterine fundus. The myoma is first exposed through an elliptic incision made transversely across the anterior fundus, taking care to avoid the interstitial portion of the fallopian tube on each side (Fig. 31.28A and B). After the primary tumor is removed (Fig. 31.28C), other leiomyomata can also be removed through the same incision. Excess myometrium can be trimmed away (Fig. 31.28D). Interrupted sutures obliterate the dead space, approximate the myometrium, and accomplish satisfactory hemostasis. The sutures are placed in such a way that the posterior flap of myometrium is folded over the anterior uterine wall and sutured in place, thus fashioning Bonney’s hood (Fig. 31.28D).

Meticulous closure of defects from the enucleated myomatosa is essential to maintain hemostasis postoperatively, but this should be deferred until all the tumors are removed. Hypertrophy of the normal myometrium is always present with uterine leiomyomata. Some of this hypertrophied myometrium is
considered excess and can be trimmed to facilitate a more normal reconstruction of the uterus. Involution of the myometrial hypertrophy is expected to occur in the first few months after myomectomy. Therefore, only a small amount of normal myometrial tissue should be removed. In reconstructing the uterus, the surgeon should refer to fixed points such as the attachments of the round ligaments and fallopian tubes on each side of the corpus. Symmetric reconstruction is preferred but is not always possible. The myoma beds are usually closed with interrupted figure-of-eight or mattress 2-0 delayed-absorbable sutures. Large defects can be closed initially with a pursestring suture to obliterate the dead space. Several layers of sutures may be required. One must be careful to avoid occlusion of the uterine vessels, the endocervical canal, or the interstitial portion of the fallopian tubes. Transfundal or transcervical chromotubation to test fallopian tube patency after uterine reconstruction is complete is not usually possible because of leakage of the dye through the myometrial incisions.

In closing a myomectomy incision, the security of the closure comes from sutures placed in the myometrium. If possible, these sutures and knots must not be exposed. In Figure 31.26E and F, several techniques of closing myometrial defects are illustrated. The serosal edge of the uterine incision should be carefully approximated with a continuous 5-0 or 4-0 delayed-absorbable “baseball” stitch. The tourniquets are removed, the hypotensive anesthesia is reversed, and the uterus is carefully inspected for evidence of bleeding. Additional sutures are sometimes required. If a
Multiple rows of interrupted sutures obliterate bed of myoma

Serosal suture

FIGURE 31.27. (Continued) C: By incising progressively deeper into the myoma, the surgeon can identify and bluntly dissect the plane between myoma capsule and myometrium. D: Sharp dissection may be necessary to separate the myoma from its capsule at its base. E: After the removal of as many myomas as possible, the remaining cavity is obliterated and hemostasis secured. F: Multiple rows of non-reactive interrupted absorbable suture material are used to close the cavity. G: When the “dead space” has been obliterated, the serosa is closed with a continuous “baseball” suture of 5-0 or 6-0 nonreactive absorbable material. H: This type of closure approximates the serosal edges.

uterine suspension is needed, a modified Coffey or modified Gilliam technique along with uterosacral ligament plication is used. Adhesion prevention can also be achieved by the use of absorbable or nonabsorbable barriers. The absorbable barrier Inderseal (oxidized regenerated cellulose) can be placed over the uterine corpus to protect the tubes and ovaries from denuded peritoneal surfaces and uterine incision. Alternatively, a non-absorbable barrier, Gore-Tex (polytetrafluoroethylene surgical membrane), can be sutured over the uterine incisions with 7-0 absorbable minimal reactive sutures. The use of Gore-Tex has been associated with a reduction in new adhesion formation. Diamond and the Seprafilm Adhesion Study Group assessed the efficacy of Seprafilm (HAL-F) Barriersorbable Membrane (sodium hyaluronate and carboxymethylcellulose) in reducing the incidence, severity, extent, and area of uterine adhesions after myomectomy. This prospective, randomized, blinded, multicenter study involved an independent gynecologic surgeon’s review of each patient’s second-look laparoscopy. One hundred and twenty-seven women undergoing uterine myomectomy with at least one posterior uterine incision were randomized to treatment with Seprafilm or no treatment at the completion of the myomectomy. All indices, including incidence, severity, and extent of adhesions, were decreased in the treatment group. This suggests that newer barriers may also have a role in adhesion prevention. Free grafts of peritoneum or omentum should not be used to cover uterine incisions.
Leiomyomata Uteri and Myomectomy

In a randomized controlled trial, Imai found fewer adhesions with GnRH analogue pretreatment compared with no treatment after both laparoscopic and abdominal myomectomy. The utility of GnRH analogues in reducing adhesions has also been demonstrated in other clinical and animal studies. Second-look laparoscopy may be indicated in patients with multiple incisions or in those with posteriorly located incisions adjacent to the adnexa. Early adhesions can be easily lysed, and an additional barrier membrane can be placed. The clinical role of second-look laparoscopy, outside of research, is not well defined, and conflicting studies can be found in the literature regarding the efficacy of this procedure.

A comprehensive review of methods to prevent adhesion formation in gynecologic surgery has been published by Damario and Rock and by diZerega.

Results of Myomectomy

An extensive multiple myomectomy is a major operation with the potential for a higher morbidity than that found with hysterectomy. The major immediate postoperative complications after myomectomy are febrile morbidity and intraperitoneal bleeding.

Postoperative febrile morbidity may be related to extensive tissue trauma or to infection for a variety of reasons. Perioperative antibiotics are routinely given, but antibiotics are not usually continued beyond the day of operation. Any evidence of infection in the recovery period should be treated vigorously and promptly because infection in the operative site may be adhesiogenic and may have devastating effects on future fertility. Unfortunately, subclinical infection in the operative site may not be recognized and therefore may not be treated, but it can also have adverse effects on fertility because of de novo adhesion formation. For these reasons, meticulous and sterile surgical technique during myomectomy must be impeccable.

Intraperitoneal bleeding after myomectomy is usually due to failure to achieve hemostasis of the myometrial vessels during closure of the myoma beds and uterine incisions. Although we do use a heparin solution (5,000 U of heparin per 1,000 mL of lactated Ringer solution) for irrigation during myomectomy,
There is no evidence to suggest that this contributes to occult intraperitoneal bleeding. The diagnosis of intraperitoneal bleeding in the postoperative patient may be difficult. The vital signs can remain stable for several hours before rapidly deteriorating. Peritoneal signs are often subtle and may be masked by incisional pain and analgesic medications. In addition, the peritoneal cavity has an enormous capacity for accommodating occult blood loss. Indeed, as much as 3,000 mL of blood can be shed into the peritoneal cavity with only a 1-cm increase in the abdominal radius.

Therefore, patients must be carefully monitored for the first 24 hours postoperatively. Vital signs should be checked every 15 minutes for the first 2 hours after surgery, then every 30 minutes until stable. Subsequently, they are monitored every 2 to 4 hours for the first 24 hours postoperatively. A hematocrit is usually performed 6 hours after the operation is completed and again on the first postoperative morning. It can also be performed whenever there is a suspicion of intraperitoneal bleeding, anemia, or hypovolemia. Any sign of restlessness, tachycardia, or tachypnea may be an indication of blood loss, especially when associated with hypotension.

When occult postoperative intraperitoneal bleeding is suspected, peritoneal lavage can be a valuable diagnostic tool. If the lavage solution yields a red blood cell count of 100,000/mm³, intraperitoneal bleeding is likely and reexploration is indicated. Across several centers, tachycardia, or tachypnea may be an indication of blood loss, especially when associated with hypotension. When occult postoperative intraperitoneal bleeding is suspected, peritoneal lavage can be a valuable diagnostic tool.

Indeed, as much as 3,000 mL of blood can be shed into the peritoneal cavity with only a 1-cm increase in the abdominal radius. Therefore, patients must be carefully monitored for the first 24 hours postoperatively. Vital signs should be checked every 15 minutes for the first 2 hours after surgery, then every 30 minutes until stable. Subsequently, they are monitored every 2 to 4 hours for the first 24 hours postoperatively. It can also be performed whenever there is a suspicion of intraperitoneal bleeding, anemia, or hypovolemia. Any sign of restlessness, tachycardia, or tachypnea may be an indication of blood loss, especially when associated with hypotension.

When occult postoperative intraperitoneal bleeding is suspected, peritoneal lavage can be a valuable diagnostic tool. If the lavage solution yields a red blood cell count of 100,000/mm³, intraperitoneal bleeding is likely and reexploration is indicated without delay. Lavage is unnecessary when the diagnosis of intraperitoneal bleeding is unequivocal and associated with definite hypovolemia. In this situation, immediate return to the operating room for reexploration is indicated.

Postoperative bleeding after myomectomy can be devastat- ing. Intraoperative control of bleeding during an extensive multiple myomectomy often requires that the uterine blood flow be managed with tourniquets, clamps, or the local injection of vasoconstrictive agents. However, the demonstration of adequate surgical hemostasis in the uterus cannot be made until the uterine circulation has been fully restored. A suspicious attention to this principle intraoperatively prevents postmyomectomy bleeding in almost all cases.

Reports by Smith and Uhlir, Rosenfeld, and LaMorte and associates indicate that the morbidity of myomectomy is no greater than the morbidity of hysterectomy. Verkauf reviewed current published reports and found that the operative risk of myomectomy does not exceed that of hysterectomy. One case of disseminated intravascular coagulation, hemolytic anemia, and acute renal failure associated with extensive multiple myomectomy was reported by Sacks and Horne.

Myomectomy has an excellent record in reducing heavy menstruation in patients reporting menorrhagia. In more than 80% of patients, menorrhagia is cured or significantly improved. Pelvic pain and discomfort and dysmenorrhea can also be relieved, but the results are not as dramatic because leiomyomata are often associated with other gynecologic diseases (e.g., endometriosis and pelvic inflammatory disease) that can also cause pelvic pain.

The impact of abdominal myomectomy on infertility is difficult to assess. Other factors besides leiomyomata may be present to a varying degree. The extent to which the uterine cavity or the fallopian tubes are distorted also varies. The percentage of patients in each series who wish to conceive after myomectomy is not the same. There is also considerable variation in the surgical technique and skill of the gynecologic surgeons. Reported controlled studies are lacking. These and other factors make it difficult to assess the impact of abdominal myomectomy on infertility.

There are a number of published reports regarding women who experience recurrent pregnancy wastage or prior infertility with another cause and who undergo myomectomy. According to Verkauf’s review, conception occurs in more than half of such women who were not previously pregnant. A comprehensive review of 23 studies by Vercellini and colleagues regarding leiomyomata and reproduction reported an overall conception rate of 57% after myomectomy among prospective studies. Among women with otherwise unexplained infertility, the conception rate was 61% after myomectomy. The conception rate is approximately 53% to 70% after myomectomy for submucous myomas and 38% to 65% after myomectomy with intramural or subserosal leiomyomata. The conception rate among women older than age 35 may not be as good. Also, the postmyomectomy conception rate may be lower when the uterus is greater than 12 weeks’ gestational size and when more than four myomata are removed. When abdominal myomectomy includes removal of submucous myomata, Garcia and Turek report that 53% of patients attempting to establish a pregnancy conceive. Both Li and colleagues and Vercellini and coworkers published retrospective reviews supporting excellent conception and pregnancy rates following abdominal myomectomies. Vercellini’s work suggests that certainly age at the time of the procedure is important, as it was one of three independent variables (age, duration of infertility before surgery, and the presence of other infertility factors) associated with postoperative cumulative conception rate.

Buttram and Reiter reviewed 1,914 cases of myomectomy and compared preoperative and postoperative abortion rates. The reduction in abortion rate after myomectomy from 41% to 19% suggests improvement in reproductive salvage through the use of this procedure. According to Verkauf’s review, 69.2% of women with previous recurrent pregnancy wastage conceived after myomectomy and a 50% reduction in fetal loss.

An ultrasonographic study of uterine remodeling after conservative myomectomy was reported by Beyth and associates. There was a gradual decrease in uterine volume in all patients during the 6 months after myomectomy, with the most remarkable decrease occurring in the first 2 to 3 months. Presumably, this represents an involution of myometrial hypertrophy and postoperative healing of uterine incisions. We recommend that all patients use local methods of contraception (diaphragm, condoms, and spermicidal jelly or foam) for at least 3 months to avoid conception until the myometomy incisions are healed.

An ultrasonographic study of uterine remodeling after conservative myomectomy was reported by Beyth and associates. There was a gradual decrease in uterine volume in all patients during the 6 months after myomectomy, with the most remarkable decrease occurring in the first 2 to 3 months. Presumably, this represents an involution of myometrial hypertrophy and postoperative healing of uterine incisions. We recommend that all patients use local methods of contraception (diaphragm, condoms, and spermicidal jelly or foam) for at least 3 months to avoid conception until the myometomy incisions are healed.

Finally, there is the matter of recurrence of myomata after myomectomy. In Verkauf’s review, leiomyomata recurred in 7.5% of patients, and 6.8% required reoperation. Most recurrences appeared more than 3 years after myomectomy, thus allowing sufficient time for conception to occur before recurrence. Friedman and associates investigated a concern that GnRH agonist-induced myoma shrinkage would make some small intramural and submucosal tumors “invisible” at myomectomy, causing early recurrence of leiomyomata once gonadal suppression ceased and estrogen production returned. In their study, there was no difference in myoma recurrence between women pretreated with GnRH agonists (67%) and those treated with placebo (58%) 27 to 38 months after myomectomy. Their myoma recurrence rate of 61% is much higher than that previously reported in combined myomectomy series. The authors believe that this discrepancy is most likely due to the use of high-resolution US to diagnose small myomata that would otherwise be missed on bimanual examination. Rossetti and associates reported on their long-term experience with 84 nonrandomized patients undergoing laparoscopic myomectomy plus 84 nonrandomized patients...
and found similar recurrence rates, 23% and 27% respectively, between the laparoscopic and abdominal myomectomy, with most recurrences seen within 24 months of surgery.

Mattai and colleagues reported that after GnRH analog treatment, the US outline of some myomata was lost or obscured. Such myomata are probably more difficult to identify and remove with myomectomy and may be more likely to reappear when GnRH analog treatment is discontinued after myomectomy.

**Embolotherapy**

With current technology progressing toward less invasive therapies, the minimally invasive procedure of uterine artery embolization (UAE) is gaining popularity. This procedure can potentially obviate the need for surgical procedures in patients who suffer from symptomatic leiomyomata.

In the female genital tract, embolotherapy for control of hemorrhage from malignancy was first reported in the late 1970s. In 1980, Fais and colleagues described successful embolization for postpartum hemorrhage. Many more reports followed in the mid-1980s. In the early 1990s, Ravina and coworkers began using embolotherapy as a preoperative maneuver to decrease intraoperative blood loss during surgery for myomata. The protocol generally included embolization about 24 hours before the surgery; however, some occurred a few days or weeks before surgery. Such an improvement in symptoms occurred that many surgeries were canceled altogether. This serendipitous discovery led to the performance of UAE as a primary procedure. UAE for leiomyomata was first performed in the United States by Goodwin and colleagues in 1995. Since then, several large series have been reported, and experience continues to grow.

UAE is appropriate for patients with symptomatic leiomyomata and a preference for treatment other than surgical treatment. Clinical findings, therapeutic goals, and overall medical conditions factor into the decision making. Several concerns have developed in treating patients who may desire future conception. Hypotheses include reduced fertility as a consequence of injury to the uterus or ovaries, placental insufficiency resulting from inadequate blood flow through the uterus, or uterine rupture during pregnancy from UAE-induced myoma necrosis. A limited number of deliveries have been reported after UAE for uterine myomas. However, embolization therapy appears to increase the risk of preterm delivery and malpresentation compared with laparoscopic myomectomy, and there is a trend toward higher spontaneous abortions and postpartum hemorrhage with UAE. Ameorrhea has been reported in 1% to 2% of patients after UAE; however, some authors have attributed this to the coincidental onset of menopause.

Contraindications to this procedure include pregnancy, active pelvic infection, severe contrast medium allergy, arterial/venous malformations, desire for future pregnancy, a strong suspicion of adenomyosis or pedunculated leiomyoma, and undiagnosed pelvic mass. The technique is generally preceded by preprocedural testing, and patients are pretreated with intravenous antibiotics. Many perform preliminary arteriographic mapping of the pelvis. A review by Hutchins and Worthington-Kirsch provides an excellent description of the procedure.

The technical success rate is consistently reported in the 96% to 98% range with experienced teams. Eighty percent to 90% of embolized patients have reported improvements in menorrheagia, bulk-related symptoms, or both. Reduction in overall uterine volume peaks at more than 60% by 6 to 9 months after the procedure because of the gradual nature of the process. Individual myomas show average volume reductions of 60% to 65%.

The Fibroid Registry for Outcomes Data (FIBROID) was established by the Society of Interventional Radiology and includes 23 core sites and 50 to 60 other participating sites. This clinical registry has enrolled more than 3,300 patients in an effort to obtain rapid and reliable data regarding patient outcomes. Based on 30-day and 1 year data, near 90% of patients responded favorably to UAE. Recurrence of symptoms and repeat procedures occur in about 10% of patients by 3 years.

Worthington-Kirsch, a leading member of the steering committee, estimates that by 5 years postprocedure, as many as 20% of patients will have another procedure. Approximately 1,300 to 1,500 patients continue to provide annual data through self-reported questionnaires, permitting continued long-term follow-up of the UAE procedure.

Forty percent of patients develop a syndrome of fever and malaise in the first 10 to 14 days after UAE. This is also associated with leukocytosis. This entity is well described as postembolization syndrome. It is typically self-limited and resolves in 3 to 5 days, and rarely requires treatment except antibiotics. Other complications include those that may be attributed to the angiographic component and target or nontarget organ embolization. Gyn infections, groin bleeding or hematoma, contrast-induced renal damage, and vascular damage may be attributed to the angiographic component. Uterine infection or perforation, sexual dysfunction, and myoma sloughing may be attributed to the target organ effects. Reported nontarget organ embolization complications include ovarian sequelae, sciatic nerve effects, and gluteal muscle pain. Current experience confirms a major complication rate of less than 1%.

### BEST SURGICAL PRACTICES

- Women with symptomatic or problematic uterine leiomyomata should be considered candidates for surgical or radioactive intervention.
- Management options, including medical, radiologic, and surgical, should be discussed with patients, emphasizing risks and benefits of each option.
- Careful preoperative evaluation for women who undergo surgical treatment of leiomyomata should include anatomic evaluation to determine the extent, location, and size of leiomyomata.
- In patients with infertility, myomectomy—performed by either an abdominal or laparoscopic approach—should only be performed after complete evaluation of other potential causes of infertility.
- Adhesion barriers are advantageous in reducing adhesions during both abdominal and laparoscopic myomectomy.
- Pregnancy rates and outcomes after laparoscopic myomectomy compare favorably with those after abdominal myomectomy.
- Meticulous repair of the uterine myometrium is essential for patients desiring pregnancy after a myomectomy.
- Hysteroscopic myomectomy is an effective surgical alternative to relieve symptoms associated with submucosal myomata.
- Current information regarding uterine artery embolization (UAE) is promising, but patients should be made aware that limited long-term data are available regarding outcomes, especially relating to fertility and pregnancy.

CHAPTER 32A ■ ABDOMINAL HYSTERECTOMY
HOWARD W. JONES III

DEFINITIONS

Incidental oophorectomy—When clinically normal ovaries are removed at the time of a hysterectomy. This is an older term. Prophylactic oophorectomy is now preferred.

Prophylactic oophorectomy—The preferred term for removing clinically normal ovaries at the time of hysterectomy. This terminology emphasizes the risk reduction of ovarian and possibly breast cancer as a result of oophorectomy.

Supracervical hysterectomy—Also referred to as a subtotal hysterectomy. This operation removes the uterine fundus, transecting the upper portion of the cervix below the level of the uterine vessels. The cervix is left in situ.

Trendelenburg position—With the patient on the operating table in the supine position, the head is lowered below the level of the pelvis.

Hysterectomy is the most common operation performed by the gynecologist, and it is the second most common major surgical procedure done in the United States. Only cesarean section is more common. There are many indications for hysterectomy, and the uterus can be removed using any of a variety of techniques and approaches, including abdominal, vaginal, or laparoscopic. In most cases, a total hysterectomy with removal of the uterine corpus and cervix is done; but in recent years, there has been a resurgence in the popularity of supracervical hysterectomy. The ovaries and tubes may or may not be removed along with the uterus, depending on the patient’s age and a variety of other factors. The gynecologic surgeon should be not only technically adept at these various procedures, but also should use history, physical examination, and discussion with the patient to match the surgical procedure to the patient to obtain the most satisfactory outcome.

The three sections of this chapter discuss abdominal, vaginal, and laparoscopic hysterectomy.

HISTORY

The history of hysterectomy is long and varied. Although significant advances in the technique of hysterectomy did not occur until the 19th century, earlier attempts are known. Some references to hysterectomy even date to the 5th century B.C., in the time of Hippocrates. The earliest attempts at removal of the uterus were made vaginally for indications of uterine prolapse or uterine inversion. By the 16th century, a number of hysterectomies already had been done in Europe, including Italy, Germany, and Spain. In 1660, Schenck of Grabenberg cataloged 26 cases of vaginal hysterectomy.

Vaginal hysterectomies were done sporadically through the 17th and 18th centuries. In 1819, Winsberg presented a paper to the Vienna Royal Academy of Medicine recommending vaginal hysterectomy for uterine cancer. Three years later, the German surgeon Langenbeck successfully performed a vaginal hysterectomy for uterine cancer. The first vaginal hysterectomy performed in the United States was in 1829 by John Collins Warren at Harvard University; however, the patient expired on the fourth postoperative day. Three years following Warren’s attempt, Herman and Werneburg in Pittsburgh successfully performed a vaginal hysterectomy for uterine cancer. By the late 19th century, techniques for vaginal hysterectomy were systematically studied and developed by Czerny, Billroth, Mikulicz, Schroeder, Kocher, Teuffel, and Spencer Wells.

The earliest abdominal hysterectomy attempts usually involved uterine leiomyomas that had been misdiagnosed as ovarian cysts. In the early 19th century, laparotomy for ovarian cysts still was considered dangerous, despite initial successes by McDowell in the United States and Emiliani in Europe in 1815. Abdominal hysterectomy for any reason was considered impossible to accomplish successfully. Many of the earliest myomectomies involved pedunculated tumors. Washington L. Atlee of Lancaster, Pennsylvania, performed the first successful abdominal myomectomy in 1844; although in a series of 125 surgeries, he did not attempt to remove the uterus.

The first reported abdominal hysterectomy was attempted by Langenbeck in 1825. The 7-minute operation for advanced cervical cancer resulted in the patient’s demise several hours later. Abdominal surgery was commonly complicated by postoperative hemorrhage that was often lethal. In the mid-19th century, an English surgeon, A. M. Heath from Manchester, was the first to ligate the uterine arteries, but it would be nearly 50 years before his technique became common practice.

Successful surgery depends on control of bleeding, infection, and pain. Ligatures were known to be used to clamp bleeding vessels as early as 1090, and artery forceps were invented in the mid-16th century by Ambroise Paré. However, information regarding the pathophysiology of hemorrhage, shock, and blood transfusions was not available until the 20th century. The importance of infection control was first recognized by Austrian Ignaz Semmelweis in his work with childbed fever. His 1840s work was furthered by Joseph Lister in the 1860s, and aided by notable discoveries by Louis Pasteur and Robert Koch. American Crawford W. Long first used ether as anesthesia in 1842, and Scotsman Sir James Y. Simpson initiated use of chloroform in his obstetric practice.

It was not until 1864 that the Frenchman Koeberle introduced his method of securing the large vascular pedicle of the lower uterus with his tool, the serrenoeud. This ligature en masse around the lower uterus with the corpus amputated above was the usual technique of controlling bleeding with hysterectomy in the earliest years. The stump thus formed was

727
such a large mass of tissue that it could not always be safely re-
turned to the peritoneal cavity owing to risk of intraperitoneal bleeding; often the stump was fixed extraperitoneally in the incision so that it could be clamped later if necessary.

W.A. Freund of Germany further refined hysterectomy tech-
niques in 1878 using anesthesia, antisepsic technique, Tren-
delenburg position, and ligature around ligaments and major vessels. The bladder was dissected from the uterus, and the cardinal and uterosacral ligaments were detached; the pelvic peritoneum then was closed. Late in the 19th century, further refinements were made to abdominal hysterectomy techniques by the surgeons of the Johns Hopkins Hospital, where they reduced their mortality to 5.9%.

In the early decades of the 20th century, hysterectomy be-
came more commonly used as treatment for gynecologic dis-
ease and symptoms. Gynecology as a specialty was develop-
ing, and little else but surgery was available to gynecologists to help their patients. Major discoveries and concepts of re-
productive organ physiology and pathology were just begin-
ing. As surgery became safer, gynecologists concentrated on developing newer surgical procedures. Estrogen and progester-
tone were not discovered until the late 1920s and early 1930s.

As gynecology matured as a specialty, knowledge of repro-
ductive organ function and disease became more complete. Spe-
cial and more accurate diagnostic techniques were developed, and effective nonsurgical methods of therapy were discovered. In the modern practice of gynecology, appropriate use of this knowledge and advanced modern diagnostic technologies al-
low more correct choices of treatment for complicated medical diseases. With proper use of blood transfusions and antibiotics, and with improvements in anesthetic techniques, a hystere-
tomy can be done safely by the skillful gynecologic surgeon. Mortality from hysterectomy in most medical centers is one to two per 1,000. It is not unusual to report no mortalities in a series of several thousand hysterectomies for benign dis-
ease. With the use of prophylactic antibiotics, infectious mor-
bidity has greatly decreased, and overall morbidity rates have been greatly reduced as a result of improved techniques and training.

Hysterectomy is a very common surgical procedure. In the United States, more than half a million women undergo hys-
terectomy each year, and it is estimated that by age 65, one third of women in this country will have had their uterus sur-
gically removed. Annual medical costs related to hysterectomy exceed $5 billion in the United States. However, there are signifi-
ant variations in hysterectomy rates within the United States and throughout the world. In a study from the Kaiser health care plan in California, Jacobson and colleagues reported an over-
all hysterectomy rate of 3.4 per 1,000 women older than age 20 in 2003. This is similar but somewhat lower than the rate of 4.7 per 1,000 women reported from Olmsted County, Minnesota, from 1995 to 2002. In a nationwide sample, Far-
quhar and Steiner reported an overall hysterectomy rate of 5.6 per 1,000 women in the United States in 1997. In Western Australia, Spilbury and colleagues recently reported an age-
standardized rate of 4.8 per 1,000 women. In Italy, Mattaria has reported a rate of 3.7, and a very low rate of 1.2 per 1,000 eligible women was reported from Norway.

This variation in rates from one location to another is due to several factors, including patient expectations and availability of medical care. But it is primarily related to the training and

practice patterns of the local gynecologic surgeons. In some re-
as, abnormal uterine bleeding may be managed primarily by hormonal therapy, whereas in other locations, hysterectomy may be quickly recommended. Alternatives to hysterectomy have decreased the rate of hysterectomy in recent years. Sys-
temic hormonal therapies have been effective for managing menorrhagia; recently, a progestational intrauterine system has been shown to be similarly effective. Intrauterine thermal bal-
loons, microwave, and electrical instruments are all effective outpatient techniques for endometrial ablation as an alterna-
tive to hysterectomy for symptomatic uterine bleeding. Leiomy-
omas can now be treated with transcervical hysteroscopic re-
section and also by transcatheter uterine artery embolization. These new management techniques, together with an overall desire to decrease the use of major surgery, have decreased the use of hysterectomy in recent years.

In addition, today’s gynecologic surgeon has several tech-
niques for hysterectomy from which to choose. Although ab-
dominal hysterectomy is still the most commonly used ap-
proach, there has been a definite increase in the use of both vaginal and laparoscopic hysterectomy in recent years. Table 32A.1 shows the frequency of the various techniques in recent reports from around the world. For the first time, this edition of the hysterectomy chapter is subdivided into sections on abdom-
inal, vaginal, and laparoscopic hysterectomy. In this section, we will concentrate on the abdominal approach to hysterectomy.
CHOICE OF APPROACH: ABDOMINAL, VAGINAL, OR LAPAROSCOPIC

Today, there are many different approaches to hysterectomy. The uterus can be removed via the abdominal route, transvaginally, or laparoscopically. Combinations of several techniques can be selected, such as a laparoscopically assisted vaginal hysterectomy. Although abdominal hysterectomy continues to be the most common approach used worldwide, there is good evidence from multiple randomized, prospective trials that vaginal hysterectomy is associated with fewer complications, a shorter hospital stay, a more rapid recovery, and lower overall costs (Table 32A.3). In addition, Kovac and others have shown that most patients who require hysterectomy can have it performed vaginally. Who, then, is a proper candidate for an abdominal hysterectomy? Most patients with gynecologic malignancy are still operated on with an abdominal incision. Although this will undoubtedly continue to be true for women with ovarian cancer, who frequently have extensive pelvic and upper abdominal metastases, laparoscopic techniques and more recently robotic surgical techniques are being used more and more frequently in women with endometrial and cervical cancer.

Another indication for abdominal hysterectomy is a large uterus that prevents safe and reasonable vaginal hysterectomy. This is obviously very dependent on the skills and experience of the surgeon, because there are various techniques that allow a very large benign uterus to be removed from below. Nevertheless, most gynecologists would agree that a uterus larger than 12 weeks' gestational size is a reasonable size to qualify for an abdominal approach. The shape and size of the pelvic outlet are also key factors; although the degree of prolapse is not an absolute factor, patients with limited uterine prolapse are

<sup>a</sup> Blood loss is percent change in preoperative versus postoperative hematocrit.
more difficult to do transvaginally. Cervical fibroids or cervical enlargement for any reason may compromise vaginal exposure and make it difficult to place clamps laterally.

An unknown adnexal mass, extensive pelvic endometriosis, or adhesions from prior surgery or pelvic infection may also be an indication for an open abdominal approach including a hysterectomy. In some cases, a diagnostic laparoscopy will clarify the ureteral and bladder injury so that laparoscopic supracervical hysterectomy has been associated with an increased risk of bladder dysfunction after the cervix has been removed. Much has been written about this in the lay press, and the diagnosis and reason for the approach selected should be thoroughly explained and discussed with the patient and any appropriate family or friends. In rare cases, the final decision concerning the type of hysterectomy will depend on the findings of the exam under anesthesia or the findings at laparoscopy. In those cases, all the “what ifs...” should be carefully reviewed with the patient before the surgery and the family kept informed as decisions are made during surgery.

Subtotal Versus Total Hysterectomy for Benign Conditions

In the United States, and throughout most of the world, the hysterectomy—whether done transvaginally or through an abdominal incision—usually includes removal of the cervix. Over the past 50 years, subtotal or supracervical hysterectomy has come to be viewed as a suboptimal procedure reserved for those instances when concern over blood loss or anatomic distortion dictates limiting the extent of dissection. Recently, there have been some concerns about a reduced quality of orgasmic function and bladder dysfunction after the cervix has been removed. Much has been written about this in the lay media, and there are undoubtedly some women who develop problems after hysterectomy. However, several recent prospective, randomized studies in the United States and abroad have shown no difference in sexual satisfaction, bowel or bladder dysfunction, and vaginal prolapse after simple total hysterectomy compared with supracervical hysterectomy for benign disease. My own clinical experience over 30 years also confirms this impression.

Nonetheless, the routine practice of removing the cervix at the time of hysterectomy for benign disease is now being challenged as many traditional surgical procedures are being modified to accommodate minimally invasive techniques. A new technique of total laparoscopic hysterectomy (as initially described by Semm) involves coring out the endocervical tissue—usually enable the gynecologist to decide on the most appropriate type of hysterectomy. The diagnosis and reason for the approach selected should be thoroughly explained and discussed with the patient and any appropriate family or friends. In rare cases, the final decision concerning the type of hysterectomy will depend on the findings of the exam under anesthesia or the findings at laparoscopy. In those cases, all the “what ifs...” should be carefully reviewed with the patient before the surgery and the family kept informed as decisions are made during surgery.

Management of Normal Ovaries

Should normal ovaries be removed at the time of hysterectomy for benign disease? The term prophylactic oophorectomy is preferred when referring to the removal of clinical normal ovaries at the time of hysterectomy. The use of incidental oophorectomy is not recommended because it suggests that an oophorectomy is done without planning or consideration and has no consequences. There is no doubt that bilateral oophorectomy reduces the risk of ovarian cancer and the need for future surgery for benign conditions of the ovaries. However, the ovaries continue to produce low levels of androgens even after the menopause; and although the benefits, if any, of this hormone production are unknown, the psychological effect of oophorectomy on some women is significant.

Prophylactic oophorectomy is done in 50% to 66% of women aged 40 to 65 who undergo hysterectomy in the United States. Averette and Nguyen have estimated that 1,000 of the approximately 24,000 new cases of ovarian cancer in the United States would be prevented if prophylactic bilateral salpingo-oophorectomy was done at the time of hysterectomy on all women older than age 40.

Clearly, there are some significant potential benefits to oophorectomy at the time of any pelvic surgery in women with a known BRCA-1 or BRCA-2 gene mutation, a strong family history of ovarian or breast cancer, or women of Eastern European Jewish heritage. In a follow-up study of 1,200 women who underwent hysterectomy with at least one ovary retained, Plockinger and Kolb found that new pathology in the remaining ovary led to reoperation in approximately 4% of the patients. Older data supports this rate of reoperation for problems related to ovaries left behind at operation.

Interestingly, an analysis of the Cancer and Steroid Hormone Study by Irwin and colleagues from the Centers for Disease Control and Prevention (CDC), including women 20 to 54 years old, found a 40% reduction in the risk of ovarian cancer in women who had a hysterectomy even with ovarian conservation, unilateral or bilateral. The protection was still present 10 years after surgery (RR = 0.6), but disappeared after two decades. The reason(s) for this risk reduction is unknown, but may be related to the opportunity to examine the ovaries at the time of hysterectomy with removal of those that are abnormal and conservation of those that are grossly normal. Other possible mechanisms include reduction in ovarian blood flow and stenodogenesis after hysterectomy, a higher frequency of previous oral contraceptive use among women who undergo hysterectomy, and protection of ovaries from transstubal migration of potential vaginal carcinogens.

Four case control studies that found a lower risk of ovarian cancer among women who had a history of previous hysterectomy with ovarian conservation have been analyzed by Weiss and Harlow. The authors felt the reduction in ovarian cancer risk was explained by incidental screening for visible ovarian malignancy at the time of hysterectomy in those women in whom the ovaries are not removed. Those women with grossly normal ovaries have a reduced risk of developing symptomatic ovarian cancer over the next few years.
Recent studies also have clearly shown a decrease in the risk of breast cancer in women who have undergone bilateral oophorectomy. This is of particular importance in women from families with a history of ovarian or breast cancer and those with known BRCA gene mutations. In a series of 377 women with BRCA1 or BRCA2 mutations who were enrolled prospectively and followed up for 8 to 13 years, Kauf and associates reported a 4% incidence of breast cancer among the 69 women who underwent prophylactic oophorectomy compared with a 13% incidence among those who elected follow-up surveillance only. In a similar retrospective review of 259 women compared with matched controls, the risk of breast cancer was reduced by 50% in the women who had bilateral oophorectomy. In both series, the risk of peritoneal or ovarian cancer was decreased by 95%.

New studies have examined the operative morbidity of adding oophorectomy at the time of abdominal hysterectomy. There is a slight theoretical risk of ligation or obstruction of the ureter at the time of ligation of the ovarian vessels, but this risk should be very minimal in women with truly normal ovaries who are undergoing abdominal hysterectomy for benign disease. The long-term consequences of the loss of minimal androgen production by the postmenopausal ovary is unknown, but the benefits of hormonal production by the normal premenopausal ovary are significant. Prevention of osteoporosis, urogenital atrophy, skin changes, and possible prevention of arteriosclerotic vascular disease are but some of the known benefits of ovarian estrogens. Clearly, removal of the normal ovaries in a premenopausal woman mandates hormone replacement therapy to prevent these undesirable side effects of the hypoestrogenic state.

However, in a study of 165 premenopausal women who were prescribed estrogen replacement therapy following bilateral oophorectomy, Castelo-Branco and colleagues found that only one third continued their medication for 3 years. Fear of cancer was the most common reason for discontinuation. The anticipated protection from osteoporosis and other consequences of premature menopause that result from oophorectomy may not be effectively prevented by oral hormone replacement therapy to prevent these undesirable side effects of the hypoestrogenic state.

PREOPERATIVE COUNSELING

The gynecologist needs to talk with the patient while trying to decide whether a hysterectomy is indicated. Fortunately for the patient and the gynecologist, time for talking is available in almost every situation. The patient is not in an emergency. Unfortunately, the time may not be used properly. In a survey of 10 women who underwent hysterectomy, Neelam and Taylor found that there is an urgent need for patient education on the physical, psychological, and sexual aspects of hysterectomy. Often, the need for hysterectomy is obvious. There is a complete prolapse, or a large and symptomatic leiomyomatous uterus, or a pelvic mass. Under these and other obvious circumstances, the patient should be told that a hysterectomy is recommended and why. The indication for surgery should be explained clearly and in such a way that the patient can understand. Treatment alternatives should be mentioned, and the reason to prefer hysterectomy should be explained. Alternative techniques for hysterectomy should be discussed, and the reasons for recommending one approach over another should be explained. The risks, benefits, and side effects, specifically including the possibility of transfusion, must be reviewed, but in such a way that the patient is not unduly alarmed. Then the patient and the physician should spend the time necessary to discuss any questions that the patient may have. Additionally, the patient should be encouraged to discuss details about the operation, how long it will take, the recuperation period in the hospital and at home, whether ovarian function should be conserved, and possible hormone replacement therapy. Patient information pamphlets and videos also are useful for preoperative education. The expectations of the patient and her family are very important in her postoperative view of the success (or failure) of the operation.

Because the uterus is the main organ associated with reproduction, it is an important part of a woman's self-image. In some cultures, a woman's sexuality and reproductive potential are viewed as important parts of her value or status in her family or society as a whole. For these reasons, it is absolutely necessary for the gynecologic surgeon to understand and help patients cope with the emotional turmoil that may accompany hysterectomy. For some women who have had their children and need a hysterectomy for prolonged heavy bleeding and cramping associated with uterine fibroids or those with a diagnosis of endometrial cancer, the indications are clear, the benefits are obvious, and the loss of reproductive capacity often is not of great concern. The emotional stress of hysterectomy on these women is usually minimal, and psychological adjustment often is rapid and complete. However, the young woman needing a hysterectomy for cervical cancer or a ruptured corneal pregnancy may have considerable difficulty adjusting to the loss of her uterus. Even the 32-year-old woman with three children and severe uterovaginal prolapse may not be comfortable able with the idea of hysterectomy. The gynecologist must be sensitive to these possible concerns and anxiety. Even when the patient does not express any emotional distress, the gynecologist can provide an opening for the patient to discuss her feelings by statements such as, “Most studies have shown no change in sexuality and sexual function after hysterectomy, but I know many patients have concerns about this. Do you have any questions?” The support of the patient's husband or partner and her family and friends are very useful elements to prevent and manage depression and the emotional stress of hysterectomy. The wise surgeon includes members of this support group in preoperative discussions and encourages them to ask questions or express opinions that actually may be questions or opinions of the patient that she is hesitant to express.
The psychological aspects of pelvic surgery are extensively reviewed in Chapter 3.

## PREPARATION FOR HYSTERECTOMY

A complete history and physical examination is indicated before any operative procedure. This evaluation is detailed in Chapter 8, but a few points deserve emphasis. Although it is important to have a complete understanding of the patient's medical condition, it is important to have a recent Pap test to rule out cervical neoplasia. A pregnancy test in reproductive-age women is recommended before surgery. Preoperative chest x-rays are no longer routinely recommended, but may be indicated in women with a history of cardiorespiratory disease or malignancy. An intravenous pyelogram or computed tomography scan of the abdomen and pelvis may be useful in women with uterine or extraterine pelvic masses, but these are not indicated routinely.

Although the value of a bowel preparation before simple hysterectomy has been questioned in recent years, we prefer to have the colon evacuated before pelvic surgery to facilitate exposure and reduce trauma to the bowel caused by retraction and packing. We recommend a clear liquid diet on the day before surgery, and 250 cc of oral magnesium citrate exposure and reduce trauma to the bowel caused by retraction and packing. We recommend a clear liquid diet on the day before surgery, and 250 cc of oral magnesium citrate the evening before surgery. In the morning of surgery, the patient should be instructed not to shave the operative site with an electric clipper or even scissors rather than shaved. The patient should be instructed not to shave the operative site before surgery because it has been shown to increase the risk of wound infection and cellulitis.

Several modifications are described in the following.

### Surgical Site Infection Risk

Surgical site infection risk is decreased by routine use of prophylactic intravenous antibiotics given immediately before induction of anesthesia. First- or second-generation cephalosporins, such as cefazolin or cefoxitin, are commonly used. Recommended antibiotic regimens are shown in Table 32A.4. Prospective, randomized trials have shown a significant reduction in the risk of febrile morbidity and infection in both abdominal and vaginal hysterectomy. Studies have shown no benefit of continuing antibiotics postoperatively, although a second dose of antibiotics generally should be given during hysterectomy procedures that last longer than 3 hours. Some have suggested that bacterial vaginosis increases the risk of postoperative infections after vaginal hysterectomy, but preoperative evaluation and treatment remains controversial. Although povidone-iodine douches and antibiotic scrubs before surgery have been widely used in the past, no added benefit is apparent when perioperative intravenous antibiotics are employed.

**Table 32A.4** RECOMMENDED PROPHYLACTIC ANTIBIOTIC REGIMENS FOR HYSTERECTOMY

Previous editions of Te Linde's text have described gradually evolving modifications of Edward H. Richardson's technique for abdominal hysterectomy with which thousands of gynecologic surgeons have been trained over the years. The operative technique was first published in 1929, and because Te Linde felt it was a classic, he quoted it word-for-word in the fourth edition of this textbook with two added "modifications." This was the edition on my bedside table when I was a resident. I have had the good fortune to operate with many fine surgeons, including E. Stewart Taylor and Felix Rutledge, and have been challenged by many young residents over the years. These experiences have been further enhanced by discussions of surgical technique with gynecologists from around the world, who have suggested changes or ideas that I have tried and sometimes incorporated into my basic technique for abdominal hysterectomy. Although it is important to learn a basic technique for standard abdominal hysterectomy, every surgeon should be interested in observing new and different techniques or modifications to be tried from time to time when appropriate. As a resident, you should try all of the different techniques used by the different attending physicians, always asking why this clamp is used, that suture or needle is selected, or why the cuff is left open or closed. Having tried many different ideas, each gynecologic surgeon gradually evolves her or his own basic techniques that feel comfortable, work for him or her, and make sense. Because each patient is unique, it is also useful to have experience with different techniques and various modifications of the basic operation so that when the occasion calls for it, an alternative technique that is more suitable for the particular situation can be employed. Our basic technique for abdominal hysterectomy and several modifications are described in the following.

### TOTAL ABDOMINAL HYSTERECTOMY: SURGICAL TECHNIQUE

PREPARATION FOR HYSTERECTOMY

A complete history and physical examination is indicated before any operative procedure. This evaluation is detailed in Chapter 8, but a few points deserve emphasis. Although it is important to have a complete understanding of the patient's medical condition, it is important to have a recent Pap test to rule out cervical neoplasia. A pregnancy test in reproductive-age women is recommended before surgery. Preoperative chest x-rays are no longer routinely recommended, but may be indicated in women with a history of cardiorespiratory disease or malignancy. An intravenous pyelogram or computed tomography scan of the abdomen and pelvis may be useful in women with uterine or extraterine pelvic masses, but these are not indicated routinely.

Although the value of a bowel preparation before simple hysterectomy has been questioned in recent years, we prefer to have the colon evacuated before pelvic surgery to facilitate exposure and reduce trauma to the bowel caused by retraction and packing. We recommend a clear liquid diet on the day before surgery, and 250 cc of oral magnesium citrate the evening before surgery. In the morning of surgery, the patient should be instructed not to shave the operative site with an electric clipper or even scissors rather than shaved. The patient should be instructed not to shave the operative site before surgery because it has been shown to increase the risk of wound infection and cellulitis.
On the day of surgery, the surgeon always attempts to see the patient and her family and supporters before she is brought into the operating room. Although surgery may be routine to the gynecologist, major surgery is often a once-in-a-lifetime, frightening experience for the patient. The calm reassurance of the surgeon and the professional and caring nature of the entire operative team is very helpful to the patient and her family at this point. The amount of attention she should have on the patient and her surgery. A certain amount of relaxed chatter about someone’s birthday or hospital gossip is reasonable, but the patient should feel that the concentration of the surgical team is focused on the surgery at hand. Remarks about other patients or how a surgeon had to stay up all night are, a difficult patient in labor are not appropriate. An equipment problem or technical difficulties that affect the operation certainly should be discussed with the surgeon before starting the procedure; however, it is inappropriate to talk about these in front of the patient. Remarks such as, “The table is broken and won’t go down” or “We weren’t able to get your favorite retractor today” may not affect the performance of the operation, but such statements just before a patient is ready to be anesthetized may raise serious doubts as to whether the operative team is optimally prepared for this operation and may raise uncomfortable questions later if complications or unexpected results occur.

**Positioning**

The patient is brought into the operating room and placed in the supine position on the operating table. It is nice to place a warm blanket on the bed immediately before the patient’s arrival and to cover the patient with a blanket from the warmer when she is positioned because most operating rooms are somewhat cool and the patient is only lightly clothed.

When the patient has been anesthetized, a careful examination under anesthesia is done. At this point, the surgeon should concentrate on potential problems affecting resectability. Is there nodulation from endometriosis in the cul-de-sac that may make dissection of the rectum off of the posterior cervix difficult? Is the myoma in the broad ligament really wedged into the pelvic sidewall or does it move freely with the uterus? The mobility and descent of the uterus under anesthesia is particularly important when a vaginal hysterectomy is being considered. These potential problems and possible solutions should be considered and possibly discussed with the operative team while the surgeon scours.

The vagina and perineum are prepped with antiseptic solutions and a Foley catheter is inserted. I prefer to position the patient supine on the operative table with a soft pillow under her knees to provide gentle flexion. The patient’s legs provide a table on which instruments can be placed. Some surgeons prefer the patient to be positioned in the low Allen starups with her legs slightly apart. This allows an assistant to stand between the legs and have ready access to the vagina for examination or manipulation, or the urethra for cystoscopy.

The abdomen then is prepped from the anterior thighs to the xiphoid, and sterile drapes are applied. In most instances, abdominal hysterectomy for benign disease can be done through a low transverse incision; most gynecologists prefer a Pfannenstiel incision, which is cosmetically appealing and strong. If more exposure is required, a Cherney or Maylard incision can be used. But for now, a midline incision is preferred for the patient and her surgery. A certain amount of relaxed chatter about someone’s birthday or hospital gossip is reasonable, but the patient should feel that the concentration of the surgical team is focused on the surgery at hand. Remarks about other patients or how a surgeon had to stay up all night are, a difficult patient in labor are not appropriate. An equipment problem or technical difficulties that affect the operation certainly should be discussed with the surgeon before starting the procedure; however, it is inappropriate to talk about these in front of the patient. Remarks such as, “The table is broken and won’t go down” or “We weren’t able to get your favorite retractor today” may not affect the performance of the operation, but such statements just before a patient is ready to be anesthetized may raise serious doubts as to whether the operative team is optimally prepared for this operation and may raise uncomfortable questions later if complications or unexpected results occur.

**Hysterectomy**

When the bowel has been packed away and exposure to the pelvis is satisfactory, the round ligaments and uteroovarian ligaments are grasped on each side with a Kocher clamp, elevating the uterus out of the pelvis. In some cases of extensive inflammatory disease, endometriosis, malignancy, or very large fibroids, uterine mobility is limited, but in most benign conditions, uterine mobility is satisfactory. The operator is generally on the patient’s left side so that the right-handed surgeon can use her or his dominant hand to extend down into the pelvis. The first assistant is on the opposite side. The uterus is retracted to the patient’s left side, and the right round ligament is stretched taunt. A 0 delayed absorbable suture is placed under the round ligament approximately halfway between the uterus and the pelvic sidewall (Fig. 32A.1). The small artery of Sampson runs just under the round ligament and, in many cases, transvaginally this allows the surgeon to easily visualize the artery and be sure that the suture is passed under it so that the artery will be ligated. A second suture is placed appropriately 1 cm medial to the first suture; these two sutures are now tied simultaneously by the surgeon and first assistant. Clamping the round ligament is an extra step that is rarely necessary.

With traction on these sutures, the round ligament is held taunt and divided with Metzenbaum scissors between the two suture ligatures. This opens the retroperitoneal space, which is almost always a free space for blunt dissection, even in the patient with extensive tumor, inflammatory disease, or endometriosis. If the ovaries are to be removed at the time of hysterectomy, the generally is done if malignant disease is present or exposure to the upper abdomen may be required. The choice of abdominal incision is discussed in Chapter 14.
the anterior cervix does not need to be divided at this time because exposure of this area is not yet required and bleeding may be encountered. With the index finger and the tip of the suction or the back of a tissue forceps, the surgeon gently divides the loose areolar tissue of the retroperitoneum, identifying the external iliac artery on the medial surface of the psoas muscle. In most cases, the artery can be identified very easily, and blunt dissection is used to extend the exposure superiorly to the level of the bifurcation of the common iliac artery. The ureter always crosses the pelvic brim at this location and should be identified easily on the inside of the medial leaf of the peritoneum at this point. The internal iliac or hypogastric artery dives into the pelvis at this location parallel to the ureter, and it should be identified also. This retroperitoneal exploration may seem awkward at first, but with practice, the external and internal iliac arteries and ureter can be visualized easily in 10 to 20 seconds.

If the ovary is to be removed, a hole in the peritoneum between the ureter and the ovarian vessels superior to the ovary can be made under direct vision. We use a fairly fine sharp-pointed 9-inch clamp that can be passed gently through the peritoneum from lateral to medial against and between two fingers, supporting the medial side of the peritoneum. Alternatively, the peritoneum may be divided sharply or with the electrosurgical blade. We prefer to use a fairly delicate tonsil clamp on the infundibulopelvic ligament because it reminds us to isolate the vessels and take a fairly small pedicle. If there is significant inflammation or edema, a larger clamp, such as a Heaney clamp, may be used on the infundibulopelvic ligament pedicle (Fig. 32A.2). A second back clamp then is placed distally and the ovarian vessels divided between the two clamps. This pedicle then is ligated with a free-tie, and then a second transfixion suture ligature is placed for safety between the free-tie and the clamp. Zero-gauge delayed absorbable sutures and ties are used throughout. The suture ligature is placed distal to the free-tie so that if the needle happens to puncture one of the ovarian vessels, the vessel has already been ligated by the more proximal free-tie. The back clamp is ligated with a single free-tie, and the posterior peritoneum then is torn or cut above the ureter toward the back of the uterus, mobilizing the ovary, which is then tied to the clamp on the right side of the uterus to keep it from flopping around and obscuring the operative field. The sutures on the round ligaments and infundibulopelvic ligament then are cut. The procedure is repeated on the patient’s left side.

If the ovary and tube are to be left in situ at the time of hysterectomy, a window in the peritoneum beneath the fallopian tube between the uterus and ovary is made sharply or bluntly, and a heavy clamp—such as a Heaney, Kocher, or similar clamp—is used to clamp the uterovarian pedicle (Fig. 32A.3, see page 736). The round ligament should not be included in this clamp. The clamp that was initially placed on the round ligament and fallopian tube just lateral to the ureterine fundus at the beginning of the procedure serves as the back clamp for this pedicle. The tube and uterovarian ligament are divided and the pedicle ligated as previously noted with a free-tie followed by a suture ligature. The ovary and tube may be left in the posterior pelvis if exposure is adequate or gently packed in the paracolic gutter, with care being taken to ensure that the blood supply is not compromised.

The next step is the dissection of the bladder from the anterior cervix. At this point, the peritoneum is divided just...
FIGURE 32A.2. A: The infundibulopelvic ligament is doubly clamped, and the ovarian vessels are cut between the clamps. Care is taken to be sure the ureter is clear as the clamps are applied. B: The proximal pedicle is ligated with a free tie followed by a transfixion suture ligature.
FIGURE 32A.3. When the ovary is to be conserved, a peritoneal window is made above the ureter and the tube and uteroovarian ligament are clamped. This pedicle is divided and doubly ligated.

FIGURE 32A.4. The bladder is mobilized inferiorly by sharp dissection away from the cervix. To avoid unnecessary bleeding, this step may be done in stages as necessary.
Abdominal Hysterectomy

FIGURE 32A.5. The bladder and, if necessary, the rectum can be gently advanced with blunt dissection. The depth of this dissection can be checked by squeezing the anterior and posterior fingers together below the cervix. (From: Richardson EH. A simplified technique for abdominal panhysterectomy. Surg Gynecol Obstet 1929;48:248, with permission.)

uterus is pulled sharply to the patient’s right side, and the surgeon gently dissects the loose fatty tissue adjacent to the lateral lower uterine segment on the left. The uterine artery is usually found immediately adjacent to the uterus at the level of the internal cervical os. In most patients, the uterine artery is easily exposed by holding the tissue laterally and gently “raking” with the Metzenbaum scissors slightly opened from medial to lateral. “Skeletonizing” the uterine artery and vein allows them to be clamped more accurately, with less adjacent tissue, and a smaller vascular pedicle, which allows more precise and more secure ligation. However, good surgical judgment should be used so that excessive attempts to isolate the vessels do not produce unnecessary bleeding. When the vessels are exposed, a fairly heavy, slightly curved clamp then is used to clamp the vessels just adjacent to the uterus (Fig. 32A.6B). We prefer to use a Heaney, Zeppelin, or Masterson clamp for these pedicles. The tip of the clamp should be around the vessels, and the clamp should come across the pedicle as close to a right angle as possible, rather than at the diagonal, so that the least amount of tissue will be incorporated in the pedicle. The tip of the clamp should not include too much cervical or uterine tissue because this makes application of subsequent clamps more difficult. A second clamp can be placed above the first for added safety, if desired, and a third or back clamp used to prevent annoying back bleeding from the uterus after the vessels have been cut.

If exposure is satisfactory after a single clamp has been placed on the left uterine artery and vein, we skeletonize the uterine vessels on the patient’s right side and place a clamp on these vessels as well. If the uterus is small, no back clamp is required because the four major vessels supplying the uterus have now been clamped or ligated. Next, the uterine vessels are cut with scissors or a knife and the pedicle doubly ligated with 0 delayed absorbable sutures. We prefer to use a small taper-point needle (CT-2, Ethicon) for these pedicles because we feel that large needles are more difficult to place in the small confines of the deep pelvis. If a back clamp has been used, it is now ligated and removed so that the field is not obscured by an excessive number of clamps.

Hemostasis should be good at this point. If not, any bleeding should be controlled. The bladder is again checked to ensure it is well below the cervix. If the rectum needs to be dissected from the posterior cervix, this should be done now. This is usually not necessary for a simple abdominal hysterectomy for benign disease. The peritoneum of the posterior cul-de-sac between the uterosacral ligaments can be divided easily, and blunt dissection of the posterior vaginal wall from the anterior rectum usually is easy, although the rectosigmoid occasionally may be densely adherent to the posterior uterine segment or cervix by endometriosis or pelvic inflammatory disease. If the bladder and/or rectum is too densely adherent and there is concern that further attempts at dissection may damage them or cause troublesome bleeding, a supracervical hysterectomy should be considered.

Once the bladder anteriorly and the rectum posteriorly have been freed from the cervix, the uterus is placed on tension, exposing the deeper portions of the broad ligament and pulling the lower uterine segment away from the uterine. A medium-width malleable retractor may be useful to retract the bladder anteriorly; if necessary, a wide malleable retractor in the posterior cul-de-sac will provide deep exposure posteriorly. In most cases, a series of straight Heaney or Zeppelin clamps can now be used to successfully clamp the remaining portion of the broad ligament (Fig. 32A.7). The tips of these clamps should be placed on the lateral portion of the cervix, and the upper portion of the jaw should lie immediately adjacent to the previous pedicle. As the clamp is gently squeezed closed, the tip slides off of the firm cervix, finally closing snugly against the lateral wall of the muscular cervix. By staying close to the cervix in this way, the risk of damaging the ureter, which is not too far away laterally, is minimized. The pedicle then is cut with heavy scissors or a knife. A millimeter or two of tissue may be left...
medial to the clamp as insurance, but this is not necessary. The tip of the transfixion suture needle is placed at the lateral tip of the clamp jaw if the pedicle is longer than 1 cm, we recommend using a Heaney suture ligature so that the upper end of the pedicle is secondarily transfixed to prevent it from slipping out of the ligature. While good exposure is maintained, one or two pedicles are tied on each side, and then the procedure is repeated on the opposite side until the level of the cervical-vaginal junction has been reached. Once again, the bladder and rectum are checked and advanced if necessary to be sure that they are well clear and the anterior and posterior vaginal walls exposed.

Sharply angled large Zeppelin clamps are used to clamp across the vagina below the cervix. These clamps include the base of the cardinal ligaments laterally, the uterosacral ligament posteriorly, and the vaginal wall anteriorly and posteriorly. A clamp is applied from each side; in most cases, the tips of these clamps meet in the middle just below the cervix (Fig. 32A.8). A knife or heavy, sharply angled Jorgenson scissors is used to divide the vagina above these clamps and below the cervix. The uterus is removed and placed in a pan on the back table for later examination. A single figure-of-eight suture is placed between the tips of the two clamps to close the midportion of the vagina. The ends of this suture are held initially and not tied. A Heaney suture ligature is placed on each of the lateral clamps with the second bite going through the uterosacral ligament posteriorly. Inclusion of the uterosacral and cardinal ligaments in this pedicle provides excellent support of the vaginal apex. When these lateral sutures have been tied, the figure-of-eight suture in the middle then is tied also. The lateral sutures are cut and the figure-of-eight in the middle of the cuff is held to provide traction on the vaginal apex. With this closed cuff technique, the vagina is never exposed, which reduces contamination of the pelvis. However, there may be instances, such as a large cervical myoma, when there is a very deep vaginal fornix, and a closed technique would remove too much vagina. Entry into the vagina with the electrosurgical blade and then carefully opening the vagina circumferentially under direct vision is an option in such cases. As the vagina is opened, the full-thickness vaginal edges are grasped with Kocher clamps as the dissection proceeds. We generally close the vaginal cuff with a series of figure-of-eight stitches of 0 delayed absorbable suture, taking care to incorporate the uterosacral and cardinal ligaments into the cuff for support. We have not run the vaginal wall with a locking stitch for hemostasis and left the cuff open for drainage (closing the pelvic peritoneum over the open cuff) since the advent of prophylactic antibiotics for hysterectomy many years ago.

In the classic Richardson technique, the peritoneum over the posterior cervix is divided, the peritoneum is dissected off the cul-de-sac, and the rectovaginal septum is entered to reflect the rectum posteriorly. In our experience, this has not been necessary in the vast majority of patients with benign disease. In contrast to the anterior bladder dissection, this posterior peritoneum is much more adherent. There is usually some bleeding associated with this dissection, making it both bloody and time-consuming. With the Richardson technique, the uterosacral ligaments also are clamped separately and subsequently attached to the vaginal cuff for support. In the technique described above, this is accomplished in a single step.
Abdominal Hysterectomy 739

FIGURE 32A.7. After the uterine artery and vein have been ligated, the remaining lower portion of the broad ligament is clamped with a series of straight clamps. The tips are placed on the edge of the cervix and the back of the jaw immediately adjacent to the previous pedicle.

Closure

After the pelvis has been copiously irrigated with warm saline, the pedicles are inspected carefully to be sure that hemostasis is present. Electrocautery or suture ligatures with 3-0 absorbable sutures on fine needles are used to control small bleeders. The location of the ureters, bladder, and major vessels should be known when placing these sutures. Common sites of ureteral injury during abdominal hysterectomy include the infundibu-
lopelvic ligament where the ovarian vessels are ligated; the area of the uterine artery ligation and the bladder base. Distorted anatomy associated with fibroids, endometriosis and malignancy is a signal for special care to avoid ureteral injury. The pelvis is not reperitonealized, but the rectosigmoid colon is gently laid over the vaginal cuff to cover this raw surface and minimize the risk of adhesions. The packs and retractor are removed, the abdomen checked again for hemostasis, and the omentum placed anteriorly to minimize the risk of small bowel adhesions to the abdominal incision. The anterior peritoneum is closed with delayed absorbable suture, although some surgeons today feel that it is unnecessary to close the abdominal peritoneum. The fascial closure should be commensurate with the patient's risk of infection and hernia. Generally, a running monofilament delayed absorbably suture such as PDS (Ethicon) on a large, curved, tapered needle (CT-1, Ethicon) can be used. If there is a significant risk of dehiscence secondary to infection, obesity, or other medical problems, interrupted sutures or a mass closure technique may be used. Closure techniques are illustrated in Chapter 14. Because patients are often discharged by the third or fourth postoperative day, we generally prefer to close the skin with a subcuticular absorbable suture, which eliminates the necessity for a return to the office for suture or staple removal.

After the patient has been taken to the recovery room, the surgeon should speak with the family, preferably face to face, to assure them that the patient is doing well and to review the operative findings with them. We also strongly recommend that the surgeon ask the circulating nurse to contact the family about once an hour to update them on the progress of the operation during the surgical procedure. This especially is helpful if there were any unknown questions going into the operation (Did the ovaries look normal? Was the endometriosis involving the ureter?). A brief operative note must be immediately recorded in the patient's chart describing the procedure, blood loss, fluid replacement and if any packs or drains were left in the patient. Postoperative orders are written. A careful operative note should be dictated with emphasis on any unusual findings or variations from standard techniques.

SUBTOTAL ABDOMINAL HYSTERECTOMY

The technique of subtotal or supracervical abdominal hysterectomy is similar to the technique for abdominal hysterectomy.

FIGURE 32.8A. A: After checking to be sure the bladder and rectum are clean, the vagina is cross-clamped with long, sharply curved Zeppelin clamps just below the cervix (dotted line). The vagina is divided just above the clamps with a knife or angled scissors. B: The vaginal cuff is closed with a figure-of-eight in the middle and Heaney suture ligatures on the angles, including the uterosacral and cardinal ligaments for support.
A shallow V-shaped incision is used both anteriorly and posteriorly until the uterine fundus is excised. The "coagulate" mode of the electrosurgical unit is used, and hemostasis usually is excellent. Several generous figure-of-eight sutures on a large needle then are used to close the upper endocervix in a hemostatic fashion. The top of the cervix is checked for bleeding, and the bladder peritoneum may be used to cover this cervical stump to minimize the risk of adhesions.

**POSTOPERATIVE CARE**

Although routine postoperative care is thoroughly reviewed in Chapter 9, there are several facets that should be emphasized following hysterectomy. Several studies over the past few years have indicated that early feeding after hysterectomy is safe and actually results in earlier discharge. In many cases, patients are able to tolerate solid food on the first postoperative day following abdominal hysterectomy. The surgeon should nevertheless take into account the amount of dissection and bowel trauma that occurred during the operative procedure and be conservative with the diet orders if a postoperative ileus is anticipated. Patients and their caregivers always should be cautioned not to eat or drink if they feel nauseous or are vomiting. Having a bowel movement or even the passage of flatus are no longer requirements for hospital discharge as long as the patient has normal, active bowel sounds, is tolerating solid food, and is not distended.

Most patients have a Foley catheter for bladder drainage overnight following abdominal hysterectomy, although Richardson and many gynecologic surgeons have shown it is possible to avoid this in most patients with the help of a good, enthusiastic nursing staff. In most situations, however, a catheter is inserted before hysterectomy and removed on the first postoperative day. In patients with bladder injury or continuous epidural for postoperative pain relief, more prolonged catheter drainage may be indicated.

The length of postoperative hospitalization has decreased dramatically in the last 20 years. Although it was common in the past for women to remain in the hospital for 7 to 10 days after abdominal hysterectomy, most patients are now discharged home in 3 or 4 days. This trend toward a shorter hospital stay requires better patient education and a reasonable home environment to which the patient can be safely and
comfortably discharged. The surgeon must also carefully evaluate the patient before discharge and resist pressure from insurance companies and hospital administrators when the patient’s condition indicates that she is not suitable for an early discharge. The patient and her family must be instructed on proper care. Can she take a bath? Can she go up and down the stairs? Can she pick up her grandchild? How soon can she drive a car? A printed set of instructions for home care as well as answers to frequently asked questions are good ideas. Liberal use of home visiting nurses is also recommended, especially in older or more debilitated patients or in those whose home situation may be less than ideal.

COMPPLICATIONS

Complications from hysterectomy can be diagnosed intraoperatively or postoperatively. In a thorough review, Harris found an overall complication rate of up to 50% associated with abdominal hysterectomy, but serious complications requiring reoperation or long-term disability are relatively uncommon. Reoperation rates of 4% to 4.3% have been reported by Gimbine and associates and Browne and Frazer. The most common complications include infection, hemorrhage, and injuries to adjacent organs (Table 32A.5). Prevention and management of hemorrhage, infection, and operative injury complications are extensively discussed in several chapters of this text. Good surgical training, proper patient selection, knowledge of the anatomy, and good surgical judgment—which includes knowing your personal skills and limits—are all keys to minimizing complications.

Several factors have been consistently shown to be associated with an increased risk of complications related to hysterectomy. These are increasing age, medical illness, obesity, and malignancy. These conditions are beyond the control of the gynecologic surgeon, but they should be considered in the risk/benefit ratio when considering surgery, and every effort should be made to have the patient in the best possible condition at the time of surgery.

BEST SURGICAL PRACTICES

- Hysterectomy is one of the most common major operations performed in the United States. The most common indications are uterine leiomyoma, endometriosis, abnormal uterine bleeding, and malignancy. There are many techniques to perform a hysterectomy, including abdominal, vaginal, laparoscopic and laparoscopically assisted, total, and subtotal. Before surgery, the surgeon should discuss the indications, other management options, choice of surgical approach, risks and potential complications of surgery, and expected outcomes with the patient and her supporters, and obtain a fully informed operative consent.

- Numerous prospective randomized studies have shown that total abdominal hysterectomy results in the same or better postoperative sexual function, urinary tract and bowel function, and pelvic support as does supracervical hysterectomy.

- Prophylactic antibiotics administered within 1 hour before the initial incision significantly reduces the risk of a surgical site infection. There is no advantage to continuing antibiotics after surgery in an uninfected patient.

- The surgeon and the surgical team should be completely focused on the operation. Thoughtful preoperative preparation, careful surgical technique, well-reasoned judgment intraoperatively, and attentive postoperative care by a well-trained and interactive team will result in the best outcomes. Good communication between all members of the team is of great importance.

- We have found that the surgical techniques described in this chapter has been highly effective, but each surgeon should be familiar with a number of variations of standard hysterectomy technique and use appropriate variations that might suit the anatomy or pathology of a specific patient.

CHAPTER 32B ■ VAGINAL HYSTERECTOMY

S. ROBERT KOVAC

DEFINITIONS

Endopelvic fascia—The layer of visceral endopelvic tissue surrounding the bladder, vagina, and rectum.

Enteroceles—Formed from a separation of the rectovaginal fascia from the pubocervical fascia. Indeed, enteroceles are pelvic hernias that descend through the posterior vaginal fornix. The most common location for an enterocele is the posterior superior vaginal segment.

Intramyometrial coring—A surgical technique for removal of a large uterus during vaginal hysterectomy. After the uterine vessels have been divided, the myometrium can be circumferentially incised with a scalpel placed parallel to the long axis of the uterus and beneath the serosal covering of the uterus. In effect, coring converts a spherical structure into an elongated rod shape, enhancing the surgeon’s ability to facilitate uterine removal.

McCall culdoplasty—The most commonly employed technique to close the posterior vaginal cuff.

The technique of operating through the vagina is a prerogative of the gynecologic surgeon. Vaginal surgery is an essential prerequisite in the cultural and surgical training of a qualified gynecologist. However, in the United States, the most common operation gynecologists perform is hysterectomy, which is predominately done abdominally.

Vaginal hysterectomy is the signature operation of the gynecologic profession. Ample evidence shows that the vaginal approach results in lower morbidity, less pain, more rapid recovery, more rapid return to normal activities, consumption of fewer health care dollars and resources, and a host of other benefits. A gynecologic surgeon should have the ability to perform both abdominal and vaginal hysterectomies. However, vaginal hysterectomy is, and should remain, the hallmark of gynecologic extirpative hysterectomy surgery and surgical excellence. Vaginal hysterectomy is the “gold standard” for the surgical removal of the uterus. At minimum, a gynecologic surgeon should perform at least 25% of his/her benign hysterectomies by the vaginal route.

INDICATIONS

With the advent of evidence-based research and outcomes studies, several randomized controlled trials have documented the advantages of the vaginal approach to hysterectomy. A recent Cochrane review concluded that vaginal hysterectomy, rather than abdominal, should be performed whenever technically feasible to reduce complications, shorten hospital stays, and accelerate the patient’s return to normal activities. Despite these results, these studies have not stimulated a change in physician practice patterns, which should be expected from this type of objective evidence. Several investigators have addressed the reasons for the continued dominance of the abdominal route for hysterectomy. Johns and colleagues suggested that the route of hysterectomy is usually determined by the skill, experience, and preference of the operating gynecologist. Few other parameters matter. Dorsey and associates stated that the hysterectomy patient is best served by a surgeon who selects the route with which he or she is most comfortable.

Suggesting that the feasibility of performing vaginal hysterectomy may restrict its implementation has always been a concern, especially for surgeons who prefer to use abdominal or laparoscopic techniques. The intent of developing hysterectomy guidelines was to identify when abdominal hysterectomy is truly mandated (Fig. 32B.1). Using these guidelines, expert gynecologic surgeons have achieved vaginal hysterectomy rates in excess of 90%, in contrast to the overall U.S. average of 30%, which includes laparoscopically assisted vaginal hysterectomy.

Vaginal hysterectomy has usually been indicated for women with uterine or pelvic prolapse, and traditional indications for abdominal hysterectomy have included an enlarged uterus, prior pelvic surgery, malignancy, and extravesical disease, such as endometriosis or pelvic inflammatory disease. We now know that successful vaginal hysterectomy can be done in most of these patients; however, special techniques, such as uterine coring or bivalving, are often helpful, and laparoscopic lymphadenectomy may be required in women with cervical or endometrial cancer. Laparoscopy may also be useful to evaluate an adnexal mass more carefully or the extent of endometriosis before completing the surgery with a vaginal hysterectomy and oophorectomy. Laparoscopy may also be used as an aid to reassure and give confidence to the young vaginal surgeon that extensive adhesions do not exist and the anatomy is relatively normal so that vaginal hysterectomy can be accomplished. With increasing confidence and skill that comes from experience, there are very few patients with indications for hysterectomy in whom the procedure cannot be performed vaginally.

PREOPERATIVE PREPARATION

If the surgeon is concerned about unintentionally injuring the rectum, it is important that he or she have the patient cleanse the rectum with an electrolyte purgative such as GoLYTELY, NuLYTELY, or CoLyte the evening before surgery. If this concern does not exist, a Fleet’s enema is adequate if it is given the evening before surgery. Bowel cleansing evacuates solid stool from the rectum, reduces the bacterial load of the intestinal tract, and reduces the incidence of postoperative enteritis and constipation.

A single-dose antibiotic as a prophylactic measure, usually a first-generation cephalosporin, should be given within 1 hour before the operation is started. Prophylactic antibiotics have been documented to reduce the risk of postoperative infections. It has been the author’s practice during the past 20 years to check the vaginal pH before prepping the patient. If the pH is not normal (3.8–4.2), the normal vaginal ecosystem has been

Abdominal Hysterectomy

altered. A vaginal pH in the range of 5.0 or greater suggests the potential for bacterial vaginosis and the likelihood that the facultative bacteria normally present in the vagina at concentrations of $10^4$ have reached concentrations of $10^8$. This strongly suggests that the vagina is infected before the start of the operation. These patients may not be protected by routine prophylactic antibiotics but may benefit from postoperative therapeutic antibiotics. In such patients, we usually administer 500 mg of metronidazole orally twice daily from the second to the seventh postoperative day. This practice has reduced my postoperative infection rate following vaginal hysterectomy from 9% from 1970 to 1986 to less than 1% from 1987 to present.

Gynecologists have long believed that a Betadine solution used as a preoperative vaginal scrub will remove most potential pathogens in the vagina, but this has recently been questioned. I prefer to prep all patients with 70% ethanol, even in the vagina, and use a self-adherent surgical drape that covers the rectum and conveniently keeps pubic hair and the labia from interfering with the operative field. Shaving of the pubic hair is unnecessary, and shaved patients are more uncomfortable postoperatively. Additionally, the author has always been averse to suturing the labia to the inner thighs.

Copious lavage of the vaginal vault before, during, and after vaginal hysterectomy may also help to prevent postoperative infections by removing bacteria adherent to the vaginal epithelium. Lavage is not used as frequently in the vaginal approach as it should be. Lavage with a lighted irrigation and suction instrument combined can also be used to accomplish this goal.

The type of stirrups used for the lithotomy position is solely at the discretion of the surgeon. No matter what type is used, careful attention is required to protect vulnerable vascular, bony, and neurologic points in the lower extremities. The author prefers the candy cane–type stirrups. The patient should be positioned with the buttocks at the end of the surgical table or just beyond. The table is placed at a zero horizontal position without Trendelenburg. In this manner, the surgeon can look directly into the vagina without having to look over the weighted speculum. Final positioning of the patient should protect the patient, allowing the surgeon to operate comfortably, and provide adequate room for surgical assistants to be effective. Assistants need to stand inside the stirrups to see the operative field to both observe and learn the operation. Pneumatic stockings are also recommended.

OPERATIVE TECHNIQUE

It is valuable to perform an examination under anesthesia before initiating the operation to reconfirm the preoperative exam. Undetected pathology may be appreciated during an
Surgery for Benign Gynecologic Conditions

anesthetized exam along with a more complete assessment of the subtleties of the patient's anatomy. Placement of a tenaculum for applying traction on the cervix can document the degree of descensus. If more descensus is desired, strong traction on the cervix with vigorous massage of the uterosacral ligaments, especially the left uterosacral ligament, for approximately 30 seconds results in a further descensus of the cervix of approximately 2 to 3 cm.

Although some surgeons prefer to stand during vaginal hysterectomy, my preference is to sit. However, to make the assistants comfortable during the operation, the surgeon's chair is raised so the assistants do not need to bend over but can stand straight during the entire procedure. This surgeon prefers to operate with an instrument tray on his lap, which makes it easier to select the desired instruments during the operation. The number of instruments used during vaginal surgery should be kept at a minimum to prevent instruments from obscuring the surgeon's vision. This author believes that the number of instruments used during any gynecologic operation is inversely proportional to the skill of the surgeon, whereas the quality of instruments is directly proportional. These concepts are especially true in vaginal surgery.

Catheterization of the bladder before the initiation of vaginal hysterectomy is usually at the preference of the surgeon. Sometimes it is easier to identify unintentional cystotomy when the bladder has some urine in it. If the bladder is distended, catheterization of the bladder may improve the visibility within this restricted operative space. Some surgeons prefer to instill a dilute solution of indigo carmine or methylene blue before initiating the operation to ensure recognition of an unanticipated operative injury to the bladder. If a cystotomy occurs, it is best to complete the vaginal hysterectomy before proceeding with repair of the bladder. In many cases, the cystotomy may make the bladder easier to dissect because now the location of the bladder is clear and the correct planes more easily visualized. Sometimes a finger in the bladder may also facilitate a difficult dissection. The bladder must be mobilized adequately around the operative injury so that the surgeon can completely evaluate the extent of the cystotomy and be certain that the repair is completed without excess tension on the injured site.

The initial vaginal incision should be made at the border of the vaginal rugae through the full thickness of the vagina (Fig. 32B.2). Unfortunately, it has been taught that the circumscibing incision should be made on the cervix to preserve vaginal length and avoid unintentional entry into the bladder. This is incorrect, because decreased vaginal rugae mark the point where the vagina truly begins. In addition, an incision at the point where the vagina begins appropriately places the mucosal incision closer to the point of entry into the posterior and anterior peritoneum (Fig. 32B.3). An incision in this location allows the surgeon to avoid dissection of the connective tissues between the vagina and the peritoneum, reducing blood loss, because this dissection frequently involves transection of several cervical branches of the uterine artery. Thus, bleeding will be less when the incision is made where the rugae begin or cease to exist.

Julian reported on the benefit of infiltrating the vaginal wall with a mixture of 1:200,000 epinephrine diluted in normal saline to control small blood vessel bleeding from the vagina. Rarely does oozing from the vaginal mucosa result in significant blood loss when the incision is made where the vaginal rugae start. If oozing from the incised edges of the vagina becomes a problem, it is easy to control with electrocautery. At the beginning of the operation, when the cervix is still within the vagina, it is often difficult to perform a circumscibing incision around the cervix with a scalpel or electrocautery.
instrument because it is difficult to maintain either device perpendicular to the circumscribing vaginal incision. This is not a concern when the cervix protrudes from the vagina. However, when the cervix cannot be brought out of the vagina with traction, the initial incision should be made on the anterior vaginal wall from approximately the 10- to 2-o’clock position and on the posterior vaginal wall between the 8- and 4-o’clock positions. These incisions provide adequate space for the subsequent entry into the posterior and anterior peritoneum (Fig. 32B.4A,B).

After completing the vaginal incisions, the cervical tenaculum is replaced on the posterior lip of the cervix with taut traction of the cervix achieved by elevating the tenaculum anteriorly. If the posterior incision in the vagina is placed at the appropriate level where rugae are not present and at the point where the uterosacral ligaments join the cervix, the posterior cul-de-sac and peritoneum can readily be identified with tissue forceps. This is done by putting the subvaginal tissue and accompanying peritoneum on stretch as the peritoneum bulges outward toward the surgeon (Fig. 32B.3). This cannot be overstated. Entry into the posterior peritoneum is best accomplished by an incision directly above the tissue forceps that grasps the outward U-shaped bulge of the peritoneal fold (Fig. 32B.6). If the incision is placed closer to the cervix in an attempt to prevent injury to the rectum, the dissection often proceeds into the posterior cervical stroma. Unfortunately, an incision placed nearer to the cervix frequently results in a retroperitoneal dissection, which pushes the peritoneum superiorly and posteriorly, obscuring identification of the peritoneum. Should this occur, the posterior lip of the cervix and vagina can be cut in a vertical direction that exposes the peritoneum at a higher level so it can be recognized and entered directly. This is a cervicocolpotomy (Fig. 32B.7).

The peritoneum is opened with curved scissors, and a long-bladed Steiner Auvard weighted speculum is introduced into the peritoneal cavity. Examination of the cul-de-sac can provide further pathology—such as endometriosis, leiomyomata, or adrenal pathology—that may be encountered later in the operation. Identification of the uterosacral ligaments by palpation can be accomplished during examination of the cul-de-sac through the posterior colpotomy incision. Transection of the uterosacral ligaments is the single most important step in successfully completing a vaginal hysterectomy. It is unnecessary to tag the posterior peritoneum to the vagina, as the edges of the peritoneum do not separate far from its edges. Oozing of blood from this space between the vagina and peritoneum may occur, but placement of a weighted speculum into the posterior peritoneal cavity will compress most bleeding points between the cut edges of the vagina and the peritoneum.

The cervix should then be retracted downward and inferiorly, and the anterior subvaginal tissue, including the supravaginal septum and the bladder, picked up with tissue forceps and elevated in the midline. The supravaginal septum is part of the pericervical ring and is identified and incised using curved scissors with the tips pointing downward. The handles are not

**FIGURE 32B.4.** A: When cervix remains within the vagina when traction is applied with a tenaculum, the anterior full-thickness vaginal incision need only to be performed between 10 and 2 o’clock. B: Initial full-thickness vaginal incision need only to be performed between the 8- and 4-o’clock position. Note this incision is placed posteriorly where the vaginal rugae begin and where the uterosacral ligaments attach to the cervix. (From Kovac SR, Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins; 2006:106.)
Surgery for Benign Gynecologic Conditions

FIGURE 32B.5. With traction on the cervix anteriorly, the posterior peritoneal fold is grasped with tissue forceps, and the peritoneum is entered by incising with scissors the peritoneal fold directly above the tissue forceps. (From Kovac SR, Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins; 2006:107.)

The peritoneum is grasped and entered above the tissue forceps by a 1-cm opening with the scissors. The shining surface of the peritoneum is recognized, and this opening is further stretched by spreading of the scissors into this space to allow insertion of the right-angle retractor into the anterior cul-de-sac.

FIGURE 32B.7. Cervical colpotomy for entry into the posterior peritoneum. Posterior cervix is grasped with Allis clamps approximately at 4- and 8-o’clock positions. The cervix is incised starting at the 6-o’clock position and incising the cervix and posterior wall of the uterus until the posterior peritoneum is entered. Once the peritoneum is entered, a weighted speculum is placed into the posterior peritoneal cavity. (From Kovac SR, Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins; 2006:108.)
Elevating subvaginal tissue exposing supravaginal septum

FIGURE 32B.8. Entry into the anterior peritoneum involves incising the supravaginal septum to gain entry into the vesicouterine space. Once the vesicouterine space has been entered, the space is developed by spreading the dissecting scissors for placement of a retractor to elevate the bladder. (From Kovac SR, Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins; 2006:109.)

Peritoneum Vesicouterine space Supravaginal septum

which remains in this position and elevates the bladder throughout the entire operation. This does not increase the risk of operative injury to the bladder if the surgeon has properly dissected into the vesicouterine space and retracts the bladder superiorly. The anterior peritoneal fold should always be opened under direct vision. Where the tissue forceps actually grasp the fold will determine the best place to enter the peritoneum (Fig. 32B.11A,B).

Because of the surgeon's desire to avoid injury to the bladder, there is the tendency to dissect as far as possible from the bladder. Thus, this may cause him or her to cut into the connective tissue capsule of the cervix, with further retroperitoneal dissection within the connective tissue stroma of the anterior cervix. Similar to the posterior dissection, this is more likely when the initial incision into the vagina is made too close to the cervix. Further dissection beneath the peritoneum covering of the anterior uterine segment results in failure to enter the anatomic plane, the vesicouterine space between the bladder and uterus. Failure to identify this correct tissue plane and/or a lack of caution results in either further retroperitoneal dissection or unintentional bladder penetration. If an injury to the bladder results, it will occur well above the trigone of the bladder and not near the ureteral orifices. This injury is simple to repair after the uterus has been removed. Unintentional operative cystotomy is a risk of any vaginal hysterectomy with any technique. The overall incidence of operative cystotomy while performing and teaching this technique has resulted in an acceptable cystotomy rate of 1.2% with vaginal hysterectomies.

The use of a sponge on the surgeon's finger to push the supravaginal septum and the vesicouterine space superiorly to
entry into the anterior peritoneum. Peritoneal fold
exposure is significant and makes the peritoneal identification/
the resulting descent of the uterus, increases visibility. This ex-
brosis plane becomes indistinguishable from the supravagi-
ligaments can be accomplished. The uterosacral and car-
anterior peritoneum should always be opened under direct vision,
never blindly, as unintentional entry into the bladder frequently
expose the anterior peritoneum is frequently taught. This could
be considered as more of a technique of *accomplish force* (i.e.,
to accomplish with force) than a surgical dissection, as the
Bladder from the peritoneal fold (Fig. 32B.12).

After both the posterior and anterior peritoneum are suc-
cessfully entered, detachment of the uterus from its support-
entry process less troublesome. Indeed, the uterine artery can
also be divided before peritoneal entry, allowing even greater
exposure.

The exact location of the ureter during abdominal, laparo-
coscopic, and vaginal hysterectomy is always a concern. Nichols
and Randall suggested that the risk of ureteral injury during a
vaginal hysterectomy is greater because the ureters may be
pulled downward and medially by the uterine artery. By study-
ing the surgical anatomy of the ureter during vaginal hysterec-
tomy, it was found that the ureteric artery is not the primary
factor drawing the ureter closer to the uterus. Instead, traction
on the cardinal ligament is the chief factor affecting movement
of the ureter, which suggests there is a margin of safety dur-
ing each step of a vaginal hysterectomy. This was confirmed
by magnetic resonance imaging studies with a brass tenaculum
placed on the cervix in a resting state and under traction. When
traction was applied to the cervix, the ureter's position was dis-
placed upward and lateral to the position of the ureter at rest
(Fig. 32B.13A,B). This movement confirmed radiographically
that the ureters were displaced further laterally and superiorly
from the cervix to a position of surgical safety. When bladder
traction was used, this effect was more pronounced. During
surgical identification of the ureter at the time of radical vagi-
ral hysterectomy, it can be observed that once the uterosacral
and cardinal ligaments complex has been cut, the ureter actually
moves out of harm's way. If the ureters have not been dissected
and identified before the cutting of uterosacral and cardinal
ligaments, it is difficult to dissect and visualize them vaginally
once the ligaments have been cut. Thus, it is evident that the
uterosacral and cardinal ligaments, not the uterine artery, play
a major role in determining the ureter's position during vagi-
nal hysterectomy. Once these ligaments have been divided, the
ureter will retract out of harm's way (Fig. 32B.13A,B).

When possible, I attempt to enter both the posterior and
anterior peritoneum before clamping the uterosacral and car-
dinal ligaments. Placement of a retractor under the bladder also
elevates the ureter out of the operative field (Fig. 32B.15A, B). It is recommended that once the retractor is placed under the bladder, it should not be removed during any stage of the vaginal hysterectomy. It was clearly demonstrated in the study of ureteral movement during vaginal hysterectomy that when forceful traction was applied to the uterus during vaginal hysterecomy with no retraction of the bladder, the uterine was pulled medially and potentially placed in harm’s way.

If the vaginal mucosa has not been completely circumscoped, once the anterior and posterior peritoneum have been entered, the vaginal incision should be completed by connecting the previous anterior and posterior incisions before the supportive ligaments of the uterus can be clamped. The uterosacral ligaments are clamped with the tip of the clamp, including the lower portion of the cardinal ligaments. The posterior tip of each clamp should be placed within the peritoneal cavity and the anterior tip around the ligament superiorly. The Kovac vaginal hysterectomy clamp (Marina Medical, Hollywood, FL) has less pelvic curve than the Hancey clamp, longer jaws, and two rat-tooth projections within the jaws to prevent slippage of tissue within the clamp (Fig. 32B.16A–C). Rotating the handles of the clamp laterally and superiorly facilitates suturing at the tip of the clamp. This brings the tip of the clamp into full view and exposes a triangular area beneath the clamp for easier retrieval of the needle. I do not believe it is necessary to double clamp each uterine supportive or vascular structures. Each uterosacral ligament is secured by a transfixation suture to the posterior lateral surface of the vagina and is tied behind the clamp at about the 4- and 8-o’clock positions. Lateral traction on this suture provides the best exposure to the remaining structures within the broad ligament. This replaces the need for lateral retractors into the vagina, which only expose the lateral vagina and not the broad ligament (Fig. 32B.17). Clamping and tagging the uterosacral ligaments separately allows for their identification, later use in cuff repair, and, if desired, a McCall’s culdoplasty at the end of the procedure. The uterosacral ligament pedicle is the only one that needs to be tagged during a vaginal hysterectomy.

After making sure the tips of the clamps are within the posterior peritoneal cavity, the cardinal ligaments are clamped. The anterior peritoneum should not be pulled into this clamp at this point of the operation. Bringing the peritoneal edges together serves to seal off the broad ligament by effectively preventing bleeding from the vascular plexus located within the leaves of the broad ligament. Because the anterior peritoneum usually begins at the level of the uterine vessels, there may not be enough stretchable peritoneum to bring both the anterior and posterior peritoneal surfaces together at the level of the cardinal ligaments. Therefore, to be certain that the surgeon can seal both leaves of the broad ligament together with the uterine artery, it is best to avoid any attempt to bring the peritoneal edges together when the uterosacral or cardinal ligament are clamped (Fig. 32B.18). A simple suture ligature first at the tip and then around the end of the clamp is usually sufficient for hemostasis of the cardinal ligament without the need for transfusion (Fig. 32B.19). This suture ligature is not tagged or held.

At this point, the uterine arteries should become visible on each side of the uterus. They are clamped with one good clamp at a time. This clamp is placed parallel to the uterus as the tip of the clamp secures the uterine artery as it bifurcates into ascending and descending branches (Fig. 32B.19). As traction is placed on the uterus when the artery is cut, there is a definite sensation that the uterus descends; this signifies that the entire uterine artery has been transected, including the ascending and descending branches. If descent of the uterus is not noted, often an additional portion of the uterine artery remains and intially be taken with another clamp. A single transfixation is all that is required if only the uterine artery is within the clamp. Limiting the tissue within the clamp to the vascular bundle helps to make the pedicle manageable and the suture ligature more secure. Many surgeons try to include middle portions of the broad ligament with the uterine artery because they feel a need to place clamps on the remaining portions of the broad ligament as they proceed up on each side of the uterus. Most gynecologic surgeons are comfortable with performing a vaginal hysterectomy to the point of ligating the uterine artery. Beyond this point, many gynecologists wonder if the uterus can be removed vaginally. This is the result of an ungrounded belief that continued clamping up each side of the remaining broad ligament is required for successful uterine removal. This is a puzzling idea, because when performing an abdominal hysterectomy, the upper portions of the broad ligament above the uterine vessels are sharply dissected, and no clamps are used. When the vaginal surgeon continues to place clamps above the uterine artery, the space to place each clamp becomes more restrictive, and placing sutures around these clamps becomes more difficult. This problem often spurs comments by surgeons that vaginal hysterectomy is a difficult operation because of restrictive access and visibility. Clamping and suturing of the broad ligament above the uterine artery
is unnecessary because there are only occasional significant blood vessels within the leaves of the broad ligament. There is no need to place clamps above the uterine artery until the round ligaments, fallopian tubes, and utero-ovarian pedicles are reached. Attempts to clamp and ligate the avascular tissue above the uterine vessels have been the major stumbling blocks for transvaginal removal of the uterus by inexperienced surgeons.

If the uterus is small and the uterine artery has been secured, the next step in uterine removal is to deliver the fundus through either the anterior or posterior colpotomy. When the uterus is small and mobile, simple traction may result in delivery of the uterus without the need for “flipping it.” In an attempt to deliver the uterus (regardless of the size) closer to the surgeon and out of the vagina when downward traction and flipping of the fundus do not appear possible, the surgeon may use the alternate technique of intramyometrial coring, instead of resorting to clamps placed on the upper portions of the broad ligament. This technique was introduced by Lash in 1941 and reintroduced in 1986 for removal of large uterus. In this simple technique, the myometrium can be circumferentially incised with a scalpel placed parallel to the long axis of

---

**FIGURE 32B.14.** A: Transection of the uterosacral ligament returns this structure back to its original position. B: After both uterosacral and cardinal ligaments have been transected, ureters are displaced upward and lateral out of harm’s way. Vaginal Hysterectomy

FIGURE 32B.15. A, B: Note elevation of the ureters out of harm’s way with upward traction on the bladder during vaginal hysterectomy. (From Kovac SR, Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins; 2006:114.)

the uterus and beneath the serosal covering of the uterus (Fig. 32B.20A,B). This removes a core inside the uterus without violating the integrity of the endometrial cavity. To facilitate the coring incision, strong traction on the uterus is necessary.

The Lash or coring incision reduces the size of the uterus by decreasing its width, thereby increasing its length, similar to a baby’s head as it becomes molded during childbirth. In effect, coring converts a spherical structure into an elongated rod shape, enhancing the surgeon’s ability to facilitate transvaginal removal of a wide uterine fundus (Fig. 32B.21A–C). This is a surprisingly bloodless maneuver once the uterine arteries have been secured. Strong traction is placed on the uterus during the coring, which restricts blood flow from the ovarian pedicles.

During the coring procedure, the uterus will begin to descend through the vagina, allowing the surgeon to visualize the cornual portion of the uterus and exposing the utero-ovarian ligament, round ligament, and fallopian tube. Once these structures become visible, the surgeon is assured that the uterus can be removed vaginally. Some surgeons prefer bivalving the uterus, but this can be more cumbersome, as it requires the surgeon to deal with two pieces of the uterus. Once the upper pedicles are visualized, they can either be clamped individually with two clamps or together with one. Depending on the surgeon’s preference and experience, a suture placed around the tip of the clamp and tied or transfixed behind is appropriate. This suture is tagged to provide traction on the pedicle and expose the ovary for evaluation or removal, but the ovary should not be removed at this time.

Once the uterus has been removed, it is appropriate to evaluate each pedicle to determine whether bleeding persists. If the ovaries are removed before it is adequately determined that all pedicles are hemostatic, the surgeon may spend considerable operative time finding the source of such bleeding, as it frequently appears to be from a higher point but may actually be from one of the uterine pedicles. Each pedicle can be evaluated by starting at the 12-o’clock position within the peritoneal cavity and proceeding in a clockwise manner. The use of a 4 x 4 sponge folded longitudinally on sponge forceps is most helpful. If brisk bleeding is noted, most often it can be found by

placing traction on the upper pedicle tags and looking between the uteroovarian and uterine artery pedicles. Bleeding from this area is usually a result of the anastomosis of vessels between the ovarian and uterine artery. Because this is the most frequent site of this type of bleeding, the surgeon should direct his or her search to this area first. Placement of a clamp at the site of bleeding followed by a suture around the clamp or placement of a figure-of-eight suture passed through the vagina into the peritoneum from outward to inward will rapidly control this bleeding (Fig. 32B.22).

If no bleeding points are discovered from any pedicle, the posterior vaginal mucosa will most likely be the source of bleeding. Posterior cuff bleeding may sometimes be rather brisk from the separation of the vagina and the peritoneal edge. It is always more brisk in patients younger than 40 years of age. Before proceeding with any concurrent procedure, it is best to control blood loss from this area with electrosurgery or a running-absorbable suture, starting from the left uterosacral ligament tag to the right uterosacral ligament tag. Once this is complete, further examination of the peritoneal cavity should reveal complete hemostasis from all potential bleeding sites.

If only the removal of the uterus has been agreed on by the surgeon and the patient, support of the vaginal apex becomes the next most important decision. If an oophorectomy is planned in conjunction with the hysterectomy, it should be performed at this point.

### VAGINAL OOPHORECTOMY

There appears to be some reluctance to combine vaginal hysterectomy with oophorectomy because vaginal oophorectomy is thought to be a risky and difficult procedure. Two factors seem to foster this perception: (i) fear of restricted access to the ovaries and (ii) inadequate visibility of the adnexa during conventional vaginal surgery.

To obtain objective evidence regarding these perceptions, a prospective study was designed by Baden and Walker to determine whether there is adequate visibility and accessibility for transvaginal oophorectomy in most patients undergoing vaginal hysterectomy. After the uterus was removed, accessibility of the ovaries for transvaginal removal was assessed by stretching the infundibulopelvic ligament, placing traction on the suture tag used to ligate the uteroovarian ligament, round ligament, and fallopian tube and grading the position of the ovaries in relation to the long axis of the vagina. The degree of ovarian descent and visibility was graded with a system used to grade pelvic organ prolapse (Fig. 32B.23) (Table 32B.1). The grade corresponded to the minimal degree of descent of either ovary.

To determine what grade would be considered accessible and visible for transvaginal oophorectomy by most gynecologic surgeons, the experience of other surgical specialties was considered. For example, the distance from the hymenal ring to the ischial spine is approximately 8 cm. In dentistry, the distance from the front teeth to the last molar is 6 cm; in otolaryngology, the distance from the front teeth to the tonsil for tonsillectomy is 10 cm. Therefore, it was postulated that any ovary grade 1 or higher should be visible and accessible for transvaginal removal by most gynecologic surgeons. Of the 875 patients between 29 and 69 years of age who were evaluated for ovarian descent after hysterectomy, 92.9% had ovarian mobility to at least the midportion of the vagina (grade II). In another 4.6%, the ovary could be pulled down outside the hymenal ring (grade II). Only 2.5% of these patients had very little ovarian mobility, which would have made vaginal oophorectomy very difficult (2.4% grade I and 0.1% grade 0). Although this study provided objective evidence that the ovaries may be more visible and accessible for transvaginal removal than previously perceived, there
may be times that the ovary may be inaccessible for transvaginal removal as a result of adhesive disease, endometriosis, suspected significant pathology, or other conditions. However, the ovary should not be considered as completely inaccessible at the start of any vaginal hysterectomy. Smale and colleagues, Davies and associates, and Sheth have reported that planned vaginal salpingo-oophorectomy is successful in 94% to 97% of women undergoing vaginal hysterectomy. The routine use of the laparoscope to perform an oophorectomy before a vaginal hysterectomy has been heralded as safe and comfortable, and has become commonplace. “To be sure we can get the ovaries” is a phrase too often heard worldwide to justify the use of
FIGURE 32B.21. A: The cervix has been circumscribed through the full thickness of the vagina around the cervix, the posterior and anterior peritoneum entered, and the uterosacral and cardinal ligaments secured. B: After ligation of the uterine arteries, an incision is made in a circumferential fashion parallel to the endometrial cavity and into the outer superficial myometrium in the same plane. Constant traction on the tenaculum while coring assists in developing the proper plane. C: Continued coring and traction reduces the size of the uterus by exteriorizing the inside of the uterus with an intact endometrial cavity through the introitus. Intramural myomas are sometimes transected during the coring process. (From Kovac SR. Intramyometrial coring as an adjunct to vaginal hysterectomy. Obstet Gynecol 1986;78:131.)
FIGURE 32B.22. Most common source of bleeding after removal of the uterus is the anastomosis between uterine and ovarian arteries. Suture placed through the lateral vagina into the lateral peritoneum in a figure-of-eight fashion and tied resolves most, if not all, bleeding from this area. (From Kovac SR, Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins; 2006:120.)

abdominal, laparoscopically assisted, or laparoscopic hysterectomy. For too many years, it was believed that the ovaries were inaccessible because they are "too high" for transvaginal removal. This has erroneously guided the selection of abdominal or laparoscopic hysterectomy.

Good surgical practice dictates that objective determination of the visibility and accessibility of the ovaries be the primary criteria for selecting a particular route of oophorectomy. Thus, if the ovaries are found to be inaccessible at the time of vaginal hysterectomy, ovarian removal can be performed with the laparoscope or by a simple laparotomy once the initial operation is complete. The correct paradigm substantiated by clinical evidence is to first attempt ovarian removal transvaginally. If that is not possible, the surgeon should proceed with laparoscopy or laparotomy after completion of a vaginal hysterectomy for removal of the adnexa.

Surgical Technique of Vaginal Oophorectomy

Vaginal salpingo-oophorectomy may be accomplished in the following manner. Downward traction is applied to the suture ligating the uteroovarian ligament, round ligament, and fallopian tube. The end of the fallopian tube is directed toward the ovary with tissue forceps; a long, sharply angled clamp is placed between the round ligament, the uteroovarian ligament, and tube across the infundibulopelvic ligament; and the tube and ovary are excised. A suture is placed approximately 2 cm from the tip of the clamp, and a single throw tie is tightened around the tip, which usually secures the ovarian artery. The suture is then placed behind the clamp for suture transfixation and firmly tied with several throws. As the suture is tied, the surgeon can appreciate the security of this suture around the infundibulopelvic pedicle. Alternatively, some surgeons have used an Endoloop (Ethicon Endosurgery, Cincinnati, OH) to secure the infundibulopelvic pedicle.

An alternative method of salpingo-oophorectomy is the three-step technique described by Zimmerman. This technique mimics the same maneuvers that are used to remove the adnexa abdominally. After removal of the uterus, the utero-ovarian pedicle is held with a clamp, and the handle is rotated laterally. This maneuver exposes the round ligament that can be clamped, transected, and ligated. Division of the round ligament gives the surgeon access to the retroperitoneal space between the leaves of the broad ligament. Division of this space makes it possible to isolate, clamp, and ligate the mesovarium.
After division of the mesovarium, the only remaining tissue connected to the adnexa is the infundibulopelvic ligament. This ligament can be clamped and suture ligated or secured with an Endoloop (Fig. 32B.24). Division of the adnexectomy into three manageable steps increases surgical control and decreases the likelihood of a complication during suture application. Transection of the round ligament and mesovarium as separate pedicles significantly increases descent of the adnexa, resulting in increased visibility of the infundibulopelvic ligament.

**CLOSURE AND SUPPORT OF THE VAGINAL CUFF**

Closure of the peritoneum with vaginal hysterectomy is frequently described as necessary by some surgeons. I have not routinely closed the peritoneum for the past 25 years and have never regretted this sometimes dangerous exercise that results in no benefit to the patient. Leaving the peritoneum open should expose any immediate postoperative bleeding.

The remaining part of the vaginal hysterectomy is to support the vaginal cuff so that an enterocele or vaginal vault prolapse does not occur in later years. Compensation for the connective tissue defect created by the removal of the cervix is best accomplished at the time of hysterectomy. Failure to adequately compensate for the cervical defect may expose the patient to an increased risk for posthysterectomy vaginal vault prolapse. Enterocele repair and suspension of the prolapsed posthysterectomy vagina are among the most technically demanding of all pelvic surgery procedures. Closure of the cervical defect along with reestablishment of the suspensory axis of the vagina by incorporating the uterosacral ligaments into the cuff are effective prophylaxis reducing the risk of future prolapse.

The incidence of enterocele after hysterectomy can range between 0.1% and 16%. Nichols and Randall described a technique of excising excess peritoneum in the cul-de-sac to prevent future development of an anterior enterocele. Because this technique only removes excess peritoneum and does not address the cause of an enterocele after hysterectomy, subsequent enterocele formation has not been prevented because no musculofascial defect has been corrected or reinforced.

Several other methods to repair the posterior vaginal cuff for prolapse prophylaxis have been described. These procedures emphasize the use of the uterosacral ligaments in any repair. Inclusion of the uterosacral ligaments in cuff repair is very important because of their role as the primary suspensory elements in the vaginal vault. Connecting the uterosacrals to the cuff reestablishes the suspensory axis of the vagina and should be considered during all hysterectomies. The most commonly employed technique to close the posterior vaginal cuff is the McCall culdoplasty. This technique is thought to obliterate the cul-de-sac while it suspends the posterior superior vagina and its fascial attachments to the uterosacral ligaments, bringing these supporting ligaments together in the midline (Fig. 32B.25). This technique was a marked improvement over previous beliefs that the only thing necessary after the uterus was removed was to close the vagina. This resulted in a high incidence of vaginal vault prolapse and associated enterocele formation. I routinely performed the McCall culdoplasty after all
vaginal hysterectomies for many years to prevent future vaginal vault prolapse and enterocele formation. Recent advancements in pelvic reconstructive techniques, as well as an understanding of the cause of enteroceles, has brought us to a new method of preventing enteroceles and vault prolapse at the time of hysterectomy, especially with those patients who have a rectocele. Rectoceles result from an apical separation of the rectovaginal fascia from the uterosacral ligaments. This distal apical displacement allows rectoceles and enteroceles to develop contiguously through the same fascial defect. In our experience, enteroceles are routinely associated with rectoceles, which may not have been identified during the vaginal hysterectomy. This suggests that failure to identify and manage the presence of an enterocele at the time of vaginal hysterectomy might be the cause of the increased incidence of enterocele formation discovered in later years.

It is further recognized that enteroceles form as a result of the separation of the rectovaginal fascia from the pubocervical fascia (Fig. 32B.26). As a result of hysterectomy and removal of the cervix, there is an iatrogenic separation of the rectovaginal septum and the fibers that normally connect this structure to the anterior vaginal fascia through the connective tissue that forms the pericervical ring. This separation widens the cul-de-sac and separates the fascial attachments from the posterior vaginal wall and the rectovaginal fascia, thus allowing the peritoneum, with its intraabdominal structures, to protrude through this weakness with any increases in intraabdominal pressure. Vaginal vault prolapse and enterocele formation differ by anatomy. The upper vagina can be well supported even though an enterocele exists, and vice versa. An enterocele (DeLancey level II of vagina) descends through the weakened floor and fascia of the posterior vaginal segment. Vault prolapse of the upper vagina can be well supported, even though an enterocele is identified, management of the vaginal cuff is performed by placing mesh or graft attached anteriorly to the pubocervical fascia and to the rectovaginal fascia posteriorly, which closes the space vacated by the absence of the cervix. The difference between the shorter anterior pubocervical fascia and the longer posterior rectovaginal fascia is resolved with the mesh or graft (Fig. 32B.27). The lateral end of the mesh/graft is attached to the uterosacral ligament at its insertion into the sacral periosseum, a vaginal sacral colpocpy (Fig. 32B.28). The presence of a rectocele requires the posterior vaginal wall be opened in the midline up to the level of the newly formed cul-de-sac. The defect from separation of the rectovaginal fascia from the uterosacral ligaments is identified. If an enterocele sac is identified, opening of the sac with high ligation of the sac is unnecessary, as the mesothelial lining of the peritoneal sac has little supportive value. The sac is simply pushed upward as a 7 × 10-cm piece of small intestine submucosa (MS) graft (Cosk; Spencer, IN) and is used to reattach the separation of the rectovaginal fascia from the pericervical ring. The central portion of the graft is reattached to the pericervical ring with permanent sutures, as permanent sutures attach the proximal lateral portion of the graft to the uterosacral ligaments or sacrospinous ligaments. The central reattachment of the graft to the pericervical ring corrects the enterocele, as the lateral sutures to the uterosacral or sacrospinous ligaments support the upper vagina to prevent future vault prolapse. The distal end of the graft is

![Surgical Techniques](Fig. 32B.26. Separation of the pubocervical and rectovaginal fascia with enterocele formation. From Kovac SR., Zimmerman CW, eds. Advances in reconstructive vaginal surgery. Philadelphia: Lippincott Williams & Wilkins, 2006:124.)
attached to the perineal body. Thus, a new rectovaginal fascia is created, correcting the enterocele and rectocele with its proximal attachment to the pericervical ring and its distal attachment to the perineal body.

The objective in closing the vaginal epithelium is to approximate the cut edges of the vagina together in a smooth line with as little irregularity as possible. This technique will aid in preventing postoperative granulation tissue from forming at the site of vaginal closure. Others have suggested that the vagina should be closed vertically to preserve vaginal length. Cruikshank and Pickles demonstrated that vaginal length depended on the support of the vaginal cuff, not any specific method of epithelial closure. They concluded that as long as there is good vault support, vaginal length is not affected by the orientation of the vaginal mucosal closure. Vertical closure places the scar at the top of the vagina, which may cause hypesthesia during coitus, requiring subsequent scar revision. The author prefers to close the vagina in a transverse direction. If the cuff has been adequately supported, the transverse closure is positioned toward the anterior vagina wall, leaving more depth to the posterior vaginal wall for accommodation with coitus.

Some investigators have recommended that the vaginal cuff be left open or a drain placed within the vaginal (closure) incision to reduce the morbidity of vaginal cuff cellulitis or abscess formation. With the widespread use of prophylactic antibiotics, there is no longer any need for those techniques. In addition, leaving the cuff open may lead to an increased incidence of enterocele formation and vaginal vault prolapse.

The decision to place packing into the vagina postoperatively is a religious one. A vaginal pack need not be used after vaginal hysterectomy unless concomitant pelvic reconstructive surgery is performed. Complete hemostasis should be achieved after vaginal hysterectomy. Significant postoperative bleeding can rarely occur from a vascular pedicle. If that does occur, it is important to become aware of this problem as soon as possible; vaginal packing will only delay this diagnosis and not prevent the problem. It is important to be aware of postoperative bleeding sooner rather than later while the patient is still hemodynamically stable, so a pelvic arteriogram may be performed early in the course of such bleeding. The arteriogram may demonstrate the bleeding site and allow arterial occlusion, thus preventing the need for laparotomy.

For some, it is not a routine practice to insert an indwelling transurethral catheter following the removal of a normal-size uterus. Removal of enlarged uterus may cause occasional transient injury to the bladder and transient postoperative voiding problems; therefore, in such patients, bladder drainage is usually suggested, at least overnight.

For 30 years, I have recommended routine cystoscopy following vaginal hysterectomy. Before cystoscopy, 5 cc of indigo carmine is administered intravenously by the anesthesiologist. The strong efflux of blue dye through each ureteral orifice following vaginal hysterectomy. Before cystoscopy, 5 cc of indigo carmine is administered intravenously by the anesthesiologist. The strong efflux of blue dye through each ureteral orifice following vaginal hysterectomy. Before cystoscopy, 5 cc of indigo carmine is administered intravenously by the anesthesiologist. The strong efflux of blue dye through each ureteral orifice following vaginal hysterectomy. Before cystoscopy, 5 cc of indigo carmine is administered intravenously by the anesthesiologist.
Randomized controlled trials have demonstrated that women treated by vaginal hysterectomy experience lower morbidity, less pain, more rapid recovery, and a more rapid return to normal activities compared with abdominal or laparoscopically assisted vaginal hysterectomy. They also consume fewer health care dollars and resources.

Using guidelines to determine the route of hysterectomy adopted by the National Guideline Clearinghouse, it is feasible to perform 90% of hysterectomies for benign disease indications via the vaginal route.

Following the National Guideline Clearinghouse guidelines for selecting the route of hysterectomy, even for a resident training environment, has been shown to decrease the number of abdominal hysterectomies.

To minimize bladder and rectal injuries, the anterior and following the National Guideline Clearinghouse guidelines for selecting the route of hysterectomy, even for a resident training environment, has been shown to decrease the number of abdominal hysterectomies.

The risk of ureteral injury can be minimized by retracting the only vascular pedicle above the uterine vessels contains the round ligament, utero-ovarian ligament, and fallopian tube. These structures can generally be clamped in a single pedicle.

Transvaginal removal of the ovaries at the time of vaginal hysterectomy should be technologically feasible in more than 90% of patients.

Following vaginal hysterectomy, the presence of pre-existing pelvic support defects should be carefully evaluated and repaired if present. The vaginal vault should always be resuspended to the uterosacral ligaments.

Bibliography

CHAPTER 32C ■ LAPAROSCOPIC HYSTERECTOMY

FRED M. HOWARD

DEFINITIONS

Laparoscopically assisted vaginal hysterectomy (LAVH)—Vaginal hysterectomy that is assisted by laparoscopy; the laparoscopic procedures may include adnexectomy and the superior portions of the hysterectomy, but not ligation of the uterine vessels. Laparoscopic subtotal hysterectomy (LSH)—Hysterectomy that is performed completely by laparoscopy; however, the uterine corpus is amputated from the cervix at the level of the isthmus, and the cervical stump will remain in situ. Total laparoscopic hysterectomy (TLH)—Abdominal hysterectomy that is performed completely by laparoscopy with no vaginal component. The vaginal cuff is closed via the laparoscope. Vaginally assisted laparoscopic hysterectomy (VALH)—Hysterectomy that is performed mostly laparoscopically, including ligation of the uterine vessels. The vaginal portion consists of only the vaginal incision and repair.

There are three major subdivisions of total hysterectomies that involve the use of laparoscopy: laparoscopically assisted vaginal hysterectomy (LAVH), vaginally assisted laparoscopic hysterectomy (VALH), and total laparoscopic hysterectomy (TLH). LAVH is a vaginal hysterectomy that is assisted by laparoscopy; the laparoscopic procedures may include adnexectomy and the superior portions of the hysterectomy, but not ligation of the uterine vessels (Fig. 32C.1). Indications for LAVH are known or suspected diseases that preclude a vaginal hysterectomy without assistance laparoscopically; i.e., laparoscopy is used to convert an abdominal hysterectomy into a vaginal hysterectomy. An example might be a patient with extensive peritoneal endometriosis that is not amenable to excision vaginally. In such a case, laparoscopy might be used to excise all of the extrauterine endometriosis, and then a vaginal hysterectomy would be performed. VALH is a hysterectomy that is performed mostly laparoscopically, including ligation of the uterine vessels, and the vaginal portion consists of only the vaginal incision and repair. For research purposes, laparoscopic hysterectomies can be more specifically classified (Table 32C.1), but these classifications have minimal usefulness in clinical practice.

HISTORY

Operative laparoscopy was introduced to gynecological practice by Rusul Palmer, from France, in the late 1930s and early 1960s. Palmer described the use of laparoscopy for adhesiolysis, cyst aspiration, ovarian biopsies, electrocautery of endometriosis, and tubal sterilization. Patrick Steptoe, from England, and Hans Frangenheim, from Germany, both of whom studied with Palmer, helped to widely popularize operative laparoscopy in Europe. Melvin Cohen is credited with introducing operative laparoscopy to the United States in 1966, after he returned from visits with Palmer and Steptoe. Initially in the United States, operative laparoscopy consisted primarily of tubal sterilization; its applications grew rapidly to treatment of adenexal disease, ectopic pregnancy, adhesive disease, and endometriosis. Reich and associates published the first case of LAH in 1969, performing it for the treatment of a patient with endometriosis and leiomyomata. Since that original description, laparoscopy has increased remarkably as a surgical approach to hysterectomy worldwide. From 1990 to 1997, the proportion of hysterectomies performed laparoscopically in the United States increased by 30-fold, from 0.3 to 9.9% (Table 32C.2). Unfortunately, this increase appeared to be the result of laparoscopic assistance of vaginal hysterectomies rather than conversion of abdominal hysterectomies to laparoscopic or vaginal hysterectomies.

INDICATIONS

The indications for hysterectomy already have been discussed in this chapter. The choice of surgical approach—vaginal, laparoscopic, or abdominal—is determined by the technical feasibility of the various procedures.
FIGURE 32C.1. Illustration of laparoscopically assisted vaginal hysterectomy (LAVH). With a LAVH, all or none of the superior portion of the hysterectomy, down to but not including ligation of the uterine vessels, may be performed laparoscopically, as illustrated by the darkly shaded portions of the diagram. The colpotomy and ligation of the uterine vessels are performed transvaginally with a LAVH, as illustrated by the lightly shaded portions of the diagram.

FIGURE 32C.2. Illustration of vaginally assisted laparoscopic hysterectomy (VALH). With a VALH, the superior portion of the hysterectomy down to ligation of the uterine vessels is performed laparoscopically, as illustrated by the darkly shaded portion of the diagram. The colpotomy is performed transvaginally with a VALH, as illustrated by the lightly shaded portion of the diagram.

FIGURE 32C.3. Illustration of total laparoscopic hysterectomy (TLH). With a TLH, the hysterectomy is performed completely laparoscopically, as illustrated by the darkly shaded portion of the diagram. None of the surgery is performed transvaginally with a TLH.

FIGURE 32C.4. Illustration of laparoscopic supracervical hysterectomy (LSH). With an LSH, the hysterectomy is performed completely laparoscopically down to the level of the internal cervical os, as illustrated by the darkly shaded portion of the diagram. The cervix is not removed, and none of the surgery is performed transvaginally with an LSH.
32C.3. Operative times averaged 30 minutes longer for LAVH, indicative of vaginal hysterectomy. The groups were similar in their ability to perform LAVH in most women who had concomitant hysterectomy (TAH). LAVH was successfully performed in 31 of 34 patients, with the LAVH group (26 of 34; \( p = .018 \)). Postoperative recovery was significantly faster with LAVH, with shorter hospital stays (2.1 versus 4.1) and fewer convalescent days (28 versus 38).

Another multicenter study from Italy of LAVH compared with TAH enrolled 116 women who were not candidates for total vaginal hysterectomy (TVH). In this trial, there was no difference in operative time between LAVH and TAH, and none of the LAVH cases required conversion to laparotomy (Ta

Another multi-institutional study of VALH-bilateral salpingo-ophorectomy (BSO) versus TAH-BSO reported by Raju and Auld showed similar results. This was a randomized trial involving 80 women, but obese women and women with uteri greater than 14 weeks' gestational size were excluded from this study. Two (5%) of the LAVH-BSO patients were converted to laparotomy because of bleeding. Although operative time was significantly longer with LAVH-BSO, hospital stay and recovery time were significantly reduced with LAVH-BSO (Table 32C.5).

Another clinical trial of VALH versus TAH was published by Falcone and colleagues and randomized 48 patients (Table 32C.8). One patient (4%) in this study required conversion from VALH to laparotomy because of bleeding. There was one intraoperative complication in the VALH group: a small bowel laceration that did not require a laparotomy for repair. There were no intraoperative complications in the TAH group. Again, results were similar to the previously reviewed trials, with no significant differences in blood loss (based on hematocrit), transfusion rates, or postoperative complications. Hospital stays were shorter and postoperative pain was decreased with VALH. Patients who had VALH returned to work sooner than patients who had TAH.

### Total Laparoscopic Hysterectomy versus Total Abdominal Hysterectomy

Laparoscopic Hysterectomy

The major arguments for subtotal hysterectomy are decreased risk of urinary tract injuries and decreased risk of infection. Randomized trials have been published comparing abdominal subtotal and total hysterectomies, but they provide no evidence of compelling advantages of one procedure over the other. These trials have found no advantage of subtotal hysterectomy on bladder function, vaginal vault prolapse, or sexual satisfaction.

Data from a Danish randomized trial of abdominal subtotal versus total hysterectomies showed a significantly lower proportion of women were incontinent 1 year after total abdominal hysterectomy than after subtotal abdominal hysterectomy (STAH) (9% vs. 18%, respectively; 21% were incontinent preoperatively in each group). At 1 year, there were no statistically significant differences in quality of life, constipation, prolapse of the vaginal or cervical stump, satisfaction with sexual life, or pelvic pain. Vaginal bleeding was present in none of the TAH patients, but was present in 20% of the STAH patients. Operative time was shorter by about 15 minutes with STAH, and median blood loss was 150 mL less. Perioperative and postoperative complications were not different.

A U.S. randomized trial of TAH versus STAH showed no statistically significant differences in procedure time, estimated blood loss, febrile morbidity, urinary tract infections, urinary tract injuries, blood transfusions, return of bladder function, or length of hospital stay. Two-year outcomes for relief of pelvic pain, back pain, pelvic or bladder pressure, prolapse, urinary urgency, incomplete urinary emptying, urinary stress incontinence, or urinary urge incontinence were not different between the two groups. Cyclic bleeding was reported in only 7% of the STAH patients in this study.

A British randomized trial showed that TAH was associated with a statistically significantly longer duration of surgery (12 minutes longer), greater blood loss (100 mL more), more febrile morbidity (19% vs. 6%), and a longer hospital stay.

NS, not significant.

(1 day longer) than was STAH. At 12 months after subtotal hysterectomy, 7% of the women had cyclical vaginal bleeding in this study. There were no differences in bladder function, bowel function, or sexual function between the two groups.

There are no randomized trials, only observational studies, comparing LSH to TLH or LAVH. Results of four such studies are summarized in Table 32C.11. On average, LSH is slightly faster, with slightly less blood loss and shorter hospital stays than LAVH or TLH.

### SURGICAL TECHNIQUE

#### Laparoscopically Assisted Vaginal Hysterectomy

After general anesthesia is induced, the patient is placed in low lithotomy position using Allen-type stirrups. Modern stirrups that allow the legs to be repositioned to full dorsal lithotomy position without the removal of sterile drapes greatly facilitate LAVH. An examination under anesthesia is done with particular attention to evaluation of the pelvic and vaginal dimensions to confirm that the vaginal part of the procedure can be readily performed. Generally the bituberous diameter should be 9 cm or more, the pubic arch 90 degrees or more, and the vaginal apex should be greater than two fingerbreadths (about 4 cm). Although a mobile uterus that descends with traction facilitates the procedure, the vaginal portion of an LAVH can be done as long as the uterine vessels are accessible to clamping and ligature vaginally.

I prefer to position the patient’s arms at her side, padding them as necessary and being sure not to hyperextend the elbows or externally rotate the arms. Many anesthesiologists oppose this placement because it makes the intravenous site less easily accessible. If the arms are placed on arm boards, they must be positioned to allow adequate surgical access without hyperextension of the shoulders, to avoid axillary injury. Shoulder braces should generally be avoided; if they are used, adequate padding is important to avoid injury. It is wise for the surgeon to personally supervise positioning of the patient.

After the patient is positioned, the abdomen, perineum, and vagina are prepared and draped. A Foley catheter should be placed. I often prefer a three-way catheter so that sterile infant formula can be instilled into the bladder to aid bladder dissection if it is done laparoscopically. A tenaculum is placed on the cervix, and an intrauterine manipulating device is inserted so that the uterus can be manipulated during the laparoscopy. As an alternative, a laparoscopic tenaculum can be used to manipulate the uterus rather than intrauterine manipulator.

OR, operating room; EBL, estimated blood loss.
Usually an umbilical incision is made to allow insertion of a Veress needle or direct insertion of a laparoscopic trocar. If the patient has had a prior laparotomy, however, either a left upper quadrant insertion or an open laparoscopic umbilical insertion is preferred. The abdomen is inflated and distended with carbon dioxide, and the laparoscope is introduced (see Chapter 17). The pelvis should be thoroughly inspected, and the placement of operative trocars should be dictated by the patient's anatomy and pathology. If there is no pathology that requires laparoscopic surgery, no other trocars are needed, and a vaginal hysterectomy can be performed. If laparoscopic surgery is to be done, then two lateral trocars are inserted. Although traditionally these lateral trocars are placed in the lower quadrants, often a more superior placement allows better adnexal and vascular pedicle access. It is crucial that the operative trocars be placed under direct visualization and lateral to the inferior epigastric vessels. The inferior epigastric vessels can almost always be identified and avoided (Fig. 32C.5). If there is extensive pelvic pathology that will require extensive laparoscopic surgery, I prefer to place a fourth trocar ≥6 cm superior to the lower lateral cannula on the primary surgeon’s side of the patient (Fig. 32C.6). This allows the primary surgeon to operate with both hands while the assistant can retract with a third instrument (the camera used the fourth port). This greatly facilitates difficult procedures. Although many laparoscopic surgeons add the fourth port suprapubically in the midline, I find this site is not as useful for extensive procedures.

After all extrauterine and extraovarian pathology has been surgically addressed, attention is turned to the hysterectomy. The ligaments and vessels of the pelvis can be coagulated and cut in a number of ways. Although some surgeons use clampless suturing to ligate the ligaments and vessels, most find this slow and cumbersome. The majority of laparoscopic gynecologic surgeons use one of the devices specifically designed for laparoscopic surgery. Bipolar forceps to coagulate and scissors to cut vascular pedicles are inexpensive and readily available. Newer technologies using bipolar electrical energy with feedback control to consistently seal vessels represent an improvement over traditional bipolar forceps. Most of these devices have a built-in cutting blade that speeds the procedure. Trade name examples are Valleylab Ligasure Sealer/Cutter™ and Gyrus PK Cutting Forceps™, both of which are available as 5-mm instruments. Another available technology uses ultrasonic energy to seal and cut tissue and vessels. An example of this type device is the Ethicon Harmonic Scalpel™. Mechanical energy may also be used with stapler-cutter devices. Examples are Tyco Endo-GIA™ and Ethicon Endopath ETS™. Clips may also be used. It is important with all of these techniques that tension on vascular pedicles be minimized during coagulation to allow proper vessel sealing.

Usually an LAVH starts the same way as a TAH. The uterus is deviated to one side with the uterine manipulator, and the round ligament on the opposite side is coagulated and cut. The peritoneum of the anterior broad ligament is then dissected and cut in an inferior-medial direction to the midline bladder reflection to start the bladder dissection. If the ovary is to be removed, the peritoneum is also divided cephalad toward the infundibulopelvic ligament. The retroperitoneal space can be opened gently with traction on both sides to allow identification of the ureter either transected before or retroperitoneally. If the ovary is to be removed, then the ureter is identified at the pelvic brim. This is usually easy on the right side, but may be more difficult on the left because of the sigmoid colon. The ovary or fallopian tube is grasped from the contralateral side to expose the infundibulopelvic ligament, and the ovarian artery and vein are ligated and cut. This should be done under full visualization to ensure that the ureter and iliac vessels are far from the surgical site. The coagulation and ligation are then carried anteriorly to join the previously ligated area of the round ligament, again ensuring that the ureter is in direct view. These procedures then are repeated on the opposite side. The bladder plane can then be sharply dissected if desired, or this can be done transvaginally.

If the ovaries are not to be removed, the proximal fallopian tubes are coagulated and cut several centimeters from the uterus, followed by transection of the uteroovarian ligaments close to the uterus. Often the uteroovarian ligaments are best coagulated and cut from the contralateral cannula site. At this point, the laparoscopic procedure is completed, and the remainder of the operation is done vaginally, exactly as one would perform a standard vaginal hysterectomy. Because the infundibulopelvic ligaments and round ligaments have already been divided via the laparoscope, once the uterine vessels have been ligated from below, there is only minimal fatty, relatively avascular, parametrical tissue to be divided...
before the uterus can be removed. Once the vaginal hysterectomy has been completed and the vagina closed, the laparoscope can be used to check the pelvis for hemostasis before removing the laparoscopic cannulas and closing the laparoscopic incisions.

**Vaginally Assisted Laparoscopic Hysterectomy**

With VALH, the uterine vessels are coagulated and cut laparoscopically. After completion of the laparoscopic procedures described for LAVH, the bladder is adequately mobilized to allow exposure of the uterine artery and venous return. I find that filling the bladder with 100 to 200 mL of infant formula aids the accurate visualization and mobilization of the bladder. Then the uterine vessels are skeletonized by opening the anterior and posterior leaflets of the broad ligament. Once this is done, the vessels can be coagulated and cut close to the uterus and well away from the ureters. Moving the uterus laterally and elevating it slightly also aids in protecting the ureters. I find that staplers tend to pull tissue medially at this level, so I prefer not to use them for the uterine vessels.

The legs are then elevated to full dorsal lithotomy, and the colpotomy is performed transvaginally, followed by ligation and cutting the uterosacral ligaments. This allows removal of the uterus, followed by closure of the vagina and the laparoscopic incisions.

**Total Laparoscopic Hysterectomy**

To perform a TLH, the surgeon continues laparoscopically after the completion of the transabdominal location of the bladder by performing anterior and posterior colpotomies. I prefer performing the anterior colpotomy first because subsequent antversion of the uterus to perform the posterior colpotomy occludes the anterior incision and helps maintain a pneumoperitoneum. The colpotomy incisions can be made with laparoscopic scissors, but most laparoscopic scissors are too delicate to readily cut the thick vaginal tissue. Also, bleeding from the vagina is an issue with this technique. I prefer the use of an ultrasonic device, but electrosurgical incision works well, too. Maintaining hemostasis is important to allow adequate visualization. This is especially important as the colpotomy is completed at the lateral vaginal apices, where the ascending vaginal arteries and veins may lead to significant bleeding.

The colpotomy is greatly aided by a colpotomy device and by a vaginal occluding device to maintain the pneumoperitoneum. I find the KOH Colpotomy Device (KOH Cup, Devices from Endocare Inc., Santa Barbara, Calif.) particularly helpful. This system works well with a RUMI™ Uterine Manipulator. When the KOH Cup is fitted properly, it allows excision of the uterus without detaching the uterosacral ligaments from the upper vagina. Using the device requires some practice. The vaginal balloon is placed onto the shaft of the RUMI manipulator, and then the disposable tip to the RUMI uterine manipulator is attached. I use a sponge forceps to grasp the rim of the KOH cup and push it into the vagina to cover the cervix. A tenaculum is used to grasp the anterior lip of the cervix through the fenestration of the KOH cup, and then the RUMI uterine manipulator is inserted through the cervix to and into the KOH cup. When it is time to make the anterior colpotomy, the grip of the RUMI uterine manipulator is rotated counterclockwise and pushed cephalad. This clearly shows the area of the anterior vagina to be incised. The pneumo-occluder balloon is inflated with 60 to 100 cc of saline just before the colpotomy incision is made. It is important that the bladder has been dissected anteriorly to expose 1 to 2 cm of vagina. The RUMI uterine manipulator is then rotated clockwise to anterior the uterus and expose the posterior rim of the KOH cup and direct the site for the posterior colpotomy. Completion of the colpotomy laterally is guided by the KOH cup by moving the uterine manipulator to expose the right and left vaginal fornices. Once the uterus is detached, it may be pulled into the vagina and left there to maintain the pneumoperitoneum while the vagina is closed with interrupted sutures placed laparoscopically.

An example of another technique for aiding in the colpotomy and maintenance of pneumoperitoneum is the McCartney tube (Tyco Healthcare, Inc., Sydney, Australia), which is a disposable silicone tube with a diameter of 45 mm or 35 mm. The vaginal end of the tube is open and is inserted transvaginally to stretch the cervicovaginal junction and aid in identifying the vaginal fornices. The outer end of the tube is covered by a cap containing 5- and 10-mm valves and maintains the pneumoperitoneum when the colpotomy is made. After the uterus is detached, it can be pulled into the tube while the vaginal apex is closed, or the tube can be removed to allow removal of the uterus. Either the uterus can be left in the vagina or the tube replaced to maintain the pneumoperitoneum while the vagina is closed.

It is possible to perform TLH without such devices. Numerous techniques have been described, but an inexpensive technique consists of removing the uterine manipulator when preparing to do the colpotomy (the tenaculum is left on the cervix). A laparoscopic tenaculum is used to move the uterus and expose the vaginal fornices and allow exposure for the colpotomy. Placing a Deaver retractor into the appropriate area of the vaginal fornix may also identify the sites for the anterior and posterior colpotomies. Either a wet towel or wet laparotomy sponge is placed in the vagina to maintain the pneumoperitoneum while the colpotomy is completed. As previously described, once the uterus is detached, it can be placed in the vagina to maintain the pneumoperitoneum while vaginal apex closure is performed.

**Laparoscopic Subtotal Hysterectomy**

LSH consists of much the same procedure as described for VALH—that is, the uterine arteries are laparoscopically isolated and occluded with a bipolar electricity or ultrasonic vessel sealing device, clips, staples, or sutures. After the uterine vessels are secured, the uterine corpus is amputated from the cervix at the level of the isthmus. Although it may be possible to do this without dissecting the bladder from the lower uterine segment and cervix, realistically, in most cases, some dissection of the bladder is necessary to assure adequate occlusion of the uterine vessels and amputation at the level of the isthmus of the uterus. Many surgeons electrosedicate or excise the epithelium of the cervical canal to decrease the risk of persistent menses postoperatively.

A major advantage of LSH is that when a subtotal abdominal hysterectomy is used, the uterine corpus is amputated from the abdominal cavity. Although this can be done by morcellating the uterus through a posterior colpotomy incision, by extension of the umbilical incision, or using a minimally invasive incision with a hand-assist device, the availability of electromechanical morcellators avoids the need to make additional or larger incisions. Such devices allow relatively rapid removal of the uterine corpus, although large uteri will add significant time to the duration of the procedure.
POSTOPERATIVE CARE

Postoperative care is thoroughly reviewed in Chapter 9. Only aspects specific to laparoscopic hysterectomy will be reviewed in this section.

A diet of the patient’s choice may be started immediately after laparoscopic hysterectomy. This has been shown to be safe and allow for same-day or next-day discharge. This recommendation may need to be amended in cases of extensive enterolysis or other tissue dissection or if procedures are performed in addition to the hysterectomy.

A Foley catheter for bladder drainage may be left overnight for patient comfort or convenience, but this is not essential, and the catheter may be removed immediately postoperatively unless there has been bladder injury or extensive dissection.

Limitations on physical activity after laparoscopic hysterectomy are minimal, and most are common sense. Wound infections are uncommon, but keeping the laparoscopic incisions clean and dry for 10 to 14 days seems important. Protection of the vaginal incision is similar to that recommended with total hysterectomy by any technique. In particular, intercourse is best avoided for at least 6 weeks. Otherwise, many women may return to full physical activity within 2 weeks postoperatively after laparoscopic hysterectomy.

COMPLICATIONS

Complications occur with laparoscopic hysterectomy with a frequency similar to that of other surgical approaches to hysterectomy. The common complications—infection, hemorrhage, and injuries to adjacent organs—are the same types as with abdominal or vaginal hysterectomies. Postoperative incisional complications are less common than with abdominal hysterectomy, but laparoscopic hysterectomies may have complications specifically related to insertion of the trocars. These complications and their management are thoroughly discussed in Chapter 17.

Bibliography

SECTION VI ■ SURGERY FOR OBSTETRICS
Chapter 33 ■ Management of Abortion

Melissa J. Kottke and Mimi Ziemann

Definitions

Abortion—Termination of a pregnancy, whether spontaneous or induced.

Cerclage—A purse-string suture placed around the cervix to treat or prevent premature cervical dilation without labor.

Dilation and curettage—Dilation of the cervix followed by suction or sharp curettage to remove intrauterine contents.

Dilation and evacuation—Termination of pregnancy by wide cervical dilation and evacuation of fetal parts with forceps.

Fetal death—In utero death of fetus after 20 weeks.

Incomplete abortion—Partial expulsion of fetal tissue with open cervical os and products of conception remaining in the uterus.

Induced abortion—Medical or surgical termination of pregnancy.

Manual vacuum aspiration—Uterine evacuation performed with suction generated by a hand-held syringe.

Medical abortion—Use of medications including misoprostol, mifepristone, and methotrexate to terminate a pregnancy.

Spontaneous abortion—Spontaneous expulsion of an embryo or fetus weighing less than 500 g or before 20 weeks’ gestation.

Threatened abortion—Vaginal bleeding early in pregnancy with a closed cervix and a potentially viable fetus.

The management of abortion remains a principal focus of gynecology. Several million spontaneous abortions occur annually, and more than 1 million induced abortions are performed each year in the United States. Induced abortion is one of the most frequently performed operations in gynecology and one of the most thoroughly studied. This chapter summarizes the medical and surgical management of abortion. It reviews the incidence, risk factors, and treatment of spontaneous, illegal, and legal abortion. Readers should keep in mind that abortion technology is rapidly evolving, and new protocols may supplant those described here.

Spontaneous Abortion

Incidence

The World Health Organization (WHO) defines spontaneous abortion as expulsion of an embryo or fetus that weighs 500 g or less. Alternative definitions support a 20-week gestational age limit. The true incidence of spontaneous abortion is uncertain because of the difficulty in recognizing early conceptions and losses. When Edmonds and colleagues monitored urine β-human chorionic gonadotropin (β-hCG) in a cohort of volunteers attempting to conceive, 62% of conceptuses died before 12 weeks’ gestation. Most (92%) of these losses occurred before the woman was aware of the pregnancy. A similar study by Wilcox and associates monitored daily urinary β-hCG. They found that 31% of pregnancies resulted in spontaneous abortion after implantation. Approximately 70% of these—therefore, 22% of all losses—were not yet clinically identified. Wang and colleagues published further data in 2003; 8% of all conceptions in their study were recognized pregnancies followed by spontaneous loss. Twenty-six percent of all conceptions in that study were losses before knowledge of the pregnancy.

Overall, reported spontaneous abortion rates in recognized pregnancies are 10% to 20%. The vast majority—approximately 80%—of spontaneous abortions occur before 12 weeks’ gestation. The average gestational age for spontaneous abortion of a recognized pregnancy is 9 weeks. However, consideration must be given to the large numbers of losses before detection of pregnancy. From a biological perspective, early pregnancy loss is a common outcome in human reproduction.

Risk Factors

Spontaneous abortion has several important risk factors. Demographic details provide some important nonmodifiable risk factors. The risk increases with advancing maternal age, particularly for women older than 35 years. In a large study published by Nybo Anderson and colleagues, the rates of miscarriage increased with maternal age. Women aged 20 to 30 years, 35 years, 40 years, and 45 years saw a 9% to 17%, 20%, 40%, and 80% miscarriage rate, respectively. Previous studies reported an increase from 12% at ages less than 20 to 24% at age 40. Likewise, the risk increases with advancing paternal age. Race also plays a role. At each stage of pregnancy, women of minority races in the United States have higher rates than do white women. Independent of the effect of age, the risk of spontaneous abortion changes with previous pregnancy history. Increasing rates of miscarriage are seen with increasing gravidity in some studies. In addition, a history of one or more spontaneous abortions increases the risk of recurrence. This effect is seen at all gestational ages. The risk of spontaneous abortion has been reported to increase with each documented miscarriage in one study, increasing from 20% after one miscarriage to 43% after three or more. Alternatively, the risk for spontaneous abortion...
is lower for a woman who has never had pregnancy or whose last pregnancy was successful. The length of the interval between pregnancies appears to have little impact.

Maternal substance use has been evaluated as a possible risk factor for spontaneous abortion. Smoking may increase the risk of spontaneous abortion. Because smoking is not teratogenic, its effect on spontaneous abortion rates may be via abortion of normal conceptuses. This may be secondary to a vasoconstrictive effect of smoking. In one study, the risk of miscarriage doubled; in other studies, the increase in risk was slight. Recent studies have not confirmed this increased risk. Alcohol consumption is associated with spontaneous abortion as a result of teratogenicity. The effect of alcohol on miscarriage rate appear to be greatest for those whose alcohol consumption is greater. Additionally, the risk appears to be greater with increased intake in the earlier gestational ages. Alcohol consumption as a teratogen has a dose-dependent effect and can result in mental retardation, microcephaly, intrauterine growth retardation, renal, and cardiac defects. Caffeine intake has been evaluated in many studies regarding spontaneous abortion. Several studies have supported an increased risk for spontaneous abortion in women who drank greater than 500 mg—or the equivalence of 5 cups—of coffee per day. However, a recent systematic review by Sognirello and McLachlan indicates that there is insufficient evidence supporting a causal relationship.

Maternal health history and certain diagnoses may lead to increased risk for spontaneous abortion. Women with poorly controlled diabetes have higher levels of pregnancy loss as well as congenital anomalies. There is ongoing research about the effects of thyroid dysfunction on miscarriage. Women with a known hypercoagulable state, including antiphospholipid antibody syndrome, are at increased risk for spontaneous abortion as well as its recurrence.

The presence of congenital anomalies can lead to spontaneous abortion as well. Uterine synechiae, or Asherman syndrome, may permit insufficient surface area to support a pregnancy and lead to miscarriage. Uterine septae and abnormalities of müllerian fusion can also result in spontaneous abortion if the pregnancy implants on the septum and outgrows its blood supply. Although no effect is seen in the first trimester, the incidence of abortion after 13 weeks’ gestation may be 20% to 4.5%. This does not hold true, however, for women older than age 35 or those with a history of recurrent pregnancy loss. This will be examined in detail later in this chapter.

Fever in early pregnancy may lead to spontaneous abortion. In one study, rates of spontaneous abortion of euploid conceptuses increased twofold to threefold if fever had preceded the abortion. Alternatively, a second study found no association between febrile episodes and miscarriage. Infection with Chlamydia trachomatis, mycoplasmas, or other organisms does not appear to influence spontaneous abortion.

### Biologic Role

Spontaneous abortion serves primarily as a quality-control mechanism. The frequency of chromosomal abnormalities in aborted conceptuses is high, ranging from 30% to 61%. In decreasing order of frequency, the most common abnormalities are trisomy, sex chromosome monosomy, and triploidy. To earlier the gestation at gestation at which abortion, the higher is the frequency of chromosomal anomaly. Almost all anomalies, including some that would not appear to handicap survival (such as cleft lip), increase the likelihood of spontaneous abortion.
of tissue and demonstration of a potentially viable fetus, has been watchful waiting. Reliably predicting fetal outcomes in such situations is not yet possible, and serial examinations may be necessary to determine viability of a pregnancy that is not actively being passed.

Distinguishing between incomplete (characterized by progressive cervical dilation without complete expulsion of products of conception) or complete abortion is often difficult. The woman’s description of tissue may not be helpful, and not all women are aware that they should save expelled tissue for the physician’s inspection. Likewise, dilation of the cervix, size of the uterus, and presence or absence of bleeding may not indicate whether the abortion is complete or incomplete. Ultrasonography, however, often provides information about the completeness of abortion.

Medical or Surgical Intervention

For women with incomplete abortion and for those with threatened abortion in whom the pregnancy has been judged nonviable, several options are available. Patient preferences should generally determine the management as long as there is hemodynamic stability and absence of infection. One option is to await spontaneous expulsion of the pregnancy. A randomized, controlled trial by Nielsen and Håhlin compared expectant versus surgical management of spontaneous abortion. Most women randomized to expectant management (79%) had completed abortions within 3 days; other outcomes were similar, except for more infections in the group having curettage. An observational study by Lause et al. in 2002 followed nearly 1,100 women with spontaneous abortions expectantly for 4 weeks and found spontaneous resolution in 81%. However, they noted a significantly longer time, approximately 2 weeks, between diagnosis and passage of the pregnancy. They also categorized patients by sonographic criteria, finding that 91% of incomplete abortions resolved spontaneously compared with 66% of anembryonic pregnancies. If choosing expectant management, a woman deserves counseling that several days or weeks may pass before resolution and that medical or surgical intervention may ultimately be necessary. Additionally, women with a diagnosis of anembryonic pregnancy may be counseled that their success rates may be lower with expectant management.

Another option is to expedite the expulsion and still avoid surgery by giving oral or vaginal misoprostol. A randomized controlled trial by Chung et al. found that this medical management was safer than surgical evacuation, although half of those receiving misoprostol subsequently required suction curettage. Several studies have been performed looking at various doses and routes of administration of misoprostol. When misoprostol (600–800 μg) was given vaginally and a 300-μg dose; later abortions mandate an 84% completion rate by day 8 when 800 μg of misoprostol was given vaginally and repeated at 48 hours if passage had not yet occurred. This study reported similar complication rates between the two groups. They also found that 83% of the woman would recommend the medical treatment to others.

However, many women faced with the disappointing diagnosis of a failed pregnancy prefer prompt surgical evacuation. If suction curettage is elected, two other decisions must be made: where the curettage is to occur and by what technique. The choice between outpatient curettage in the physician’s office and curettage in an emergency room may depend on the time of day and equipment available. For uncomplicated cases, curettage in an operating room adds to the costs and inconvenience yet offers no medical benefits over outpatient curettage. The choice of evacuation technique depends on the state of the cervix, gestational age, and availability of equipment. Suction curettage is a fast and safe procedure in the first trimester. Practitioners may choose between an electric suction device attached to a rigid or flexible curette or a flexible Karman cannula with syringe as a source of suction. The Karman cannula is portable, inexpensive, and convenient for outpatient use. Both methods are discussed in further detail later in this chapter.

According to a recent metaanalysis, there is insufficient evidence to prescribe one of the above management plans in any given clinical situation. Surgical management is more likely to result in completion than medical management, and medical management is more likely to result in completion than expectant management, but the inverse is true of costs incurred. Patient satisfaction can be seen with any of these management plans. Certainly in the face of severe anemia, hemodynamic instability, or infection, surgical evacuation should be performed. Without these, patient preference should be strongly considered.

Complications and Considerations

Attentive gynecologic care has reduced the risk of complications. Nevertheless, women continue to die from spontaneous abortions. The Centers for Disease Control and Prevention identified 62 maternal deaths from spontaneous abortion in the United States between 1983 and 1991. This represented a case-fatality rate of 0.7 deaths per 100,000 spontaneous abortions. In 2002, there were two maternal deaths that were due to spontaneous abortion. Infection, hemorrhage, and embolism were the leading causes of death. The mortality risk increased with gestational age; women who were older and of minority races also were at increased risk of death.

Spontaneous abortion is a potentially sensitizing event for Rh-negative women. Rates of use of Rh immunoglobulin (RhIG) after spontaneous abortion are significantly lower than after induced abortion. RhIG candidates at 12 weeks’ gestation or earlier should receive a 300-μg dose; later abortions mandate a 300-μg dose.

The profound grief that frequently accompanies spontaneous abortion often receives insufficient attention. Women and men experience the stages of grief. Guilt may be a difficult stage to resolve without help, and counseling plays an important role.

Fetal Death

Definitions

Physicians often categorize fetal death by gestational age and length of retention of the dead fetus. Death before the 20th week of gestation, or at less than 500 g, is spontaneous abortion; thereafter, it is an antepartum fetal death. If a dead fetus remains in the uterus for 8 or more weeks, then the term becomes missed abortion. However, many use this term to refer to any failed pregnancy that is not promptly expelled. These diagnostic categories all should be viewed as variations of a single obstetric entity: a nonviable or failed pregnancy.
Incidence

Fetal death is uncommon after the first trimester. The 2003 data from the U.S. National Center for Health Statistics shows a fetal death rate of 6.23 per 1,000 live births. The incidence of fetal demise decreases with increasing gestational age. In 2003, greater than 50% of fetal deaths occurred between 20–27 weeks, with over one-third occurring between 20–23 weeks.

Management

Data on the natural history of fetal death are scarce. The uterus expels most dead fetuses within 3 weeks of death. The gestational age, however, influences the probability of expulsion within a given interval. The more remote from term, the longer is the time required.

After confirmation of fetal death, the next, and perhaps most important, step is to counsel the parents. Helping the couple to grieve appropriately can minimize psychological sequelae from this often devastating loss. After these initial steps, subsequent clinical management is largely discretionary. The risk of coagulation defects within 5 weeks of fetal death is minimal, as is the risk of infection, provided the membranes are intact. The emotional burden of carrying a dead fetus, however, often for weeks, can compound the misery experienced by the parents. Thus, although either watchful waiting or uterine evacuation is appropriate, most women opt for intervention.

Two approaches to evacuation exist: surgery or labor induction. The choice between surgery and labor induction should reflect the skill and experience of the physician, the size of the fetus and uterus, the availability of equipment and drugs, and the preference of the woman. Before uterine evacuation by surgery or induction, the physician should confirm that the woman's coagulation system is intact.

Suction curettage is a safe and easy way to evacuate early pregnancies; however, if the pregnancy is more advanced, dilation and evacuation (D&E), accurate determination of fetal size by ultrasonography is helpful. Both procedures will be detailed later in this chapter. If the patient declines surgical evacuation or if the physician chooses not to perform a D&E procedure, then labor induction can be accomplished in several ways. These include use of misoprostol, vaginal prostaglandin E2 suppositories, high-dose oxytocin, or intrauterine balloon catheters. Intraamniotic hypertonic abortifacients are inappropriate in this setting, as their use may cause extension of decidual plate hemorrhage and coagulation defects within 5 weeks of fetal death is minimal, as is the risk of infection, provided the membranes are intact. The emotional burden of carrying a dead fetus, however, often for weeks, can compound the misery experienced by the parents. Thus, although either watchful waiting or uterine evacuation is appropriate, most women opt for intervention.

Two approaches to evacuation exist: surgery or labor induction. The choice between surgery and labor induction should reflect the skill and experience of the physician, the size of the fetus and uterus, the availability of equipment and drugs, and the preference of the woman. Before uterine evacuation by surgery or induction, the physician should confirm that the woman's coagulation system is intact.

Suction curettage is a safe and easy way to evacuate early pregnancies; however, if the pregnancy is more advanced, dilation and evacuation (D&E), accurate determination of fetal size by ultrasonography is helpful. Both procedures will be detailed later in this chapter. If the patient declines surgical evacuation or if the physician chooses not to perform a D&E procedure, then labor induction can be accomplished in several ways. These include use of misoprostol, vaginal prostaglandin E2 suppositories, high-dose oxytocin, or intrauterine balloon catheters. Intraamniotic hypertonic abortifacients are inappropriate in the setting of fetal death. Instillation of hypertonic saline may be hazardous because of rapid uptake into the woman’s circulation owing to altered membrane permeability.

Complications

Fetal death carries risks of both morbidity and mortality for the woman. The risks of coagulation disorders and infection have received the most attention, yet recent data on their incidence are lacking. The risk of maternal death associated with fetal death is small, although no recent data are available. In the 1970s, the maternal case-fatality rate was estimated to be 4.5 deaths per 100,000 fetal deaths. The risk of maternal death from fetal death increases with maternal age. The risk for women age 35 years and older was 3.6 times that for women aged 15 to 24 years. The most frequent causes of maternal death from fetal death were uterine perforation and coagulopathy. As with all pregnancy terminations, physicians must identify all Rh-negative candidates and give them an appropriate dose of RhoG.

CERVICAL INCOMPETENCE

Incidence

Cervical incompetence is an imprecise term used to explain spontaneous abortions thought to be secondary to cervical factors. Premature cervical dilation without labor is a more descriptive term. Furthermore, it avoids the language “incompetent” which may carry with it some negative inferences for a woman who is having problematic pregnancies.

There is wide disagreement about the case definition and diagnostic criteria, making estimation of incidence difficult. The classic picture: repetitive, painless abortion midpregnancy without associated uterine contractions. Some physicians base their diagnosis on this picture, whereas others rely on tests performed on nonpregnant women. These include passage of an 8-mm Hegar dilator, traction on an intrauterine Foley catheter, or hysteroscopy. These techniques appear to have poor validity.

Significant attention has been paid in recent years to sonographic evaluation of the cervix and its role in prediction of premature cervical dilation. Serial ultrasound examination of the cervix may accurately identify a shortened cervix or funneling of amniotic membranes. It appears that identification of this entity is plagued by low sensitivity and positive predictive values, particularly in low-risk women. However, there may be a role for this evaluation in high-risk women.

The history of unexplained spontaneous abortion without labor in midpregnancy may be the most useful diagnostic criterion, yet its sensitivity and specificity remain unknown. This diagnostic impression appears in reported incidence rates. Rates range from 0.05 to 1 per 100 pregnancies. Differences in diagnosis, rather than differences in women, probably account for most of this variation. In 2000, according to the National Center for Health Statistics, 23,000 discharge summaries cited the diagnosis of cervical incompetence.

Risk Factors

The cause of premature cervical dilation without labor is unknown but may be multifactorial. Early theories about this problem focused on cervical trauma, such as conization, laceration, or excessive mechanical dilation. Data are lacking, however, to confirm or refute these. The occurrence of this condition in primigravidas suggests alternative causes. These may include associated uterine anomalies, prenatal exposure to diethylstilbestrol, or abnormal histology of the cervix. In addition, premature cervical dilation without labor may be inheritable.

Management

A variety of approaches have been used to treat premature cervical dilation without labor. The least invasive, bed rest, has been suggested as primary therapy, as well as adjunctive therapy after cerclage. This may be effective in the woman who is having problematic pregnancies.

Suction curettage is a safe and easy way to evacuate early pregnancies; however, if the pregnancy is more advanced, dilation and evacuation (D&E), accurate determination of fetal size by ultrasonography is helpful. Both procedures will be detailed later in this chapter. If the patient declines surgical evacuation or if the physician chooses not to perform a D&E procedure, then labor induction can be accomplished in several ways. These include use of misoprostol, vaginal prostaglandin E2 suppositories, high-dose oxytocin, or intrauterine balloon catheters. Intraamniotic hypertonic abortifacients are inappropriate in the setting of fetal death. Instillation of hypertonic saline may be hazardous because of rapid uptake into the woman’s circulation owing to altered membrane permeability.
in the United States, it has the appeal of exerting a mechanical effect without requiring an operation.

Surgery is the principal form of therapy for premature cervical dilatation without labor in the United States. Several types of cerclage procedures are used; the McDonald and Shirodkar are the most common. Contraindications to cerclage include rupture of membranes, uterine bleeding, uterine contractions, chorioamnionitis, cervical dilation of more than 4 cm, polyhydramnios, or known fetal anomaly.

The Shirodkar operation places a reinforcing band around the cervix beneath the mucosa at the level of the internal os (Figs. 33.1 and 33.2). Spinal or epidural anesthesia is recommended; Trendelenburg positioning and adequate retraction facilitate placement of the suture. The original operation used aneurysm needles to place a band of fascia lata around the cervix; then the knot was tied anteriorly. In recent years, many physicians have used a wide (e.g., 5-mm) Mersilene band swaged onto large atraumatic needles, with the knot tied posteriorly to avoid erosion into the bladder. The cervical canal should remain open 3 to 5 mm. After the band is tied, the band and knot can be secured with several interrupted sutures of silk or other permanent material; the incisions in the mucosa are then closed with absorbable suture, thus burying the band.

The McDonald procedure places a reinforcing purse-string suture around the proximal cervix. Unlike the Shirodkar procedure, however, the McDonald suture is not buried entirely (Fig. 33.3). Instead, several deep penetrations into the cervical stroma are made with a nonabsorbable suture, such as Mersilene. The advantages of this approach compared with the Shirodkar procedure are simplicity, ease of removal, and usefulness when the cervix is effaced or when fetal membranes are bulging. Vaginal discharge may be associated with the exposed suture material. Because the McDonald and Shirodkar procedures have been reported to have similar efficacy, the simplicity and versatility of the McDonald operation make it preferable for most patients in need of cerclage.

Opinions are divided as to whether the cerclage procedure is best performed during or between pregnancies. Studies suggest that the timing of cerclage during pregnancy influences outcome. Cerclage at about 14 weeks’ gestation appears preferable. Ideally, fetal viability must be demonstrated and major fetal anomalies ruled out sonographically if possible. If substantial dilation or bulging of fetal membranes has occurred, then the likelihood of a successful cerclage is lessened. An attempt can be made, however, to replace the protruding membranes by means of a sterile Foley catheter. Thereafter, the suture is placed and tied down, and the Foley balloon is deflated and withdrawn.

Postoperative care after cerclage for pregnant women has not been uniform. Although most investigators advise bed rest for several days, and some advocate prophylactic antibiotics, tocolytic drugs, or progesterone, the usefulness of these measures has not been established. The cerclage suture can be removed at 38 weeks’ gestation or when fetal pulmonary maturity has been confirmed; it should be removed immediately if membranes rupture or labor starts. Although some physicians leave a well-placed Shirodkar suture in place and deliver infants by cesarean, evidence supporting this course of action is limited.

Intraabdominal cerclage may be appropriate in rare instances. Indications include traumatic cervical laceration, congenital shortening of the cervix, previous failed vaginal

![FIGURE 33.1. Shirodkar cerclage operation. Left: A transverse incision through the anterior vaginal mucosa at its junction with the cervix. Right: The surgeon pushes the bladder cephalad to enable high placement of the suture.](image)
FIGURE 33.2. Shirodkar cerclage operation. Left: The encircling suture leaves the cervix with an opening of 3 to 5 mm. The surgeon anchors the suture anteriorly with fine silk. Right: Cross section with suture in place.

Cerclage, and advanced cervical effacement. This procedure places a band around the cervix at the level of the internal os in an avascular space between the branches of the uterine artery. Compared with the vaginal cerclage operations, this procedure has several important disadvantages: two abdominal operations are needed (one to place the suture, one for cesarean delivery), the surgery is performed in a highly vascular area adjacent to the ureters, and the complication rate is higher than with vaginal cerclage. Hence, this approach should be used only when vaginal cerclage has failed or is not feasible.

Consistent with the diagnostic conundrum associated with premature cervical dilation, there remains a challenge in appropriate and effective management of these patients. The largest randomized trial by the Medical Research Council/Royal College of Obstetricians and Gynecologists included nearly 1,300 patients. The goal was to evaluate the efficacy of prophylactic cerclage placement based on historical risk factors of second-trimester abortion/preterm delivery or cerclage conization/amputation. They demonstrated a significant decrease in preterm delivery (15% in cerclage group vs. 37% in controls) in the subset of women with three previous second-trimester losses or preterm delivery only. It is estimated in this study that 25 cerclages must be placed to prevent one preterm delivery. For women occupying the stratum of three previous second-trimester deliveries without evidence of labor, a cerclage can be supported by the literature.

The CIPRACT (Cervical Incompetence Prevention Randomized Cerclage Trial) randomly assigned women with a previous preterm delivery to cerclage or bed rest. Secondary randomization occurred as both groups were followed with serial transvaginal ultrasonography. Those in the control group were further randomized if they were noted to develop cervical shortening less than 25 mm below the 10th percentile. This study was small in its subject numbers but identified significantly decreased preterm deliveries and neonatal morbidity in the cerclage group. Additionally, it provides some evidence for serial sonography and late cerclage placement for those at high risk with cervical change, a potentially surgery-sparing approach. In contrast, a large study by To and colleagues screened more than 47,000 women at 22 to 24 weeks, identifying approximately 1% of these with a very short cervix of less than 15 mm. These women were then randomized to either Shirodkar cerclage or observation. This study confirmed that women with shortened cervixes in the midtrimester are at increased risk for preterm delivery; however, they did not find a difference between the cerclage or observation group with regards to gestational age at delivery. Several other studies including systematic reviews and metaanalyses do not support cerclage placement based on ultrasonographic findings alone, especially in low-risk women. There is evidence in small studies that support placement of emergency cerclage after clinical cervical dilation has reduced reliance on instrumentation of the cervix.

The CIPRACT study was small in its subject numbers but identified significantly decreased preterm deliveries and neonatal morbidity in the cerclage group. Additionally, it provides some evidence for serial sonography and late cerclage placement for those at high risk with cervical change, a potentially surgery-sparing approach. In contrast, a large study by To and colleagues screened more than 47,000 women at 22 to 24 weeks, identifying approximately 1% of these with a very short cervix of less than 15 mm. These women were then randomized to either Shirodkar cerclage or observation. This study confirmed that women with shortened cervixes in the midtrimester are at increased risk for preterm delivery; however, they did not find a difference between the cerclage or observation group with regards to gestational age at delivery. Several other studies including systematic reviews and metaanalyses do not support cerclage placement based on ultrasonographic findings alone, especially in low-risk women. There is evidence in small studies that support placement of emergency cerclage after clinical cervical dilation has reduced reliance on instrumentation of the cervix.

Complications

Complications of cerclage range significantly in their severity. A partial inventory of reported complications includes hemorrhage; rupture of membranes; infection, including chorioamnionitis; abcess, and death; cervical dystocia; uterine rupture; vesicovaginal fistula; and fotal death. Most commonly, rupture of membranes is seen in 0.8% to 18% and chorioamnionitis is seen in 1% to 6.2% of electively placed cerclages. Complications increase as the cerclage is placed emergently, with 0% to 51% incidence of rupture of membranes and 9% to 37% chorioamnionitis.

ILLEGAL ABORTION

Incidence

Despite the availability of legal abortions, small numbers of illegal procedures continue to occur. Estimates of the incidence of illegal abortion in the United States before 1970 or legalization ranged from 200,000 to 1.2 million per year; estimates for the late 1970s ranged from 5,000 to 23,000 per year. More recent estimates are not available. However, illegal abortions occur in large numbers in developing countries, where, according to WHO estimates, 30,000 to 100,000 women continue to die of illegal abortion complications each year.

Risk Factors

Lack of access to safe, legal abortion is the most important risk factor for having an illegal procedure in the world today. Little is known about characteristics of women in the United States who may still obtain illegal abortions.

Techniques

Although a wide variety of illegal abortion methods are used around the world, two methods dominate in the United States: oral abortifacients and intrauterine instrumentation. Orally administered substances include turpentine, laundry bleach, and large doses of quinine: all unsafe. Intrauterine techniques were less common, more effective, and more dangerous; these ranged from intrauterine injection of soap or phenol disinfectants to insertion of foreign objects.

Complications

Transcervical administration of toxic substances carries a high risk of serious complications. The most frequently reported complication of illegal abortion is retained products of conception, although the incidence of such complications is unknown. In countries such as Brazil, where elective abortion is illegal, recent black-market availability of misoprostol has led to important improvements in abortion safety, because misoprostol has reduced reliance on instrumentation of the cervix. The number of illegal abortion deaths in the United States declined dramatically during the 1970s. During the 1975 to 1979 interval, women in both extremes of the reproductive age span had higher death rates from illegal abortion than did other women. The racial discrepancy in death rate is more striking: The mortality rate for black and Hispanic women is more than 10 times greater than for white women. As with morbidity, the likelihood of mortality is strongly related to the abortion technique. Of the 17 illegal abortion deaths from 1975 to 1979, only one followed ingestion of an abortifacient (pennyroyal oil). The other deaths were related to intrauterine techniques, ranging from infection of cleaning solutions to insertion of foreign bodies (e.g., catheters, cotton swabs, thermometers, and coat hangers). Sepsis (10 cases) and air embolism (three cases) accounted for most of these deaths.
Management of Septic Abortion

Most women with septic abortion respond rapidly to uterine evacuation plus broad-spectrum antibiotics. Before beginning treatment, intrauterine and blood cultures should be obtained. An upright radiograph of the abdomen may identify a residual foreign body, gas bubbles in the uterus, or free air under the diaphragm; these findings direct management.

Antibiotic administration should begin in the emergency department. Coverage should include Gram-positive, Gram-negative, and anaerobic bacteria. Ideally, in a case of septic abortion, the patient should go directly from the emergency department to the operating room. Peak serum levels of antibiotics will be present within an hour of their administration. Further delay of uterine evacuation is unwarranted and can compromise recovery. Prompt elimination of the necrotic infected tissue is critical. Tissue obtained during curettage should quickly go for microbiologic cultures. The yield of organisms, especially anaerobes, is often higher from a tissue specimen than from a swab inserted into the uterus.

Subsequent management is governed by the response of the woman and by microbiologic findings. All women with septic abortions should be closely observed after surgery, with special attention to vital signs and urine output, to detect incipient shock. Prompt aggressive therapy is essential if septic shock develops. Administration of glucocorticoids is not helpful in shock. Prompt aggressive therapy is essential if septic shock develops. Administration of glucocorticoids is not helpful in this setting.

Postabortal sepsis from Clostridium perfringens has become rare. When this infection occurs, however, it can be catastrophic. In the absence of hemolysis, C. perfringens bacteremia can be managed by curettage and antibiotics. In the presence of hemolysis, hysterectomy and more aggressive medical therapy are indicated.

LEGAL ABORTION

Incidence

Legal abortion is one of the most frequently performed operations in the United States. In 2000, 1.3 million induced abortions were reported. The national abortion ratio was 245 abortions per 1,000 women age 15 to 44 years. Stated alternatively, about one in four recognized pregnancies ends in abortion. The numbers of abortion, associated with lack of access to services. Most (59%) abortions took place at 8 weeks’ gestation or earlier; 88% occurred at 12 weeks’ gestation or earlier. Only 4.3% of all procedures were done between 16 and 20 weeks gestation and 1.4% at more than 21 weeks. Before 1995, provision of very early (<6 weeks gestational age) abortions was rare. In 1999, these procedures accounted for 22% of all abortions. Most abortions take place safely in freestanding clinics (93%) and physician’s offices (2%). In-hospital procedures (5%) are necessary when women have a higher risk of medical or surgical complications.

Preoperative Considerations

In a recent large study, the reasons most often cited by women for choosing abortion were that having a baby would interfere with her education, work, or ability to care for her other dependents. A majority (73%) could not afford a baby, and almost half were having relationship problems and did not want to be single mothers. Preoperative counseling should include a nonjudgmental discussion of all alternatives available, including continuing the pregnancy and adoption. Abortion procedures are reviewed and compared, including the risks, benefits, and expected experience with each method.

Legal Considerations

It is important for physicians to know the legal restrictions to abortion in their state. State regulations include waiting periods, counseling requirements, parental involvement for minors, and insurance regulations.

Preoperative Medical Evaluation

The preoperative evaluation should include counseling, informed consent, a brief history, and a limited physical examination. The history taking should focus only on relevant data, such as gynecologic problems (e.g., leiomyomas) or medical problems (e.g., cardiac disease, asthma, or drug sensitivities) that might influence the course of the operation. Physical examination should include the heart, lungs, abdomen, and pelvis. Although ultrasonography is not necessary on a routine basis, it is useful if the size, shape, or position of the uterus is unclear. A large survey of abortion providers in the United States reported that 66% of clinics do use ultrasound routinely before first-trimester surgical abortion. In contrast, ultrasonography is a routine component of early medical abortions, which requires accurate dating of the gestation. Routine laboratory tests include the hematocrit (or hemoglobin) and Rh type. Many physicians perform a urine pregnancy test on all patients requesting abortion. Screening for chlamydia and gonorrhea need not be routine, but should be targeted. If bacterial vaginosis is detected preoperatively, it should be treated.

Techniques

All methods of abortion fall into two broad categories: surgical and medical. Surgical evacuation includes suction curettage (vacuum aspiration by electric or manual vacuum source), sharp curettage, D&E (defined as transcervical evacuation at 13 menstrual weeks’ gestation or later), hysterotomy, and hysterectomy. Medical abortifacients in the United States include uterotonic drugs, such as prostaglandins and oxytocin, the aniprostaglandin mifepristone, and intrauterine instillation of hypertonic agents, such as saline or urea. Early medical abortion has also begun to play a significant role in provision of abortion, accounting for 6% of procedures in 2001. In addition to several adjutants, such as cervical preparation with misoprostol or osmotoc dilators, have an important role in abortion practice.
Suction Curettage

Sharp curettage is an obsolete abortion method, supplanted by suction curettage, which usually involves dilation of the cervix, followed by vacuum aspiration at 12 weeks’ gestation or earlier. Menstrual regulation, menstrual extraction, and minisuction are euphemisms for early suction curettage. The more recent term, encompassing this early “regulation” as well as later procedures done by manual vacuum with syringe, is manual vacuum aspiration (MVA). This technique uses a plastic cannula as small as 3 mm in diameter, with a self-locking syringe (50–60 cc) as a source of suction (Fig. 33.4). The largest series using MVA in early pregnancy reported a 99% success rate on nearly 2,400 abortions done at less than 6 weeks’ gestation. MVA has been shown to be as safe and effective as electric vacuum through 10 weeks’ of gestation. For early MVA procedures, dilation is often unnecessary. Consequently, anesthesia may not be necessary, although analgesia can ease the cramping that occurs toward the end of the evacuation. After insertion of the appropriate cannula, the physician attaches the syringe and releases the pinch valve to begin the suctioning. Blood and tissue flow into the syringe. Alternatively, some physicians connect the cannula to the syringe before insertion. The abortion involves rotary and in-and-out cannula movement until the gritty feel of the endometrium occurs. Bubbles appear in the syringe. The physician should not remove the cannula from the uterus while a vacuum exists in the syringe, because the endocervical canal should not be aspirated; likewise, the physician should not advance the plunger of the syringe while the cannula is connected and is within the uterus. Air embolism can result. The syringe and cannula are disposable, although some physicians clean and disinfect the syringe and use it multiple times.

If local anesthesia is to be used alone, no preoperative fasting is necessary, but if conscious sedation is a possibility, the patient should fast for at least 6 hours before the procedure. Similarly, if conscious sedation is used, the patient should be instructed to bring someone with her to escort her home. She should empty her bladder before being placed in the dorsal lithotomy position; catheterization is unnecessary. An anesthetic is applied to the cervix and vagina (e.g., povidone-iodine or chlorhexidine). Routine sterile precautions (e.g., drapes, caps, masks, and gowns) are unnecessary. The physician should use a “no-touch” technique: He or she wears sterile gloves and does not touch those ends and portions of the sterile instruments inserted into the uterus. Use of local anesthesia predominates in the United States. Although local anesthesia does not completely relieve discomfort, it is less expensive and safer than general anesthesia. It is a good general rule, when performing abortions under local anesthesia, to use slow, controlled movements. A support person who can talk to the patient also helps alleviate anxiety and discomfort.

Preoperative Cervical Dilation

Osmotic dilators help to prepare the cervix for curettage abortions (Fig. 33.5). Laminaria are hygroscopic sticks of seaweed that dilate the cervix over several hours. The mode of action is not well understood, but the principal mechanism appears to be desiccation of the cervix. This drying can alter the ratio of collagen to ground substance, thus changing collagen cross-linkages. Alternatively, laminaria can alter the elaboration, release, or degradation of uterine prostaglandins. Laminaria cause the cervix to dilate the areas not in physical contact with the laminaria; whatever the mechanism, it is more complex than mere passive stretching, as used to be thought.

One synthetic osmotic dilator is currently marketed in the United States. Lamicel is a cylinder of polyvinyl alcohol sponge impregnated with magnesium sulfate. It works within several hours and has the advantage of uniform size (either 5- or 3-mm diameter), assured sterility, and easy insertion and removal. Unlike laminaria, the Lamicel device does not assume a rigid hourglass shape that hinders removal.

Osmotic dilators are convenient in an outpatient setting. Placement of laminaria or Lamicel for 3 to 4 hours before abortion frequently dilates the cervix sufficiently for abortion. Women can be sent home with laminaria in place overnight, allowing for maximal dilation. Compared with use of metal dilators, use of laminaria dramatically reduces the risk of cervical
Injury, requiring suturing and of uterine perforation. This protection against trauma can be especially important for young teenagers with immature cervixes who are at increased risk for cervical injury. Disadvantages include the cost, inconvenience, and occasional cramping involved.

Alternatively, preoperative preparation of the cervix with misoprostol can facilitate abortion. Misoprostol, a prostaglandin, softens the cervix and increases its resiliency. Administration 1 hour before was recently found not to be effective. Disadvantages of cervical preparation with misoprostol include the delay required, spotting and cramping, and occasional abortion in the waiting room. Recent data show an inferior effect of same-day misoprostol for preoperative cervical ripening in second-trimester procedures as compared with inferior effect of same-day misoprostol for preoperative cervical ripening in second-trimester procedures as compared with the use of laminaria administered the day before the procedure.

**Paracervical Anesthesia**

Paracervical block, the physician should use the smallest volume of the lowest concentration of local anesthetic. Local anesthetics vary in their toxicity; for example, chloroprocaine is substantially less toxic than lidocaine. With lidocaine, a 0.5% concentration is safer than a 1% solution and is equally effective. The total dose of lidocaine should not exceed 2 mg/kg or 300 mg, whichever is less. Maximum is approximately 20 cc of 1% lidocaine or 0.25% bupivacaine for a 50-kg woman, or 10 cc being typically sufficient. Alternatively, use of local anesthetic with vasoconstrictor (e.g., epinephrine 1:200,000) slows systemic absorption of anesthetic and allows a larger total dose, although the epinephrine has additional risks and side effects. Some physicians buffer the lidocaine solution with sodium bicarbonate to decrease burning. Vasovagal episodes occur rarely and can be treated with atropine.

Paracervical anesthesia affords excellent anesthesia regardless of the site of injection. Approaches include infiltration of the cervix at the 12-o'clock position (for application of the tenaculum), then injection at four sites (at the 3-, 5-, 7-, and 9-o'clock positions) or two sites (at the 3- and 9-o'clock positions) at the junction of cervix and vagina. Submucosal injection precludes inadvertent intravascular injection. Slow injection is less painful than rapid injection. Suction curettage requires few instruments. It is useful to have an ultrasound machine available in case one is not able to enter the uterus or suction adequate tissue. Most physicians prefer to use a bivalve speculum. A speculum with standard-length blades, however, prevents the cervix from being drawn toward the introitus during the procedure and makes the operation more difficult. The commercially available Moore modifications of the Graves speculum, which has 1-inch shorter blades of standard width, is excellent. Some physicians prefer anatraumatic tenaculum. Alternatively, having an extra single-toothed tenaculum can sometimes be helpful. If difficulty during dilation occurs, the physician can place the second tenaculum on the posterior cervix to stabilize it. Sounding before the procedure should not be done; there is no need to know where the fundus is at the start of the procedure, and it increases the risk of perforation. If the direction of the cervical canal is in question, then the physician can gently probe with a small dilator. Pratt dilators are preferable to Hegar dilators for abortion because they require less force to dilate the cervix. A useful modification of the Pratt dilators is the Denniston dilator; this is similar to the Pratt dilator but is plastic. Hence, it is light, slightly flexible, and inexpensive, yet it is capable of being autoclaved. Other instruments required for suction curettage include the vacuum machine, hose, swivel handle, and a cannula. Some physicians use a sharp curette to check for completeness at the end of the operation. Use of small (e.g., 8-mm-diameter) Karman-type double-port cannulas provides the same gritty sensation as a metal curette.

**FIGURE 33.6.** Traction on cervix during dilation. Top: Tenaculum placed vertically on the anterior lip. Bottom: Tenaculum placed vertically on the posterior lip for a retroverted uterus. Note posterior direction of dilator.
procedure often need to be at an angle, with the intrauterine tip of the instrument pointing upward. If the instrument was inserted straight back in a patient like this, there would be an increased risk for posterior perforation.

Gentleness is the key to safe cervical dilation. Dilution should allow insertion and rotation of the desired cannula. Pratt dilators are measured in French units, or mm of circumference. Hence, to determine the diameter, the physician needs to divide by π, or approximately 3. For example, to insert an 8-mm cannula, dilation with Pratt dilators to 25F allows for free rotation. The physician should hold the dilator between the thumb and index finger to limit the force applied. In addition, the other fingers can remain extended to prevent plunging forward in case of sudden loss of resistance. Dilution need not start with the smallest dilator on the set; starting with a larger size (e.g., 13F instead of 1F) may reduce the risk of perforating the uterus or creating a false channel.

If more than two fingers of force are necessary during dilation, the physician should stop and reassess the situation, rather than risk injuring the cervix. One option is to use a smaller cannula than originally planned. Alternatively, the physician can pack the cervix with one or more osmotic dilators, interrupt the procedure, then complete the operation several hours later, by which time adequate dilation will have been achieved. Another treatment option is to administer oral or vaginal misoprostol and complete the procedure in several hours. Performance of the procedure in two stages is far preferable to forceful dilation.

After adequate dilation, the physician inserts the cannula. In general, the diameter of the cannula in millimeters should be about one less than the weeks of gestation from last menses. For example, an 8-mm cannula is adequate for evacuating a pregnancy of 9 weeks’ gestation. Skilled physicians often prefer to use even smaller cannulas than this guideline suggests; the physician must weigh the advantage of needing less dilation against the potential disadvantages of longer operating time and an increased risk of incomplete abortion.

The most frequently used cannulas in the United States are clear plastic, with a slight angulation (Fig. 33.7). The physician should insert the cannula into the lower uterine segment. The physician then turns on the suction machine and aspires the uterus with the cannula (Fig. 33.8). One of the principles of abortion technique is to start working in the lower uterine segment. The fundal contents of the uterus are brought down by suction and the involution of the uterus as it empties. When bubbles appear in the cannula and the interior of the cavity feels empty, some physicians use a sharp curette to confirm the completeness of evacuation. The flexible plastic cannula (Fig. 33.7) suctions opposite sides of the cavity simultaneously and provides a distinct gritty sensation when the evacuation is complete. The operation is not finished until the physician or another trained observer has examined the aspirated tissue. This is to confirm the presence of fetal tissue, which usually excludes the possibility of an ectopic pregnancy. Since 1972, more than 20 women in the United States have died from ectopic pregnancies undetected at the time of attempted suction curettage. This tissue inspection will not detect the rare twin ectopic pregnancy, commonly termed “heterotopic.”

Pregnancies of 9 weeks’ gestation and later will have recognizable fetal parts; earlier pregnancies may not. Identification of chorionic villi and membranes in these earlier pregnancies is essential. The physician rinses the aspirated tissue in a fine-mesh strainer under tap water to remove blood and clots. A glass dish is useful for examining the tissue suspended in water. For early pregnancies, white vinegar (instead of water) may facilitate the recognition of villi. Back lighting from a horizontal x-ray viewing box is especially useful (Fig. 33.9). Villi appear soft, fluffy, and feathery, with discernible fine projections; in contrast, decidua appears coarse and shaggy (Fig. 33.10). Amnion and chorion are filmy and transparent; decidua is translucent. With early pregnancies, a magnifying glass, dissecting microscope, colposcope, or standard microscope (3100) can help identify villi (Fig. 33.11). It is essential to learn the difference between the appearance of villi and decidua; this is useful in the management of early pregnancy failure as well as in distinguishing between bleeding from miscarriage from that of an ectopic pregnancy.

When the physician cannot confirm fetal tissue, he or she should reevaluate the patient, with special attention to the adnexa. Repeat aspiration (perhaps with ultrasound guidance) is often appropriate. A sensitive urine pregnancy test or a quantitative β-hCG can be helpful. Ultrasound can sometimes identify a gestational sac. Failure to identify villi in the presence of a positive pregnancy test suggests several possibilities: recent spontaneous abortion, failed attempted abortion, perforation...
FIGURE 33.9. Examination of aspirated tissue over x-ray viewing box for back lighting.

with aspiration outside the uterus, or ectopic pregnancy. The physician must carefully evaluate these possibilities.

Women with uterine anomalies, such as a bicornuate uterus, have a high risk of failed attempted abortion. Sometimes the unique anatomy makes it difficult to enter the horn with the pregnancy. One useful approach is to perform the aspiration under ultrasound guidance. If the physician can insert a bent sound into the cavity with the pregnancy, he or she can then place the bent sound inside a flexible 8-mm plastic cannula as a stent or guide. With ultrasound guidance, the physician then inserts the cannula into the cavity and removes the sound, conects the cannula adapter, and then aspirates the cavity. Another alternative is to use medical abortion. Rarely, hysteroscopy may be needed if curettage and medical abortion fail in the setting of mullerian anomalies.

Postoperative Care

Women should expect some spotting and bleeding after the procedure that improves with time and usually stops by 1 to 2 weeks. They should know to notify the physician with any signs of a complication: fever, pain, bleeding more than a period, dizziness or weakness, passage of tissue, and ongoing symptoms of pregnancy. Pregnancy symptoms that do not dissipate within 1 week or normal menses not returning within 6 weeks are reasons to return. They should have 24-hour emergency phone numbers. Any woman whose procedure did not definitively identify tissue should be actively managed to rule out ectopic pregnancy. Women may resume work the day following an abortion or when they feel up to it.

Almost all forms of contraception may be started on the day of an abortion procedure, including the placement of intrauterine devices. Commonly a postoperative visit is scheduled 2 to 3 weeks after the procedure to ensure complete abortion and rule out any complications. It has been suggested that this visit may not be necessary, as women can be trained to return for certain signs and symptoms. Many providers find this visit useful to assess contraceptive use and satisfaction, as well as to provide regular gynecologic care that may not be a routine part of the preoperative abortion care—e.g., cervical cytology. Routine β-hCG testing should not be done at this visit. After an uncomplicated procedure, β-hCG can be detected for a mean of 30 days and up to 60 days. Therefore, it is not useful for ruling out retained tissue and causes confusion when found to be positive.

Use of Oxytocic Agents

The usefulness of administering oxytocic agents during suction curettage is unclear, although administering oxytocin or ergot derivatives reduces blood loss from suction curettage performed under general anesthesia. Although statistically significant, the reduction in blood loss is clinically unimportant. Because blood loss is less with local anesthesia, oxytocic agents probably are not necessary. Although physicians commonly give ergot derivatives by mouth for several days after suction curettage, evidence of the benefit of this practice is lacking, and the drugs cause painful uterine cramping in some women.

Prophylactic Antibiotics

Induced abortion patients should receive prophylactic antibiotics. A metaanalysis of the randomized, controlled trials on this topic by Sawaya and colleagues showed decreased risk for postabortal endometritis for women deemed low and high...
risk for infection. Administration of drugs such as doxycycline to an anxious, fastiging pregnant woman before surgery can cause nausea and vomiting. Hence, the most practical approach may be to begin a short-course antibiotic with food promptly after the abortion. The choice of antibiotic and duration of therapy is unclear. However, if one administers antibiotics for more than 24 hours, prophylaxis ends and presumptive treatment of C. trachomatis is not likely. The presumptive treatment of all patients for chlamydia may be a reasonable course of action.

Medical Abortion in Early Pregnancy

The marketing of the antiprogestin mifepristone has opened a new chapter in abortion practice. Mifepristone is a derivative of norethindrone; it binds to the progestosterone receptor but does not activate it. When bound, it blocks progestosterone activity and acts to alter the decidua, allowing trophoblast separation. This alone can lead to bleeding and in vivo prostaglandin release that can cause an abortion in early pregnancy. Mifepristone alone, however, results in completed abortion 64% to 85% of the time. Therefore, the drug is generally followed by a prostaglandin analog to vastly improve the completion rates. The regimen recommended by the distributor and approved by the U.S. Food and Drug Administration (FDA) calls for a single oral dose of mifepristone 600 mg, followed in 48 hours by misoprostol 400 μg orally, both doses given in the clinician’s office. This has been approved for use up to 49 days’ gestation. Success rates with this regimen range from 92% to 97%.

Several randomized controlled trials have investigated this regimen. Data currently support alternative dosage, route, timing, and gestational age criteria than those established by the FDA and the company guidelines. These changes result in improved efficacy and patient convenience, decreased cost, and sustained safety. Several studies have shown that 200 μg of mifepristone effect abortion at rates equivalent to 600 μg. El Rafaei and colleagues first reported this finding in 1995. This was confirmed by a study by WHO, reporting in 2000 that there was no difference in the completed abortion rate between women given 200 μg of mifepristone compared with those given 600 μg, Additional studies showed women up to 63 days’ gestation. This equivalence in dosing is secondary to nonlinear pharmacokinetics. The binding site for the mifepristone is rapidly saturated. Women given 100 μg, 200 μg, and 800 μg have a peak serum concentration of 2.0 to 2.5 μg/ml approximately 2 hours after ingestion, regardless of dosage given. Therefore, pharmacology and economics support use of 200 μg mifepristone.

Several studies have also investigated misoprostol dosing and route of administration. Vaginal dosing of misoprostol has been shown to increase bioavailability when compared with oral dosing. Furthermore, the gastrointestinal side effects of the medicine are often fewer with this route. Schaff and colleagues compared oral (400 μg and 800 μg) versus vaginal (800 μg) misoprostol following 200 μg mifepristone. They found a statistically significant higher level of completed abortion in those who received vaginal misoprostol compared with either dose of oral misoprostol (84%, 92%, and 96%, respectively). In 2003, WHO published results of a large study comparing vaginal misoprostol with oral/vaginal combinations after mifepristone administration to confirm by ultrasonography that the pregnancy has ended. An inability to follow up in the time frame specified or in the event of an emergency should preclude provision of a medical abortion. In the few percent of women who fail to abort or who have incomplete abortion, suction curettage is recommended because of the teratogenic effects of misoprostol.

Medical abortion is safe, effective, and well tolerated. With current regimens, cramping and bleeding are common, but infection and bleeding heavy enough to require transfusion are rare. Data collected from postmarketing experience since the FDA approval of mifepristone in the United States in September 2000 have demonstrated the safety. More than 460,000 women have undergone medical abortion in the United States between 2000 and mid-2005. Serious complications have included seventeen ectopic pregnancies, hemorrhage requiring blood transfusion (in -0.03%), and seven serious bacterial infections, including five deaths from Clostridium sordellii sepsis. In light of potential complications and the abortion experience occurring outside of the provider’s office, thorough counseling and patient understanding are imperative.

Before the marketing of mifepristone in the United States, physicians relied on other medical abortion regimens. One regimen included a single intramuscular injection of methotrexate, 50 mg/m² body surface area, followed 3 to 7 days later by
vaginal administration of misoprostol, 800 μg. The efficacy of the combined regimen was 90%. In a randomized, controlled trial, this regimen proved superior to the same dose of misoprostol given alone. At 49 days’ gestation or less, methotrexate and misoprostol can achieve success rates similar to those with mifepristone and misoprostol, but the process is slower with methotrexate. From 20% to 30% of women require 1 to 3 weeks to complete the abortion. On the other hand, methotrexate is much less expensive than is mifepristone. Methotrexate works as an antimitabolite; it continues to be used in the medical management of ectopic pregnancy.

Another alternative is use of misoprostol alone. Varying success rates have been reported with different doses, frequency, and routes of administration. The success rates with misoprostol alone appear lower than when misoprostol is used as an adjunct with mifepristone or methotrexate. Protocols that have achieved a high success rate with misoprostol alone have had high rates of side effects as well, including nausea, vomiting, and diarrhea.

Medical approaches may be especially useful for challenging abortions. These include patients with mullerian anomalies, large cervical leiomyomas, prior failed attempted abortion, or obesity (e.g., 150 kg and more). Should the medical regimen not effect abortion, surgical completion is made substantially easier by this preparation of the cervix.

Dilation and Evacuation

Dilation and evacuation is the generic term for suction curettage abortions at 13 weeks’ gestation or later. During the 1970s, D&E emerged as the most frequently used method for second-trimester abortions. The proportion of abortions performed by curettage techniques is inversely related to gestational age (Table 33.1). Even at gestations greater than 20 weeks, D&E remains the dominant method of abortion in the United States. In April 2007, the US Supreme Court upheld a decision to ban an abortion procedure called D&X, in which there is a surgical completion of the pregnancy. Intra-amniotic instillation of prostaglandin E₂ appears to be a viable alternative to D&E. (Fig. 33.12). For example, five laminaria placed overnight result in 1.5- to 2-cm dilation with minimal or no discomfort for most women. Use of a single Lamicel for about 4 hours produces as much dilation as do several laminaria at 14 to 16 weeks’ gestation. To achieve adequate dilation, many physicians insert osmotic dilators several hours to several days before D&E. (Fig. 33.12). For example, five laminaria placed overnight result in 1.5- to 2-cm dilation with minimal or no discomfort for most women. Use of a single Lamicel for about 4 hours produces as much dilation as do several laminaria at 14 to 16 weeks’ gestation. In the 13- to 16-week interval, vacuum alone is adequate; thereafter, forceps extraction predominates. A cannula 14 mm in diameter can evacuate pregnancies through about 16 menstrual weeks’ gestation. For later pregnancies, the cannula primarily drains amniotic fluid at the beginning of the evacuation and draws tissue into the lower uterus for forceps extraction. Specially designed forceps for D&E are far superior to standard sponge forceps. As with suction curettage, extraction should occur from the lower uterus to minimize the risks of often prefer D&E because they avoid experiencing labor. Many physicians have not been surgically trained to provide later D&E procedures. Often the choice of abortion method at this later stage depends on access to abortion services, the presence of skilled personnel, and whether the fetus needs to be intact for autopsy. Some physicians prefer to administer feticidal agents, such as digital or potassium chloride, under ultrasound guidance preoperatively. A randomized, controlled trial by Jackson and colleagues found that doing so had no operative benefit.

For D&E procedures, accurate determination of gestational age by ultrasound preoperatively is essential. Underestimation of gestational age can lead to inadequate dilation, which complicates the procedure. D&E differs from suction curettage in two principal ways: D&E requires wider cervical dilation, and physicians need forceps to evacuate more advanced pregnancies.

Dilating the cervix to a large diameter over several minutes manually can damage the cervix. Indeed, the first large study of this question revealed a higher incidence of low-birth-weight infants in subsequent desired pregnancies. Hence, D&E procedures beyond about 14 weeks’ gestation should use osmotic dilators. Patients must understand that once osmotic dilators have been inserted, the abortion needs completion. Occasionally the patient may abort just from the dilator. Rarely, a patient changes her mind about abortion after placement of an osmotic dilator. Although some women have continued their pregnancies uneventfully after removal of the devices, others have developed infections and/or aborted.

To achieve adequate dilation, many physicians insert osmotic dilators several hours to several days before D&E. (Fig. 33.12). For example, five laminaria placed overnight result in 1.5- to 2-cm dilation with minimal or no discomfort for most women. Use of a single Lamicel for about 4 hours produces as much dilation as do several laminaria at 14 to 16 weeks’ gestation. In the 13- to 16-week interval, vacuum alone is adequate; thereafter, forceps extraction predominates. A cannula 14 mm in diameter can evacuate pregnancies through about 16 menstrual weeks’ gestation. For later pregnancies, the cannula primarily drains amniotic fluid at the beginning of the evacuation and draws tissue into the lower uterus for forceps extraction. Specially designed forceps for D&E are far superior to standard sponge forceps. As with suction curettage, extraction should occur from the lower uterus to minimize the risks of

perforation. Some physicians use a flexible 8-mm cannula to confirm complete evacuation.

The physician must confirm completion by identifying all major fetal parts (4 extremities, spine, and calvarium). The calvarium is the component most frequently missed during the initial evacuation. Gentle exploration of the fundal and cornual areas with a large curette or forceps usually enables location and removal of the last remaining tissue. Ultrasound can be helpful. If ultrasonography is not available, the physician may be able to remove the speculum and insert one digit into the uterine cavity to locate the missing part.

If the abortion cannot be completed with ease, the physician should interrupt the procedure. A safe and simple remedy is to discontinue the operation and administer intravenous oxytocin to the woman for 2 to 3 hours in the recovery room. After the patient returns to the operating room, the physician usually finds the retained tissue at the internal os, from which it can be easily removed. No D&E abortion needs to finish in a single session; time often helps. Once membranes rupture, the uterus contracts to expel its contents.

In D&E abortions, the skill of the physician is critical. D&E abortion requires specific training that is often not routinely acquired in a U.S. ob/gyn residency. The likelihood that a physician will offer abortion services is highly correlated with whether he or she was trained in residency. The physician should study operative technique. He or she should then observe and assist skilled physicians and then perform D&E procedures only under direct supervision. Use of ultrasound guidance for residents learning D&E was associated with a dramatic lowering of the perforation rate and a reduction in operating time. The gestational age range can advance as skill grows. In summary, D&E is a specialized surgical technique that can be learned with appropriate training.

Labor Induction

Although D&E has supplanted many labor-induction abortions, the need for such abortions continues, particularly at later gestational age. In contrast to D&E, the proportion of abortions performed by labor induction increases with gestational age (Table 33.1).

Abortifacients include two broad groups: hypertonic solutions (e.g., saline or urea) and uterotonic agents (e.g., oxytocin or misoprostol). The mechanism of action of hypertonic solutions is unclear, but these agents usually result in fetal death from osmotic insult; labor then generally ensues. Uterotonic agents act directly on the myometrium to stimulate contractions. Prostaglandins available in the United States include misoprostol, prostaglandin E₂, prostaglandin E₁, prostaglandin F₂α, and mifepristone. Ashok et al. gave 800 μg misoprostol vaginally every 12 hours, with a maximum of four doses. Following 200 mg of mifepristone, Ashok et al. gave 800 μg misoprostol vaginally every 12 hours, with a maximum of four doses. This regimen resulted in 97% successful abortion with a mean induction to abortion time of 6.25 hours (in those that were successful). Of the 1,002 patients in the study, complications were seen in 11. Ten had significant bleeding, and seven required transfusion. One woman had significant hemorrhage and was found to have a myometrial tear upon laparotomy. She had received one dose of prostaglandin. Both misoprostol and misoprostol are not currently labeled for second-trimester termination.

Interest in high-dose oxytocin infusion for abortion has renewed. Oxytocin alone or rapid systemic administration of oxytocin can achieve complete abortion (80% to 90% of the time). The frequency of fever, vomiting, and diarrhea was significantly lower with oxytocin compared with prostaglandin E₂ and misoprostol. One regimen includes
oxytocin, 50 U in 500 mL of dextrose and normal saline administered intravenously over 3 hours; maintenance fluid (dextrose in normal saline) then follows for 1 hour. In stepwise fashion, the concentration of oxytocin increases by 50 U every 4 hours to a maximum of 300 U/500 mL. The investigators administered oxytocin in isotonic fluid and interrupted the oxytocin infusion every 4 hours for diuresis. With prolonged high-dose oxytocin infusion in hypotonic solutions, water intoxication and death can result.

The decision about labor induction in women with a previous uterine scar remains a difficult one for clinicians. There are reports of uterine rupture with previous cesarean delivery in both misoprostol and prostaglandin E2. Some have reported uterine rupture rates of approximately 4% in those with previous hysterotomies undergoing medical induction compared with 0.2% in those with unscarred uteri. Conversely, a case series of 100 women at 14 to 28 weeks with previous cesarean delivery undergoing induction with misoprostol reported no uterine ruptures. Further study is necessary. Women with a uterine scar require detailed counseling about the risk of rupture. If induction is chosen, it should be completed in a hospital setting where complications can be managed appropriately.

Direct cervical dilation has been investigated in its role for decreasing the induction interval. Some studies show that osmotic dilators can shorten induction-to-abortion times if placed before the initiation of induction. A study by Borgota and associates indicates that placement of osmotic dilators at the time of induction may actually prolong the induction process. Further study is needed to answer this question. If induction progress stalls, a metotrexytine can be attempted. The physician inserts a sterile Foley catheter with a 30- to 75-mL balloon into the uterus, inflates the balloon with a sterile solution (not air), and ties the catheter to 0.5-kg orthopedic traction at the foot of the bed. A liter bag of intravenous fluids hung over the foot of the bed and tied to the catheter by a string also suffices. This method has the disadvantage of placing a foreign body in the uterus.

Much of the morbidity (and mortality) associated with labor induction abortion is preventable. Women undergoing labor induction need the same meticulous, attentive obstetric care as do women in labor with childbirth. If the membranes rupture, then labor must conclude within a reasonable period. In many cases, the preferred means of concluding a slow induction abortion is D&E. Twenty-four hours is a reasonable limit for labor-induction abortions. Frequently, the cervix is open several centimeters, and D&E proceeds quickly. Similarly, active management of a retained placenta after abortion prevents morbidity. If spontaneous delivery of the placenta has not occurred after delivery, the placenta should be removed by suction curettage. Notably, misoprostol is associated with a significantly lower rate of retained placenta when compared with prostaglandin E2 or oxytocin (2% vs. 15%).

**Complications**

### Morbidity

Legal abortion in the United States is safe. Less than 1 woman in 100 develops a serious complication, and fewer than 1 in 100,000 dies as a result of the operation. This mortality rate is one tenth the rate for women who elect to continue their pregnancy.

Gestational age is one of two important determinants of the likelihood of morbidity. In Table 33.2, which lists serious
Abortion complications have three temporal categories: immediate, delayed, and late complications. Immediate complications are those that develop during or within 3 hours of the operation. Delayed complications occur more than 3 hours and up to 28 days after the procedure. Late complications develop thereafter.

### Immediate Complications

#### Hemorrhage

Reported rates of hemorrhage vary widely, reflecting both diverse definitions (100 to 1,000 mL blood loss) and imprecision in estimating volumes of blood loss. Rates of hemorrhage range from 0.03 to 4.9 per 100 abortions in large case-series reports. The best index of clinically important hemorrhage is probably the rate of blood transfusion. The rate of transfusion associated with suction curettage in a large multicenter study was 0.06 per 100 abortions. For abortions performed later in pregnancy, investigators have reported rates of 0.26 for D&E, 0.32 for urea-prostaglandin, and 1.72 for saline.

Vasopressin administered with paracervical anesthesia decreases blood loss with D&E abortion after 14 weeks' gestation. As little as 4 U (0.2 mL) mixed in with the anesthetic lowers the blood loss significantly; overall, vasopressin lowers fourfold the risk of a hemorrhage of 500 mL or more. It is important to remember to administer vasopressin when opting to administer regional or general anesthesia. In these instances, one would usually forego the paracervical block; however, use of a cervical anesthetic with vasopressin lowers risk of bleeding.

When hemorrhage occurs after suction curettage, it is most often due to uterine atony. Administration of uterotonic agents and manual compression usually resolve the problem. As with labor-related atony, methylergonovine maleate may be given (0.2 mg intramuscularly) as well as prostaglandins: carboprost 2.5–25 μg intramuscularly or misoprostol 1,000 μg per rectum. Should bleeding persist, assessment of the endometrial cavity by suction curettage should be done to rule out retained tissue. Occasionally, internal compression of the cavity by a large Foley catheter balloon or a vasopressin-soaked pack can be helpful. If these measures fail, uterine artery embolization can be done in a stable patient, with the last resort being hysterectomy.

With the increasing cohort of women who have had cesarean deliveries, the risk of encountering placenta accreta during abortion is increasing as well. In a series of more than 16,000 D&E abortions, the incidence of placenta accreta leading to hysterectomy was 4 per 10,000 cases.

#### Cervical Injury

Cervical injury encompasses a broad spectrum of trauma. The most common type is a superficial laceration caused by the tenaculum tearing off during dilation. At the other extreme are the cervicovaginal fistula and the longitudinal laceration ascending to the level of the uterine vessels. Rates of cervical injury range from 0.01 to 1.6 per 100 suction curettage abortions. In older studies, the incidence of cervical injury requiring sutures was about 1 per 100 suction curettage abortions.

Several risk factors for cervical injury during suction curettage have emerged. Among factors within the control of the physician, use of laminaria and performance of the abortion by an attending physician (rather than a resident) lower the risk significantly, whereas use of general anesthesia raises the risk significantly. Use of laminaria and performance of the abortion under local anesthesia by an attending physician together yield a 27-fold protective effect. Cervical preparation with misoprostol may confer similar benefits as laminaria, although more extensive experience will be needed to confirm this. Among factors beyond the control of the physician, a history of a prior abortion lowers the risk, and age of 17 years or younger increases the risk.

*a For women with follow-up and without concurrent sterilization or preexisting conditions. Serious complications include temperature of 38°C or higher for 3 days or more, hemorrhage requiring blood transfusion, and any complication requiring unintended surgery (excluding curettage).

*b Per 100 abortions.
Acute Hematomata. Also termed the postabortal syndrome, acute hematomata is an important complication of suction curettage; its cause is unknown. The incidence of this syndrome ranges from 0.1 to 1.0 per 100 suction curettage abortions, according to the available literature.

Women with this condition develop severe cramping, usually within 2 hours of the abortion. Vaginal bleeding is less than expected. The woman may be weak and sweaty, and her uterus is large and markedly tender. Treatment consists of prompt repeat curettage, usually without anesthesia or dilation. Evacuation of both liquid and clotted blood leads to rapid resolution of the symptoms. The physician can aspirate the blood with a suction cannula, a Karman cannula and syringe, or even a catheter attached to wall suction. Administration of a uterotonic after the repeat evacuation is standard. Whether routine prophylactic use of an oxytocic would reduce the incidence of acute hematomata is unknown.

Anesthesia Complications. Pain experienced during abortion relates not only to the choice of anesthesia but also to the characteristics of the patient. Young women (13 to 17 years old) and those with depression before the abortion report more pain than do other women. Local anesthesia is safer than general anesthesia for both first- and second-trimester abortions. In an Italian study, use of general anesthesia had a relative risk for all complications combined of 1.8 (95% confidence interval, 1.4 to 2.5). The largest effect occurred with hemorrhage. Similarly, use of general anesthesia for D&E abortion in the United States increases the risk of serious complications. Overall, the attributable risk related to general anesthesia is low, and many women are willing to assume incremental risks in order to have no discomfort during the operation.

Perforation. Perforation is a potentially serious, but infrequent complication of abortion. According to most reports, the incidence of perforation is about 0.2 per 100 suction curettage abortions.

Several risk factors for perforation exist. Performance of a curettage abortion by a resident rather than by an attending physician increases the risk more than fivefold; on the other hand, cervical dilation by laminaria decreases the risk about fivefold. The risk of perforation increases significantly with advancing gestational age. Multiparous women have three times the risk of nulliparous women. The use of routine ultrasonic guidance for D&E reduces the risk of perforation.

The two principal dangers of perforation are hemorrhage and damage to the abdominal contents. Lateral perforations in the cervicocervicocervical region are particularly hazardous because of the proximity of the uterine vessels. Perforations of the fundus are more likely to be innocuous. Indeed, most perforations are not suspected or detected. In a series of patients undergoing combined abortion and sterilization by laparoscopy, the investigators found a sixfold higher rate of uterine perforation than they had suspected clinically (20 versus 3 per 1,000 abortions).

Not all perforations require treatment. Many suspected or documented perforations require only observation. Perforation with a dilator or sound is unlikely to damage abdominal contents. If the perforation occurs before suction, the procedure can be completed under either ultrasound or laparoscopy guidance with extra observation after the procedure. On the other hand, perforation with a suction cannula or forceps warrants further surgery to rule out organ injury. It is recommended to administer broad-spectrum prophylactic antibiotics when perforation occurs. If the physician suspects a perforation, the procedure should stop immediately. If unmanageable hemorrhage, expanding hematoma, or injury to abdominal contents occurs, prompt laparotomy is necessary. In a stable patient, laparoscopy can be useful in documenting perforation and assessing damage; if necessary, the physician can complete the abortion under laparoscopic visualization. Any woman with severe pain within hours after the abortion should be evaluated for possible perforation with bowel injury.

Delayed Complications

Retained Tissue. Although retained tissue after abortion can pass without incident, it can also lead to hemorrhage, infection, or both. This complication occurs infrequently, however. Its incidence after suction curettage abortion is less than 1 per 100 abortions.

This complication usually manifests itself within several days of the abortion. Women present with cramping and bleeding, with or without fever. When women develop pain, bleeding, and low-grade fever after abortion, retained tissue may be present. Prompt administration of antibiotics along with outpatient suction curettage is needed. Close follow-up is necessary.

Infection. Postabortal infection can result simply from the procedure or from retained tissue. The presence of retained products warrants suction curettage. The likelihood of febrile morbidity after abortion depends on the method used. The incidence of fever of 38°C or higher for 1 or more days is usually less than 1 per 100 abortions by suction curettage. Corresponding figures for D&E are 1.5 per 100 abortions; for intrauterine prostaglandin, 6.3; and for hypertonic saline, 5.0. The organisms responsible for postabortal infection are similar to those responsible for other gynecologic infections.

A number of risk factors for infection exist. Women are at increased risk if they have untreated endocervical gonorrhea or chlamydial infection. Late abortions also increase the risk. Likewise, use of labor-induction abortion instead of D&E and use of local rather than general anesthesia for suction curettage increase the risk. Prophylactic antibiotics decrease the incidence of infection. Administration of broad-spectrum antibiotics and uterine curettage are the cornerstones of therapy.

Late Complications

Rh Sensitization. Legal abortion is a potentially important cause of Rh sensitization for women at risk. The likelihood of sensitization increases with advancing gestational age (and, hence, larger volumes of fetal erythrocytes). One study has quantified the risk of Rh sensitization from first-trimester suction curettage without RhIG prophylaxis. A total of 3.1% of women whose first pregnancy terminated by suction curettage without RhIG prophylaxis had antibodies in their second pregnancy. Subtracting 0.5% (the percentage of women estimated to have become sensitized primarily during the second pregnancy), the investigators estimated the risk of sensitization from suction curettage to be 2.6%. Thus, on a nationwide basis, the clinical impact of failure to administer RhIG to candidates after abortion may be substantial. Candidates should receive 50 μg of RhIG after abortions performed at 12 weeks’ gestation or earlier or 300 μg after abortions performed later in pregnancy.

Adverse Pregnancy Outcomes. Investigators have linked induced abortion with a broad array of adverse reproductive
outcomes, ranging from infertility to ectopic pregnancy. Most published reports, however, suffer from serious methodological shortcomings that limit their usefulness. To examine the potential association between first-trimester induced abortion and subsequent reproductive performance, epidemiologists have performed an exhaustive review and analysis of the world literature. This includes more than 150 epidemiologic studies published in 11 languages. The findings of this analysis are largely reassuring. No increase in the risk of secondary infertility and ectopic pregnancy appears, even in studies with substantial power to detect differences in rates. Midtrimester spontaneous abortion is no more common among women who have had one previous abortion than among women pregnant for the first time. Similarly, the risk of premature delivery does not increase for women having undergone induced abortion.

On the other hand, low birth weight is more frequent in first births after abortion by sharp curettage performed under general anesthesia compared with first-pregnancy births. This does not occur after other methods of abortion, such as suction curettage. The question of the effect of repeat induced abortion and second-trimester abortion remains unresolved, but repeat sharp curettage may carry increased risks. First-born infants of women who had one induced abortion have risks of morbidity and mortality similar to those of other first-born children.

Additional studies have corroborated the absence of adverse effects of induced abortion on subsequent reproduction. Outcomes studied included infertility, ectopic pregnancy, spontaneous abortion, and adverse obstetric outcomes. One unresolved issue is placenta previa. Sophisticated studies have found either no or a marginally significant increase in the risk (relative risk, 1.3; 95% confidence interval, 1.0 to 1.6), which was comparable to that with spontaneous abortion.

Induced abortion does not threaten a woman's emotional health. In contrast, the most common emotional reactions to induced abortion are a sense of relief accompanied by sadness and loss. In several studies, abortion appeared to improve the emotional well-being of women by resolving an intense personal crisis. Specifically, claims of a postabortion trauma syndrome lack scientific merit.

The putative association between induced abortion and breast cancer remains controversial. Although a number of case-control studies have found an association, this appears because of recall bias among controls. Women who are well (controls) are less likely to report prior induced abortions than are women with breast cancer (cases). This type of information bias has been documented in studies from Sweden. Two large cohort studies, which are less likely to be biased than are case-control studies, have shown either no effect or a protective effect of induced abortion on later breast cancer. No firm evidence links abortion to other cancers.

**Mortality**

Since 1972, when the Centers for Disease Control and Prevention first began nationwide surveillance of abortion deaths, the safety of abortion has improved dramatically. As shown in Figure 33.15, the overall death rate fell from 4.1 deaths per 100,000 abortions in 1972 to 0.7 in the data published for the decade between 1988-1997.

The causes of death from legal abortion have changed as well. After abortion became legal in 1973, abortion-related deaths declined because of an increase in the skill and experience of providers. When the abortion surveillance system identified procedures that increased risks, practitioners changed their procedures to increase safety. For example, this led to the decline of instillation procedures identified as riskier in the 1970s and the use of general anesthesia in the 1980s. For the last time period reported, 1988 to 1997, the main causes of death were infection and hemorrhage, which accounted for...
about half of deaths. Embolism, anesthesia, and other causes accounted for the rest.

The risk of death from legal abortion, as reported by Bartlett and colleagues, increases exponentially with increasing gestational age: The earlier the abortion, the safer the abortion (Table 33.4). The risks from 1988 to 1997 (and therefore not including mifepristone abortions) are as follows: The risk with gestational age ≤8 weeks is 1 per million, at 12 weeks is 0.4 per 100,000, at 16 to 20 is 3.4, and at ≥21 weeks is 8.9 per 100,000 procedures (76 times higher than with the earliest procedures). Given the fact that earlier abortions are safer, issues such as access to abortion are medically relevant. These include number of trained providers, cost, and gestational age limit of particular institutions.

The risk of death for women of black and other races was about twice that of white women. For women having second-trimester procedures, mortality rates for D&E were 2.5 times lower than those for instillation and other procedures, although this was not statistically significant. No statistically significant risk category was higher than 10 per 100,000.

**Note:**
- Number of legal abortion-related deaths.
- Rate of legal abortion deaths as number per 100,000 abortions.
- Denominators for calculating rates by parity use previous live-birth data from abortion surveillance. Deaths with unknown parity are excluded.
- Deaths with unknown gestational age are excluded.

### Best Surgical Practices

- Management of spontaneous abortion includes expectant management, medical management with misoprostol, and suction curettage. Suction can be accomplished with a hand-held syringe or an electric vacuum source. Patient preference can direct management plan in most cases.
- Diagnosis of cervical incompetence remains variable in consistency. Cerclage placement can be used in women with a history of repeated premature cervical dilation without labor. The McDonald and Shirodkar cerclages are most common, with the McDonald being technically easier to place.
- Septic abortion requires aggressive management. This includes obtaining intravenous and blood cultures, administration of broad-spectrum antibiotics, and prompt surgical evacuation of the uterus.
- Suction curettage is the most frequent method of legal abortion in the United States. Manual vacuum aspiration is increasing in use. Both may safely be done in outpatient facilities.
- Preoperative medical evaluation for elective abortion should include patient’s medical, surgical, and anesthetic history, confirmation of gestational age, and thorough counseling about all available options, including continuing pregnancy, adoption, and medical and surgical abortion. Abortion regulations vary by state and should be followed by providers.
- Cervical dilation necessary for suction curettage can be achieved with osmetic dilators, medical preparation with misoprostol, or manual dilation. If manual dilation is necessary, a variety of dilators are available. Gentle dilation is critical in preventing uterine perforation.
- The incidence of retained products of conception after suction curettage can be decreased if aspirated tissue is inspected for presence of fetal tissue or chorionic villi.

### Conclusion

Abortion is the most frequent outcome of human conception; thus, management of abortion complications is an important responsibility for physicians. Chromosomal anomalies are the single most important cause of spontaneous abortion. For women with threatened abortion, use of ultrasonography and β-hCG monitoring can help predict the outcome of the pregnancy. Evacuation of the uterus in cases of fetal death is primarily for psychological rather than medical indications; either curettage or labor induction may be appropriate. Premature cervical dilation without labor is a poorly understood cause of spontaneous abortion. There is no uniform case definition and no valid diagnostic test. Randomized clinical trials reveal modest benefit of cervical cerclage on obstetric outcomes.

Small numbers of illegal abortions continue to occur in the United States. Legally induced abortion, however, is one of the most frequently performed—and one of the safest—operations in contemporary practice. Less than 1 per 100 of those having an abortion suffers a major complication, and less than 1 per 100,000 dies from causes associated with the procedure. The marketing of mifepristone in the United States for early abortion has broadened the options available to women, and use of misoprostol for cervical preparation before curettage represents important advances in gynecology.
Prophylactic antibiotic use is indicated when instruments are introduced into the uterus, as in suction curettage, manual evacuation, aspiration, and D&E.

Medical abortion with misoprostol and misoprostol is a safe way to terminate early pregnancies. Two regimens exist: one approved by the FDA and another that reflects recent evidence in the literature. Either one, with thorough understanding of the regimen, have access to emergency care if needed, and be able to follow up to ensure completion of the procedure.

Second-trimester pregnancy terminations can be achieved by surgery with dilation and evacuation (D&E) or with medications to cause labor. D&E is generally safer and faster, often can be performed on an outpatient basis, and can be used to terminate pregnancies up to 15 weeks gestation. D&E is generally considered best when the pregnancy is larger than about 10 weeks, in order to decrease the risk of complications. Surgical complications, and Rh sensitization. Morbidity and mortality from legal abortion is very rare.

CHAPTER 34 ■ ECTOPIC PREGNANCY

MARK A. DAMARIO AND JOHN A. ROCK

DEFINITIONS

Abdominal pregnancy—A pregnancy that develops in the peritoneal cavity. Most abdominal pregnancies are secondary, the result of early tubal abortion or rupture with secondary implantation of the pregnancy into the peritoneal cavity. A primary abdominal pregnancy is one that implants directly into the peritoneal cavity.

Arias-Stella reaction—A reaction in endometrial cells associated (but not exclusively) with ectopic pregnancy, showing nuclear enlargement, irregularity, and hyperchromasia with cytoplasmic vacuolization.

β-hCG assay—A quantitative determination of the serum concentration of the human chorionic gonadotropin hormone obtained using a highly sensitive immunoassay that is specific for the β-subunit of human chorionic gonadotropin. Useful in the early diagnosis of ectopic pregnancy.

Cervical pregnancy—A pregnancy developing in the cervical canal below the level of the internal os.

Culdocentesis—Aspiration of fluid from the cul-de-sac (pouch of Douglas) via a needle puncturing the vaginal wall between the uterosacral ligaments.

Dilatation and curettage—A surgical procedure in which the endometrial cavity contents are removed and submitted for histologic study. Useful in the early diagnosis of ectopic pregnancy when β-hCG assays and transvaginal ultrasonography are nondiagnostic and a nonviable pregnancy is suspected.

Ectopic pregnancy—A pregnancy that develops following implantation anywhere other than the endometrial cavity of the uterus.

Heterotopic pregnancy—Combined intrauterine and extrauterine pregnancy.

Interstitial pregnancy—A pregnancy developing in the interstitial portion of the oviduct.

Laparoscopy—A surgical technique that allows for both diagnosis and treatment of an ectopic pregnancy. Remains as the “gold standard” method of diagnosis.

Ovarian pregnancy—A pregnancy developing in the ovary. Criteria for diagnosis includes the following: (i) the ipsilateral tube is intact and clearly separate from the ovary, (ii) the gestational sac definitely occupies the normal position of the ovary, (iii) the sac is connected to the uterus by the uteroovarian ligament, and (iv) ovarian tissue is unquestionably demonstrated in the wall of the sac.

Persistent ectopic pregnancy—Continued presence of viable trophoblastic tissue after conservative surgical treatment of an unruptured ectopic pregnancy. The typical presentation includes persistence of β-hCG concentrations that do not fall appropriately following conservative surgery.

Salpingotomy—Operative opening made in the oviduct that is used to remove an unruptured tubal pregnancy for the purpose of retaining the oviduct.

Salpingectomy—Operative removal of an oviduct.

Serum progesterone assay—A quantitative determination of the serum concentration of progesterone hormone. Useful in the early diagnosis of ectopic pregnancy.

Transvaginal ultrasonography—Ultrasound imaging of the female pelvis using an endoscopic probe placed in the vagina. Useful in the early diagnosis of an ectopic pregnancy.

Tubal pregnancy—The most common type of ectopic pregnancy. May involve the ampullary, fimbrial, or isthmic portion of the oviduct.

ECTOPIC PREGNANCY

Salpingotomy was first recognized in 1693 by Busiere when he was examining the body of a prisoner executed in Paris. Gifford of England made a more complete report in 1731 that described the condition of a fertilized ovum implanted outside the uterine cavity. Ectopic pregnancy has since become recognized as one of the more serious complications of pregnancy. One of the leading causes of maternal morbidity and mortality in the United States, it still accounted for 6% of all maternal deaths from 1991 to 1999, according to the Centers for Disease Control and Prevention (CDC). Despite significant advances in diagnosis and treatment, ectopic pregnancy remains the leading cause of maternal death in the first trimester.

Today, early diagnosis of ectopic pregnancy is possible with highly sensitive and rapid β-human chorionic gonadotropin (β-hCG) assays and the aid of advanced vaginal ultrasonographic equipment. The benefit of early diagnosis is that expectant medical therapy or conservative surgery becomes possible. Conservative management in the case of a small ectopic pregnancy that is present without rupture is usually successful when preservation of the oviduct to maintain or enhance fertility is important. Physicians should maintain a high index of suspicion for ectopic pregnancy and should be cognizant of the importance of early diagnosis and early intervention. This chapter summarizes the contemporary methods for diagnosis and treatment of ectopic pregnancy.

EPIDEMIOLOGY OF ECTOPIC PREGNANCY

Although the total number of pregnancies has declined over the past three decades, the rate of ectopic pregnancy has continued to increase in most western nations. In the United States, the incidence of ectopic pregnancy has increased from 4.5 per 1,000 pregnancies in 1970 to 19.7 per 1,000 pregnancies in 1995 (the last year for which national data are available). In Norway, an increase from 12.1 to 18.0 per 1,000 pregnancies was reported from 1976 to 1993. One contributing factor for the rising ratio of extrauterine to intrauterine pregnancies is felt to be the rising incidence of sexually transmitted diseases as well as the efficacy of modern antibiotic treatments for pelvic inflammatory disease (PID). A second factor may be the increased ability to detect the disease. Although the risk of death from ectopic
addition, Westrom found that approximately 4% of all preg-
two infections, and in 75% after three or more infections. In
bilateral tubal occlusion occurs in approximately 12.8% of pa-
oclusions, agglutination of the cilia can still occur, and synechial
After initial appropriate treatment of an infection with antibi-
are related to the increasing incidence of ectopic pregnancy.
levi and associates have demonstrated that the risk of ec-
topic pregnancy is increased in women with a primary history of
without antibiotics. After initial appropriate treatment of an infec-
the tubal lumen to cause partial tubal obstruction. Westrom has
demonstrated that trophoblastic infiltration can be predominantly
or, occasionally, mixed. It is impossible to ascertain in the op-
erating room the predominant pattern of growth of a given
women who attempted to conceive after a pelvic infection were suc-
totally occluded, and permanent sterility was the result. Women
who underwent salpingostomy for distal tubal obstruction ranges from 2%
with intrauterine pregnancies at the same stage of gestation.
were PCR positive for C. trachomatis DNA. Therefore, the in-
nutes old at the time of the study. In a subsequent study, Gerard and
found that of the patients undergoing salpingostomy for distal tubal
operative procedure on the oviduct, whether a sterilization
procedure or tubal reconstructive surgery, can cause an ectopic pregnancy. The incidence of ectopic pregnancies occurring after
neosalpingostomy for distal tubal obstruction ranges from 2% to
18% (Table 34.1). The rate of ectopic pregnancy after a microsurgical
reversal of a sterilization procedure is only about 4%, presumably because the tubal tubes have not been damaged by
prior infection.
the overall risk of an ectopic pregnancy is lowered in women
using oral contraceptives. When oral contraceptives fail, how-
ever, the risk of an ectopic pregnancy is slightly increased. This
increase is presumed secondary to the inhibitory progesterin ef-
fect on tubal motility. This hypothesis is supported by several
studies implicating progestin-only oral contraceptives in the
etiology of ectopic pregnancies.
risk that the pregnancy will be ectopic. The type of steriliza-
tion procedure and age of the patient at the time of sterilization
appear to be relevant factors. Women sterilized by bipolar tubal
coagulation before the age of 30 years had a probability of ec-
topic pregnancy that was 27 times as high as that of women of
similar age who underwent postpartum partial salpingectomy
(31.9 versus 1.2 ectopic pregnancies per 1,000 procedures).
In addition, ectopic pregnancy was often seen many years after
the sterilization procedure. The annual rates of ectopic preg-
nancy in the 4th through 10th years after sterilization were no
lower than that seen in the first 3 years.

The pathophysiology of ectopic pregnancy after elective
tubal sterilization is not clear. It is possible that a tuboperi-
toneal fistula in a previously coagulated segment of fallopian
tube may allow spermatozoa to escape and reach the oocyte.
Such fistulas have been demonstrated radiographically by Shah
and colleagues in 11% of 150 women after laparoscopic elec-
trocoagulation. Improper surgical technique (such as incom-
plete coagulation or misplacement of a mechanical device) may
also influence the sterilization failure rate and incidence of ec-
topic pregnancy, although their likelihood is presumably low.

**Assisted Reproductive Technologies**

Ectopic pregnancies are known to occur with increased fre-
quency after in vitro fertilization (IVF) and related techniques.
The Society for Assisted Reproductive Technology (SART) re-
ported that 2.1% of pregnancies established after IVF in the
United States during 2000 were ectopic. Several theories have
been proposed regarding the occurrence of ectopic implanta-
tion after transcervical intrauterine embryo transfer. Potential
factors include the possibility of direct injection of embryos
into the fallopian tube, uterine contractions provoked by the
transfer catheter that propel the embryos retrograde, position
or depth of the transfer catheter in the uterine cavity, and the
volume of transfer medium. Verhulst and colleagues reported
that tubal damage was a major risk factor. These researchers
found that the ectopic pregnancy rate after IVF was signifi-
cantly greater in patients with tubal disease (3.65% of pregnan-
cies) than in those without tubal disease (1.19% of pregnan-
cies). Strandell and associates found that a history of a previous
ectopic pregnancy and a history of a previous myomectomy
also appear to be risk factors for ectopic pregnancies following
IVF.

Tummon and coworkers reported a 2% risk of heterotopic
pregnancy in women undergoing IVF who had distorted tubal
anatomy. This is about 100 to 200 times the reported inci-
dence of combined intrauterine and extrauterine pregnancies
occurring spontaneously. These authors also found that the risk
of heterotopic pregnancy appeared to increase proportionately
with the number of embryos transferred.

**Developmental Anomalies**

Intramural polyps and tubal diverticula can block or alter tubal
transport of fertilized ova. Congenital absence of segments of
the fallopian tube with peritoneal fistulas can also predispose
to tubal pregnancy. Women exposed to diethylstilbestrol (DES)
in utero are at higher risk of ectopic pregnancy. These women
may have absent or minimal fimbriae and fallopian tubes that
are shorter and thinner than normal.

**Other Causal Factors**

Several studies have demonstrated that cigarette smoking seems
to be an independent, dose-related risk factor for ectopic pre-
gnancy. Other lifestyle factors, such as multiple sex partners and
early age at first intercourse, are associated with an increased
risk. Vaginal douching has also been associated with a slightly
increased risk of ectopic pregnancy, probably by increasing the
overall risk of pelvic infections and resultant tubal damage. A
summary of risk factors related to ectopic pregnancy is sum-
morized in Table 34.2.

About 95% of extrauterine implantations occur in the oviduct.
About 35% of these tubal implantations occur in the ampulla,
the most common site. Implantation in the isthmic portion ac-
counts for 20% to 25%, implantation in the infundibulum and
fimbria accounts for 17%, and implantation in the interstitial
segment (cornua) accounts for 2% to 4%. Ectopic implanta-
tions occur less often in the ovary, the cervix, and the peritoneal
cavity (Fig. 34.1).

Walters and colleagues reported that 16% of tubal preg-
nancies result from a contralateral ovulation. Transmigration

---

**SUMMARY: ECTOPIC PREGNANCY AFTER TUBAL SURGERY**

---
of the ovum in the peritoneal cavity can occur because the oviducts and ovaries may be situated close together in the cul-de-sac. Alternatively, this phenomenon could also result from transmigration of the embryo through the endometrial cavity into the opposite oviduct.

### EFFECTS OF ECTOPIC PREGNANCY ON FUTURE REPRODUCTION

Tubal pregnancy is associated with a poor prognosis for subsequent reproduction. In most cases, an extrauterine pregnancy represents an impairment of the fertilized ovum’s ability to migrate through the deep rugae of the oviduct as a result of altered tubal function. The morphologic abnormality is usually bilateral and irreversible, and can produce repeated ectopic pregnancies or permanent sterility. In a 1975 study, Shoen and Nowak concluded that about 70% of patients who have an ectopic first pregnancy are unable to produce a living child. As many as 40% of the patients who have an ectopic first pregnancy will have a repeat ectopic pregnancy, which compares with the total repeat ectopic rate of 10% to 15% for the overall population of reproductive-age women. More than half of the subsequent extrauterine pregnancies will occur within a 2-year period, and 80% will occur within 4 years of the initial ectopic pregnancy. In reviewing the experience of the Kaiser Foundation hospitals, Hallatt reported a 9.2% overall incidence of repeat ectopic pregnancies among 1,330 women who had extrauterine pregnancies. The potential reproductive capacity for a patient who has had an ectopic pregnancy therefore depends on her reproductive history. If an ectopic pregnancy was the result of her first reproductive effort, then the prognosis for future pregnancies is much worse than if the complication occurred after one or more successful pregnancies.

Mueller and associates have estimated that 92% of infertility in women who have had a tubal pregnancy results from tubal damage that is due to the tubal pregnancy itself or other factors that had predisposed to its occurrence. A history of infertility itself is a risk factor for ectopic pregnancy. A twofold increase in the risk of tubal pregnancy exists among infertile women with no evident abnormality during infertility evaluation.

### TUBAL ECTOPIC PREGNANCY

The morbidity and mortality associated with extrauterine pregnancy are directly related to the length of time required for diagnosis. In a CDC survey, two thirds of all patients who were later proven to have an ectopic pregnancy were previously seen by a physician, and either the diagnosis was deferred or the condition was incorrectly assessed. The mortality rate from an ectopic pregnancy is higher in rural areas, where patients are less likely to receive early medical care.

For a successful outcome, an ectopic pregnancy must be diagnosed early. In some clinics where the condition is treated frequently, more than 50% of cases are diagnosed and treated before tubal rupture occurs. In some cases, however, the symptoms that bring a patient to seek medical care are caused by an already leaking or ruptured ectopic pregnancy. As many as 15% of all tubal pregnancies rupture before the first missed menstrual period, particularly if a patient’s usual menstrual pattern is very irregular.

Diagnostic accuracy is often improved in repeat ectopic pregnancies. The vast majority of patients with repeat ectopic pregnancies will be diagnosed and treated before tubal rupture occurs. A difference with a repeat ectopic pregnancy is that the patient herself often raises the question of an extrauterine pregnancy. Being suspicious, the patient may seek medical care earlier and provides a more specific medical history than does a patient experiencing her first ectopic pregnancy. The result is often an earlier diagnosis and an improved chance for a successful outcome.

Some form of vaginal bleeding occurs around the expected time of menses in more than 50% of women with an ectopic pregnancy, so that many patients and their physicians are unaware that a pregnancy has occurred. The vaginal bleeding may be followed by a period of amenorrhea. Clinical symptoms of an ectopic pregnancy usually appear 6 to 10 weeks after the last normal menstrual period.

### DIAGNOSIS

#### Classic Symptoms: Pain, Bleeding, and Adnexal Mass

The classic presentation of pain and uterine bleeding with the finding of an adnexal mass has been the clinical hallmark of an extrauterine pregnancy, but even classic presentations can be misleading. Schwartz and DiPietro observed that of the

**FIGURE 34.1.** Sites and incidence of ectopic pregnancy.
 Third IS, and Fourth IS are highly purified preparations that IS has been exhausted and is no longer used. The First IRP, β unit of initially developed for use in hCG bioassays. One international reference standards used by the available commercial kits national Standards (Third or Fourth IS) are the most commonly determining the viability of pregnancy. To optimally use β reference standards for should first have a thorough understanding of the particular data in treating a patient with a problematic pregnancy, one serum as early as 7 to 8 days after ovulation, or approximately β hCG as low as 5 IU/L of serum with less than a 0.2% incidence in the past. A immunoassay for to the traditional radioimmunoassay methods commonly used automated β-hCG assays; (ii) the ability to use ultrasound to β-hCG levels is useful in de- β-subunit, on the other hand, is specific to hCG, and antibodies against the β-subunit form the basis for current immunoassays. Current commercial automated β-hCG immunoassays use enzyme fluorometry, en- zyme spectrometry, or chemiluminescence methods, as opposed to the traditional radioimmunoassay methods commonly used in the past. A immunoassay for β-hCG can detect levels of hCG as low as 1 IU/L of serum with less than a 0.2% incidence of false-negative results, β-hCG can be detected in maternal serum as early as 7 to 8 days after ovulation, or approximately the day after blastocyst implantation.

The quantification of serum β-MG levels is useful in de- termining the viability of pregnancy. To optimally use β-hCG data in treating a patient with a problematic pregnancy, one should first have a thorough understanding of the particular assay used. The World Health Organization has established ref- erence standards for β-hCG assays. The Third or Fourth Inter- national Standards (Third or Fourth IS) are the most commonly used reference standards used by the available commercial kits of today. These standards are roughly equivalent to the First International Reference Preparation (First IRP), but are quite a bit different from the Second International Standard (Second IS). The Second IS contains about 20% intact hCG and was ini- tially developed for use in hCG biosyntheses. One international unit of β-hCG based on the First IRP is equal to approximately 0.58 IU of β-hCG using the Second IS. Fortunately, the Second IS has been exhausted and is no longer used. The First IRP, Third IS, and Fourth IS are highly purified preparations that were developed to overcome the deficiencies seen in the use of a heterogeneous standard. This notwithstanding, due to the continuing variation of assay methodologies and β-hCG stan- dards, there remains considerable between-method variation in β-hCG assay results. Serum hCG concentrations increase in an exponential fash- ion in early pregnancy. During the period of gestation in which the hCG concentration is less than 10,000 IU/L (First IRP), or about 23 to 30 days postovulation, the time required for doubling of hCG levels remains constant, with a mean of 1.9 days. Kadar and colleagues reported that 87% of women with ectopic pregnancies and 15% of women with normal intrauterine pregnancies could expect to have hCG doubling times of more than 2.7 days when the hCG concentration measured less than 6,000 IU/L. The lower limits of the increase in serum hCG for viable intrauterine pregnancies have been established by Barnhart and colleagues in a large cohort study. In this study, the serial β-hCG titres of 287 women who presented with pain and/or bleeding in the first trimester and were ultimately di- agnosed with a viable intrauterine pregnancy were evaluated. For viable intrauterine gestations less than 10 weeks from last menstrual period or those with an initial β-hCG titre less than 5,000 mIU/mL, the investigators noted that the curve generated for serial hCG concentrations best fit a log-linear model. Overall, β-hCG concentrations tended to double every 2 days. The median rise of hCG after 1 day was 50% and after 2 days was 124%. The slower or minimal rise for a normal viable in- trauterine pregnancy, however, was 24% at 1 day and 53% at 2 days. Interval β-hCG determinations interpreted within the context of several values can therefore be of prognostic signifi- cance in the differentiation between normal intrauterine versus extraterine pregnancies. A normal rise in hCG production, however, does not always differentiate an ectopic from a vi- able intrauterine pregnancy. Shepherd and associates reported that, in their experience, a normal rise in hCG production, not reliably differentiate an ectopic from a viable intrauterine pregnancy in the symptomatic patient. Early ectopic pregnan- cies can initially secrete appropriate amounts of hCG because of a well-vascularized placental bed.

### Diagnostic Studies

Three major advances have made early diagnosis of exsterrau- ine pregnancy possible: (i) the development of highly sensitive and rapid β-hCG assays; (ii) the ability to use ultrasound to evaluate the uterus and the adnexa (vaginal sonography further increases the accuracy of diagnosis); and (iii) the application of laparoscopy as a diagnostic tool. Culpodocentesis or suction curettage, or both, can be useful under certain circumstances (e.g., to help establish the presence of a hemoperitoneum or a notviable intrauterine pregnancy, respectively). Other newer diagnostic methods, such as serum progesterone assays or color Doppler flow analyses, can also provide useful information.

### β-hCG Assays

The principal endocrine marker of pregnancy is human chori- onic gonadotropin (hCG), which is synthesized by the tro- phoblast. Human chorionic gonadotropin is a glycoprotein consisting of two subunits: α and β. The α subunit has signif- icant homology with other glycoprotein hormones, such as follicle-stimulating hormone, luterenizing hormone, and thyroid-stimulating hormone. The β-subunit, on the other hand, is specific to hCG, and antibodies against the β-subunit form the basis for current immunoassays. Current commercial automated β-hCG immunoassays use enzyme fluorometry, en- zyme spectrometry, or chemiluminescence methods, as opposed to the traditional radioimmunoassay methods commonly used in the past. A immunoassay for β-hCG can detect levels of hCG as low as 1 IU/L of serum with less than a 0.2% incidence of false-negative results, β-hCG can be detected in maternal serum as early as 7 to 8 days after ovulation, or approximately the day after blastocyst implantation.

The quantification of serum β-MG levels is useful in de- termining the viability of pregnancy. To optimally use β-hCG data in treating a patient with a problematic pregnancy, one should first have a thorough understanding of the particular assay used. The World Health Organization has established ref- erence standards for β-hCG assays. The Third or Fourth Inter- national Standards (Third or Fourth IS) are the most commonly used reference standards used by the available commercial kits of today. These standards are roughly equivalent to the First International Reference Preparation (First IRP), but are quite a bit different from the Second International Standard (Second IS). The Second IS contains about 20% intact hCG and was ini- tially developed for use in hCG biosyntheses. One international unit of β-hCG based on the First IRP is equal to approximately 0.58 IU of β-hCG using the Second IS. Fortunately, the Second IS has been exhausted and is no longer used. The First IRP, Third IS, and Fourth IS are highly purified preparations that were developed to overcome the deficiencies seen in the use of a heterogeneous standard. This notwithstanding, due to the continuing variation of assay methodologies and β-hCG stan- dards, there remains considerable between-method variation in β-hCG assay results. Serum hCG concentrations increase in an exponential fash- ion in early pregnancy. During the period of gestation in which the hCG concentration is less than 10,000 IU/L (First IRP), or about 23 to 30 days postovulation, the time required for doubling of hCG levels remains constant, with a mean of 1.9 days. Kadar and colleagues reported that 87% of women with ectopic pregnancies and 15% of women with normal intrauterine pregnancies could expect to have hCG doubling times of more than 2.7 days when the hCG concentration measured less than 6,000 IU/L. The lower limits of the increase in serum hCG for viable intrauterine pregnancies have been established by Barnhart and colleagues in a large cohort study. In this study, the serial β-hCG titres of 287 women who presented with pain and/or bleeding in the first trimester and were ultimately di- agnosed with a viable intrauterine pregnancy were evaluated. For viable intrauterine gestations less than 10 weeks from last menstrual period or those with an initial β-hCG titre less than 5,000 mIU/mL, the investigators noted that the curve generated for serial hCG concentrations best fit a log-linear model. Overall, β-hCG concentrations tended to double every 2 days. The median rise of hCG after 1 day was 50% and after 2 days was 124%. The slower or minimal rise for a normal viable in- trauterine pregnancy, however, was 24% at 1 day and 53% at 2 days. Interval β-hCG determinations interpreted within the context of several values can therefore be of prognostic signifi- cance in the differentiation between normal intrauterine versus extraterine pregnancies. A normal rise in hCG production, however, does not always differentiate an ectopic from a vi- able intrauterine pregnancy. Shepherd and associates reported that, in their experience, a normal rise in hCG production, not reliably differentiate an ectopic from a viable intrauterine pregnancy in the symptomatic patient. Early ectopic pregnan- cies can initially secrete appropriate amounts of hCG because of a well-vascularized placental bed.

### Serum Progesterone Assay

Serum progesterone levels reflect the production of proges- terone by the corpus luteum in early pregnancy. During the first 8 to 10 weeks of gestation, serum progesterone concentrations change little; as pregnancy fails, the levels decrease. Matthews and colleagues and reported progesterone levels in 29 patients with ectopic pregnancy using a direct radioimmunoassay that offers results within 4 hours. Patients with normal intrauterine pregnan- ncies had serum progesterone levels greater than 20 ng/mL, and all patients with ectopic pregnancies had progesterone lev- els less than 15 ng/mL. Yeko and associates proposed that all ectopic pregnancies could be potentially diagnosed at the first emergency visit with a single serum progesterone determina- tion using a discriminatory value of 15 ng/mL. Other authors, however, have demonstrated some overlap in the serum pro- gesterone concentrations in ectopic and normal intrauterine pregnancies. One large study by Gelder and colleagues reported that 98% of patients with a normal intrauterine pregnancy had progesterone levels greater than 10 ng/mL and that 98% of pa- tients with ectopic pregnancies not associated with ovulation induction had progesterone levels less than 20 ng/mL. Unfortu- nately, 31% of viable intrauterine pregnancies, 23% of abnor- mal intrauterine pregnancies, and 31% of ectopic pregnancies in this series had progesterone levels that fell between 10 and 20 ng/mL, which greatly limited the clinical usefulness of the test. Hahlin and colleagues reported that a serum progesterone
value of less than 9.4 ng/mL combined with an abnormal hCG increase had a positive predictive value of 1.0 for pathologic pregnancy. In a group of more than 1,000 first-trimester pregnant patients, the lowest serum progesterone level associated with a viable pregnancy was 5.1 ng/mL. Therefore, these investigators established the lower cutoff limit of serum progesterone levels of 3 mg/mL; patients below this threshold had a nonviable pregnancy with 100% certainty and therefore underwent curettage. Patients with serum progesterone levels greater than 2.5 mg/mL had a 97% likelihood of having a viable intrauterine pregnancy in this study.

Transvaginal Ultrasonography

Pelvic ultrasound has revolutionized the diagnostic process of ectopic pregnancy. Transvaginal ultrasonography, in particular, may identify masses in the adnexa as small as 10 mm in diameter and can provide more detail about the character of the mass than clinical exam (Fig. 34.2). At the same time, transvaginal ultrasonography can evaluate the contents of the endometrial cavity and can document the presence of a viable intrauterine pregnancy with great accuracy. In addition, transvaginal ultrasonography allows for the simultaneous assessment for the presence of free peritoneal fluid.

Transvaginal ultrasonography is usually considered superior to transabdominal ultrasonography in the diagnosis of ectopic pregnancy. Although the latter provides a broader perspective of the abdominal cavity and pelvis, transvaginal ultrasonography generally provides better resolution of the internal female genitalia. A 5-MHz transvaginal transducer allows for a deeper penetration of the pelvis than transducers of higher frequency, whereas a 7.5-MHz transvaginal transducer provides for better near-resolution at the cost of shallower penetration. On rare occasions, an ectopic pregnancy may be located beyond the reach of the transvaginal transducer and can provide more detail about the character of the mass. Techniques such as the direct imaging of the ectopic pregnancy using transvaginal ultrasonography is highly specific for ectopic pregnancy (98.9%), with a high positive predictive value (96.3%). These authors described that the direct imaging of the ectopic pregnancy using transvaginal ultrasonography allows for the simultaneous assessment for the presence of free peritoneal fluid.

Although diagnosis by transvaginal ultrasound can be quite useful, it may at times be confusing. One problem is that a pseudogestational sac that is due to a decidual cast can be mistaken for an amnionic sac. A useful differentiating feature is the “double-line” image, caused by the faint hypoechogenic decidual lining of the uterus and the hyperechogenic rim of the trophoblast surrounding the gestational sac. The double-line image can be seen as early as 5 weeks after the last menstrual period. Even in the presence of the double-line image, however, it is important to further follow the course of pregnancy and subsequently confirm a viable intrauterine pregnancy with the ascertainment of ultrasonographically imaged intrauterine cardiac motion.

Although not always seen, Frates and Laing reported that the presence of a nonscystic extravasation adrenal mass, extratubal cardiac motion, or a “tubal ring” by transvaginal ultrasonography is highly specific for ectopic pregnancy (98.9%), with a high positive predictive value (96.3%). These authors described that the direct imaging of the ectopic pregnancy using transvaginal ultrasonography allows for the simultaneous assessment for the presence of free peritoneal fluid.

FIGURE 34.2. Tubal ectopic pregnancy documented by endovaginal sonography.
The advent of color-flow Doppler technology may even further improve the accuracy of noninvasive diagnostic methods. Kurjak and colleagues reported that ectopic pregnancies are characterized by the identification of peritrophoblastic flow associated with an adnexal mass by color Doppler techniques. Kurcler and coworkers showed that color Doppler qualitative blood flow analyses of the tubal arteries can help localize the side of a tubal ectopic pregnancy. These investigators reported a between-side difference in tubal blood flow of 20% to 45%, with increased blood flow seen on the side of the ectopic pregnancy. Emerson and colleagues demonstrated that color-flow Doppler capability can help differentiate between viable intrauterine pregnancy, completed abortion, incomplete abortion, or ectopic pregnancy. Histologic endometrial changes associated with an adnexal mass identified as an ectopic pregnancy by transvaginal ultrasonography identified an ectopic pregnancy with 100% accuracy. Even using a discriminatory serum β-hCG concentration of 1,000 IU/L or higher, an empty uterus on transvaginal ultrasonography reliably detects intrauterine gestations as early as 1 week after missed menses (β-hCG > 1,350 IU/L; 5–6 weeks’ gestation), Burnhart and associates reported that with a β-hCG concentration of 1,500 IU/L or higher, an empty uterus on transvaginal ultrasonography identified an ectopic pregnancy with 100% accuracy. Even using a discriminatory serum β-hCG concentration of 1,000 IU/L, Cacciatore and associates identified an intrauterine gestation in all intrauterine pregnancies and in none of the ectopic pregnancies. Furthermore, these investigators reported that the detection of an adnexal mass in combination with an empty uterus had a sensitivity of 97%, specificity of 99%, positive predictive value of 98%, and negative predictive value of 98%, provided that serum β-hCG concentrations exceeded 1,000 IU/L. The coupling of hCG titers with transvaginal ultrasound equipment, and sonographer experience, each institution must determine their own discriminatory thresholds for the sonographic detection of an intrauterine pregnancy.

The atypical epithelial changes of the gestational endometrium in a case of tubal pregnancy were first described by Polak and Wolfe in 1924 and these changes were further expanded on by Arias-Stella in 1954 (Fig. 34.3). These comprise a highly controversial set of histologic criteria that depend, for accuracy, on the precise definition of the particular cell type involved in the morphologic change, together with ill-defined physiologic events that reportedly produce the changes. Arias-Stella and others were convinced that these histologic changes are a progressive phenomenon resulting from the exaggerated proliferative and secretory endometrial responses to the elevated hormonal levels of pregnancy. Lloyd and Fienberg disagreed, maintaining that these endometrial changes are progressive, involutorial, and are the result of declining hormonal levels. Whichever hypothesis is ultimately proven, similar endometrial changes may be seen with a normal pregnancy, spontaneous abortion, or ectopic pregnancy. Histologic endometrial criteria, therefore, seems to have limited value in the specific diagnosis of extrauterine pregnancies.

FIGURE 34.3. Arias-Stella reaction in endometrial cells associated with ectopic pregnancy, showing nuclear enlargement, irregularity, and hyperchromasia with cytoplasmic vacuolation.
Culdocentesis

Culdocentesis is a diagnostic tool for identifying the presence of intrauterine bleeding. This simple procedure of inserting an 18-gauge spinal needle attached to a 50-mL aspirating syringe into the cul-de-sac between the uterosacral ligaments (Fig. 34.4) provides immediate clinical information when unclotted blood is aspirated from the cul-de-sac. The procedure cannot be used for a definitive diagnosis, of course, because a tubal pregnancy may not have ruptured or leaked into the peritoneal cavity. In addition, a culdocentesis does not provide information concerning whether the blood is from an ectopic pregnancy or from some other cause of intraabdominal bleeding. The rupture of a corpus luteal hemorrhagic cyst, for instance, may cause a similar bleeding pattern. The availability of sensitive transvaginal ultrasonographic technology presently limits the usefulness of the culdocentesis procedure, such that it is rarely presently performed. Free intraperitoneal blood has a characteristic ultrasonographic appearance and can be seen in nearly all cases in which a significant intraperitoneal hemorrhage has occurred. In the absence of the immediate availability of transvaginal ultrasonography or in an emergency setting, however, a culdocentesis may still be of value.

Laparoscopy

Laparoscopy remains the gold standard in the detection of ectopic pregnancy, although noninvasive diagnostic methods continue to improve. In addition to permitting the diagnosis of an ectopic pregnancy, it enables surgical treatment. Laparoscopy also provides an opportunity to visualize the entire pelvis and other peritoneal organs. In particular, the condition of the unaffected fallopian tube can be assessed, as well as the presence of pelvic adhesions and endometriosis. This information may be particularly valuable for those patients interested in future fertility. The disadvantage of laparoscopy is that it is an invasive procedure that carries some risk of complications. Using standard methods, it requires general anesthesia and an operating room setting, thereby contributing to increased medical costs. Recent investigators, however, have been exploring the potential of “microlaparoscopy,” in which improved optics and smaller-diameter laparoscopes and trocars allow for a definitive diagnosis and possible treatment in the nonoperating room setting. Several authors have reported the encouraging use of microlaparoscopy in the office setting, using local rather than general anesthesia. The specific utility of microlaparoscopy, however, for the primary evaluation and treatment of ectopic pregnancy remains to be established.

Laparoscopy may be useful when an ectopic pregnancy is suspected but no signs of an ultrasonographically visualized extrauterine gestational sac is evident. This includes situations in which there is an inability to visualize an intrauterine gestational sac and serial β-hCG determinations are rising inappropriately. This also includes situations in which a D&C fails to identify products of conception. One must be careful, however, in settings in which the β-hCG determinations are very low or the gestational age is limited. In these settings, the ectopically implanted gestational mass may be so small that it is still not able to be seen at laparoscopy. The clinician and patient might therefore be falsely reassured by negative laparoscopic findings. All patients without a definitive diagnosis established at laparoscopy should continue to be followed closely.

Other Potential Diagnostic Aids

Gleicher et al. described the use of hysterosalpingography and selective salpingography in differentiating early (biochemical) intrauterine from failing intratubal gestations. A characteristic tubal opacification pattern was seen in the cases of early tubal pregnancy. Confino and coworkers reported that selective salpingography was useful in diagnosing early tubal pregnancies in some patients with equivocal clinical, laboratory, and sonographic findings. In addition, these investigators injected a single dose of methotrexate through the selective salpingography catheter after cannulation of the tubal ostia and identification of a characteristic ampullary radiolucency in seven patients. Each had subsequent complete resolution of the pregnancy without complication. Risquez and colleagues reported the successful visualization of two ectopic pregnancies by transcervical tubal cannulation and falloposcopy. The falloposcope is a microendoscopic instrument 0.5 mm in external diameter that is introduced by a 1-mm coaxial catheter. Although limited by the presence of blood in the tubal lumen, direct visualization of the ectopic pregnancies was accomplished in both cases and confirmed by concurrent laparoscopy. Other investigative teams have explored the potential of other imaging methods, such as magnetic resonance imaging (MRI), in the diagnostic workup for ectopic pregnancy. MRI might be useful if the sonographic image is inconclusive, although it is likely to be rarely needed, particularly if laparoscopy is generally considered in uncertain cases.

Summary of Diagnostic Methods for Detecting Tubal Ectopic Pregnancy

When a patient is seen with a clinical history suggestive of ectopic pregnancy, a careful examination is performed (Fig. 34.5). Quantitative serum β-hCG and rapid serum progesterone levels (if available) are obtained. If the β-hCG titre is positive, a transvaginal ultrasound is performed. If an intrauterine sac is visualized with fetal heart activity, then the diagnosis of...
intrauterine pregnancy is established. If, however, there are no intrauterine sacs or there is a questionable intrauterine sac without fetal heart activity, then the asymptomatic patient may be expectedly treated awaiting further testing. If the serum progesterone level is, with certainty, below the threshold level for viability, then an asymptomatic patient may be expectantly treated awaiting further testing. If the serum progesterone level is, with certainty, below the threshold level for viability, then a uterine curettage can be performed. The subsequent failure to find chorionic villi on curettage is very suggestive, but not diagnostic, of an ectopic pregnancy. If the serum progesterone level is more than 25 ng/mL, in the absence of ovulation induction, then there is a strong likelihood that a viable pregnancy is present. If the quantitative serum β-hCG level is above the discriminatory zone for a particular institution and no intrauterine gestational sacs are apparent using transvaginal ultrasonography, then an ectopic pregnancy is likely. The level of hCG at which an intrauterine gestational sac should be identified has been established by each institution.

When the diagnosis is uncertain and the patient is in an unstable condition, tests for serial β-hCG levels should be taken at 48-hour intervals, and the serum progesterone level should be above the discriminatory zone (≥5-10 ng/mL). If the hCG level increases more than 50% within a 48-hour period, then the patient may have a normal intrauterine pregnancy and nonsurgical care (expectant management) is indicated. If the increase in the serial hCG level is less than 50% of the original value, then a nonviable pregnancy should be suspected. Ultrasound can often then corroborate the diagnosis of an ectopic pregnancy with the demonstration of a gestational sac in the adnexa or fluid in the cul-de-sac.

Initially, a normal increase in the β-hCG level may be observed. Over time, however, the level may slowly plateau, never reaching the discriminatory zone. If a potential intrauterine pregnancy is thought to be nonviable, then a D&C can be performed. If there is any question of viability, however, laparoscopy is preferred to rule out ectopic pregnancy first. Once fetal heart motion is observed within the uterine cavity, the possibility of a tubal ectopic pregnancy is virtually excluded.
and ectopic pregnancy. Nevertheless, the overall risk of the two existing simultaneously even after a superovulation regimen is quite small.

The use of vaginal ultrasonography with improved resolution and the addition of color Doppler flow analysis will invariably define a lower discriminatory zone in the future. Both modalities appear to complement each other in attaining improved sensitivity and specificity in the diagnosis of ectopic pregnancy. Other investigative diagnostic techniques, such as selective salpingography and falloposcopy, should be considered strictly experimental.

TREATMENT FOR ECTOPIC PREGNANCY

Expectant Therapy

Before the advent of effective therapy for ectopic pregnancy, it was noted that the condition was not uniformly fatal and that some patients had spontaneous resolution of the ectopic gestation, either through spontaneous regression or tubal abortion. The natural history of ectopic pregnancy therefore suggests that a number of tubal pregnancies can resolve without treatment. In 1988, Fernandez and associates reported a spontaneous resolution of ectopic pregnancy in 64% of carefully selected patients. The mean time for resolution was 20 ± 13 days. Spontaneous resolution occurred more frequently when the initial hCG concentration was less than 1,000 mIU/mL. The authors observed that a β-hCG threshold of 1,000 mIU/mL and a hemoperitoneum of less than 50 mL with a hematosalpinx of less than 2 cm appeared to be most compatible with successful expectant management.

Subsequent large studies have demonstrated similar results with expectant therapy. Korshon and colleagues have published the largest series to date. Criteria for patient selection included decreasing β-hCG levels, an absent intrauterine pregnancy by transvaginal ultrasonography, and an adnexal mass of less than 4 cm without an embryonic heartbeat. Seventy-seven patients were diagnosed with a nonlaparoscopic algorithm by the use of serial hCG titers, serum progesterone, transvaginal ultrasonography, and a hemoperitoneum of less than 3 cm with the tubal serosa intact and no evidence of bleeding. Treatment consisted of 1.0 mg/kg MTX administered intramuscularly on postoperative days 1, 3, 5, and 7, along with 0.1 mg/kg CF administered intramuscularly on postoperative days 2, 4, 6, and 8. Twenty-one pregnancies resolved without the need for laparotomy. Two patients required blood transfusions, including one patient who required laparotomy and salpingectomy for a hemoperitoneum. In both of these cases, fetal heart activity in the adnexa was identified initially on ultrasound examination. This led the authors to suggest that MTX + CF can be safely used in selected cases of unruptured ectopic pregnancies that have not formed fetal elements that can be visualized by ultrasound.

In 1991, Stovall and colleagues reviewed the results of several series of tubal ectopic pregnancies treated with MTX + CF. Of 100 cases, 50 were diagnosed by laparoscopy, and 50 were diagnosed by a nonlaparoscopic algorithm. Complete resolution was achieved in 96 patients over a range of 14 to 92 days. In four patients, laparotomy was necessary because of tubal rupture; in one case, rupture occurred as late as 23 days after MTX administration. In five patients, cardiac activity was observed on ultrasound, and treatment was successful in four of them. Three patients experienced minor side effects. In 49 of 58 (84%) women who underwent subsequent hysterosalpingograms, tubal patency was demonstrated on the ipsilateral side. Of 56 patients desiring to conceive, 37 subsequently became pregnant; 33 of these were intrauterine pregnancies and 4 were repeat ectopic pregnancies.

Stovall and Ling further studied the efficacy and safety of a simplified regimen of single-dose systemic MTX. All patients were diagnosed with a nonlaparoscopic algorithm by the use of serial hCG titers, serum progesterone, transvaginal ultrasonography, and curettage. Patients were treated with a single dose of 30 mg/m² MTX intramuscularly if they were hemodynamically stable and the unruptured ectopic pregnancy did not exceed 3.5 cm in diameter. In the initial report, 120 patients were treated, including 14 (11.7%) with visualized cardiac activity. One hundred thirteen (94.2%) patients had complete resolution with treatment, with a mean time to resolution of 35.5 days. Four (3.3%) of the successfully treated patients required a second course of MTX on day 7. Seven (5.8%) patients required surgical management of the ectopic pregnancy, including two of the patients with cardiac activity. No major chemotherapy-related side effects were seen. Posttreatment hysterosalpingograms demonstrated tubal patency on the ipsilateral side in 51 of 62 (82.3%) patients. Of those attempting pregnancy, 79.6% subsequently became pregnant; 87.2% of these were intrauterine and 12.8% were ectopic.

Lipscomb and colleagues further reported on the expanded Memphis cohort of patients treated with single-dose MTX. They used similar inclusion criteria, with the exception of further allowing pregnancies up to 4.0 cm in diameter provided that ectopic cardiac activity was not present. In this series, 287 patients were treated with a single dose of 50 mg/m² MTX.
of 315 (90.1%) patients were successfully treated with MTX. Forty-four patients with positive ectopic cardiac activity were treated with an 87.3% success rate. Of note, however, is that approximately 20% of these patients required more than one cycle of treatment. The authors’ protocol reported that follow-

ing the MTX dosing on day 1, serum choriocarcinoma gonadotropin was measured on days 1, 4, and 7. In many patients, they noted that β-hCG levels frequently continued to rise up until day 4. If the choriocarcinoma gonadotropin levels then declined less than 15% be-
tween days 4 and 7, the MTX protocol was repeated. If the levels declined 15% or more between days 4 and 7, serum β-hCG was measured weekly until the level was less than 15 IU/L. If the choriocarcinoma gonadotropin level declined less than 15% during any subsequent week of follow-up, the MTX protocol was also then repeated. Other potentially difficult issues with single-dose MTX therapy include the management of “resolution pain” (which may occur in 20% of patients) and the prolonged time to resolution sometimes seen.

A further review of the variables related to the success of single-dose MTX in the treatment of singleton ectopic preg-
nancy has been compiled. In this review, logistic regression analysis demonstrated that the serum choriocarcinoma gonadotropin level before treatment was the only factor that contributed sig-
nificantly to the failure rate (Table 34.4). Interestingly, the size of the mass, the volume of hematomas, and the presence or absence of free peritoneal blood in the pelvis were not associated with a significant risk of treatment failure.

Use of mifepristone as an adjunct to MTX treatment for ectopic pregnancy has also been assessed in two randomized controlled trials. In the first trial, Barvani and colleagues re-

ported both treatment approaches were successful, although the time to resolution was significantly faster in the group receiving MTX and mifepristone in comparison to the MTX alone group. In the subsequent, multicenter randomized trial, Rosenberg and colleagues failed to demonstrate an overall ben-
ef

efit from the addition of mifepristone to MTX. These investi-
gators, by contrast, demonstrated a higher efficacy of MTX and mifepristone in the subgroup of patients with higher ini-
tial serum progesterone levels (≥10 ng/L). Further studies are

needed to define the role of mifepristone in combination with MTX in the treatment of ectopic pregnancy.

MTX has also been used to treat persistent ectopic preg-
nancy after conservative surgery. In these patients, persistent ectopic pregnancy results from proliferation of residual tro-

phoblastic tissue remaining after a conservative surgical proce-
dure. The trophoblast can be located within the muscular layer of the ovary or between the muscles and the serosa such that at the time of salpingotomy, only the portion of the tro-

phoblast within the tubal lumen is removed. In those patients with persistent ectopic pregnancy described in the literature, the majority have been managed by a second operation and salpingectomy. Some patients, however, have been treated with either expectant management or systemic MTX. Hoppe and colleagues have reported that of the 19 patients treated following laparoscopic salpingotomy.

All patients should therefore have a follow-up β-hCG titer 1 to 2 weeks after conservative surgery. If the titer is elevated, then serial β-hCG titers are indicated. If the titer then continues to fall, the patient can be treated expectantly. If the β-hCG level remains the same or increases, however, consideration should be given to a single dose of MTX or perhaps further surgery to remove the remaining portion of the ectopic pregnancy.

Systemic MTX is an alternative that can be used for the treatment of patients with small unruptured ectopic pregnan-
cies or patients with persistent ectopic pregnancies follow-
ing conservative surgery. Safeguards are necessary to enhance the success and minimize the toxicity of therapy. Patients should be carefully monitored with hematologic indices and liver chemistries. A history of active hepatic, renal, or peptic ulcer disease, elevated baseline liver enzyme concentrations, and thrombocytopenia or neutropenia are contraindications to therapy. Patients should avoid exposure to the sun, because photosensitivity can be a complication. Patients should refrain from sexual intercourse during therapy. Patients should also avoid folate-containing vitamins. Appropriate candidates for systemic medical therapy should also be willing to accept a small risk of tubal rupture and participate in closely monitored follow-up.

### Medical Therapy by Local Injection

In 1987, Felchtinger and Kemeter reported the direct injec-
tion of MTX under transvaginal ultrasound guidance into an ectopic gestational sac. They instilled 10 mg of MTX and ob-
served resolution of the pregnancy within 2 weeks. Other in-
vestigators, including Kojima and colleagues, have reported the success application of local MTX administered by di-
rect injection at the time of laparoscopy. In 1993, Fernandez and colleagues reported a large series of patients who un-
derwent intratubal MTX at a dose of 1 mg/kg under transvaginal sonographic control. Eighty-three of 100 patients were success-
fully cured; however, 28 of the 83 successfully cured patients required additional MTX, which was subsequently given in-
trauterally.

Direct injection of MTX has theoretic advantages over sys-
temic treatment. The concentration of MTX at the site of im-
plantation is many times higher after local injection than af-
ter systemic administration. With less systemic distribution of the drug, a smaller therapeutic dose might be necessary and toxicity would be less. Schiff and associates, however, evalu-
ated the pharmacokinetics of MTX after local tubal injection and found that the peak serum level of MTX after local injec-
tion was not significantly lower than that of patients who were treated systemically with a similar dose of the drug. In addi-
tion, the success rates in practice appear to be unacceptably low. A review by Carson and Buster revealed that only 83% of the direct tubal injection procedures reported were success-
ful.

Several trials have been conducted evaluating other in-
tratubal agents administered for the treatment of ectopic pregnancy. Studies using prostaglandins (prostaglandin F2α, 
15-methyl-prostaglandin F2α) were discouraging because of
poor efficacy and serious adverse effects, including cardiac arrhythmia, malignant hypertension, and gastrointestinal symptoms. Other investigators have studied the use of hyperosmolar glucose, a less toxic agent, injected locally into the gestational sac of the ectopic gestation by either laparoscopy or transvaginal ultrasound-guided needle puncture. Lang and colleagues reported a 92% success rate using hyperosmolar glucose by laparoscopy, but in 1973, Stromme reported his surgical experience with 36 cases of salpingotomy to treat a patient with tubal pregnancy. In 1898, Kelly was among the first to advocate conservative surgery for tubal gestation. He recommended drainage of the pregnancy through a self-retained needle to eliminate the risk of rupture. Subsequently, and those with a specific contraindication to laparoscopy. Among recent reports of salpingotomy performed on a single remaining oviduct, an intrauterine pregnancy rate of about 50% has been achieved by several investigators, although the results are quite variable, and some reports have only a limited number of patients treated. The repeat ectopic pregnancy rate in the single-tube salpingotomy patients appears to be about 20%, a slightly higher rate than that in series of patients with both oviducts.

In general, conservative salpingotomy is the preferred treatment for patients who desire further pregnancies. For results to be optimal, the oviduct should be unruptured and without serosal invasion, and the patient should be in a surgically stable condition.

**Surgical Treatment**

**Conservative Surgical Treatment**

Conservative management of an unruptured ectopic pregnancy usually consists of one of two possible procedures: linear salpingotomy or segmental resection. A conservative surgical approach is possible when the diagnosis of ectopic pregnancy is made sufficiently early so that rupture of the oviduct has not yet occurred.

**Linear Salpingotomy.** In women who wish to preserve their fertility, conservative surgery by linear salpingotomy is considered the gold standard for the management of a distal tubal pregnancy. Recent studies have reported that the uninvolved tube may be abnormal, either grossly or subclinically, in at least 50% of cases of ectopic pregnancy. Although there have been no randomized studies comparing the fertility outcome after conservative and radical surgery for ectopic pregnancy, most of the available information suggests that the subsequent intrauterine pregnancy rate is higher after conservative surgery (linear salpingotomy).

In 1898, Kelly was among the first to advocate conservative surgery for tubal gestation. He recommended drainage of the pregnancy through the tube using a self-retained needle to eliminate the risk of rupture. Subsequently, and those with a specific contraindication to laparoscopy. Among recent reports of salpingotomy performed on a single remaining oviduct, an intrauterine pregnancy rate of about 50% has been achieved by several investigators, although the results are quite variable, and some reports have only a limited number of patients treated. The repeat ectopic pregnancy rate in the single-tube salpingotomy patients appears to be about 20%, a slightly higher rate than that in series of patients with both oviducts.

In general, conservative salpingotomy is the preferred treatment for patients who desire further pregnancies. For results to be optimal, the oviduct should be unruptured and without serosal invasion, and the patient should be in a surgically stable condition.

**Transabdominal Conservative Procedure.** The procedure for linear salpingotomy starts by exposing, elevating, and stabilizing the tube. A linear incision is then made over the distended segment of the tube (Figs. 34.6 and 34.7). The incision is extended through the antimesenteric wall until entry is made into the lumen of the distended oviduct. When gentle pressure is exerted from the opposite side of the tube, the products of gestation are gently expressed from the lumen. Because a certain amount of separation of the trophoblast has usually occurred, the conceptus generally can be easily removed from the lumen. Gentle traction by suction or by forceps teeth can be used if necessary, but care should be taken to avoid trauma to the mucosa. Any remaining fragments of the anchoring trophoblast should be removed by profuse irrigation of the lumen with warm Ringer lactate solution to prevent further damage to the mucosa.

Care must be taken to provide complete hemostasis in the tubal mucosa; failure to do so results in troublesome postoperative bleeding, which can lead to the formation of intraluminal adhesions. The small tubal vessels are easily identified while the tube is being irrigated, and diathermy or laser coagulation can be used if necessary for better resolution. An operating microscope is usually not needed.

The mucosal margins are then closed with interrupted sutures, taking care that only the serosa and muscularis are approximated and that there is no undue tension. Care should be taken also to ensure that no suture material is retained on the mucosal surface, because even a small amount can produce a secondary inflammatory reaction with subsequent adhesion formation.

**Laparoscopic Conservative Procedure.** Currently, most ectopic pregnancies are treated by laparoscopic surgery. In fact, most studies have suggested that laparoscopic surgery is superior to laparotomy in hemodynamically stable patients. Advantages of laparoscopy include lower cost, shorter hospital stay, less surgical blood loss, less analgesia requirement, and a shorter postoperative convalescence. Not all patients, however, may be suitable for laparoscopic treatment. Those include patients with an unstable hemodynamic status, those with severe pelvic adhesions, and those with a specific contraindication to laparoscopy.

The presence of a hemoperitoneum should not preclude laparoscopic treatment if the diagnosis of ectopic pregnancy is certain. Although a hemoperitoneum is not diagnostic of an ectopic pregnancy, it is often associated with other signs of an ectopic gestation such as an abnormal hCG level and uterine asymmetry. The degree of hemoperitoneum may be graded on a scale of 1 to 3, with grade 1 being a small amount of blood in the peritoneal cavity, grade 2 being a moderate amount of blood, and grade 3 being a large amount of blood. When a hemoperitoneum is present, it is important to perform a meticulous pelvic examination to rule out other causes of pelvic pain such as appendicitis, ovarian cysts, or diverticulitis. After the diagnosis of ectopic pregnancy is confirmed, the next step is to determine the location of the gestation. This can be done by transvaginal ultrasound, which allows for precise localization of the gestation and exclusion of other causes of pelvic pain. Once the location of the gestation is confirmed, the next step is to perform a graded aspiration of the gestation. This is typically performed using a 16- or 18-gauge needle inserted through the abdominal wall. The needle is advanced into the gestation and aspirated to remove as much of the gestation as possible. The amount of fluid aspirated should be recorded and compared with the estimated amount of blood present in the peritoneal cavity. If the amount of fluid aspirated is less than the estimated amount of blood, it is likely that additional blood is present elsewhere in the peritoneal cavity. In this case, a more thorough exploration of the peritoneal cavity is necessary to rule out other causes of pelvic pain. After the graded aspiration of the gestation, the next step is to perform a laparoscopic evaluation of the oviducts. This can be done by inserting a laparoscope into the abdominal cavity and visualizing the oviducts. The oviducts should be inspected for any evidence of tubal pregnancy, such as a mass or an area of abnormal color. If a tubal pregnancy is present, it can be removed using electrocautery or mechanical instruments. If a tubal pregnancy is not present, the oviducts should be evaluated for any signs of abnormality, such as scarring or inflammation. If any abnormalities are found, the peritoneum should be examined for signs of adhesions. If adhesions are present, they should be released using electrocautery or mechanical instruments. If no abnormalities are found, the laparoscopic evaluation of the oviducts is complete.

In general, conservative salpingotomy is the preferred treatment for patients who desire further pregnancies. For results to be optimal, the oviduct should be unruptured and without serosal invasion, and the patient should be in a surgically stable condition.

**Transabdominal Conservative Procedure.** The procedure for linear salpingotomy starts by exposing, elevating, and stabilizing the tube. A linear incision is then made over the distended segment of the tube (Figs. 34.6 and 34.7). The incision is extended through the antimesenteric wall until entry is made into the lumen of the distended oviduct. When gentle pressure is exerted from the opposite side of the tube, the products of gestation are gently expressed from the lumen. Because a certain amount of separation of the trophoblast has usually occurred, the conceptus generally can be easily removed from the lumen. Gentle traction by suction or by forceps teeth can be used if necessary, but care should be taken to avoid trauma to the mucosa. Any remaining fragments of the anchoring trophoblast should be removed by profuse irrigation of the lumen with warm Ringer lactate solution to prevent further damage to the mucosa.

Care must be taken to provide complete hemostasis in the tubal mucosa; failure to do so results in troublesome postoperative bleeding, which can lead to the formation of intraluminal adhesions. The small tubal vessels are easily identified while the tube is being irrigated, and diathermy or laser coagulation can be used if necessary for better resolution. An operating microscope is usually not needed.

The mucosal margins are then closed with interrupted sutures, taking care that only the serosa and muscularis are approximated and that there is no undue tension. Care should be taken also to ensure that no suture material is retained on the mucosal surface, because even a small amount can produce a secondary inflammatory reaction with subsequent adhesion formation.

**Laparoscopic Conservative Procedure.** Currently, most ectopic pregnancies are treated by laparoscopic surgery. In fact, most studies have suggested that laparoscopic surgery is superior to laparotomy in hemodynamically stable patients. Advantages of laparoscopy include lower cost, shorter hospital stay, less surgical blood loss, less analgesia requirement, and a shorter postoperative convalescence. Not all patients, however, may be suitable for laparoscopic treatment. Those include patients with an unstable hemodynamic status, those with severe pelvic adhesions, and those with a specific contraindication to laparoscopy. The presence of a hemoperitoneum should not preclude laparoscopic treatment if the diagnosis of ectopic pregnancy is certain. Although a hemoperitoneum is not diagnostic of an ectopic pregnancy, it is often associated with other signs of an ectopic gestation such as an abnormal hCG level and uterine asymmetry. The degree of hemoperitoneum may be graded on a scale of 1 to 3, with grade 1 being a small amount of blood in the peritoneal cavity, grade 2 being a moderate amount of blood, and grade 3 being a large amount of blood. When a hemoperitoneum is present, it is important to perform a meticulous pelvic examination to rule out other causes of pelvic pain such as appendicitis, ovarian cysts, or diverticulitis. After the diagnosis of ectopic pregnancy is confirmed, the next step is to determine the location of the gestation. This can be done by transvaginal ultrasound, which allows for precise localization of the gestation and exclusion of other causes of pelvic pain. Once the location of the gestation is confirmed, the next step is to perform a graded aspiration of the gestation. This is typically performed using a 16- or 18-gauge needle inserted through the abdominal wall. The needle is advanced into the gestation and aspirated to remove as much of the gestation as possible. The amount of fluid aspirated should be recorded and compared with the estimated amount of blood present in the peritoneal cavity. If the amount of fluid aspirated is less than the estimated amount of blood, it is likely that additional blood is present elsewhere in the peritoneal cavity. In this case, a more thorough exploration of the peritoneal cavity is necessary to rule out other causes of pelvic pain. After the graded aspiration of the gestation, the next step is to perform a laparoscopic evaluation of the oviducts. This can be done by inserting a laparoscope into the abdominal cavity and visualizing the oviducts. The oviducts should be inspected for any evidence of tubal pregnancy, such as a mass or an area of abnormal color. If a tubal pregnancy is present, it can be removed using electrocautery or mechanical instruments. If a tubal pregnancy is not present, the oviducts should be evaluated for any signs of abnormality, such as scarring or inflammation. If any abnormalities are found, the peritoneum should be examined for signs of adhesions. If adhesions are present, they should be released using electrocautery or mechanical instruments. If no abnormalities are found, the laparoscopic evaluation of the oviducts is complete.
allow manipulation of the fallopian tube (Fig. 34.8). Using a 22-gauge injection needle inserted either directly through the abdominal wall or through a 5-mm portal, a dilute solution of vasopressin (prepared by mixing 20 U of vasopressin with 100 mL of physiologic saline) is injected into the tubal wall at the area of maximal bulge. This step is crucial and allows for minimal bleeding and the precise removal of the ectopic pregnancy without damaging the surrounding mucosa. Either laser, unipolar needle electrocautery, or scissors can than be used to make the salpingotomy incision. It is important to make the incision along the antimesenteric wall of the tube in the area of maximal distension and large enough to allow for complete extrusion of the products of conception without difficulty. It is also important to keep the fallopian tube taut. If the products of conception do not spontaneously extrude following completion of the incision, either hydrodissection or gentle tubal compression with a blunt probe or suction irrigator will usually work. The tissue is then placed in an endoscopic bag and removed from the abdominal cavity. Special care is taken to remove all of the placental tissue as it is known that persistent peritoneal implants of trophoblastic tissue following laparoscopic salpingotomy may occur. After the tissue is removed, the tube is irrigated carefully and checked for hemostasis. The tube is then either left to heal by secondary intention or sutured, with secondary intention being appropriate for most cases. A laparoscopic salpingotomy study by Fujishita and colleagues failed to demonstrate any benefit from suturing over the nonsuturing technique.

The results of salpingotomy are very similar, whether performed by either laparotomy or laparoscopy. Yao and Tulandi reported that among the 811 patients attempting to conceive after the laparotomy approach, the intrauterine pregnancy rate was 61.4%, and the recurrent ectopic pregnancy rate was 15.4%. Similarly, of the 703 patients attempting to conceive following laparoscopy, 61.0% had an intrauterine pregnancy, and 15.5% had a repeat ectopic pregnancy.

Persistent Tubal Ectopic Gestation. Persistent trophoblastic tissue can remain after linear salpingotomy. Although there can be an initial decrease in the β-hCG level after surgery, the level can then slowly rise, ultimately resulting in symptoms. For this reason, it is recommended to obtain weekly β-hCG measurements after linear salpingotomy. Yao and Tulandi reported that persistent ectopic pregnancy was encountered in 8.3% of patients treated by laparoscopic salpingotomy and in 3.9% of patients treated by a similar procedure at laparotomy.
The incidence of persistent ectopic pregnancy following laparoscopy, however, was quite variable, ranging from 3.5% to 20.0%. Pouly and colleagues achieved a relatively low 3.5% incidence of recurrent ectopic pregnancy in the largest series of patients treated to date by laparoscopic salpingotomy. Indeed, in many current practices, the incidence of persistent ectopic pregnancy appears to be low. There is a tendency for persistent trophoblastic tissue to be found in the proximal portion of the tube; therefore, special attention to this area is important. The use of hydrodissection to flush out the gestational products rather than removal of trophoblastic tissue piecemeal with forceps is recommended. One must, however, never assume that the chance for persistent trophoblast is entirely mitigated by the characteristics and ease of the procedure.

Risk factors for persistent ectopic pregnancy include small ectopic pregnancies (<2 cm diameter), early therapy (<42 days from last menstrual period), and high concentrations of $\beta$-hCG (>3,000 IU/L by the Third IS) preoperatively. In high-risk cases, a single dose of MTX (1 mg/kg) can be administered postoperatively for prophylaxis. Graczykowski and Mishell demonstrated that the rate of persistent ectopic pregnancy was reduced to a rate of 1.9% using MTX prophylaxis in comparison with a rate of 14.5% among controls. Spandorfer and associates suggested that the postoperative day 1 serum $\beta$-hCG concentration can be used as a predictor of persistent ectopic pregnancy. They reported that a day 1 serum $\beta$-hCG decrease of <50% from preoperative levels may be predictive of persistent ectopic pregnancy. If day 1 serum $\beta$-hCG concentrations decreased >50% of the preoperative value, there was more than an 85% probability that a persistent ectopic pregnancy would not occur.

Options for treatment of persistent ectopic pregnancy include reoperation and medical therapy. The choice of treatment can also include expectant therapy if the patient is asymptomatic and $\beta$-hCG levels are not rapidly increasing. MTX appears to be particularly effective in the setting of
persistent ectopic pregnancy following linear salpingotomy. In the largest series reported to date, all 19 patients with persistent ectopic pregnancies were successfully treated with a single intramuscular dose of systemic MTX (50 mg/m²). The patient’s reproductive prognosis does not appear to be particularly lessened following a persistent ectopic pregnancy. In a review of 50 cases, Seifer and colleagues reported that after 36 months of follow-up, there were 19 (59%) intrauterine pregnancies and no recurrent ectopic pregnancies in 32 such women attempting to conceive.

FIGURE 34.8. Laparoscopic salpingostomy for ectopic pregnancy. A: An incision is made with the fine monopolar diathermy needle along the antimesenteric border of the oviduct. B: The trophoblastic mass is removed with forceps. C: The lumen is allowed to heal by secondary intention.
Because of the chance for persistent ectopic pregnancies to present relatively late following initial appropriate decreases in β-hCG concentrations, it is recommended to obtain weekly β-hCG measurements until they return to the normal range.

**Segmental Resection.** The optimal surgical approach to the isthmic ectopic pregnancy remains controversial. Three conservative operations have been described: segmental resection of the involved portion of oviduct with primary microsurgical anastomosis, segmental resection with reanastomosis at a later operation, and linear salpingectomy. In Sweden, Svolin initially advocated for segmental resection in 1967. Subsequently, other surgeons, including Stangl and Gomel as well as DeCherney and Boyers, have found segmental resection to be preferable to salpingectomy in most cases of isthmic pregnancy. In the isthmus, the tubal lumen is narrower and the muscularis is thicker than in the ampulla. Thus, the isthmus is more predisposed to severe postoperative damage, and the rate of proximal tubal obstruction seems to be higher following linear salpingectomy.

With segmental resection and end-to-end reanastomosis, the implantation site is removed so that it cannot be involved in a subsequent tubal pregnancy. A more normal architecture for the oviduct is consequently achieved. The anatomic restoration is a time-consuming process requiring special expertise and extensive microsurgical experience; it should not be undertaken by an inexperienced surgeon. Extensive hemoperitoneum places a patient in serious jeopardy of cardiopulmonary crises. In reality, the benefits of removal of the contralateral ovary are outweighed by the consideration that any future oophorectomy would then mean castration. The high success rate of IVF is a postoperative deep venous thrombosis.

Some earlier reports advocated for the combined use of a prophylactic oophorectomy with salpingectomy. Theoretically, removal of the ipsilateral ovary would cause the other ovary to ovulate more frequently, perhaps favoring future pregnancies. In reality, the benefits of removal of the contralateral ovary are outweighed by the consideration that any future oophorectomy would then mean castration. The high success rate of IVF is a further incentive to maintain functioning of both ovaries.

As stated earlier, most patients with an ectopic pregnancy currently are candidates for laparoscopic surgery. Radical surgical procedures, such as salpingectomy, are also easily adapted to laparoscopic surgery. Of course, certain patients remain noncandidates for laparoscopic surgery, including those with unstable hemodynamic status or severe pelvic adhesions. The latter patients are still best treated by laparotomy.

At laparotomy, total salpingectomy with partial cornual resection has been criticized for providing a residual sinus tract that allows development of a subsequent interstitial pregnancy. This problem may not lie in the procedure per se, but rather the surgeon's performance of the procedure. Complete peritonealization of the cornual incision and advancement of the round and broad ligaments over the uterine cornua (the modified Coffey technique of uterine suspension) should provide complete protection from recurrent interstitial pregnancy (Fig. 34.10). A too-vigorous resection of the uterine cornua can also cause problems. A residual myometrial defect can cause uterine rupture, interstitial recanalization, or placental encroachment during a subsequent intrauterine pregnancy and should be avoided by making certain that the interstitial resection includes less than one third the thickness of the cornual portion of the myometrium.

Dubuisson and colleagues reported the first large series of patients treated by total salpingectomy at laparoscopy for ampullary ectopic pregnancies. They used a three-puncture laparoscopic technique. They thermocoagulated the tubal isthmus, mesosalpinx, and tubal-ovarian ligament, followed by excision with hook scissors. The tube was subsequently removed with polyp forceps through one of the suprapubic punctures. They reported no immediate complications in 98 patients successfully treated at laparoscopy, although one patient experienced a postoperative deep venous thrombosis. Two patients initially intended for laparoscopy, however, required laparotomy either because of severe pelvic adhesions or significant...
intraperitoneal blood. In a later report, Dubuisson and associates advised opening the tube first to aspirate the trophoblast in cases in which the tube is large to more easily remove the tissue through a 12-mm trocar.

**Technique of Salpingectomy at Laparotomy.** A suprapubic Pfannenstiel or low midline vertical abdominal incision is used, and the distended tube is elevated. The mesosalpinx is clamped with a succession of Kelly clamps as close to the tube as possible (Fig. 34.10A). The tube is then excised by cutting a small myometrial wedge at the uterine cornu (Fig. 34.10B). Care should be taken to avoid a deep incision into the myometrium. A figure-of-eight mattress suture of no. 0 delayed-absorbable material is used to close the myometrium at the site of the wedge resection. The mesosalpinx is closed with interrupted ligatures of no. 2-0 delayed-absorbable suture. Complete hemostasis is essential to avoid a hematoma of the broad ligament.

The fundus is held forward and the round and broad ligaments are sutured over the uterine cornu (Fig. 34.10C). This procedure, the modified Coffey suspension, accomplishes complete peritonealization. Mattress sutures anchor the broad ligament to the uterus. The no. 0 delayed-absorbable suture first penetrates the broad ligament from its anterior surface, just below the round ligament, at a distance of 2 to 3 cm from the cornu. The next “bite” is taken into the fundus of the uterus, a little posterior and superior to the uterine incision. The suture is then placed through the posterior aspect of the broad ligament, about 1 cm lateral to the previous suture. When this suture is tied, the cornual incision and the mesosalpinx are covered with mesothelium (Fig. 34.10D). If there is excessive tension on this suture, or if peritonealization is incomplete, then supporting sutures can be placed in the myometrium and the round ligament to ensure that the peritonealization suture will remain in place.

**Technique of Salpingectomy at Laparoscopy.** Several methods have been successfully used for laparoscopic salpingectomy, including endoscopic stapling devices, endocoagulation, bipolar cautery, and pre-tied endoscopic ligatures. Following placement of laparoscopic trocar ports (usually three puncture technique), irrigation of the pelvis, and the evacuation of all blood clots, the involved tube is then grasped with a toothed grasper. One method then includes cauterizing the tubal-ovarian ligament first with bipolar forceps, followed by transection with scissors (Fig. 34.11) or the blade of a coagulation-cutting tool.
FIGURE 34.10. (Continued) B: The mesosalpinx has been completely clamped and cut. The dashed line indicates the line of excision of the tube at the cornu. Inset shows the superficial wedge resection of the interstitial portion of the tube and the suture of the cornu. C: The method of placing a mattress suture for peritonealization is shown with anchoring of the medial portion of the broad ligament to the uterus, a little posterior and superior to the uterine incision. D: Peritonealization is completed by tying the mattress suture, which brings the broad and the round ligaments over the uterine cornua.

FIGURE 34.11. Techniques of laparoscopic salpingectomy using bipolar cautery and excision.
of interstitial pregnancies may manifest later ( timor-Tritsch and colleagues established transvaginal ultrasound criteria for interstitial pregnancy. These criteria include:

1. An empty uterine cavity,
2. A chorionic sac seen separately and >1 cm from the most lateral edge of the uterine cavity,
3. A thick myometrial layer surrounding the chorionic sac.

All of these parameters were relatively specific (88% to 93%), but lacked high sensitivity (only about 40%) for the diagnosis of interstitial pregnancy. Other investigators have described an “interstitial line sign.” This sign refers to the visualization of an echogenic line extending from the endometrial cavity into the cornual region and abutting the interstitial mass or gestational sac. Ackerman and associates reported that the “interstitial line sign” was 80% sensitive and 98% specific for the diagnosis of interstitial pregnancy.

Often the difference between an interstitial pregnancy and an angular pregnancy is subtle. In addition, it may be easy to confuse an angular pregnancy with a pregnancy in a septated or bicornuate uterus. Because ultrasound cannot always confirm the position of the pregnancy, laparoscopy may be required to confirm the diagnosis. In cases of massive intraabdominal bleeding, an immediate laparotomy should be performed.

**Treatment for Interstitial Pregnancy**

The choice of treatment for an interstitial (cornual) pregnancy depends on the extent of trauma that has occurred in the uterine wall and on the interest of the patient in preserving her
childbearing function. Systemic MTX has been used in a limited number of patients with unruptured interstitial pregnancies. Tanaka and coworkers reported the first successful treatment of an interstitial pregnancy with systemic MTX. Since this report, according to Lau and Tulandi, there have been 40 additional published cases of interstitial pregnancies treated with the use of systemic or local MTX, or a combination of both. An overall success rate of 83% was reported.

If an interstitial pregnancy is observed when it is still small, it might be excised using conservative laparoscopic techniques. In their review, Lau and Tulandi noted 22 successful cases of laparoscopic treatment of interstitial pregnancy. Techniques used varied from cornuostomy with careful extraction of the products of conception to a more formal cornual resection. In only one case was bleeding severe enough to require a transfusion. Hemostatic methods have included ligation of the ascending branches of the uterine vessels, intracorporeal and extracorporeal suturing, and surgical stapling. Although the immediate efficacy of laparoscopic conservative procedures for interstitial pregnancy is high, the risk of uterine rupture in a subsequent pregnancy is unknown. Uterine rupture can occur at the site of a previous interstitial pregnancy. Patients treated by conservative laparoscopic techniques should therefore be carefully counseled about this risk. The risk of uterine rupture also emphasizes the importance of proper suturing of the uterine cornu during conservative surgical treatment of an interstitial pregnancy.

For many surgeons, cornual resection and repair of the defect by laparotomy remains the standard conservative surgical procedure for interstitial pregnancy. Provided that uterine rupture has not occurred, this is technically feasible in most cases. Unfortunately, in many cases in which uterine rupture has occurred or a very large interstitial pregnancy is present, a hysterectomy may be required. Hysterectomy remains the treatment of choice for pregnancies advanced to such a stage that repair of the cornu would be technically difficult and medically hazardous.

**Excision of Interstitial Pregnancy by Cornual Resection and Salpingectomy**

Whenever possible, the ovary should be saved. A cornual resection and salpingectomy is performed by first ligating the ascending uterine vessels where they approach the cornu (Fig. 34.12A). Each is ligated separately with a figure-of-eight suture. One may also consider the use of a dilute solution of vasopressin (prepared with mixing 20 U of vasopressin with 30 mL of physiologic saline) injected in the intended myometrial incisional line to further optimize intraoperative hemostasis. The interstitial pregnancy is excised in a V-shaped manner, and the myometrium is approximated with a figure-of-eight closure using no. 0 delayed-absorbable suture (Fig. 34.12B). The remainder of the fallopian tube is excised. If it becomes necessary, the round ligament can be cut and resutured to the cornu and the uterine serosa by use of interrupted sutures (Fig. 34.12C). The round and broad ligaments are brought over the incision with mattress sutures (the modified Coffey suspension) (Fig. 34.12D), and additional interrupted sutures of no. 2-0 or no. 3-0 delayed-absorbable material can be used to secure the serosa of the round ligament to the serosa of the uterus to maintain the operative site in a permanent retroperitoneal position.

**OVARIAN ECTOPIC PREGNANCY**

Because IUDs protect the endometrium and, to a lesser extent, the proximal oviducts from implantation, it was expected that when IUDs were introduced, future reports of extrauterine pregnancies might show an increased rate of ovarian

---

**FIGURE 34.12. Salpingo-oophor-rectomy with excision of interstitial pregnancy.** A: The dotted line denotes line of excision. B: Tube, ovary, and the cornual pregnancy have been excised. Myometrium is being approximated with figure-of-eight sutures of no. 0 delayed-absorbable suture. Note that the uterine vessels have been ligated separately. C: The round ligament, which was cut, is being resutured to the cornu. The ovarian vessels have been ligated, and the broad ligament has been closed with a continuous lockstitch. Serosa of the uterine wound is closed with a simple continuous stitch. D: The cornual wound is covered with the round and broad ligaments.
involvement. Data from the Cooperative Statistical Program of the Population Council show that 1 of every 9 ectopic pregnancies among IUD users, 4.3% are extraterine.

There are several reviews in the English literature on the subject of primary ovarian pregnancy. Boronow and associates summarized 62 cases in a review of the literature between 1950 and 1973. Campbell and associates reported an additional 10 new cases in 1974. Crimes and associates summarized the major reviews through 1980 and added 18 previously unreported cases of primary ovarian pregnancy from the records of six hospitals. Their combined data from this review, the hospital cases, and four other recent reports totaled 34 cases of primary ovarian pregnancy among 236,983 deliveries, a rate of 1 ovarian pregnancy in 7,000 deliveries.

In an intrafollicular ovarian pregnancy, the second stage of meiosis, ovum capacitation, and fertilization each occur within the follicle. Only 15% of cases of ovarian pregnancy are intrafollicular in origin. In an intrafollicular pregnancy, a well-preserved corpus luteum can be identified in the wall of the gestational sac. Four other criteria presented by Spiegelberg for identifying an intrafollicular pregnancy are that the tube, including the fimbria ovarica, is intact and is clearly separate from the ovary; that the gestational sac definitely occupies the normal position of the ovary; that the sac is connected to the uterus by the uteroovarian ligament; and that ovarian tissue is unquestionably demonstrated in the wall of the sac.

Diagnosis of Ovarian Pregnancy

Early diagnosis of an ovarian pregnancy, of all the diagnoses relating to extraterine gestations, is perhaps the most difficult. As stated previously, the classic symptoms of a tubal gestation are abdominal pain, amenorrhea, and bleeding; however, persistent pelvic pain alone, a symptom not always easily related to its cause, is the most frequent clinical manifestation of an ovarian gestation. Although an adnexal mass is palpable in as many as 60% of ovarian pregnancies, the mass is frequently confused with a leaking corpus luteum hematoma. All of the test criteria used for diagnosing a tubal pregnancy are helpful in diagnosing a primary ovarian pregnancy. In particular, the highly sensitive β-hCG immunoassay is effective for identifying the presence of low hCG levels. The test can confirm the presence of a gestational process, but knowing the β-hCG level does not help to precisely locate the gestation. Incomplete spontaneous abortion with a leaking corpus luteum hematoma, one of the most common complications of pregnancy, mimics an ovarian pregnancy. In such cases, a D&C will often show the remnants of trophoblastic villi responsible for the low levels of β-hCG.

A tubal pregnancy can easily be ruled out with laparoscopy, but an ovarian pregnancy is sometimes difficult to differentiate from a leaking corpus luteum hematoma by gross appearance. Ultrasonography can be helpful, but only in advanced ovarian pregnancies will the ultrasound image show a discrete gestational sac, therefore confirming an ovarian pregnancy. Critical evaluation of all of the diagnostic studies, particularly the sensitive β-hCG immunoassay and vaginal ultrasonography, is necessary in making the diagnosis. When the β-hCG is positive, ultrasonography shows no intrauterine gestational sac, and free blood exists in the peritoneal cavity, a laparoscopy should be performed to confirm or refute a diagnosis of suspected ovarian pregnancy.

Treatment for Ovarian Pregnancy

Raziel and Golan, as well as Chelmow and colleagues, reported cases in which an intact ovarian pregnancy was diagnosed by laparoscopy and systemic MTX treatment was successful. In many cases, an ovarian pregnancy is diagnosed after a significant hemoperitoneum has occurred and medical therapy is contraindicated. An ovarian pregnancy is easily confused with a leaking corpus luteum hematoma. For this reason, a safe approach is to proceed with localized surgical resection of the bleeding mass with conservation of the ovary, if possible. Unless the diagnosis is made late, the ovary can usually be preserved. In 1997, Seimera and colleagues reported successful laparoscopic treatment of ovarian pregnancy in eight patients over a 12-year time span. Einenkel and associates even reported the successful conservative resection of an ovarian pregnancy in a patient with ovarian hyperstimulation. The concomitant increased ovarian size, fragility, and vascularity presented an additional surgical challenge for these authors, although the use of intraoperative ultrasound greatly facilitated the precise localization of the ectopic pregnancy within the ovary. Only rarely is the hemorrhage so profuse that oophorectomy is required to control bleeding. Even if the last trophoblastic villi cannot be removed in the ovarian resection, the ovary should be preserved. Any remaining trophoblastic tissue will usually degenerate rapidly or respond to postoperative MTX therapy and therefore should produce no long-standing clinical problem.

ABDOMINAL ECTOPIC PREGNANCY

An abdominal pregnancy is perhaps both the rarest and the most serious type of extraterine gestation. Reports of the frequency of abdominal pregnancy vary, ranging from 1 in 3,771 deliveries to greater than 1 in 10,200 deliveries. Stafford and Ragan reported an incidence of 1 abdominal pregnancy in 7,269 deliveries, a figure that is representative of the reports in the literature. Abdominal pregnancies are classified as primary or secondary. Most are secondary, the result of early tubal abortion or rupture with secondary implantation of the pregnancy into the peritoneal cavity. To be considered a primary abdominal pregnancy, the pregnancy must meet the three criteria defined by Studdiford in 1942:

1. Both tubes and ovaries must be in normal condition with no evidence of recent or remote injury.
2. No evidence of uterotubal fistula should be found.
3. The pregnancy must be related exclusively to the peritoneal surface and be early enough to eliminate the possibility that it is a secondary implantation following a primary implantation in the tube.

Secondary abdominal pregnancy occurs when a tubal gestation attaches itself to other visera as the enlarging placenta spreads through the wall of the tube or is aborted through the fimbriated end. The placenta probably retains some tubal attachment, which supplies blood for the gestation to continue developing in the new peritoneal site. Rare types of secondary abdominal pregnancies have occurred after spontaneous separation of an old cesarean section scar, after uterine perforation during a therapeutic or elective abortion, and after subtotal or total hysterectomy.
Diagnosis of Abdominal Pregnancy

Early diagnosis of an abdominal pregnancy is difficult but critical, because a catastrophic hemorrhage can result from separation of the placenta later in pregnancy. A history of recurrent abdominal discomfort, fetal movement beneath the abdominal wall, and the presence of fetal movements high in the upper abdomen should alert the clinician to the possibility of an abdominal implantation. Other clinical clues include cessation of fetal movement, vomiting late in pregnancy, fetal malposition, a closed and uneffaced cervix, or the failure of oxytocin to stimulate the gestation.

Confirmation of the diagnosis requires demonstration of the fetus outside the uterine cavity. In their review of 199 cases, Costa and colleagues reported that only in 68 cases (40.2%) was a mass adjacent to or distinct from the uterus found. The radiologic finding of fetal small parts in the lateral position overlapping the maternal spine was first noted by Weinberg and Sherritt in 1956; this finding is a fairly reliable sign of an abdominal pregnancy. A radiologic examination of the abdomen, including anterior, posterior, and lateral views, is also helpful in defining malposition of the fetus, which is most often discovered to be in the transverse position. Ultrasound, however, is the most effective method for diagnosing an abdominal pregnancy. Ultrasound can usually identify an abdominal gestation as separate from the nonpregnant uterus. Ultrasonography can be expected to have high diagnostic accuracy in most cases. In those cases in which ultrasonography is equivocal, MRI may be useful.

The maternal mortality risk from abdominal pregnancy in the United States is 7.7 times greater than the maternal mortality risk from tubal ectopic pregnancy and 90 times greater than that with intrauterine pregnancy. Reported maternal mortality rates in the literature have varied in the past from 4% to 29%. Maternal morbidity can also be substantial, with high incidences of pelvic abscess, peritonitis, and sepsis caused by retained placental remnants. Rare instances of massive rectal bleeding or rectal passage of fetal bones secondary to the formation of a colo-intestinal fistula have also been reported. Fetal mortality is notoriously high, ranging from 75% to 95% of all cases.

Management of Advanced Abdominal Pregnancy

Recent techniques of fetal monitoring serve as diagnostic adjuncts to the management of the advanced abdominal pregnancy. Fetal assessment—including repeated ultrasonography to measure biparietal diameter, nonstress testing, monitoring of fetal movements, and biophysical profiles—can provide clinical evidence of fetal viability and fetal welfare. Despite the use of these diagnostic tools, fetal death occurred in all of the 15 cases of abdominal pregnancy reported by Martin and associates. Clark and Jones reported a fetal salvage rate of only 11.4% in a study of 35 advanced abdominal pregnancies.

One of the major factors in fetal survival is the condition of the fetal membranes. If the membranes rupture, the fetus usually dies from respiratory distress in the peritoneal cavity within a short time of the rupture. When the volume of amniotic fluid is significantly decreased or absent, the incidence of fetal demise increases significantly, pressure deformities occur, and pulmonary hypoplasia precludes the possibility of delivering a viable fetus. In situations in which the pregnancy is advanced and there is sufficient volume of amniotic fluid, there exists a reasonable possibility of a good fetal outcome. In rare instances, there may be justification for postponement of surgery to allow for further fetal maturity and a better perinatal prognosis.

Preoperative preparation of a patient with an advanced abdominal pregnancy should include an adequate supply of compatible blood and blood products and appropriate intravenous infusion lines that can deliver large amounts of fluid quickly. The use of a cell-saver or MAST (Military Antishock Trousers) suit has been reported in management of patients experiencing massive hemorrhage and shock. A surgical team should be standing by that is capable of handling the possible bowel, vascular, or genitourinary complications that may arise.

Following incision into the amniotic sac and delivery of the fetus, the management of the placenta still remains a controversial issue. Most clinicians believe the best treatment is to clamp the cord, to leave the placenta in situ, and to close the abdomen, but to allow retroperitoneal drainage if possible. The placenta can be removed after complete cessation of function is demonstrated by quantitative β-hCG titers. The placenta should be removed during laparotomy only if it is accessible and if its removal can be accomplished without excessive blood loss. In case of doubt, the placenta should be left in place. Thompson has reported leaving the placenta in the peritoneal cavity for a period of 13 years without physical harm to the patient. MTX has been used occasionally to hasten trophoblastic degeneration, but it leads to the accelerated accumulation of necrotic placental tissue, which may become infected. For this reason, it is currently felt best not to administer MTX in this clinical setting.

CERVICAL ECTOPIC PREGNANCY

The cervix is a rare but hazardous site for placental implantation because the trophoblast can penetrate through the cervical wall and into the uterine blood supply. Cervical gestations have, until recently, received little attention in the literature, but increased awareness of the condition has resulted in a number of recent reports.

The following three criteria for the diagnosis of cervical pregnancy were established by Rubin in 1911:

1. Cervical glands must be opposite the placental attachment.
2. Placental attachment to the cervix must be situated below the entrance of the uterine vessels or below the peritoneal reflection of the anterior and posterior surfaces of the uterus.
3. Fetal elements must be absent from the corpus uteri.

Because strict anatomical and histological criteria necessitate a hysterectomy for a complete study of the entire uterus, Paalman and McElhin proposed five more clinically practical criteria for the diagnosis of this condition:

1. Uterine bleeding without cramping pain following a period of amenorrhea
2. A soft, enlarged cervix equal to or larger than the fundus (the “hourglass” uterus)
3. Products of conception entirely confined within and firmly attached to the endocervix
4. A closed internal cervical os
5. A partially opened external cervical os

The incidence of this rare entity varies. The Mayo Clinic reported 1 in 16,000 pregnancies. The highest incidence, 1 in 1,000 pregnancies, was reported from Japan. The high incidence of elective abortion in Japan is probably a factor in the higher rates. Dilatation and curettage (D&C) seems to be
FIGURE 34.13. Differential diagnosis of cervical pregnancy. A: In the cervical phase of uterine abortion, the placenta is mainly within the expanded cervix, and the external and internal os are dilated. B: In a cervical abortion (abortion into the cervix), because of stenosis of the external os, spontaneous rupture of the cervical wall can cause severe hemorrhage. C: Ragged, friable cervix seen in cervical pregnancy mimics carcinoma of the cervix. (Redrawn from Rothe DJ, Birnbaum SJ. Cervical pregnancy: diagnosis and management. Obstet Gynecol 1973;42:675.)

a predisposing factor for cervical pregnancy. Shinagawa and Nagayama noted that in 18 of 19 cases of cervical pregnancy there was a history of legal abortion. In the review by Ushakov and associates, 68.6% of patients with a cervical pregnancy had a previous uterine curettage. It has also been suggested that a previous cesarean section may play a role in the etiology of cervical pregnancy.

Cervical gestation is frequently confused with a neoplastic process because of the marked vascularity and friable appearance of the cervix. Profuse bleeding can occur if the placenta is mistaken for a tumor and a biopsy is taken. A cervical gestation also can be mistaken for a spontaneous abortion in which the products of conception were retained within the cervical canal (Fig. 34.13).

Treatment for Cervical Pregnancy

The treatment for a cervical pregnancy is surgical, and the condition often requires an abdominal hysterectomy. In selected patients, conservative evacuation of an early cervical pregnancy may be accomplished by skillful D&C, although the procedure has the potential to be complicated by profuse hemorrhage. Further preoperative preparations directed to reduce the vascularity of the uterine cervix—such as transcervical ligation of cervical branches of the uterine arteries, a Shirodkar type cerclage, angiographic uterine artery embolization, or intracervical vasopressin injection—may reduce operative morbidity. In a review by Ushakov and colleagues, of the 16 cases in which one of these methods was employed, 15 had minimal (50–200 mL) blood loss, one patient had a hemorrhage of 1,200 mL requiring transfusion, and no patient required laparotomy or hysterectomy. Among 41 cases in which D&C was performed without cervical preparation, minimal bleeding occurred in just five cases (12.2%), massive bleeding (1,200–5,000 mL) occurred in 70.7%, and hysterectomy was performed in seven cases (17.1%). Laparotomy with bilateral internal iliac artery ligation or bilateral uterine artery ligation was also required in an additional five (12.2%) of these patients. To control postevacuation bleeding, several authors, including Kuppuswamy and colleagues and Werberand associates, have described the successful use of a Foley catheter balloon to tamponade the cervical implantation site in patients who continued to have blood loss after cervical pregnancy evacuation. A 26 French Foley catheter with a 30-mL balloon is preferably used and left inflated for 0.5 to 6 days, as clinically indicated.

Medical therapy can also be considered for the primary treatment of cervical pregnancy or as an adjunct to surgical therapy through decreased vascularity of the mass. Kung and Chang reviewed the use of MTX administration for cervical ectopic pregnancy from 1983 to 1997. Among 35 cases of viable cervical ectopic pregnancies <12 weeks’ gestation, 63% of patients received either systemic MTX alone or a combination of systemic MTX with a local (intraamniotic or intracervical) injection of either MTX or potassium chloride. Among the 23 cases of nonviable cervical pregnancy <12 weeks’ gestation, 96% of women required systemic MTX alone. The ultimate success rate of uterine preservation was similar (94% for the viable pregnancy group; 91% for the nonviable pregnancy group), although the patients in the viable pregnancy group required a significantly higher number of concomitant additional surgical procedures (43% vs. 13%).

HETEROTOPIC PREGNANCY

Heterotopic pregnancy (coexistence of intra- and extraterine pregnancies) is rare. The incidence has been estimated to be about 1 in 30,000 spontaneous pregnancies. With the use of assisted reproductive technologies, the incidence is higher, as high as 0.75% to 1.5% of pregnancies.

Although the precise cause of a combined pregnancy is frequently obscure, most of the risk factors are the same as those
The benefits derived from the early diagnosis of an ectopic pregnancy. The use of ovulation-inducing agents has increased the incidence of multiple gestations and heterotopic pregnancies. Berger and Taylor reported an incidence of combined pregnancy in as many as 2 in 100 stimulated patients. The most common predisposing anatomic finding associated with heterotopic pregnancies is preexisting tubal disease.

Abdominal pain, an adnexal mass, peritoneal irritation, and an enlarged uterus together constitute the major clinical features associated with a heterotopic pregnancy. Additional diagnostic findings include the presence of two corpora lutea found at the time of laparotomy or laparoscopy, hemoperitoneum, acute abdominal pain after the termination of an intrauterine pregnancy, and the persistence of an enlarged uterus with amenorrhea after excision of an ectopic pregnancy.

As opposed to extrauterine pregnancies, which are presently diagnosed and treated electively at an early preclinical stage, heterotopic pregnancies are still mostly diagnosed after clinical signs develop. In their review, Rejansky and Schenker report that nearly half of the cases present with rupture, hemoperitoneum, and emergency intervention. This is due to the fact that serial β-hCG determinations and transvaginal ultrasonography are often not helpful in establishing an early diagnosis of heterotopic pregnancy. The majority of heterotopic pregnancies consist of a single tubal gestation combined with an intrauterine pregnancy. Rarer varieties include combined cervical-intrauterine, ovarian-intrauterine, abdominal-intrauterine, and interstitial-intrauterine pregnancies.

Treatment for Heterotopic Pregnancy

Laparoscopy has been employed with reasonable success for the diagnosis of combined tubal and intrauterine pregnancies. Louis-Sylvestre and associates reported treating 13 patients laparoscopically, 10 by salpingectomy and three by salpingostomy. Subsequently, 60% of the patients with a viable intrauterine pregnancy at the time of surgery had a favorable outcome. On the other hand, in cases in which hemodynamic instability or an interstitial-extrauterine pregnancy is present, a laparotomy is indicated. Expectant management does not seem to have a role in the care of a patient with a heterotopic pregnancy.

This is due to the fact that the specific course of the extrauterine component can not be monitored by serial β-hCG determinations. Likewise, either local or systemic MTX therapy would be contraindicated in the presence of a viable intrauterine gestation. The use of a local injection of potassium chloride into the extrauterine gestational sac, however, has been used successfully in a few cases. There are very rare cases in which extrauterine abdominal pregnancies progress simultaneously with intrauterine pregnancies to viability. In their review of the world’s literature, Rejase and associates found only 13 cases in which both pregnancies reached term and both infants were delivered and survived the neonatal period. In the absence of such rare circumstances, the outcome for intrauterine pregnancy is optimized by immediate therapy of the extrauterine pregnancy.

RH IMMUNOGLOBULIN USE AFTER ECETOPI PREGNANCY

Grimes has reported that Rh-negative mothers were recognized as the only 36% of cases. Fetomaternal hemorrhage associated with ectopic pregnancy can sensitize Rh-negative women at risk. A dose of 50 μg Rh immunoglobulin is usually sufficient to prevent Rh sensitization.

BEST SURGICAL PRACTICES

- The benefits derived from the early diagnosis of an ectopic pregnancy include the potential use of medical and conservative surgical procedures that optimize future fertility. Early diagnosis may also preclude ectopic pregnancy rupture and therefore result in lower patient morbidity and mortality.

- The astute clinician is aware of the risk factors for ectopic pregnancy, thereby increasing the level of suspicion in the appropriate clinical context. Risk factors for ectopic pregnancy include chronic inflammatory disease, prior tubal surgery, surgical sterilization, and use of an intrauterine device. Previous ectopic pregnancy, DES exposure, progestin-only contraceptives, assisted reproductive technologies, infertility, tubal developmental anomalies, multiple sex partners, early age at first intercourse, cigarette smoking, and vaginal douching.

- The classic presentation of pain and uterine bleeding with the finding of an adnexal mass is present in only 14% of patients with ectopic pregnancy. Even when present, these classic signs and symptoms are not entirely specific for ectopic pregnancy.

- Highly sensitive β-hCG assays have greatly aided in the early diagnosis of ectopic pregnancies. Serum β-hCG concentrations increase in an exponential fashion in early pregnancy. During the period of gestation in which the β-hCG concentration is less than 10,000 IU/L, the time required for doubling of β-hCG levels remains consistent, with a mean of 1.9 days. The slowest minimal β-hCG rise for a normal viable intrauterine pregnancy is 53% in 2 days. Transvaginal ultrasonographic evidence of an intrauterine pregnancy can be expected to be seen with very high sensitivity when β-hCG concentrations exceed 1,500 IU/L.

- Serum progesterone assays are useful in the early diagnosis of an ectopic pregnancy. In one large study, 98% of patients with a normal intrauterine pregnancy had progesterone levels greater than 10 ng/mL. On the other hand, 99% of patients with an ectopic pregnancy had progesterone levels less than 20 ng/mL. Diagnostic limitations of the serum progesterone assay included the fact that 31% of viable intrauterine pregnancies, 25% of abnormal intrauterine pregnancies, and 51% of ectopic pregnancies had progesterone levels between 10 and 20 ng/mL in this study. In another large trial, the lowest serum progesterone concentration associated with a viable pregnancy was 5.1 ng/mL.

- A dilatation and curettage procedure is helpful when β-hCG assays and transvaginal ultrasonography are nondiagnostic and the pregnancy is suspected. Appropriate indications include (i) a failure of β-hCG concentration rise of greater than 50% in days, (ii) a serum progesterone level less than 5 ng/mL, and (iii) a failure to visualize an intrauterine gestational sac by transvaginal ultrasonography when the β-hCG concentration exceeds 1,500 IU/L. An ectopic pregnancy is suspected after uterine curettage if choriocarcin villi are not present on frozen section or if β-hCG concentrations do not fall by at least 15% 8 to 12 hours after the procedure.

- Laparoscopy remains the gold standard for the diagnosis of ectopic pregnancy, although it still has a low rate of false-negative and false-positive outcomes.

- Systemic MTX is an alternative that can be used for the treatment of patients with unruptured tubal pregnancies or patients with persistent ectopic pregnancies.
following conservative surgery. A history of active hepatic, renal, or peptic ulcer disease; elevated liver enzyme concentrations; and thrombocytopenia or neutropenia are contraindications to MTX therapy. Appropriate candidates for systemic MTX therapy should be willing to accept a small risk of tubal rupture and participate in closely monitored follow-up.

- In women who wish to preserve their fertility, conservative surgery by linear salpingotomy is the preferred treatment of a distal unruptured tubal pregnancy. Contraindications to conservative tubal surgery include an extensive hemoperitoneum and potentially compromised cardiovascular status, a recurrent ectopic pregnancy in the same fallopian tube, an ectopic pregnancy in a severely damaged tube, and an ectopic pregnancy in a woman who has completed her family. Laser or unipolar needle electrocautery, or scissors can then be used to make the salpingotomy incision. It is important to make the incision along the antimesenteric wall of the tube in the area of maximal distention and large enough to allow for complete extrusion of the products of conception without difficulty. It is important to keep the fallopian tube taut. If the products of conception do not spontaneously extrude following completion of the incision, either hydrodissection or gentle tubal compression will usually work. The tissue is then placed in an endoscopic bag and removed from the peritoneal cavity.

After the tissue is removed, the tube is irrigated carefully and inspected for hemostasis. If hemostasis is present, the tube is then either left to heal by secondary intention or sutured with fine suture. Secondary intention is felt appropriate for most cases.

- Several methods have been successfully used for laparoscopic salpingectomy, including endoscopic stapling devices, endocauterization, bipolar cautery, as well as the application of pre-tied endoscopic ligatures. Following placement of laparoscopic trocar ports (usually three-plate technique), irrigation of the pelvis, and the evacuation of the full blood clots, the involved tube is grasped with a toothed grasper. One method then includes cauterizing the tubal-ovarian ligament, first with bipolar forces, followed by transaction with scissors or the blade of a coagulation-cutting device. The mesosalpinx is similarly cauterized and transected, taking care to stay as close as possible to the fallopian tube. The proximal tubal uterus is then cauterized and transected. Care should be taken such that excess cauteronization of the uterine cornu does not occur because of concerns about the potential of interstitial sinus tracts or diminished myometrial integrity. Alternatively, the tube can be excised distal to a no. 0 polyglycan 910 endoligature secured proximal to the ectopic implantation site. This technique works optimally if the entire mesosalpinx is first transected such that the endoligature can be placed precisely at the tubal insertion at the cornu. The specimen is then placed in an endoscopic specimen retrieval bag and removed from the peritoneal cavity. Consideration may be given to covering the proximal tubal pedicle with an absorbable adhesion prevention barrier.

- All Rh-negative patients with an ectopic pregnancy should be offered at least 50 μg of Rh immunoglobulin to prevent Rh sensitization caused by fetomaternal hemorrhage.

Surgery for Obstetrics

CHAPTER 35A ■ OBSTETRIC PROBLEMS

CORNELIA R. GRAVES

DEFINITIONS

**B-Lynch stitch**—A large mattress suture used to control postpartum hemorrhage following cesarean section delivery. A deep suture is placed vertically on the side of the uterus from 3 cm below the level of the uterine incision to 3 cm above the incision. The suture is then taken over the fundus, and a horizontal bite is taken on the posterior wall of the uterus below the level of the uterine vessels entering the myometrium on the same side as the anterior stitch. The suture is again passed over the fundus on the opposite side, and a deep suture is placed starting 3 cm above the other end of the anterior uterine incision and exiting 3 cm below the incision. This large four-corner mattress suture is then tightly tied down compressing the fundus.

Cervical insufficiency—Premature, painless dilation of the cervix leading to midtrimester delivery if not treated. The etiology of the condition is poorly understood and may be due to prior cervical trauma and/or some inherent cervical defect.

Late postpartum hemorrhage—Hemorrhage occurring more than 24 hours following delivery.

McDonald suture—Surgical treatment for cervical insufficiency. A purse-string suture of heavy caliber is placed around the cervix at the level of the internal os.

Postpartum hemorrhage—Although the clinical significance of postpartum blood loss will vary from one patient to the next, and blood loss during and after delivery is difficult to estimate accurately, the American College of Obstetricians and Gynecologists has suggested postpartum hemorrhage be defined as blood loss of greater than 1,000 mL with a vaginal delivery or greater than 500 mL with a cesarean section or greater than 1,000 mL with a cesarean section or a 10% drop in the hematocrit.

Shirodkar suture—A thick suture or mesh band is placed submucosally around the cervix to treat cervical insufficiency.

Surgery in the pregnant patient presents several unique challenges. There is, of course, the added complexity of caring for two patients simultaneously. Illness and surgery both affect the fetus as well as the mother, and every decision to recommend surgery and when that surgery should be done requires weighing the risks and advantages to both patients. In many cases, there may be some urgency required to prevent or reduce maternal or fetal morbidity or mortality. In addition, the physiologic and anatomic changes of pregnancy may complicate diagnosis and alter the surgeon’s normal operative field so that the size of the uterus and increased vascularity of the pelvis may make it significantly more difficult to perform routine gynecologic procedures.

PHYSIOLOGIC CHANGES

There are a number of physiologic changes that occur during pregnancy. It is important for the surgeon to understand these changes because they may affect laboratory interpretation, blood product replacement, and surgical approach.

**Cardiovascular System**

Blood volume increases by 45% to 50% at term. Placental hormone production stimulates maternal erythropoiesis, increasing red cell mass by approximately 20%. This results in a functional hemodilution manifested by a physiologic anemia. Therefore, pregnancy should be considered a hypervolemic state. Maternal heart rate increases as early as 7 weeks. In late pregnancy, maternal heart rate is increased by approximately 20% over antepartum values, often resulting in mild tachycardia. The increase in blood volume and heart rate predisposes the parturient to an increased incidence of cardiac ectopy.

Systemic vascular resistance decreases by 20% but gradually increases near term. This results in a decrease in systolic and diastolic blood pressure during pregnancy, with a gradual recovery to nonpregnant values by term. As there is increased pressure in the venous system, there is decreased return from the lower extremities, resulting in dependent edema.

**Respiratory System**

In pregnancy, minute volume is increased while functional residual volume is decreased. It seems intuitive that lung volume would be decreased during pregnancy, but an increase in minute volume in association with an expansion of the anterior and posterior diameter of the chest results in increased tidal volume, thereby also increasing minute ventilation. These changes result in a compensated respiratory alkalosis. Normal Pco2 in pregnancy ranges from 28 to 35 mm Hg. Pco2 is usually greater than or equal to 100 mm Hg. Oxygen consumption and basal metabolic rate are also increased during pregnancy by approximately 20%.

These physiologic changes result in less pulmonary reserve for the acutely ill pregnant patient; therefore, this reduces the time interval from respiratory distress to respiratory failure. Because of this, early intervention for cases of respiratory challenge is mandatory.

**Gastrointestinal Tract**

During pregnancy, there is a decrease in gastrointestinal motility. This is caused by mechanical changes in the abdomen with...
the enlarging uterus and smooth muscle relaxation induced by high production of progesterone in pregnancy. Gastric empy- 
ery may be delayed for up to 8 hours; therefore, pregnant 
women should be considered to have a functionally full stom-
ach at all times. In addition, a decrease in large intestine motility 
may result in constipation severe enough to cause significant 
abdominal pain.

Coagulation Changes

Pregnancy is a hypercoagulable state. Fibrinogen is increased 
approximately 30% over baseline values. The hypercoagulable 
state of pregnancy is associated with increased risk of deep ve-
nous thrombosis and pulmonary embolus. This is particularly 
compounded when bed rest or immobilization occurs during the 
gestational period.

Renal Changes

Pregnancy increases blood flow to the renal pelvis approxi-
mately 50%. This results in an increased glomerular filtration 
rate accompanied by frequent urination. Serum creatinine is ap-
proximately 40% less than in a nonpregnant state. Therefore, a 
creatinine of 1 mg/dL during gestation should be considered 
abnormal.

Ureteral diameter increases in pregnancy secondary to com-
pression and smooth muscle relaxation. Peristalsis is delayed, 
and reflux occurs freely from the bladder into the lower ureteral 
segment. This results in an increased incidence of pyelonephri-
tis during pregnancy, making treatment of significant asym-
ptomatic bacteruria mandatory.

IMAGING TECHNIQUES

The most common imaging technique used during pregnancy is 
ultrasound. Ultrasound is considered safe and primarily is used 
for fetal assessment. In patients with abdominal pain, an ultra-
sound should be considered the first-line diagnostic test. During 
ultrasound, the presence of an intracranial pregnancy should be 
documented if possible, and evaluation of the cul-de-sac for fluid, 
the uterus for dilatation or stones, the gallbladder for the 
presence of gallstones, and the placenta for abnormalities can be 
noted.

Magnetic resonance imaging can be also safely used dur-
ing pregnancy. There is no data to suggest an increased risk 
from this modality. Magnetic resonance imaging is now used to 
diagnose fetal abnormalities, especially abnormalities of the 
central nervous system.

Although there are theoretical risks associated with ioniz-
ing radiation, fortunately, most diagnostic x-ray procedures 
are associated with minimal or no risk to the fetus. Existing 
evidence suggests that there is no increased risk of fetal con-
genital malformations, growth restriction, or abortion from x-ray procedures that expose the fetus to doses of 5 rads or 
less. The American College of Obstetricians and Gynecologists has published guidelines regarding diagnostic imaging during pregnancy. Women should be reassured that concern about ra-
diation exposure should not prevent medically indicated diag-
nostic procedures. It cannot be stressed enough that maternal 
well-being is of the utmost importance, and appropriate di-
agnostic procedures should be obtained to facilitate a rapid 
diagnosis.

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage is poorly defined by estimation of 
blood loss; therefore, it is difficult, if not impossible, to deter-
mine actual or percentage of blood loss at the time of delivery. 
Additionally, blood volume expansion is variable during preg-
nancy and can be affected by several factors including hyperpres-
sion, renal disease, maternal size, and the presence of multifetal 
gestations. The potential effects of blood loss largely depend 
on the degree of blood volume expansion. For example, the 
average blood loss from a cesarean delivery is 1,000 mL. This 
degree of blood loss is generally well tolerated by the promi-

pregnant woman. A blood loss of 500 to 750 mL, however, 
may not be tolerated in a woman with minimal volume ex-
pansion, or one who is homoconcentrated secondary to severe 
preeclampsia or eclampsia. The American College of Obstetri-
cians and Gynecologists has noted that a number of definitions 
have been used to define hemorrhage, including a blood loss 
greater than 500 mL with a vaginal delivery or greater than 
1,000 mL during a cesarean section or a drop in hematocrit of 
10% regardless of the amount of documented blood loss.

Gilstrap and Ramin have defined clinically significant hem-
orrhage as that amount of bleeding “that produces signs and 
symptoms of hemodynamic instability or that is likely to pro-
duce such if left unabated.”

Incidence and Etiology

Although the exact incidence of hemorrhage associated with 
pregnancy is unknown, it remains one of the leading causes 
of maternal mortality in this country. Kaunitz and associates 
reported that 13% of more than 2,000 maternal deaths were 
secondary to hemorrhage, and one third of these occurred post-
partum. Rochat and colleagues reported a similar incidence of 
11% of maternal deaths resulting from hemorrhage.

In a recent randomized trial in the United States, birth 
weight, labor induction and augmentation, chorioamnionitis, 
magnesium sulfate use, and previous postpartum hemorrhage 
were associated with increased risk of postpartum hemorrhage. 
A large population-based study supported these findings with 
significant risk factors identified using a multivariable analy-
sis. These risk factors are retained placenta (odds ratio [OR] 
3.5; 95% confidence interval [CI], 2.1–5.8), failure to progress 
during the second stage of labor (OR 3.4; 95% CI, 2.4–4.7), 
placenta accreta (OR 3.3; 95% CI, 1.7–6.4), lacerations (OR 
2.4; 95% CI, 2.0–2.8), instrumental delivery (OR 2.3; 95% CI, 
1.6–3.4), large-for-gestational-age newborn (OR 1.9; 95% CI, 
1.6–2.4), hypertensive disorders (OR 1.7; 95% CI, 1.2–2.1), 
induction of labor (OR 1.4; 95% CI, 1.1–1.7), and augmenta-
tion of labor with oxytocin (OR 1.4; 95% CI, 1.2–1.7).

Diagnosis and Medical Management

The most important aspects in the management of postpartum 
hemorrhage are prompt recognition of the condition and ascer-
tainment of its etiology. Recognition is no problem with exter-
nal bleeding, and such bleeding almost always can be controlled 
with medical or minor surgical means. Hypotension without 
obvious external blood loss should serve as a sign of pos-
tional internal bleeding, and virtually all such hemorrhage will 
require a major surgical procedure to arrest the hemorrhage. 
If the etiology of the hemorrhage is not determined quickly,
Other methods of uterine tamponade reported in the literature may stop the bleeding so that no further treatment is necessary. Replacement, as well as slowing bleeding enough to allow for parturial hemorrhage. Uterine packing allows time for volume replacement before surgical intervention. Maier described the use of a packing device called a Torpin packer. The device uses a plunger to place several yards of 4-inch-wide gauze into the uterine cavity. The hallmarks of medi-cal management consist of volume replacement and oxytocic agents, including intravenous oxytocin and parenteral meth-ylergonovone and prostaglandins. Volume can be maintained with crystalloid or blood or blood products. Invasive monitoring, such as with a pulmonary artery catheter, generally is not necessary and may be dangerous in the presence of a coagulopathy. Its use should be reserved for those patients who do not respond to usual and expected therapy. As a general rule, monitoring of urine output, vital signs, and oxygen saturation will be sufficient. Volume replacement generally is adequate when the blood pressure is maintained at 90 to 140 mm Hg systolic, pulse rate is less than 100 beats per minute, and urine output is at least 25 to 30 mL per hour. When a patient has required transfusion of significant amounts of packed red blood cells, transfusion of coagulation products should be performed to replace those lost in the hemorrhage. Calcium also should be re-placed in these patients because of risk of complications related to hypocalcemia in patients receiving massive transfusions. Coagulation factors should be replaced in patients who receive extensive transfusions with packed red blood cells. Fluid over-load generally can be detected with a stethoscope and an oxygen saturation monitor in conjunction with clinical signs and symptoms. Diuretics should only be used to remove excess fluid if the pa-tient becomes hypoxic related to volume overload. A medical management protocol is summarized in Table 35A.1.

**Surgical Management**

Lower genital tract lacerations usually are best managed by suturing. The rare case of uterine rupture also is managed surgically. Other techniques to control hemorrhage include uterine and uteroovarian artery ligation, hypogastric or internal iliac artery ligation, hysterectomy, or uterine or hypogastric artery embolization.

Uterine packing, which until recently had been abandoned by most clinicians, may allow adequate time for blood and fluid replacement before surgical intervention. Maier described the use of a packing device called a Torpin packer. The device uses a plunger to place several yards of 4-inch-wide gauze into the uterine cavity and has been used successfully to control postpartum hemorrhage. Uterine packing allows time for volume replacement, as well as slowing bleeding enough to allow for surgical techniques short of hysterectomy. In many cases, it may stop the bleeding so that no further treatment is necessary. Other methods of uterine tamponade reported in the literature have included the use of a Foley catheter with a 30- to 50-cc balloon or a Sengstaken-Blakemore tube with the esophageal balloon inflated with 30 cc of normal saline.

The choice of a specific surgical technique to control bleeding depends on several factors, such as the degree of hemor-rhage, the condition of the patient, parity, and the desire for future childbearing; although probably the single most impor-tant factor is the experience of the surgeon.

**Arterial Embolization**

Angiographically directed arterial embolization has been described for the successful control of obstetric and gynecologic bleeding. Gelfoam, polyvinyl alcohol dehydrated particles, and other substances have been used for such embolizations. Pelage and associ-ates, in two separate reports, describe use of arterial embolization in patients with primary or secondary postpartum hemorrhage. Following transcatheter embolization, immediate decrease or cessation of bleeding occurred in all patients. Two patients required repeat embolization the next day with no further complications. Fourteen women were diagnosed with secondary postpartum hemorrhage after the first 24 hours fol-lowing delivery. All of these patients had complete resolution of bleeding with embolization with no further complications. Arterial embolization can be performed quickly and safely; therefore, it should be considered in patients with postpartum hemorrhage. There have been reports of successful pregnancies following embolization, which makes it an especially attractive alternative to hysterectomy in the patient who desires preser-vation of fertility.

**Uterine Artery Ligation**

Uterine artery ligation is a relatively safe procedure that can be performed by most obstetricians. It also allows for future...
childbearing. The technique consists of ligating the uterine artery and vein at the lower uterine segment 2 to 3 cm below the level of the transverse uterine incision. An absorbable ligature is placed 2 to 3 cm medial to the uterine vessels through the myometrium (to obliterate any intramyometrial ascending branches) and then lateral to the vessels through the broad ligament. It is imperative that the bladder be advanced before placement of the suture to prevent bladder injury. Because of collateral flow from the ovarian artery, some recommend that a second ligature be placed at the junction of the uteroovarian ligament and uterus. The technique of uterine artery ligation is shown in Figures 35A.1 and 35A.2.

O’Leary, in a review of 90 women who underwent uterine artery ligation (30 were for uterine atony), reported that only six (7%) procedures resulted in failure. There were no major complications from the procedure itself. In a follow-up review of 265 women who underwent uterine artery ligation, O’Leary reported a greater than 95% success rate. This technique is most useful (and successful) when hemorrhage is of a moderate degree and originates from the lower uterine segment. Such an example is bleeding from a low placental implantation site. Uterine artery ligation also can prove beneficial for lower segment extensions or lacerations, as well as for a uterine artery laceration itself. Philippe and associates reported a vaginal approach to ligation of the uterine arteries in two patients after vaginal delivery, but a larger case series would have to be performed to determine the feasibility of this approach. B-Lynch and colleagues also described five cases in which hemorrhage was controlled by placing an absorbable suture vertically from 3 cm below the uterine incision to 3 cm above the uterine incision on the right side of the uterus (Fig. 35A.3). The stitch is then taken vertically over the fundus and

FIGURE 35A.1. Uterine artery ligation. (From: Clark SC, Phelan JP. Surgical control of obstetric hemorrhage. Contemp Obstet Gynecol 1984;24:70, with permission.)

placed horizontally in the posterior uterus at the same level as the anterior suture. The suture is threaded over the left side of the uterus to place another stitch on the left from 3 cm above the uterine incision to 3 cm below the uterine incision. The long suture is tied, compressing the fundus. A large suture, such as #1 Prolene on a large needle, is used. The uterine incision is closed in the usual fashion (Fig. 35A.3C). There are several case series in the literature supporting the efficacy of the B-Lynch stitch for the treatment of uterine atony. In all series, the suture has been reported to be effective. It has been suggested that the B-Lynch be considered in all cases of severe postpartum hemorrhage before resorting to hysterectomy.

**Hypogastric Artery Ligation**

The major blood supply to the uterus and pelvis comes from the internal iliac artery, commonly called the hypogastric artery. Bilateral ligation of this artery can effectively control significant bleeding and thus prevent the need for hysterectomy and permanent sterilization. Burchell has aptly described the physiology of internal iliac artery ligation. It appears that ligation of this artery controls bleeding by converting an arterial system into a venous system, which decreases the pulse pressure by as much as 85%. This allows pressure and packing to produce clotting. Hypogastric artery ligation probably interferes little, if at all, with subsequent pregnancies. Mengert and colleagues reported successful pregnancies in five women who had undergone internal iliac artery ligation. This technique may also prove useful for controlling bleeding in patients with large hematomas of the broad ligament or for a lacerated artery that has retracted into the broad ligament. Such vessels or active bleeding sites often are difficult to identify. If the bleeding is from the hypogastric vein, ligation of the hypogastric artery decreases outgoing flow, as well as allowing exposure to the vein.

The technique of hypogastric artery ligation is illustrated in Fig. 35A.4. The peritoneum overlying the common iliac artery is opened by directly cutting on the surface of the artery. The ureter should be identified and retracted medially, if necessary. The sheath covering the internal iliac (hypogastric) artery then can be opened longitudinally. A right-angle clamp is gently passed under the artery in the lateral to medial direction with blunt dissection. Great care must be taken not to perforate the internal iliac vein, and the clamp is passed lateral to medial to avoid injury to the vein by the tip of the clamp. The ligation should be performed about 2 cm distal to the bifurcation to avoid disrupting the posterior division of the hypogastric, which can lead to ischemia and necrosis of the skin and subcutaneous tissue of the gluteus. Two nonabsorbable sutures of 2-0 silk should be used for ligation. It is important that hypogastric artery ligation be performed bilaterally to adequately decrease pressure to the uterus. Clark and associates reported on the successful control of bleeding in 8 (42%) of 19 women who underwent hypogastric artery ligation. In a review of hypogastric artery ligation from three series, Clark reported that this procedure prevented hysterectomy in about half of the cases associated with uterine atony and placenta accreta. Interestingly, in the series by Clark and associates, the success of this procedure did not appear to be related directly to the conditions for which it was performed. It must be noted, however, that the number of patients in each category is small.

Although this procedure is successful in about 50% of the cases and does not interfere with subsequent fertility, it is not technically easy to perform and requires special expertise and skill. Many obstetricians have little, if any, experience with this procedure. Moreover, potential complications of hypogastric artery ligation include laceration of the iliac vein, ligation of the external iliac artery, ureteral injury, and death.

**Hysterectomy**

Because of the lack of experience and skill with the technique of hypogastric artery ligation, many clinicians prefer to do a hysterectomy to control postpartum hemorrhage. Peripartum hysterectomy is extensively discussed later in this
chapter. Hysterectomy usually is the safest procedure and also the quickest that can be performed for refractory bleeding. For example, Clark and associates reported that patients undergoing hypogastric artery ligation who subsequently required hysterectomy had an increased incidence of cardiac arrest secondary to blood loss. The increased morbidity associated with hypogastric artery ligation followed by hysterectomy may be secondary to a delay resulting from attempted conservative management short of hysterectomy. Hypogastric artery ligation was attempted before hysterectomy 64% of the time in nulliparous women, compared with 10% of the time for multiparous patients. Lack of experience with hypogastric artery ligation adds to the overall time required to attempt the procedure and overall blood loss.

In a review of 70 women who underwent emergency hysterectomy for postpartum hemorrhage, Clark and colleagues reported that almost all required blood transfusion, and 50% had postoperative febrile morbidity. The most common indication for hysterectomy in this series was uterine atony, followed by placenta accreta. Of the 70 procedures, 60 were performed after cesarean delivery. Mean operating time was 3.1 hours, and mean blood loss was 3,375 mL.

**LATE POSTPARTUM HEMORRHAGE**

Late postpartum hemorrhage is that which occurs more than 24 hours after delivery. The etiology of such bleeding includes placental site subinvolution, infection, coagulopathy, and retained products of conception. Initial therapy for this complication is the same as for early hemorrhage. If infection is present, antibiotics should be used. Endometrial curettage may be necessary for retained placental fragments. Angiographic embolization may prove especially useful in the case of late postpartum hemorrhage. Uterine artery ligation, hypogastric artery ligation, and hysterectomy are rarely required for control of late postpartum hemorrhage.

**PERIPARTUM HYSTERECTOMY**

Horatio Storer performed the first cesarean hysterectomy in 1869. Initially, the procedure was performed only for emergency situations, but in the early 20th century, it became an accepted means of sterilization. In the modern obstetrical age, elective cesarean hysterectomy is rarely performed, except in cases of cervical neoplasia.

Peripartum hysterectomy can be performed in conjunction with a cesarean delivery (e.g., cesarean hysterectomy) or after a vaginal delivery for complications such as postpartum hemorrhage. In a recent review of a nationwide sample of deliveries from 1998 to 2003, Whiteman and colleagues estimated that the rate of peripartum hysterectomy in the United States is 0.77 per 1,000 deliveries.

Although there is little controversy regarding peripartum hysterectomy for emergency conditions, there is significant debate in modern obstetrics regarding an elective hysterectomy.
performed at the time of cesarean delivery. There has been legitimate concern about increased morbidity related to peripartum hysterectomy—including damage to the ureters, bladder, and rectum—and an increased rate of reoperation. However, Plauche has pointed out that morbidity often is associated with the conditions leading to the hysterectomy and not necessarily the procedure itself. Lower morbidities have been reported for elective cesarean hysterecomies when compared with emergency hysterecomies. However, there is inherent bias in these retrospective reviews. Emergent surgery for lifesaving maternal indications would be expected to have higher morbidities, such as blood loss and injury to surrounding structures. Castaneda and colleagues noted, in a retrospective study, that over the years the indications for peripartum hysterectomy have changed from predominately elective to almost exclusively emergencies. In their data, the average blood loss was 3,009 mL in emergent cases and 1,262 mL in nonemergent cases. They concluded that in current times, peripartum hysterectomy is almost always emergent in nature and associated with a significant blood loss. As might be expected, there are no randomized prospective studies of elective cesarean hysterectomy, and it is unlikely that such a study could ever be done given the ethical dilemma involved.

Emergency Peripartum Hysterectomy

There are several indications for emergency peripartum hysterectomy. The three most common reasons are uterine rupture, abnormal placentation, and uterine atony. Although the exact incidence of emergency peripartum hysterectomy is not known, several authors have reported widely varying rates of 0.06% to 1.5 per 1,000 deliveries. Obstetric hemorrhage secondary to a variety of etiologies is a common indication reported for peripartum emergency hysterectomy. Chestnut and associates reviewed 70 cases of emergent hysterectomy for obstetric hemorrhage and found that 60 (86%) of these procedures were performed after cesarean delivery, and 10 (14%) were performed after vaginal delivery. Uterine atony and placenta accreta accounted for almost three fourths of the cases. Other indications were uterine rupture, extension of the uterine incision, and fibroids precluding closure of the uterine incision. Other indications included broad ligament hematoma, placenta previa, and chorioamnionitis. Twenty-three of the cases in this series followed cesarean deliveries, and 15 were postpartum hysterectomies.

In another series of 117 cases of peripartum hysterectomy, Zelop and colleagues reported uterine atony accounted for 25 (21%) of the cases, and most (75% or 64%) were secondary to an abnormally adherent placenta. The rate of emergent hysterectomy increased with increasing parity, placenta previa, and history of previous cesarean section.

It is clear from the literature that abnormal adherent placenta or placenta accreta (with or without hemorrhage) is emerging as the most common condition leading to an emergency hysterectomy. In three studies from 1993 to the present, 156 (16%) of the 279 emergent peripartum hysterectomies were performed for placenta accreta. These studies are outlined in Table 35A.2. The increase in placenta accreta is related to the high rate of cesarean deliveries, which has risen in the United States from 5% in the early 1960s to 30% at the present time. A recent study of more than 60,000 deliveries at the University of Chicago by Wu et al. found that the rate of placenta accreta had increased to 3 per 1,000 deliveries in 2003. They observed that this was directly associated with the increase in cesarean section rate. Placenta previa also is significantly associated with placenta accreta. Zelop et al. reported that the risk of peripartum hysterectomy in women with placenta previa increases from 7 in 1,000 deliveries in nulliparous women to one in four deliveries in women with a history of four or more live births. Clarke and colleagues found that in the presence of a placenta previa, the risk of having placenta accreta increased from 24% in women with one prior cesarean delivery to 67% in women with 3 or more prior cesareans. Zorlu and colleagues evaluated the risk of placenta accreta in women with placenta previa increases from 7 in 1,000 deliveries in nulliparous women to one in four deliveries in women with a history of four or more live births. Clarke and colleagues found that in the presence of a placenta previa, the risk of having placenta accreta increased from 24% in women with one prior cesarean delivery to 67% in women with 3 or more prior cesareans. Zorlu and associates evaluated the risk of emergent hysterectomy in two distinct time periods. Forty-three patients underwent emergent hysterectomy between 1985 and 1989. The incidence of hysterectomy was 1 in 2,495 deliveries, and the indications for hysterectomy included uterine atony (43%), placenta accreta (25.5%), and uterine rupture (21%). Five years later, from 1990 to 1994, the incidence of hysterectomy had decreased by almost 50% to 1 in 4,228 deliveries, and the indications for hysterectomy included placenta accreta (41.7%), uterine atony (29.2%), and uterine rupture (20.8%). The authors felt the increase in placenta accreta as an indication for emergent hysterectomy most likely reflected an increase in the cesarean section rate nationwide.

Elective Cesarean Hysterectomy

Although a number of conditions have been reported as indications for elective cesarean hysterectomy, currently accepted indications are usually limited to macroscopic or invasive cervical cancer. In retrospective reviews that go back to the 1950s and 1960s, sterilization, menstrual abnormalities, and uterine fibroids are listed as indications; however, most practitioners would not consider these appropriate indications for such an invasive surgical procedure in the 21st century.

Morbidity and Mortality of Hysterectomy

The conditions leading to emergency hysterectomy also are responsible for much of the morbidity reported with the procedure. Two other important factors associated with morbidity, both of which are difficult to quantify, are training and experience (or surgical skill) of the surgeon. Chestnut and associates reported statistically significant reductions in operative time, estimated blood loss, intraoperative and total blood replacement, and length of hospital stay if the patient was in the care of an experienced surgeon. It seems reasonable, however, to conclude that morbidity and complications are higher in women undergoing emergency versus elective procedures despite the skill of the surgeon.

Zelop and associates reported 102 (87%) of the patients in their series required transfusion of blood products. Complications of three series, totaling 279 cases of emergency peripartum hysterectomy, are summarized in Table 35A.3. Maternal mortality rates in these studies varied between 0% and 4.5%. As with morbidity, mortality is better correlated with the specific complication than with the hysterectomy per se.

In a review of 80 women undergoing elective cesarean hysterectomy, McNulty reported that only five (6%) experienced febrile morbidity, and 15 (19%) received blood transfusions. Four (5%) women sustained bladder injuries, and four (5%) women developed broad ligament hematomas. Yancey and colleagues compared the outcomes in 43 women undergoing scheduled cesarean hysterectomy with those of 86 women who underwent cesarean delivery and subsequent scheduled hysterectomy. Although women in the cesarean hysterectomy group were more likely to need a blood transfusion than were women in the subsequent hysterectomy group (OR 1.4; 95% CI, 1.4–8.4), they were less likely to have other complications, such as infection (OR 0.34; 95% CI, 0.25–0.45). The overall postoperative complication rate was the same in both groups (31%). Thus, it is likely that elective cesarean hysterectomy is not associated with an increased risk of complications or morbidity compared with a cesarean delivery followed by an elective hysterectomy at a later time. However, in a healthy population, one must weigh the infectious risk of blood transfusion versus the benefit of the combined procedure. As pointed out by Baker and D’Alton, however, there is little doubt that elective cesarean hysterectomy does result in increased morbidity when compared with a cesarean delivery and a tubal ligation.

Emergency Versus Elective Hysterectomy

In two studies comparing emergency with elective peripartum hysterectomy, morbidity was greater with the emergency procedure. Estimated blood loss, number of women transfused, and operating time were all higher in the emergency group. It is important to remember that many of the patients who undergo emergent delivery already had significant blood loss and hemorrhage before the decision being made to proceed with hysterectomy.

Cesarean Hysterectomy Technique

Elective cesarean hysterectomy can be accomplished through either a midline or low transverse (Pfannenstiel) skin incision. Often, it is more prudent to use a midline skin incision in cases of placenta percreta because placental invasion can ensue. In cases of placenta previa and suspected placenta accreta, it is prudent to arrange for urologic support preoperatively. In cases of anterior placenta previa and suspected placenta accreta, it is prudent to arrange for urologic support preoperatively. In cases of suspected accreta, interventional radiology may place bilateral hysterectomy. Although women in the cesarean hysterectomy group were more likely to need a blood transfusion than were women in the subsequent hysterectomy group (OR 3.4; 95% CI, 1.4–8.4), they were less likely to have other complications, such as infection (OR 0.34; 95% CI, 0.25–0.45). The overall postoperative complication rate was the same in both groups (31%). Thus, it is likely that elective cesarean hysterectomy is not associated with an increased risk of complications or morbidity compared with a cesarean delivery followed by an elective hysterectomy at a later time. However, in a healthy population, one must weigh the infectious risk of blood transfusion versus the benefit of the combined procedure. As pointed out by Baker and D’Alton, however, there is little doubt that elective cesarean hysterectomy does result in increased morbidity when compared with a cesarean delivery and a tubal ligation.

Emergency Versus Elective Hysterectomy

Estimated blood loss, number of women transfused, and operating time were all higher in the emergency group. It is important to remember that many of the patients who undergo emergent delivery already had significant blood loss and hemorrhage before the decision being made to proceed with hysterectomy.

Cesarean Hysterectomy Technique

Elective cesarean hysterectomy can be accomplished through either a midline or low transverse (Pfannenstiel) skin incision. Often, it is more prudent to use a midline skin incision in cases of placenta percreta because placental invasion can ensue. In cases of placenta previa and suspected placenta accreta, it is prudent to arrange for urologic support preoperatively. In cases of anterior placenta previa and suspected placenta accreta, it is prudent to arrange for urologic support preoperatively. In cases of suspected accreta, interventional radiology may place bilateral hysterectomy. Although women in the cesarean hysterectomy group were more likely to need a blood transfusion than were women in the subsequent hysterectomy group (OR 3.4; 95% CI, 1.4–8.4), they were less likely to have other complications, such as infection (OR 0.34; 95% CI, 0.25–0.45). The overall postoperative complication rate was the same in both groups (31%). Thus, it is likely that elective cesarean hysterectomy is not associated with an increased risk of complications or morbidity compared with a cesarean delivery followed by an elective hysterectomy at a later time. However, in a healthy population, one must weight the infectious risk of blood transfusion versus the benefit of the combined procedure. As pointed out by Baker and D’Alton, however, there is little doubt that elective cesarean hysterectomy does result in increased morbidity when compared with a cesarean delivery and a tubal ligation.
well down before the start of the hysterectomy. This is best accomplished at the time of the cesarean delivery. The bladder should be dissected off the anterior, lower uterine segment with sharp dissection if firm adhesions are encountered. Firm adhesions often are present in patients who have undergone multiple cesarean deliveries. If bleeding is a problem, further dissection of the bladder from the lower uterine segment can be accomplished after ligation of the uterine artery.

The actual hysterectomy is begun by ligating the round ligament close to the uterus and ligating the distal stump with a 0-Vicryl suture ligature. The vesicouterine serosa, where the bladder was attached before its dissection, then is extended laterally to the severed round ligaments.

The peritoneal incision should be extended superiorly. Because the ureters are dilated in pregnancy, they should be identified quickly to avoid injury. The ureter can be seen crossing the iliac artery at the level of the bifurcation in the medial leaf of the broad ligament and is most easily identified at this location. The uteroovarian ligaments can be secured by first making a "window" through the posterior leaf of the broad ligament and then doubly clamping, cutting, and ligating the uteroovarian ligament bilaterally (Fig. 35A.5). This step is easy and uncomplicated in the nonpregnant patient; but the dilated vasculature of pregnancy requires the surgeon to carefully select a clear window and handle the tissues gently to avoid troublesome bleeding from easily torn veins. The uterine vessels are skeletonized as in the nonpuerperal hysterectomy. These vessels are large and easy to identify. Dissection is made easier with continuous upward traction of the uterus. If possible, the uterine vessels are clamped bilaterally (usually with a Heaney or Zepplin clamp); before the vessels are cut. If there is room, we prefer to place three large clamps on each side, and divide the pedicle between the first and second clamp (Fig. 35A.6). This provides two clamps on the active vessels for security and one back clamp to prevent back bleeding from the enlarged, blood-engorged uterus. The vascular pedicles are doubly ligated with 0 synthetic absorbable sutures, and we generally prefer to suture ligate the back bleeders also, so that the back camps can be removed from the field. This provides better exposure and reduces the risk of tearing the uterine tissues by excessive traction on these clamps. As with all hysterectomies, care must be exercised in identifying and avoiding the ureter. The next pedicles encountered should be the broad ligament, the base of which is the cardinal ligament. A slightly curved or a straight clamp, whichever fits the anatomy best, can be used for these ligaments. It is better to take several small pedicles instead of one large bite because an excessively large pedicle can slide out of a clamp or suture. This is especially true with the edematous tissues associated with pregnancy. Once the cardinal and uterosacral ligaments have been clamped, cut, and tied at the level of the cervix, the specimen can be removed by clamping across the vagina on each side and incising the vaginal mucosa (Fig. 35A.7). It may be difficult to identify the lower extent of the cervix, especially if the cervix is effaced. The cervix can be grasped with a thumb anteriorly, and the hand wrapping around the cervix with the fingers posteriorly. The cervix is then pinched between the thumb and middle finger as the hand slowly slides down the cervix toward the vagina. Usually, it is possible to feel the lower end of the cervix in this way. If there is any doubt, it may also be helpful to make an incision into

**FIGURE 35A.5.** A: The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, uteroovarian ligaments, and ovarian vessels. B: These are then doubly clamped close to the uterus and severed. (From: Cunningham FG, MacDonald PC, Gant NF, et al. Caesarean section and caesarean hysterectomy. In: Williams Obstetrics. 19th ed. Norwalk, CT: Appleton & Lange;1993:591, with permission.)

**FIGURE 35A.6.** A: The uterine artery and veins on either side are doubly clamped immediately adjacent to the uterus and divided. B, C: The vascular pedicles are doubly suture-ligated. (From: Cunningham FG, MacDonald PC, Gant NF, et al. Caesarean section and caesarean hysterectomy. In: Williams Obstetrics. 19th ed. Norwalk, CT: Appleton & Lange;1993:591, with permission.)
A curved clamp is swung in across the lateral vaginal fornix below the level of the cervix, and the tissue is incised medially to the point of the clamp. (From: Cunningham FG, MacDonald PC, Gant NF, et al. Caesarean section and caesarean hysterectomy. In: Williams Obstetrics. 19th ed. Norwalk, CT: Appleton & Lange;1993:591, with permission.)

After removal of the uterus and cervix, each of the angles of the lateral vaginal fornix is secured to the cardinal ligaments using the electrosurgical blade. A finger can be inserted into the vagina, and the cervix palpated directly to confirm its location. Once the specimen has been removed, the cervix should be inspected for any tissue remaining. After removal of the uterus and cervix, each of the angles of the lateral vaginal fornix is secured to the cardinal and uterosacral ligaments with a figure-of-eight or delayed absorbable suture. There is no unanimity of opinion regarding whether the vaginal cuff should be run and left open or closed. The vaginal cuff can be closed with interrupted figure-of-eight sutures. If there is continued oozing, as with a coagulopathy or in the presence of purulent fluid, then the vaginal cuff is left open to allow for adequate drainage. Hemostatic agents such as Gelfoam, with or without topical thrombin, or Surgicel can be considered. An intraperitoneal suction drain can prove helpful in monitoring patients who are at high risk of developing hematoma or abscess.

There is no consensus of opinion regarding reperitonization of the pelvis. It is not necessary in most cases. All pedicles should be closely inspected for bleeding before the abdominal incision is closed.

Subtotal Versus Total Hysterectomy

Some clinicians have a tendency to perform a subtotal or supracervical hysterectomy in most cases of emergency peripartum hysterectomy. There is a general belief that both operating time and blood loss are significantly lower with the subtotal technique. In addition, it is said that the risk of bladder or ureteral injury is less. There is no question that in the select patient who has been or is hemodynamically unstable, it may be prudent to perform a supracervical hysterectomy, especially if all bleeding has been controlled to that point. However, it is necessary to remove the cervix in cases of placenta previa or placenta accreta involving the lower uterine segment.

Despite the reputed advantages of a supracervical hysterectomy, there is evidence that performance of a complete hysterectomy with removal of the cervix adds little to either operating time or blood loss. Clark and associates reported no significant differences in mean values for blood loss and operating time in obstetric patients undergoing emergency total hysterectomy versus supracervical hysterectomy. Mean hospital stay also was not significantly different. However, the women in this study were not randomized to supracervical versus total hysterectomy. In 1998, Zorlu and associates also reported no significant difference between total and supracervical hysterectomy in operative time, blood transfusion, and mean hospital stay. It is important to separate emergency cesarean hysterectomy for hemorrhage, and so on, from elective peripartum hysterectomy for indications such as microminvase cervical cancer because the blood loss and other morbidity are generally significantly greater for the emergency procedure. A prospective, randomized study would be very helpful.

Episiotomy

An episiotomy is a surgical incision into the perineal body for the purpose of either aiding the actual delivery process or preventing tears and lacerations.

Incidence

The incidence or frequency of episiotomy varies according to parity, patient population, indication, and the health care provider practicing obstetrics. The use of episiotomy has significantly declined in recent years. In 1983, Thacker and Banta reported that about two thirds of all vaginal deliveries in the United States were associated with the performance of an episiotomy. However, more recently, Bansai and associates reported a decrease in the use of episiotomy from 86.8% to 10.4% between 1976 and 1994 at their institution. Among medical professionals, there is extreme variability in the use of episiotomy. In 2000, Robinson and associates evaluated 1,576 consecutive spontaneous vaginal deliveries and found that midwives had a lower incidence of episiotomy use (21%), followed by medical school faculty (33%). Private practice providers had the highest rate of episiotomy (55%). Other predictors of episiotomy were prolonged second stage of labor, fetal macrosomia, and epidural anesthesia. Hueston reported that nulliparity, use of forceps, or vacuum extraction also were predictors of episiotomy.

The literature is clear that the use of episiotomy, especially when associated with an operative vaginal delivery, is directly related to an increase in perineal sphincter injury. It has been suggested that given the morbidity associated with these injuries, that the combination of these two procedures be avoided, if possible.

Indications

The routine use of episiotomy with vaginal delivery has been strongly challenged. A recent Practice Bulletin from the
American College of Obstetricians and Gynecologists stated that the previously held ideas that episiotomy facilitated vaginal delivery, especially difficult or operative vaginal delivery, or improved neonatal outcome when expeditious delivery was indicated, are not supported by current evidence. Studies by Myles and Santolaya and Bodner-Adler and colleagues failed to show any reduction in anal sphincter damage, rectal mucocoe tears, or improved neonatal outcomes in women who underwent episiotomy.

In the past, it was thought that episiotomy prevented vaginal and perineal damage that led to subsequent pelvic relaxation. However, there is little evidence to support the premise that a "prophylactic" episiotomy prevents cystocele, rectocele, enterocele, urethral prolapse, vaginal prolapse, or stress urinary incontinence. Rockner and associates evaluated pelvic floor muscle strength using vaginal cones and found that women with episiotomies had less strength than those with spontaneous vaginal deliveries. Neural testing of the perineal muscle lature in other studies showed that the amount of denervation was associated with weight of the baby and the length of the second stage of labor, and was unrelated to episiotomy. Sleep and Grant looked at deliveries in those who restricted use of episiotomy and those who reported liberal use of episiotomy. Over 3 years of follow-up, there was little difference between the two groups in severity of incontinence or the reported incidence of incontinence. These studies indicate that episiotomy does not appear to prevent the physical/anatomic or symptomatic changes of pelvic relaxation.

In addition, there are no good data to support prophylactic episiotomy for the prevention of "trauma" to the fetus, especially the preterm fetus. Although there is no evidence that the risk of shoulder dystocia can be decreased by the use of an episiotomy, many experts feel that a generous episiotomy may help in the management of a shoulder dystocia when it presents.

In summary, current opinion does not support the routine use of episiotomy for vaginal delivery. Previous ideas that suggested episiotomy decreased the risk of perineal injury, reduced trauma of operative delivery, or improved neonatal outcome have not been supported by recent studies. An episiotomy undoubtedly provides more room for a difficult vaginal delivery. Such deliveries are inherently associated with an increased risk of fetal distress and maternal trauma. The obstetrician must individualize each patient and weigh the potential advantages of an episiotomy against the known risks of episiotomy or vaginal delivery without an episiotomy or even cesarean delivery.

### Midline Versus Mediolateral Episiotomy

There is little question that the midline perineal incision is easier to perform and repair, and is associated with less postoperative pain than the mediolateral episiotomy. In general, it is also associated with less blood loss and better anatomic results. Midline perineal incisions are used more frequently in the United States, whereas mediolateral episiotomy is used more commonly in Europe. The major disadvantage of midline episiotomy is an increased risk of third- and fourth-degree lacerations. Owen and Haush report that 20% of primigravid women with a midline episiotomy had a third- or fourth-degree laceration, compared with 9% of women with a mediolateral episiotomy and only 1%, when no episiotomy was performed. Of interest, multiparous women with a midline episiotomy had fewer third- and fourth-degree lacerations than those with a mediolateral episiotomy. Although these data appear to favor performing either a mediolateral episiotomy or no episiotomy at all, caution must be exercised when interpreting the data because this was not a randomized, prospective study, and it does not control for possible confounding factors. For example, patients who underwent episiotomy may well have had larger babies, a higher incidence of forceps assistance, or other characteristics resulting in an increased risk of laceration.

Although the mediolateral episiotomy may be associated with fewer third- and fourth-degree lacerations (at least in the primiparous patient) (Table 35A.4), there are several disadvantages to this technique. Blood loss is greater, mediolateral episiotomies are more difficult to repair, and anatomic results may be faulty. Postoperative pain also is more common and can be very troublesome. In the absence of good, prospective, randomized trials, the decision to perform a mediolateral or midline episiotomy must be based on clinical judgment and experience. A mediolateral episiotomy may provide more room for a difficult delivery with a lower risk of third- and fourth-degree laceration, but it also results in more blood loss and a greater risk of long-term dyspareunia.

### Episiotomy Repair

An episiotomy can be repaired in numerous ways. One popular method is to close the vaginal mucosa and submucosa with a continuous locking suture of 3-0 synthetic absorbable or chromonic suture or the chromic suture through the subcutaneous tissue and skin. In cases of fourth-degree lacerations, it is important to approximate the edges of the rectal mucosa with a running submucosal 3-0 or 4-0 delayed absorbable or chromonic suture through the subcutaneous tissue and skin. If the external anal sphincter is severed, it should be carefully reapproximated with several interrupted 2-0 sutures through the mucous and fibrous capsule. The technique for primary episiotomy closure is illustrated later in this chapter and is also discussed in Chapter 40.

Complications of Episiotomy

Extensions and Fistula Formation

The major complications of episiotomy include infection, hematoma, breakdown, and fistula formation. Probably the single most common complication is extension (i.e., third- or fourth-degree laceration). Extensions in turn can lead to incontinence of flatus and stool, rectovaginal fistula, and infection. The association of extensions with the type of episiotomy has been discussed already. In the report by Harris, 11.6% of the more than 7,000 women with midline episiotomies had a third- or fourth-degree laceration. In the women with these lacerations, 2% subsequently had poor sphincter tone, and 0.1% developed a rectovaginal fistula. Signorelli and colleagues performed a retrospective cohort study to evaluate the relationship between midline episiotomy and anal incontinence postpartum. Women with episiotomies had a higher risk of fecal incontinence 3 months and 6 months postpartum. Episiotomy tripled the risk of fecal incontinence at 3 months and 6 months postpartum and doubled the risk of flatus incontinence compared with women with spontaneous lacerations. In a prospective evaluation of 16,583 deliveries, Walsh and colleagues found that 0.56% of deliveries were complicated by third-degree lacerations. Lacerations were not prevented by episiotomy, but were associated with forceps delivery. Of the 81 patients followed, 30 had abnormal analorectal examination; 7% were incontinent of stool, and 12% were incontinent of flatus. Fistula is fortunately an uncommon complication of episiotomy. Causes include unrecognized lacerations in the rectovaginal septum at the time of episiotomy repair or infected hematoma. Risk factors for fistula formation include obesity, poor hygiene, malnutrition, anemia, history of inflammatory bowel disease, connective tissue disease, or prior exposure to radiation therapy. Half of those fistulae spontaneously heal, but repair should be considered if the patient is very symptomatic.

Dehiscence

The exact incidence of episiotomy dehiscence is unknown, but it appears to occur infrequently. In a review of 390 women with fourth-degree perineal lacerations, 18 (4.6%) experienced a dehiscence, and 11 of these were associated with infection. Several predisposing factors have been reported to be associated with episiotomy dehiscence, including infection, human papillomavirus, cigarette smoking, hematomta, or trauma. Infection is probably the most common factor. In the study by Ramin and associates, 86% of patients with midline episiotomy dehiscence and 69% of patients with mediolateral episiotomy dehiscence had evidence of infection that was based on the presence of fever or purulent discharge. Infection with human papillomavirus also has been reported by some to be associated with dehiscence. Although inadequate or “faulty” repair has been reported to be associated with dehiscence, this is a rare cause.

Early Repair of Dehiscence. In the past, it has been taught that repair of episiotomy dehiscence should be delayed for several months to allow for revascularization and healing. However, current surgical opinion supported by recent data favors early repair. Delayed repair is an inconvenience for the woman and may be associated with fecal incontinence and loss of sexual function. Delay also can increase the hospital stay, cost, and increase risk of litigation.

There are many advantages to early repair of episiotomy dehiscence. Hauth and colleagues reported on the efficacy and safety of early repair in eight women who had a dehiscence of a fourth-degree midline episiotomy. Early repair was successful in seven of the eight women. One woman developed a pinpoint rectovaginal fistula 4 days after early repair. This was fixed with a 3-cm rectal flap 4 months later.

Monberg and Hammen reported on the successful resurfacing of episiotomy breakdown in 20 women with infection, dehiscence, or both. Although four of the women had superficial resurfacing, all subsequently healed spontaneously. Hankins and associates updated the initial report by Hauth and colleagues to include 22 women with dehiscence of an initial fourth-degree repair, four with dehiscence of a third-degree repair and five with breakdown of a mediolateral repair. Initial success of early repair was achieved in 29 (94%) of 31 women. Two women with a pinpoint rectovaginal fistula were subsequently repaired with a rectal flap procedure. Of the 27 women with a follow-up of 1 year or greater, all were continent and had resumption of normal coital activity. The follow-up of the 22 women with early repair of episiotomy dehiscence revealed no complications in 18 patients. Occasional incontinence of flatus and stool, dyspareunia, dyschezia, and numbness occurred in the remaining patients. All of the symptoms resolved by 9 months, except for two patients who had persistent dyspareunia.

Ramin and coworkers reported on the early repair of 34 women with episiotomy dehiscence, most of whom were infected (Table 35A.3). These women received care from a large urban hospital serving primarily an indigent population. The timing of repair for dehiscence ranged from 3 to 13 days. Two women with initial third-degree episiotomy dehiscence had unsuccessful repairs. Thus, successful repairs were accomplished in 32 (94%) of the women. The average time from delivery to subsequent discharge after repair of the dehiscence was 15.5 days. This is similar to the time reported by Hankins and colleagues. This time probably can be shortened significantly with outpatient management of the wound and repair in ambulatory care units.

accomplished either on the ward with intravenous sedation or local anesthesia or in the operating room under regional anesthesia. All necrotic tissue and suture fragments should be removed and the wound irrigated with a diluted povidone-iodine solution or half-strength Dakin’s solution. Broad-spectrum antibiotics are indicated for overt infection or significant cellulitis. After initial debridement, the wound should be scrubbed and cleansed at least twice daily. Scrub brushes impregnated with povidone-iodine or gauze dressing pads can be used. A 1% lidocaine jelly is applied to the wound several minutes before cleansing, and analgesics should be used as necessary. The liberal use of sitz baths helps keep the wound clean.

Secondary repair of the episiotomy is not attempted until the wound is free of exudate and covered by granulation tissue. A mechanical bowel preparation with an oral electrolyte solution should be administered the evening before surgery for fourth-degree breakdowns. Prophylactic antibiotics are recommended for all repairs. One to three doses of a first-generation cephalosporin generally prove satisfactory.

The first step in the surgical repair of dehiscence is debridement of granulation tissue and dissection to ensure good tissue mobility. If the anal sphincter muscle has been severed, extensive retraction usually has occurred. It is important to identify the fibrous capsule and mobilize the muscle and capsule for successful reapproximation. If the rectal mucosa has been lacerated, it should be reapproximated as described in this chapter. In a prospective, randomized trial, Fitzpatrick and colleagues compared 55 women who underwent a sphincter overlap procedure with 57 women who underwent staple approximation repair of third-degree lacerations. In this study, there were no significant differences in anal manometry or endoanal ultrasound in the two groups. Therefore, either approach is acceptable. The rest of the closure is the same as for a secondary episiotomy repair. The secondary repair of a fourth-degree episiotomy breakdown is shown in Figures 35A.8 through 35A.11.

Postoperatively, women can be placed on a regular diet if the rectal mucosa is not involved. If the rectal mucosa is involved, a low-residue diet should be used for several days and advanced to a regular diet. Stool softeners may prove useful, but diarrhea should be avoided because of the increased likelihood of infection. Postoperative care should also include sitz baths and a heat lamp.

CERVICAL CERCLAGE

Premature dilation of the uterine cervix is a major cause of loss or delivery in midpregnancy. Although the pathophysiology of cervical insufficiency is poorly understood and the diagnosis challenging, data are ever involving regarding the management of this complex situation. The concept of cervical insufficiency, its diagnosis, and its management have been well reviewed in a Practice Bulletin issued by the American College of Obstetricians and Gynecologists. Although a variety of diagnostic criteria—including prior midtrimester losses and history of cervical surgery (including loop electrode excision procedure or cone biopsy) and painless dilatation of the cervix—have been used in the past and serve as useful clinical risk factors, today ultrasound monitoring of cervical length and funneling are usually used to make a diagnosis of cervical insufficiency.
Shirodkar first described cerclage placement in 1955 as a new method to prevent habitual abortion in the second trimester. McDonald, in 1957, reported a simplified technique. The technique for the abdominal approach for cerclage was described by Benson and Durfer in 1963. Data regarding the efficacy of cerclage placement has been conflicting. The Cervical Insufficiency Prevention Randomized Cervical Trial (CIPRACT) concluded that serial ultrasounds for evaluation of cervical insufficiency with secondary intervention is a safe alternative to traditional prophylactic cerclage. Cerclage is rarely performed after 24.5 weeks' gestation because the risks of surgery are outweighed by the benefits of bed rest for a few weeks to achieve improved fetal survival. Zaveri and colleagues noted that transabdominal cerclage may be associated with a lower risk of perinatal death, but has a higher risk of intraoperative complications. Data suggest that an abdominal cerclage may be preferable in patients in whom a transvaginal cerclage has failed. The abdominal approach is also indicated in patients whose cervix has been shortened significantly by cone biopsy or other surgery. Laparoscopic transabdominal suture insertion during and before pregnancy has recently been described. Recent case reports suggest that placement of the abdominal cerclage by a laparoscopic approach is safe and may reduce maternal recovery time; however, its efficacy over the additional abdominal approach has not been examined. Studies have supported the uses of cerclage for pregnancy prolongation in singleton gestations; however, there are conflicting data about its utility in multiple gestations.

**Technique**

The modified Shirodkar and the McDonald procedure are performed using the transvaginal approach. In the *modified Shirodkar approach*, a transverse incision is made in the vaginal mucosa of the anterior cervix to allow for upward displacement of the bladder to avoid injury. A posterior incision is made in similar fashion to avoid entry into the rectum. The lateral angles of the anterior and posterior incisions are then expanded with blunt fingertip dissection of the lateral cervix (Fig. 35A.12). A 5-mm woven Mersilene tape on a large needle (Ethicon, USA) is then passed through the submucosal tunnel from anterior to posterior on both sides of the cervix. It is preferable to avoid entering the cervical canal because the tape may irritate the fetal membranes; this can be done by placing an index finger in the cervical canal as the needle is passed through the lateral cervix. The lateral cervical mucosa at 3 and 9 o'clock can also be grasped with an Allis clamp or ring forceps as shown in Figure 35A.12 to facilitate placement of the sutures. After the suture is placed on both sides of the cervix, the knot is tied in the posterior defect. The defects are then closed with 3-0 Vicryl in figure-of-eight fashion. We usually leave a whisker of the Mersilene band extending through the anterior colpotomy associated with the anterior colpotomy associated with the modified Shirodkar cerclage only increased the distance from the external os by 2.7 mm. Rust and colleagues noted that the anterior colpotomy associated with the modified Shirodkar cerclage on a large needle is placed in a purse-string fashion and tied securely (Fig. 35A.13).

Proponents of the modified Shirodkar feel that cervical dissection assists in placing a higher cerclage, but Rozenberg and associates noted that the anterior colpotomy associated with the modified Shirodkar cerclage on a large needle is placed in a purse-string fashion and tied securely (Fig. 35A.13).

The McDonald approach requires no dissection into the cervical tissues. A suture of braided Mersilene or a heavy monofilament suture (Prolene) may be placed around the cervix in purse-string fashion and tied securely (Fig. 35A.13).

Placement of the abdominal cerclage traditionally has required a low transverse abdominal incision, usually performed by Pfannenstiel technique. The vesicouterine peritoneum is incised in transverse fashion to allow for retraction of the bladder inferiorly. A suture of 5-mm Mersilene is placed through the broad ligament close to the cervical stroma with care taken to avoid the uterine vessels. The suture is then tied securely. Unlike the transvaginal cerclage, the suture cannot be removed vaginally; thus, the patient requires a cesarean delivery. This suture may be left in place until childbearing is complete.
products of conception, uterine atony, or coagulation defects. Aggressive fluid replacement and oxytocic agents are indicated while a diagnostic evaluation is undertaken. Uterine packing has recently been rediscovered as an effective way to treat hemorrhage from uterine atony.

Transcatheter arterial embolization may be very effective to control postpartum hemorrhage. Bilateral uterine artery or hypogastric artery embolization is recommended. This technique is highly effective, preserves the uterus, and does not preclude future pregnancies.

Surgical techniques for the management of peripartum hemorrhage include uterine artery ligation, hypogastric artery ligation, B-Lynch compression sutures, and hysterectomy. Emergency hysterectomy for hemorrhage is associated with a significantly increased risk of complications, including urinary tract injury and infection. It is not clear whether elective hysterectomy performed at the time of a scheduled cesarean delivery is associated with increased morbidity, but blood loss and risk of transfusion are increased, and delivery followed by hysterectomy 3 to 6 months later may be considered as an alternative.

The use of episiotomy has declined significantly in recent years. Recently, studies have not shown any benefit of episiotomy in reducing the risk of third- and fourth-degree lacerations, reducing the risk of long-term pelvic support defects, or improving neonatal outcome. Episiotomy should not be used routinely. Median episiotomy is associated with a higher risk of anal sphincter and rectal injury. Medial-lateral episiotomy is associated with increased blood loss and perhaps an increase in postpartum pain and long-term dyspareunia. Repair of episiotomy, especially if there is rectal or sphincter injury, should be done meticulously, using good surgical technique with adequate anesthesia and sterile technique.

Surgical treatment of cervical insufficiency is complicated by a poor understanding of the pathophysiology of the condition. Painless dilatation and effacement of the cervix in the second trimester, usually documented by ultrasound, is an indication for treatment. Both the McDonald and Shirodkar techniques have been used successfully. An abdominal cerclage may be considered if the cervix has been shortened or damaged by surgery or trauma.

CHAPTER 35B ■ OVARIAN TUMORS COMPLICATING PREGNANCY

CORNELIA R. GRAVES AND LYNN PARKER

DEFINITIONS

Aminopterin syndrome—Fetal anomalies caused by exposure to antifolate chemotherapy in the first trimester. Multiple fetal anomalies commonly include growth deficiency, craniofacial anomalies, hydrocephalus, mental retardation, and skeletal defects.

Hyperreactio luteinalis—A benign, frequently large (15–20 cm), usually bilateral ovarian enlargement caused by an increased sensitivity to human chorionic gonadotropin (hCG). These masses are composed of numerous luteinized follicular cysts and are more common in conditions in which the hCG is increased (e.g., hydatiform mole, multiple gestation). This condition is benign and will resolve spontaneously after pregnancy.

Luteoma of pregnancy—A solid, usually unilateral ovarian mass found in late pregnancy or at cesarean delivery. It may cause virilization. It is benign and resolves spontaneously after pregnancy.

Pulsatility index (PI)—An arterial waveform index that has shown to be useful in differentiating benign from malignant adnexal masses. A PI > 1.0 is almost always associated with a benign mass. A PI < 1.0 is suggestive of malignancy but can be seen in a corpus luteum cyst or an inflammatory mass.

The coexistence of an adnexal mass with pregnancy presents problems to both the clinician and the patient, the most serious being that of malignancy. This possibility must be discussed with the patient when obtaining informed consent before surgery. The therapeutic implications of possible hysterectomy with loss of the current pregnancy and loss of future fertility result in an emotionally charged environment because of the young age of the patient and the desire to preserve the ovaries.

The appropriate diagnosis of ovarian tumors complicating pregnancy depends on the use of certain windows of opportunity. These include the initial pelvic examination in the first trimester, the initial ultrasound, and careful evaluation at the time of operative intervention. A thorough pelvic examination at the time of termination of pregnancy and careful examination of the ovaries at the time of cesarean section or postpartum tubal ligation are other opportunities to evaluate the ovaries. The increasing (nearly routine) use of ultrasound examination affords an excellent opportunity for the diagnosis of coexistent ovarian pathology; it is for this reason that such an examination should always include the adnexa. The results of ultrasound, although potentially very useful in the relatively rare patient with an ovarian malignancy, may give the clinician a difficult dilemma trying to decide how to proceed when an ovarian cyst is diagnosed in pregnancy.

The increasing (nearly routine) use of ultrasound examination affords an excellent opportunity for the diagnosis of coexistent ovarian pathology; it is for this reason that such an examination should always include the adnexa. The results of ultrasound, although potentially very useful in the relatively rare patient with an ovarian malignancy, may give the clinician a difficult dilemma trying to decide how to proceed when an ovarian cyst is diagnosed in pregnancy.

Cancer complicates 1:1,000 pregnancies in the United States. The most common malignancies seen in pregnancy include malignant melanoma (1.2:1,000), Hodgkin lymphoma (1:1,000–6:000), breast cancer (1:3,000–10,000), cervical cancer (1.2:10,000), ovarian cancer (1:10,000–100,000), colorectal cancer (1:13,000), and leukemias (1:75,000–100,000).

Benign ovarian tumors complicating pregnancy are more common. The exact incidence, however, depends on whether one considers simple cysts noted on ultrasound examination (1 in 50 live births) or during pelvic examination (1 in 80 live births) or those that ultimately require laparotomy (1 in 1,000–4 in 1,500 live births). Ueda and Ukita reported 106 patients who required ovarian surgery during pregnancy. Of these patients, 29.2% had physiologic ovarian cysts, 46% were benign, and 4.7% were malignant. More recent observations have noted that adnexal masses >5 cm were observed in 0.05% of patients, with 6.8% of masses and 0.0032% of deliveries diagnosed as malignant.

Koonings and colleagues noted the incidence of ovarian tumors complicating cesarean section to be about 1 in 200 cesarean births, and Ballard observed that ovarian tumors complicated termination of pregnancy in 1 of 594 procedures. Hill and colleagues reported that ovarian cysts were diagnosed in 4.1% of second- or third-trimester ultrasounds. Most of these cysts were <3 cm and resolved spontaneously. Eighteen of the 7,996 patients had an exploratory laparotomy, which was equivalent to one surgery in 444 deliveries. All of these lesions were benign on pathologic examination.
required surgical intervention. Hogston and Lifford, in a review of 24,000 patients who received routine ultrasound, noted an incidence of cyst formation of 0.52%. All complex cysts and those > 6 cm were operated on primarily (10%). Eighty-five percent of the remaining patients who were followed conservatively showed a spontaneous resolution, with the exception of five patients who ultimately required laparotomy.

Surgery is generally postponed because of the importance of sonostructural diagnosis of adnexal masses during pregnancy. They evaluated all patients with an adnexal mass measuring 4 cm or greater noted beyond 12 weeks’ gestation. One hundred and thirty-one lesions were noted; of these, 89.3% were accurately diagnosed as benign. Of the 10.7% of patients with sonographic characteristics of malignancy, 1 of 14 (7%) of these patients had ovarian cancer, for a 0.8% malignancy rate in this study.

Doppler sonography also has been evaluated for use in complex adnexal masses in pregnancy. Wheeler and Fleischer evaluated 14 pregnant patients with complex adnexal masses. Diagnosis was made by color Doppler sonography was compared with actual histopathologic diagnosis. Three malignant and five low malignant potential tumors were correctly identified by Doppler with a sensitivity of 0.89 and a mean pulsatility index (PI) of 0.71. The mean PI for benign lesions was > 1, and the negative predictive value for PI < 1 was 0.42, indicating that some benign lesions were incorrectly classified as malignant when a PI < 1 is used as a cutoff for possibly malignant tumors. However, color Doppler appears to be highly predictive of a benign lesion when the PI is > 1.

From a treatment standpoint, the first trimester is clearly the best time to diagnose an adnexal mass complicating pregnancy. Because tumors are rarely symptomatic during this period, most such tumors are discovered by ultrasound examination (and then typically noted at cesarean section). With the increasing incidence of ultrasound examination and use of cesarean section, recent articles suggest that about only 30% of ovarian tumors complicating pregnancy are symptomatic. When symptomatic, the patient typically presents with abdominal pain, abdominal distention, and vague gastrointestinal symptoms. All these symptoms can be directly attributable to pregnancy itself; therefore, it is not surprising that most pregnant women with these symptoms are not evaluated for an ovarian tumor.

Ovarian tumors complicating pregnancy can be divided into three groups, depending on the severity of presentation.

- Those who are asymptomatic
- Those with symptoms compatible with torsion
- Those with catastrophic presentations consistent with hemorrhage, rupture, and shock

A successful outcome for both mother and fetus depends on a high index of suspicion with early diagnosis. One should consider an ovarian mass in any woman who experiences abdominal pain in pregnancy. Furthermore, torsion, rupture, infection, or hemorrhage of an ovarian tumor should be included in the differential diagnosis of any catastrophic abdominal obstetric event. This is particularly true during times of rapid change in uterine size or position (e.g., 8–16 weeks), during termination of pregnancy, during labor and delivery, or in the immediate postpartum period.

The incidence of torsion complicating an ovarian tumor in the nonpregnant state is about 2%. Torsion complicating an ovarian tumor is much higher (52%) and varies from 11% to 50%. Ueda and Ueki report a 21.8% rate of torsion in ovarian tumors in pregnancy. Other recent studies in which there is a high incidence of incidental asymptomatic tumors report much lower incidences of torsion, rupture, and dystocia. Nevertheless, it is clear that the unrecognized symptomatic ovarian tumor complicating pregnancy can become catastrophic, accompanied by hemorrhage, shock, peritonitis, or death. Wang and colleagues retrospectively evaluated 174 patients who underwent surgery for ovarian masses during pregnancy. These patients were divided into two groups: those with emergency surgery (12 patients) and those with elective surgery (142 patients). They found in the emergency surgery group that half of the surgeries occurred in the first trimester; they contributed to 75% of total fetal wastage and 87% of spontaneous fetal loss; and tumor sizes were significantly larger. In their experience, lesions with sonographic characteristics of malignancy were correctly identified with a sensitivity of 0.89 and a mean pulsatility index (PI) of 0.71. The mean PI for benign lesions was > 1, and the negative predictive value for PI < 1 was 0.42, indicating that some benign lesions were incorrectly classified as malignant when a PI < 1 is used as a cutoff for possibly malignant tumors. However, color Doppler appears to be highly predictive of a benign lesion when the PI is > 1.

Ovarian Tumors Complicating Pregnancy

Pathology

Benign neoplasms complicating pregnancy include two tumor-like conditions with which every gynecologist should be familiar. Hyperreactio luteinalis (first described by Burger in 1938 as a grossly multilocular, usually bilateral ovarian enlargement, often 15–20 cm in size) is a term used to describe numerous luteinized follicular cysts of the ovary complicating pregnancy (Fig. 35B.1). Microscopically, one notes extensive luteinization of the theca and granulosa cell layers. Bradshaw and associates suggest that the hyperandrogenicity seen in this condition is related to increased ovarian sensitivity to human chorionic gonadotropin (hCG). Therefore, it is seen in conditions in which the hCG is elevated, such as molar pregnancies, multifetal pregnancies, choriocarcinoma, and erythroblastosis fetalis. Hyperreactio luteinalis also has been associated with normal pregnancy, and, in these patients, it has not been associated with fetal virilization. These tumors spontaneously regress after delivery but may take up to 6 months to resolve. Hyperreactio luteinalis may also occur in subsequent pregnancies.

Luteoma of pregnancy is a specific benign, usually unilateral, solid lutein cell tumor of the ovary found in late pregnancy, often noted at cesarean section (Fig. 35B.2). First described by Sternberg in 1966, this tumor is grossly bossedated, soft, fleshy, yellow, or hemorrhagic. Microscopically, it exhibits an acidophilic granular cytoplasm with sparse lipid formation and a distinctive reticular pattern. It is likely the most common cause of maternal virilization during pregnancy. The etiology is unknown, but theories have included luteinized stromal cell present before pregnancy that respond to hCG or “hyper-luteinized” theca cells, granulosa cells, or a combination of the two. Fifty percent of female infants born to virilized mothers with pregnancy luteoma exhibit signs of virilization.

The most common benign neoplasm of the ovary in pregnancy is the benign cystic teratoma, which accounts for about one third of all benign ovarian tumors seen in pregnancy (Fig. 35B.3). The second most common group of ovarian tumors complicating pregnancy is that of cystadenomas. These represent about 15% of tumors (Fig. 35B.4). Endometrioma, endometriosis, cystadenofibromas, and solid, multilocular cysts, corpus luteal cysts, tubal cysts, myomas, and other miscellaneous lesions constitute the remaining types of tumors seen in pregnancy (Table 35B.1).
Malignant ovarian tumors constitute only about 1% to 2% of all adnexal masses that complicate pregnancy and require surgical exploration. The single most common malignant ovarian tumor complicating pregnancy probably is dysgerminoma. Malignant tumors of epithelial origin as a group, however, are more common; tumors of low malignant potential occur most frequently (Fig. 35B.3). Sex-cord stromal tumors are the third most common primary malignant ovarian neoplasms, representing about 17% to 20% of such tumors. Krukenberg and other metastatic tumors represent about 12% to 13% of malignant ovarian neoplasms complicating pregnancy. Whether malignant or benign, most ovarian tumors complicating pregnancy are unilateral. Karlen and associates reported 90% of dysgerminomas in pregnancy to be unilateral, and Young and colleagues reported 35 of 36 sex-cord stromal tumors to be unilateral when complicating pregnancy. Even malignant tumors of epithelial origin noted during pregnancy are unilateral in 90% of cases. The rarer germ cell tumors, such as endodermal sinus tumors, virtually always are unilateral as
The benign cystic teratoma is the most common benign neoplasm of the ovary complicating pregnancy. This tumor has undergone torsion and infarction. It is also interesting that most bilateral tumors occurring in pregnancy are not malignant; these include benign cystic teratoma, endometriosis, and hyperreactio luteinalis. The most common bilateral malignant ovarian tumors are the metastatic Krukenberg types. Somewhat less common are primary malignant tumors of epithelial origin.

Virilization secondary to an ovarian tumor sometimes complicates pregnancy (Fig. 35B.6). The classic painting titled Magdalena Ventura with Husband and Son, painted in 1631 by Ribera, documents such a problem (Fig. 35B.7). Magdalena, after having several children, became virilized at age 37, with apparent infertility thereafter. However, when she was 52, a son was born. One would speculate that she probably had an ovarian Sertoli-Leydig cell tumor. Young and colleagues have noted that although about 50% of Sertoli-Leydig cell tumors in the non-pregnant state are functional, only about 15% of those complicating pregnancy result in maternal virilization. They proposed two possible explanations for this apparent decrease in virilization. The first is that the most active of such tumors result in anovulation; therefore, women with virilizing tumors rarely become pregnant. The second is that the placenta may aromatize the tumor-produced androgens into estrogens. In any event, Sertoli-Leydig cell tumors are not the most common tumors in pregnancy associated with virilization. This distinction falls to those tumors associated with a functioning ovarian stroma.

The most common virilizing ovarian tumor that complicates pregnancy is a mucinous cystadenoma (Fig. 35B.4). Tumors of epithelial origin are the second most common benign neoplasm of the ovary complicating pregnancy. Mucinous tumors are relatively more common in pregnancy.
pregnancy is the luteoma, followed by Krukenberg tumors and mucinous epithelial tumors (Table 35B.2).

The clinical implications of virilizing tumors complicating pregnancy are somewhat different from those of such tumors in the nonpregnant state. Virilization usually occurs late in pregnancy, is of short duration, and usually is reversible. The majority of such cases, as mentioned, are secondary to luteoma; therefore, they resolve spontaneously. If sex-cord stromal or epithelial tumors are present, the ultimate outcome remains quite good. However, patients with Krukenberg lesions have a poor outcome.

Malignancies also can be metastatic to the placenta or products of conception. Although this is an uncommon occurrence, tumors that may metastasize to the placenta include malignant melanoma, leukemias and lymphomas, breast carcinoma, lung carcinoma, and some sarcomas.

THERAPY

The first successful oophorectomy for an ovarian tumor complicating pregnancy was performed in 1846 by Bund. Although the woman survived, the fetus aborted at 12 weeks' gestation.

At about the same time, J. Marion Sims was the first to successfully remove an ovarian tumor in a pregnant woman and to have both the woman and fetus survive. As late as 1906, McKerran reported a 21% maternal mortality rate and a 50% fetal mortality rate with surgical management of ovarian tumors in pregnancy.

In general, one should avoid elective surgery in the first trimester, because many lesions represent the cystic corpus luteum of pregnancy and resolve spontaneously. Therefore, ultrasound should be repeated in 6 weeks to determine if the mass is persistent before considering surgical intervention. Buttery and colleagues noted an abortion rate of about 30% in those patients operated on in the first trimester, so first-trimester procedures are high risk. Nevertheless, symptomatic, complex, bilateral, and solid tumors should be operated on immediately (Fig. 35B.8). Preoperative evaluation should be limited to careful clinical evaluation and pelvic ultrasound examination. Barium enema, computed tomography, and other such studies are best avoided. Magnetic resonance imaging can be used safely in pregnancy but has not been helpful in evaluation of adnexal masses.

Tumor markers such as CA-125 generally are not helpful in pregnancy, because they can be elevated as a result of the

Pregnancy itself. Alpha fetoprotein is heterogenous, and the yolk sac variant can be separated by affinity chromatography to determine if the elevation is due to the yolk sac or liver variant. Lactate dehydrogenase (LDH) can be produced by dysgerminomas. Except in preeclampsia, LDH levels should remain within normal limits in pregnancy.

Wang and colleagues, in their evaluation of surgical management of ovarian masses in pregnancy, found that elective surgery had a much lower rate of fetal wastage and was more likely to occur in the second trimester. Therefore, elective management of adnexal masses in pregnancy appears to be safer than awaiting symptoms or emergency intervention.

The optimum time for surgical intervention is 16 to 18 weeks. In general, the first trimester should be avoided if possible because of the naturally occurring high rate of spontaneous abortion. It is difficult to avoid the conclusion that any pregnancy loss occurring within a short time of surgery is related to the surgery, so that if it is possible to wait until the second trimester, the risk of an unrelated spontaneous abortion is decreased. Patients in whom the asymptomatic mass is noted at or near term may be considered for delivery by cesarean section with careful intraoperative evaluation of the adnexa. Vaginal delivery in this situation has been associated with torsion, rupture, and hemorrhage that can occur during labor or immediately postpartum. The size and ultrasound characteristics of

The mass will help to guide the clinician’s decision concerning the best route of delivery. Caapi and colleagues described conservative management of 63 patients who had dermoid cysts ≤ 6 cm. None of these patients had an increase in size of the dermoid during pregnancy. In this study, 55 patients had normal vaginal deliveries, and none had complications related to the cyst. They also evaluated the use of ultrasound-guided cyst aspiration in patients with persistent simple cysts into the second trimester. In this study, 50% of the patients avoided surgical intervention with this procedure. Every case of an adnexal mass should be independently evaluated to determine the best management.

General anesthesia is the anesthesia of choice, although a combination of epidural and general anesthesia can be considered. One should remember that delayed gastric emptying and esophageal reflux can occur in pregnancy; therefore, appropriate precautions are necessary. One also should be aware of and prevent vena caval and aortic compression.

The next consideration is laparoscopy versus laparotomy as primary surgical management. Several case series have evaluated the safety and efficacy of laparoscopic management of adnexal masses in pregnancy. These studies have shown that laparoscopic surgery can be used without increased risk to mother or fetus. Moore and Smith evaluated 14 patients with adnexal masses treated with laparoscopy. The average gestational age was 16 weeks, with average operating time of 84 minutes. The tumors included three mucinous cystadenomas, three mature teratomas, three functional cysts, and one endometrioma. Three patients had tumors > 10 cm; the remainder were > 7 cm in size. There were no postoperative complications, except for one case of mild peritonitis that spontaneously resolved. Laparoscopy should be considered early in the second trimester if the mass is mobile, accessible, and does not have characteristics of malignancy such as ascites or calcification.

If laparotomy is the chosen surgical approach, a vertical incision is preferred, because after 16 weeks’ gestation, the ovary is an abdominal rather than pelvic structure. The incision should be placed higher than usual. Thorough gross examination of the lesion, with frozen section— as well as evaluation of the upper abdomen, omentum, and paraaortic nodes—should be performed, along with pelvic washings. The involved ovary should be sent for frozen section to establish a preliminary diagnosis. The contralateral ovary should be carefully inspected. However, biopsy or wedge resection of the contralateral ovary should be avoided if no gross evidence of involvement is present. One possible exception is if the primary tumor is a dysgerminoma, because these tumors can involve the contralateral ovary in a clinically undetectable, microscopic manner. If the patient has a malignant germ cell tumor or low malignant potential tumor, staging should be performed to include omentectomy, peritoneal biopsies, and pelvic and paraaortic lymph node biopsies on the side of the mass. If the tumor is mucinous, either cystadenoma or low malignant potential tumor, an appendectomy should be performed.

The uterus should be handled gently in any case, and frequent irrigation should be used to prevent the tissue from drying. When ovarian cystectomy is required, an interval closure with use of a 3-0 absorbable is recommended. Alternatively, one can decide to perform no closure. The traditional Buxton-type closure should be avoided.

Before the decision is made to perform oophorectomy, one must always consciously exclude hyperreactio luteinalis and luteoma of pregnancy. Furthermore, because most malignant ovarian tumors are unilateral, total abdominal hysterectomy and bilateral salpingo-oophorectomy is rarely indicated (Fig. 35B.9). Total hysterectomy and removal of ovaries should never be performed on the basis of a frozen section diagnosis of borderline or low-grade malignancy unless the patient has clearly expressed a desire to abort this pregnancy and does not wish to preserve fertility and ovarian function.

When faced with a clearly malignant bilateral or metastatic tumor, one usually treats the patient as if she were nonpregnant, with total hysterectomy, bilateral salpingo-oophorectomy, pelvic and abdominal washings, omentectomy, and pelvic and paraaortic node biopsies. Even with bilateral malignant disease, one can consider omitting hysterectomy if the uterus is not grossly involved, thus allowing preservation of the existing pregnancy, especially because platinum-based chemotherapy can safely be given during pregnancy. Although
other tumors are known to metastasize rarely to either the placent or fetus, primary ovarian tumors almost never do so. All the possible findings at surgery and possible surgical management options should be carefully discussed with the patient, and a good understanding of the planned therapy should be agreed on by all. A careful preoperative note about the discussion should be made in the patient's chart. The family should be informed of the findings and plans during the course of surgery, and consultation should be obtained if necessary. The role of progesterone to prevent labor in the postoperative period is unclear but should be considered if the surgery occurs in the first trimester. The patient should be monitored for contractions and fetal heart tones checked in the postoperative period. If contractions occur, these can be treated with hydration, sedation, indomethacin (if before 32 weeks), or standard tocolytic therapy.

**TREATMENT OUTCOME**

Conservative surgical treatment outcome for benign disease should be excellent. With malignant disease, the overall 5-year survival rate depends on stage and cell type. In a classic paper on ovarian cancer in pregnancy, Novak and associates reported a 5-year survival rate of 75% from the Johns Hopkins Hospital. In a review of 27 dysgerminomas, Karlen and associates reported a tendency toward local recurrence with conservative treatment but an overall 5-year survival rate of 90%. Young and coworkers, in a review of 36 sex-cord stromal tumors, noted a 5-year survival rate of 100%, although they cautioned that granulosa cell tumors are prone to late recurrence. However, patients with Krukenberg tumors or metastatic disease have a poor prognosis.

Fetal mortality also should be minimal with early diagnosis and appropriate surgical intervention. Although Karlen and associates reported a fetal mortality rate of 25%, two of the five deaths were secondary to hysterotomy. Young and colleagues reported three fetal deaths in 36 cases, two of which resulted from hysterectomy. Ueda and Ueki reported on 106 surgeries with a spontaneous abortion rate of 10%. Two patients desired termination of pregnancy in the second trimester owing to ovarian diagnosis, and one fetus died despite intensive efforts.

**CYTOTOXIC CHEMOTHERAPY DURING PREGNANCY**

At no time is the treatment of cancer during pregnancy more complicated than when adjunctive therapy is indicated.
Can such therapy be given safely during pregnancy? Although single-agent or combination chemotherapy may be teratogenic in the first trimester, it is now apparent that cytotoxic chemotherapy can be used safely in the second and third trimesters. Antimetabolite therapy, including both aminopterin and methotrexate, has been shown to be associated with an increased rate of congenital abnormalities. The aminopterin syndrome—which consists of cranial dysostosis, hypopituitarism, anomalies of the external ear, micrognathia, and cleft palate—has occurred in the fetuses of about 20% of patients treated in the first trimester. Staging biopsy for frozen section is indicated. If metastatic cancer is diagnosed, conservative therapy offers a good prognosis. Delivery may be delayed, and further surgery may be unnecessary.

The best time for surgery is 16 to 18 weeks. General anesthesia is recommended. Laparoscopy may be preferable if laparoscopy can be used for similar findings in a non-pregnant patient. A conservative approach is advised. Most ovarian masses in pregnancy are benign. If the lesion is unilateral and other malignancies are excluded, ovariectomy is indicated. Staging biopsies and washings are done, and final treatment plans are deferred pending a definitive pathology diagnosis. If metastatic cancer is diagnosed, debulking can be done and the pregnancy continued while the patient is started on chemotherapy. Careful consideration of all options should be discussed with the gynecologic oncologist, the maternal fetal specialist, and the patient and her family.

Best Surgical Practices

Other Issues Surrounding Malignancy

Symptom control is very important in pregnant patients with malignancy. Symptoms commonly seen in malignancy include pain, nausea, vomiting, anorexia, dyspnnea, fatigue, and depression. Oxycodone, hydrocodone, with acetaminophen can be used safely for pain. Codeine should be avoided in the first trimester because of possible fetal malformation. Opiates can be used, but the neonate should be monitored for withdrawal after delivery. For nausea, options include chlorpromazine, prochlorperazine, prednisone, metoclopramide, and ondansetron. Morphine and albuterol have been successfully used to control dyspnea in patients with malignancy. Forty percent of patients with advanced cancer have depression. Fluoxetine and other antidepressants have been used in pregnancy; the risks and the benefits should be discussed with these patients before starting them on medications.

SECTION VII  ■  SURGERY FOR CORRECTIONS OF
DEFECTS IN PELVIC SUPPORT AND PELVIC
FISTULAS
CHAPTER 36A ■ PELVIC ORGAN PROLAPSE: BASIC PRINCIPLES

CARL W. ZIMMERMAN

The judgment as to surgical correction should depend upon a correlation of the history and physical findings. Even marked prolapse in the absence of complaint should rarely be corrected. The patient should ask the gynecologist for relief; the gynecologist should not urge the patient to have corrective surgery if she does not feel sufficiently uncomfortable to request it.

—Richard Te Linde, 1966

DEFINITIONS

Endopelvic fascia—The deep endopelvic connective tissue located between the dependent portion of the pelvic peritoneum and the superior fascia of the pelvic diaphragm. This continuum of tissue serves to support, suspend, and separate the central pelvic organs.

Kegel exercise—Voluntary contraction of the pelvic diaphragm, primarily the puborectalis muscle, and the external anal sphincter.

Interspinous diameter—The distance between the ischial spines and the narrowest diameter in the human pelvis. The components of the deep endopelvic connective tissue suspend the cervix and pericervical ring within this plane in normal anatomy.

Pelvic diaphragm—The skeletal muscles of the pelvic floor and their parietal fasciae. These muscles cover the majority of the pelvic outlet. These muscles originate on the pelvic sidewall and insert on the sacrum, coccyx, or sacrococcygeal raphe.

Rugae—Transverse creases in the vaginal wall that signify the presence of deep endopelvic connective tissue. Conversely, the absence of rugae implies the absence of deep endopelvic connective tissue.

Urogenital hiatus—The large central opening in the pelvic diaphragm. The vagina, urethra, and anus exit the pelvis through this structure.

Uterosacral ligaments—The primary apical suspensory elements of the uterovaginal complex. They extend from the pericervical ring to the presacral peristeum and hold the cervix behind the urogenital hiatus.

Vakalba maneuver—Pressure exerted downward on the pelvic floor by fixing the respiratory diaphragm and the anterior abdominal wall.

BASIC CONCEPTS

Pelvic organ prolapse is the downward displacement of structures that are normally located at the level of or adjacent to the vaginal vault. Because these displacements are each associated with defects in integrated connective tissue structures, they may each be considered a pelvic hernia. These conditions are common and affect a progressively larger percentage of women as age advances. Whereas mortality from this condition is negligible, significant morbidity or deterioration of lifestyle may be associated with prolapse. Women in developed countries who have access to modern health care can benefit from the advances that have been made in treating prolapse. If the problem is viewed from a worldwide perspective, however, the scope of suffering is much greater. In areas of high parity and little or no access to health care, countless women suffer from problems associated with pelvic organ prolapse with no real possibility of resolution. The direct effect that these conditions have on urinary, gastrointestinal, and sexual functions can only be appreciated by those women burdened with these problems on a daily basis.

Treatment of pelvic organ prolapse and the associated symptoms constitutes a major subject in gynecology. Especially in the advanced state, management of these conditions is one of the most challenging problems a pelvic surgeon can face. Indeed, success in treating prolapse is frequently used to judge the overall skill of those surgeons. Providing permanent relief from this classic malady by restoring normal anatomy and maximum physiologic function always tests the ingenuity of gynecologists. As medical sophistication has progressed, so has the ability to understand more completely and better treat pelvic organ prolapse.

A brief review of the history of treatment of prolapse is helpful in understanding modern treatments and current concepts of these conditions. Because it was mentioned in the writings of Hippocrates and Galen, prolapse was clearly known to the ancients. Early treatments may seem quaint by today's standards. Yet some of these interventions continue to be used today. Fortunately, others have not survived. Vaginal packing, tampons, massages, and exercises were used with some success. Other patients were suspended from their feet for a period of 24 hours to treat prolapse. Rodericus A. Castro advised that prolapse should be attacked with a red hot iron as if to burn it, “when fright would cause it to recede into the vagina.” Various caustics were used, including silver nitrate, nitric acid, acid nitrate of mercury, hot metal, and sulfuric acid.

Perhaps the first real advance in treatment was the development of pessaries. These devices functioned as trusses. Their fitting and placement became a desirable skill. They continue to bring relief to a large number of women and seldom do any serious harm. They were especially popular in the middle of the 19th century. Some were held in place by waistbands. In some cases, pessaries were deliberately left in place until erosion occurred. The subsequent healing was expected to reduce the caliber of the vagina with scarification adding to support, but serious complications could occur. Reports exist of neglected pessaries being retrieved from the peritoneal cavity and bladder. Fistulae may also occur.
The earliest surgical attempts to relieve prolapse were relatively simple. These procedures included labial suturing and removing portions of the vaginal epithelium to reduce the caliber of the vagina. Although Heming operated on the anterior vaginal wall in 1831, surgery for uterovaginal prolapse was not common until the advent of anesthesia and antisepsis in the middle of the 19th century. The first vaginal hysterectomy for prolapse was performed by Samuel Chappuis of New Orleans in 1861. Many years passed before this surgical technique became common. By the beginning of the 20th century, European and American reports of hysterectomy, colpohysterectomy, cervical amputation, transposition/interposition operations (Manchester-Foley, colpotomy, vaginal platypodia, colpocleisis), vaginal fixation of the uterus to the abdominal wall, and trachelectomy for procidentia were being published. The timing of this ingenuity was certain to be consistent with the development of anesthesia and various surgical techniques in all fields of medicine.

During the 20th century, advances in understanding and treatment of prolapse have progressed at an ever-increasing rate. In 1909, George R. White of Georgia published an account of cystocele repair using a transvaginal paravaginal approach. His correct perspective on the importance of lateral vaginal support took nearly 50 years to be rediscovered by mainstream gynecologic surgeons. The paravaginal repair was not widely known and accepted at the time because it was overshadowed by the work of Howard A. Kelly of Johns Hopkins. This great and influential surgeon popularized the concept of fascial attenuation. Midline anterior and posterior plications were touted as the correct surgical approach to the problem of prolapse. The Kelly-Kennedy anterior plication and levator ani plication of the posterior vaginal wall remain as commonly performed procedures today, despite the fact that more contemporary surgical techniques described in this chapter more correctly correct the anatomic defects of pelvic prolapse and achieve better clinical results.

In the 1950s, Milton L. McCall of Louisiana developed a culdoplasty technique that emphasized the important suspensory function of the uterosacral ligaments. He believed this operation prevented enteroceles and posthysterectomy vaginal vault prolapse when it was performed at the time of hysterectomy. Currently, the repair of vaginal vault support at the time of any type of hysterectomy is considered a very important step in prevention of future prolapse. In the 1960s, Baden and Walker of Texas began to systemize a new defect-specific approach to pelvic organ prolapse repair. Page 1 of their 1992 book, Surgical Repair of Vaginal Defects, stated, “In a sense, the defect approach reverses the prior evolution toward ‘compensatory’ reparative techniques—our goal is to return all vaginal supports to their original anatomic status.” Many other surgeons have contributed to this powerful concept of pelvic reconstructive surgery. A. Cullen Richardson and associates of Georgia developed the concept of classifying anatomic defects as proximal, distal, central, and lateral. This observation and the teaching of such master surgeons as David H. Nichols of New England encouraged gynecologists to not only identify and repair each vaginal defect but to also return support attachments to their original anatomic locations.

Emphasis was focused on the hernial nature of prolapse and led to the abandonment of absorbable sutures in favor of permanent sutures in repairs. In the 1990s, pelvic anatomist John O. L. DeLancey of Georgia developed the concept of pelvic reconstructive surgery. A. Cullen Richardson, while working with Russell W. Pulsifer, developed the concept of pelvic reconstructive surgery. The authors of the various chapters of this section describe intervention and operations that gynecologic surgeons should consider when managing pelvic organ prolapse. Each of these surgeons possesses a combination of operative skill, experience, and special interest in their topics that have led to their selection. The operative techniques presented should be combined with appropriate clinical evaluation and skillful technical performance to obtain maximum benefit for the patient.

ANATOMIC CONSIDERATIONS

The normal position, support, and suspension of the uterus, vagina, bladder, and rectum rely on an interdependent system of bony, muscular, and connective tissue elements. This entire...
system is three-dimensional, and even subtle alterations in one part may lead to stresses in other parts that eventually lead to failure of normal anatomy. An understanding of normal applied pelvic anatomy is imperative in the repair of pelvic organ prolapse.

The bony pelvis has a central opening that is necessary for reproductive function. During evolutionary transition to upright bipedal posture, the potential for prolapse became more likely because of gravitational stress. In the human female, a lordosis of the lumbosacral portion of the spine places the pelvic inlet in an oblique orientation reminiscent of the pelvic posture of a quadruped. The physical result of this shift is that the posterior aspect of the pelvic inlet is approximately 60 degrees above the anterior aspect (Fig. 36A.1). This partially vertical orientation of the pelvic inlet deflects force onto the superior symphysis pubis rather than directly on the pelvic outlet and urogenital hiatus. Consequently, the pelvic outlet is partially shielded from downward stresses in the anatomically normal woman.

The muscles of the pelvic diaphragm primarily provide pelvic support. These muscles form a bason or covering of the pelvic outlet and are often grouped together as the levator ani or levator sling (Fig. 36A.2). Within this diaphragm is the urogenital hiatus, which is large enough to allow childbirth. This large central opening in the muscular pelvic floor explains why prolapse is such a significant problem. The most medial portion of the pelvic diaphragm is formed by the puborectalis, the muscular boundary of the urogenital hiatus. The obstetric axis of the pelvis passes through the urogenital hiatus medial to the puborectalis muscle. In the standing patient, the puborectalis muscle is horizontal and is palpable as a 2- to 2.5-cm band of voluntary muscle on each lateral side of the distal one third of the vagina. When well innervated and contracted, the puborectalis muscle closes the distal vagina and displaces the posterior rectum anteriorly. Forming the bulk of the pelvic diaphragm, the pubococcygeus and iliococcygeus muscles cover the posterior and lateral portions of the pelvic outlet (Fig. 36A.3). The superior insertion of the iliococcygeus muscles is an important landmark in pelvic support anatomy. These insertions are thickenings of the pelvic sidewall parietal fascia that extend from the ischial spines posteriorly to points on the pubic bone known as the pubic tubercles. These lines of insertion are known as the arcus tendineus levator ani or muscular arches (Figs. 36A.4 and 36A.5). Immediately inferior to the muscular arches are thickenings of the parietal fascia of the bellies of the iliococcygeus muscles known as the arcus tendineus fasciae pelvis (fascial arches) or white lines. These structures are
the lateral attachment points for the pubocervical fascia and proximal rectovaginal septum. The white line serves the function of midvaginal lateral support. Paravaginal and proximal pararectal defects are located immediately medial to the white line. In the standing patient, the white line is nearly horizontal; in the lithotomy position, it is nearly vertical.

During paravaginal repair, the white lines are palpable as stringlike structures between the ischial spines and the pubic arch. Another fascial thickening has been described that runs posteriorly from the white line and serves as lateral support for the distal rectovaginal septum of the posterior vagina. This structure has been named the arcus tendineus fasciae rectovaginalis (Fig. 36A.6). The lateral supports of the anterior and posterior vaginal septa merge and are not separate in the proximal half of the vagina. Superior to the muscular arch is the uppermost portion of the obturator internus muscle and the parietal obturator fascia. The obturator internus muscles qualify as pelvic muscles because they form the lateral borders of the upper portion of the pelvic basin inferior to the linea terminalis. Posterior to the iliococcygeus, the pelvic floor is covered by
the coccygeus muscle and the closely associated sacrospinous ligament. These structures pass between the ischial spine and the coccyx. The most posterior portion of the pelvis is covered by the perineum. The midline confluence of the levator muscles forms a particularly strong band of connective tissue between the coccyx and anus known as the levator plate or sacrococcygeal raphe. This plate is oriented horizontally in the standing patient. The vagina and the rectum are suspended by the endopelvic fascia directly over the levator plate. Myopathies or neuropathies cause weakness of the pubococcygeus and iliococcygeus muscles and may allow the levator plate to sag and descend permanently. This descent causes the genital hiatus to remain open as it does during defecation. This increased opening changes the normal horizontal axis of the proximal vagina to a vertical orientation and predisposes the central pelvic organs to prolapse.

The pudendal nerve is an important motor and sensory nerve of the pelvic floor and perineum. It descends through the pelvic diaphragm between the coccygeus and perineum muscles in the area posterior to the ischial spine into Alcock’s canal. Alcock’s canal is located in the ischiorectal fossa immediately adjacent to the fascia of the obturator internus muscle on the lateral wall of this space. Because of its location, the pudendal nerve is subjected to significant stretch and pressure during the descent of a fetus through the pelvis. The muscles of the pelvic diaphragm are also subjected to great pressure and stretch during labor. Magnetic resonance imaging studies have demonstrated atrophy and breaks in the levator muscles of parous women. Neuropathy of the pudendal nerve and myopathy of the levator muscles are believed to be significant contributing factors in the development of pelvic organ prolapse.

The connective tissues of the pelvis are collectively known as the endopelvic fascia. This fibroelastic connective tissue matrix contains varying amounts of smooth muscle. It supports and invests all the midline organs and structures of the pelvis. Only the ovaries and fallopian tubes lie outside this investment. At various locations, the endopelvic fascia manifests different characteristics. These forms include loose areolar tissue capable
The deep endopelvic connective tissue is of central importance in the clinically applied anatomy of the pelvis and is especially significant to the pelvic reconstructive surgeon. This structure is part of a continuum of retroperitoneal connective tissue that extends from the respiratory diaphragm in the upper abdomen to the pelvic diaphragm. Included in this continuum of structures are the mesenteries and ligaments of the upper abdomen. Anatomists debate whether the condensations of this connective tissue should be considered as true ligaments and fasciae. Part of this debate stems from the fact that some of these structures contain a significant muscular component and others serve as neurovascular conduits. Certainly, from a functional standpoint in the pelvis, they meet criteria for being so named. The endopelvic connective tissue is continuous from one part to the other. Separate portions serve different functions, take various forms, and therefore are given different names. The named structures of the deep endopelvic connective tissue include six ligaments, two septa, and one ring. Important anatomic details of these elements are summarized in the following tables.

The six pericervical ligaments form the paracolpium (Tables 36A.3, 36A.4, and 36A.5). The net effect of these structures is the suspension of the cervix in the posterior pelvis and the consequent placement of the vagina directly over the levator plate and away from direct exposure to the urogenital hiatus. In the normal anatomic position, pressure from above tends to close and away from direct exposure to the urogenital hiatus. Two septa or fasciae (Tables 36A.6 and 36A.7) are located within the deep endopelvic connective tissue. These condensations of fibroelastic connective tissue are in close contact with the vaginal epithelium and visceral fasciae of the adjacent structures of the deep endopelvic connective tissue include six ligaments, two septa, and one ring. Important anatomic details of these elements are summarized in the following tables.

The points of insertion are on the posterior and lateral supravaginal cervix at the 5-o’clock and 7-o’clock positions. The ligaments are continuous with and form part of the pericervical ring.

---

The deep endopelvic connective tissue is of central importance in the clinically applied anatomy of the pelvis and is especially significant to the pelvic reconstructive surgeon. This structure is part of a continuum of retroperitoneal connective tissue that extends from the respiratory diaphragm in the upper abdomen to the pelvic diaphragm. Included in this continuum of structures are the mesenteries and ligaments of the upper abdomen. Anatomists debate whether the condensations of this connective tissue should be considered as true ligaments and fasciae. Part of this debate stems from the fact that some of these structures contain a significant muscular component and others serve as neurovascular conduits. Certainly, from a functional standpoint in the pelvis, they meet criteria for being so named. The endopelvic connective tissue is continuous from one part to the other. Separate portions serve different functions, take various forms, and therefore are given different names. The named structures of the deep endopelvic connective tissue include six ligaments, two septa, and one ring. Important anatomic details of these elements are summarized in the following tables.

The six pericervical ligaments form the paracolpium (Tables 36A.3, 36A.4, and 36A.5). The net effect of these structures is the suspension of the cervix in the posterior pelvis and the consequent placement of the vagina directly over the levator plate and away from direct exposure to the urogenital hiatus. In the normal anatomic position, pressure from above tends to close and away from direct exposure to the urogenital hiatus. Two septa or fasciae (Tables 36A.6 and 36A.7) are located within the deep endopelvic connective tissue. These condensations of fibroelastic connective tissue are in close contact with the vaginal epithelium and visceral fasciae of the adjacent structures of the deep endopelvic connective tissue include six ligaments, two septa, and one ring. Important anatomic details of these elements are summarized in the following tables.

The points of insertion are on the posterior and lateral supravaginal cervix at the 5-o’clock and 7-o’clock positions. The ligaments are continuous with and form part of the pericervical ring.

Simply stated, the goal of the defect-specific pelvic reconstructive surgeon is the restitution of the anatomical connections of the pericervical ring. If the dissection and reconstructive efforts during such a surgery do not extend proximally to the interspinous diameter, the surgery is likely to fail. Because the cervix is located on the anterior vaginal wall, the pubocervical septum is shorter than the rectovaginal septum by a length equal to the diameter of the pericervical ring. If one carries this line of reasoning further, an inherent structural problem is present in the posthysterectomy prolapse patient. If the cervix and its surrounding support tissues are absent, no completely anatomic method to reconstruct the proximal anterior vaginal support exists. Some form of anatomic distortion (e.g., shortening of the vagina or plication) or bolstering is necessary to compensate for this defect. Likely, this dilemma is the reason that the dominant support defect in the posthysterectomy patient is most frequently in this location.

The three-dimensional structure of the endopelvic fascia has another distinguishing anatomic characteristic that is of interest to the pelvic surgeon. Outside the confines of the named condensations of this tissue are avascular potential spaces (Table 36A.9). When properly used, these spaces give the surgeon access to important support structures deep within the pelvis. Gynecologic oncologists base their surgical training around mastering the surgical manipulation of these spaces, usually from the abdominal approach. These spaces are not only available to the vaginal reconstructive surgeon, but they are also critical in identification of pelvic support landmarks.

DeLancey’s biomechanical analysis of normal uterovaginal support by the deep endopelvic connective tissue helps to unify the anatomic principles pertinent to pelvic organ prolapse (Fig. 36A.7). These concepts of support and suspension also help to define a set of goals for the reconstructive surgeon. Each goal must be satisfied for the long-term success of a prolapse surgery. DeLancey divided vaginal support into three levels (Fig. 36A.8). Proximal vaginal level I support is attributed to suspension by the ligaments of the paracolpium. Damage to level I support results in uterovaginal prolapse, posthysterectomy vaginal prolapse, and enterocele. The cause for level I support problems is necessarily at or above the level of the ischial spines. The primary load-bearing elements are the uterosacral ligaments and, to a lesser extent, the cardinal ligaments. This fact is consistent with cadaver observations made many years ago by Mengert showing that prolapse occurred only after 85% of the integrity of the paracolpium was severed. Midvaginal level II support is due to lateral attachment of the fascial septa to

In the vast majority of women who will develop pelvic organ prolapse, the process begins with their first vaginal delivery. Each subsequent vaginal delivery contributes to the likelihood that a clinically symptomatic prolapse will occur. Labor and delivery are certainly desired, necessary, and important physiologic events. Nonetheless, childbirth does have a traumatic aspect by contributing to the development of pelvic organ prolapse. Commonly, many years pass and other factors contribute to the progression of prolapse before such patients present for evaluation.

During labor, the fetal presenting part (about 95% are vertex) must overcome a significant amount of soft tissue resistance presented by the lower uterine segment and cervix, the endopelvic fascia, and the muscular pelvic floor. Because of the lordosis of the lumbar spinal spine, the obstetric axis of the pelvis is noticeably angled, differing by 90 degrees between the inlet and outlet. This right angle occurs at the level of the interspinous diameter. This diameter is the narrowest in the female human pelvis and therefore is the plane of greatest resistance of the pubocervical septum, significant downward pressure is placed on the maternal right pelvic sidewall. The fetus then usually rotates into the occiput anterior position as it encounters the interspinous diameter. This diameter is the narrowest in the female human pelvis and therefore is the plane of greatest pressure during labor and delivery. The fetal head flexes to allow passage under the pubic symphysis. The anterior sacrococcygeal curve is concave. As the fetus passes under the pubic arch, this concavity makes it necessary for the fetal head to extend to complete labor. This change in orientation places intense pressure on the posterior perineal ring. The usual result is further uterosacral stress and a transverse proximal detachment of the rectovaginal septum at its junction with the perineal ring. As extension of the head progresses, displacement of the rectovaginal septum toward the perineum results in the creation of a midu for proximal vaginal enterocele and midvaginal rectocele formation. If the rectovaginal septum is displaced far enough distally, pararectal defects form as the septum is sheared away from its lateral attachments. The process of rectovaginal detachment and displacement weakens proximal support for the perineal body and predisposes to perineal descent. Subsequent deliveries progressively contribute damage to the endopelvic fascia. During descent and extension, the fetus passes through the urogenital hiatus. During this process, pressure is transmitted to the levator muscles and the pudendal nerve. If a patient dilates completely, pushes in an attempt to deliver, and then receives a cesarean section, she may have much of the same fascial damage as a woman with a successful vaginal delivery. A nulliparous patient with prolapse would likely suffer from isolated failure of the paracolpium, with the perineal ring and fascial septa remaining intact. A major shortcoming of the profession is that the effect of labor and delivery on the female pelvis has not been more completely objectified. Only recently has the study of pudendal neuropathy and levator myopathy been brought under scientific scrutiny. Even less has been done to determine the most common overall patterns of fascial and ligament damage during parturition. The pattern described in the previous paragraph is simply the most common one encountered. Other fetial presentations would result in different patterns of damage. Any experienced prolapse surgeon recognizes the variations in pattern of herniation, leading to the adage that no two patients are exactly alike. However, knowledge of the common pattern does help the surgeon who is new to the defect-specific approach know where to look to identify fascial edges and visually discriminate between various tissues in the dissection field.

Fortunately, most women who bear children will not suffer a significant symptomatic degree of prolapse. Parturition then

ETIOLOGY AND PREVENTION

In the vast majority of women who will develop pelvic organ prolapse, the process begins with their first vaginal delivery. Each subsequent vaginal delivery contributes to the likelihood that a clinically symptomatic prolapse will occur. Labor and delivery are certainly desired, necessary, and important physiologic events. Nonetheless, childbirth does have a traumatic aspect by contributing to the development of pelvic organ prolapse. Commonly, many years pass and other factors contribute to the progression of prolapse before such patients present for evaluation.

During labor, the fetal presenting part (about 95% are vertex) must overcome a significant amount of soft tissue resistance presented by the lower uterine segment and cervix, the endopelvic fascia, and the muscular pelvic floor. Because of the lordosis of the lumbar spinal spine, the obstetric axis of the pelvis is noticeably angled, differing by 90 degrees between the inlet and outlet. This right angle occurs at the level of the interspinous diameter. This diameter is the narrowest in the female human pelvis and therefore is the plane of great resistance of the pubocervical septum, significant downward pressure is placed on the maternal right pelvic sidewall. The fetus then usually rotates into the occiput anterior position as it encounters the interspinous diameter. This diameter is the narrowest in the female human pelvis and therefore is the plane of greatest pressure during labor and delivery. The fetal head flexes to allow passage under the pubic symphysis. The anterior sacrococcygeal curvature is concave. As the fetus passes under the pubic arch, this concavity makes it necessary for the fetal head to extend to complete labor. This change in orientation places intense pressure on the posterior perineal ring. The usual result is further uterosacral stress and a transverse proximal detachment of the rectovaginal septum at its junction with the perineal ring. As extension of the head progresses, displacement of the rectovaginal septum toward the perineum results in the creation of a midu for proximal vaginal enterocele and midvaginal rectocele formation. If the rectovaginal septum is displaced far enough distally, pararectal defects form as the septum is sheared away from its lateral attachments. The process of rectovaginal detachment and displacement weakens proximal support for the perineal body and predisposes to perineal descent. Subsequent deliveries progressively contribute damage to the endopelvic fascia. During descent and extension, the fetus passes through the urogenital hiatus. During this process, pressure is transmitted to the levator muscles and the pudendal nerve. If a patient dilates completely, pushes in an attempt to deliver, and then receives a cesarean section, she may have much of the same fascial damage as a woman with a successful vaginal delivery. A nulliparous patient with prolapse would likely suffer from isolated failure of the paracolpium, with the perineal ring and fascial septa remaining intact. A major shortcoming of the profession is that the effect of labor and delivery on the female pelvis has not been more completely objectified. Only recently has the study of pudendal neuropathy and levator myopathy been brought under scientific scrutiny. Even less has been done to determine the most common overall patterns of fascial and ligament damage during parturition. The pattern described in the previous paragraph is simply the most common one encountered. Other fetial presentations would result in different patterns of damage. Any experienced prolapse surgeon recognizes the variations in pattern of herniation, leading to the adage that no two patients are exactly alike. However, knowledge of the common pattern does help the surgeon who is new to the defect-specific approach know where to look to identify fascial edges and visually discriminate between various tissues in the dissection field.

Fortunately, most women who bear children will not suffer a significant symptomatic degree of prolapse. Parturition then
is a necessary cause but not a sufficient cause for the vast majority of prolapse cases. Other factors work over time and in combination with the damage caused by childbirth to convert incipient prolapse into a clinically apparent problem.

Prolapse becomes more common with advancing age. The likely cause is general weakening of tissues, including the pelvic floor muscles. Passage of time increases the cumulative effect of these factors. Most cases of prolapse become evident after the age of menopause. Virtually all the tissues of the pelvis possess estrogen receptors, and the atrophic changes that occur in the absence of estrogen are a contributing cause for prolapse. With age and a prolonged hypogonadal state, oestrogen may develop. The kyphotic changes in the spine that result from osteoporosis displace the pelvic inlet into a more horizontal plane. This change in the pelvic floor allows the weight of the abdominal contents to act more directly on the pelvic floor and on the urogenital hiatus.

Lifestyle may contribute to prolapse. Lifting objects heavy enough to require a Valsalva maneuver or fixation of the respiratory diaphragm displaces stress directly down on the pelvic floor. This process may be aided by shoulder, back, and extremity weakness. Defecation or micturition are commonly assisted with straining. This straining ocurs when the pelvic diaphragm is intentionally relaxed. This action places substantial force on a passive pelvic floor and open urogenital hiatus several times a day. Straining has essentially the same effect as heavy lifting. Obesity, which is epidemic in the United States, directly increases the load on the pelvic floor and decreases mobility, as well as the ability to do muscle strengthening exercises.

Medical conditions and their complications may contribute to the development of prolapse. A few examples suffice to illustrate how a chronic medical condition or the treatments for medical problems may affect the pelvic floor. The natural hormone deficiency disorders, such as menopause, and obesity, both of which contribute to the tendency to prolapse. Chronic cough accompanying asthma, bronchitis, or smoking places repeated stresses on the pelvic floor. The effects of repeated or paroxysmal coughing help to convert incipient prolapse into a clinical problem. Paroxysmal coughing also has antiestrogenic properties, contributes to vascular disease, and creates a chronic hypoxic state. Corticosteroid therapy is used in many chronic medical conditions. The weakening effect of these medications on connective tissue is well known. People with constitutional connective tissue disorders have been shown to be at increased risk for prolapse. Ehlers-Danlos syndrome, for example, is characterized by generalized fascial and connective tissue weaknesses. The pelvic floor is also affected by these deficits. More subtle connective tissue weakness, such as joint hypermobility, has been suspected to increase the long-term risk for prolapse. Development of ascites may cause a rapid increase in the degree of prolapse. This list is by no means complete. Any condition that affects the physical load on the pelvic floor or the integrity of the muscular and connective tissues of the pelvis will increase the likelihood that symptomatic prolapse will develop.

Some medical conditions may reduce the tendency to develop prolapse. This is the case for any condition that causes an inflammatory reaction in the paracervical or parametral tissues with subsequent tissue fibrosis. Pelvic inflammatory disease, purperal or postabortal sepsis, endometriosis, and pelvic radiation therapy are conditions that could lead to such a circumstance. Pelvic adhesions, regardless of the cause, may be strong enough to secondarily suspend a prolapse. Large uterine leiomyomata or other pelvic masses can mechanically prevent the development and descent of prolapse.

The list of contributing causes to pelvic organ prolapse is varied. Prevention should begin early in a woman’s life and be continued into the later years. Many of the measures discussed as preventions also have a positive effect on a woman’s general health. Any discussion of pelvic organ prolapse prevention must include the obstetric management of childbirth. Vaginal delivery undoubtedly has a primary and profound effect on pelvic support anatomy. Debates have occurred for decades about the wisdom of operative vaginal deliveries, optimal length for the second stage of labor, management of macrosomia, usefulness of episiotomy, and multiple other obstetric practices. In truth, little evidence-based information exists regarding these concepts as they relate to the subsequent development of prolapse. The most likely major contributing factor is simply vaginal delivery. The pelvis is contoured so that even in a normal labor and delivery, substantial forces are applied to the endopelvic fascia, muscular floor of the pelvis, and pudendal nerves. The greatest forces generated are at the level of the interspinous diameter. This plane is the location of the singularly important perirectal ring and its junction with every other septa and ligament associated with normal vaginal support and suspension. For example, an episiotomy may shorten the second stage of labor but is unlikely to have any effect on the stresses generated in the interspinous diameter. Does prophylactic cesarean section represent the ultimate in prolapse prevention? This tactic certainly has attained popularity in some parts of the world. One might argue that if vaginal delivery is a necessary cause for prolapse, then this strategy would be preventative. This topic has generated an active and emerging debate in obstetrics and gynecology. Evidence-based resolutions to these questions are unlikely to ever be available. In my opinion, prophylactic cesarean section will never be widely applied. Replacing a desired physiologic process with a major surgery is illogical when better strategies can be developed. This is a relatively uncommon and not life threatening. However, occasional patients may present convincing arguments in favor of prophylactic cesarean section. The individual practitioner and patient must resolve the course of action in the privacy of the consultation room.

In the adult parous woman, strategies to prevent the development of prolapse center on efforts that decrease physical stress on the urogenital hiatus and the pelvic floor. Physical therapists have known for years that protection of the lower back is improved by strengthening the shoulder girdle, quadriceps muscles, and abdominal muscles, as well as the muscles of the low back. These concepts are valid for protection of the pelvic floor. A program of exercises that develops strength in all these muscle groups allows women to accomplish the activities they desire without straining or using the assistance of a Valsalva maneuver. Care must be taken to respect the urogenital hiatus so that during such training, undue stress is not repeatedly placed on the pelvic floor. Likewise, in daily activity, the proper techniques to lift, push, and pull objects should be learned and practiced. The control of obesity must be considered part of the effort to reduce the load placed on the pelvic floor. Osteoporotic spinal changes cause a gradual kyphosis, replacing the normal lumbar lordosis. The net effect is to rotate the pelvic brim into a more horizontal position. This shift places more stress on the pelvic floor. Estrogen therapy not only prevents osteoporosis but also has positive effects on the various estrogen-sensitive tissues of the pelvis. Hormone replacement therapy is complicated, controversial, and beyond the scope of this discussion. Other effective treatments for osteoporosis exist.

Pelvic floor strengthening by voluntary contraction of the muscles innervated by the pudendal nerve was popularized by...
Arnold Kegel. The associated exercises have been known by his name ever since. Many women know this term because it is used frequently in postpartum instructions. Several different strategies help to remind patients to do their Kegel exercises. One of the most effective techniques is briefly outlined below. The Kegel contraction should be confirmed during a pelvic examination to ensure that the patient understands the correct muscle to contract. Frequent patients may either perform a Valsalva maneuver or tighten the gluteus maximus muscle instead of the external anal sphincter and levator ani muscles. The proper time to Kegel is after micturition. After the bladder is emptied, the patient is instructed to lean as far forward as they comfortably allow. While leaning forward, the patient performs three or more isometric Kegel exercises by tightening the muscles until they voluntarily relax on their own. The dependent portion of a cystoscope is below the level of the internal urethral orifice. The forward tilt physically elevates the bladder floor and allows for more complete emptying. The muscular action of the Kegel contractions also aids the process of emptying. Coupling this activity with voiding habituates the patient to perform the exercises several times a day. The result is the combination of more complete emptying and a strengthened pelvic floor, both of which are advantageous for the patient. The patient may then be able to use the Kegel contraction during physical stress to prevent incontinence or to protect against the pelvic floor impact of sudden increases in abdominal pressure. If the patient knows how to use Kegel muscles that are strong and easily controlled, they become an asset in her daily life.

Splitting is particularly effective in alleviating the dysfunctional defecation related to symptomatic rectoceles. If a significant rectocele/interescele herniation is present, patients frequently experience entrapment of the leading edge of the descending bowel segment. Entrapment leads to straining, which further enhances the entrapment. Often patients in this circumstance will strain until the bowel movement fragments and allows partial defecation and descent of another segment of stool into the rectal pocket. Several trips to the toilet and a large amount of time are required to complete this process. This unfortunate problem may be avoided if the patient simply places upward pressure with her finger tips against the perineum or the area lateral to the perineum during the initial urge to defecate. Occasionally, the patient needs to place one or two fingers against the anterior vaginal wall. These maneuvers effectively reduce the rectocoele pocket, allowing the stool to evacuate while bypassing the rectocoele. This “digital defecation” or splitting technique may avoid surgery and certainly empowers the patient to be in better control of her daily activities. I encourage the use of this technique postoperatively to protect the suspended posterior vaginal segment against undue strain. This protective maneuver is particularly important while acute healing is under way. Control of chronic diseases and habits are helpful preventative strategies. Effective treatment of persistent cough may decrease incontinence and prevent progression of prolapse. Cessation of smoking certainly may be considered part of the preventative effort. Diabetic complications such as obesity, myopathy, and neuropathy may be prevented by modern management strategies.

The prevention of pelvic organ prolapse involves care of the entire body. A healthy, fit, and well-nourished patient is aware of ways to actively protect her pelvic floor is less likely to experience this potentially disabling problem. Many of the strategies outlined in this section should be part of the care of patients from their obstetric years onward. Prevention is always preferable to intervention in the operating room.

The correct management of pelvic organ prolapse depends on a careful evaluation of each patient. Only after a thorough history and physical examination is the practitioner able to develop an effective treatment plan for the individual patient. The history should begin with the patient’s perception of the problem. This information helps to determine what specific goals the patient may have. The patient might be afraid that the prolapse could rupture or that it may be caused by a malignant growth. Reassurance may suffice if such ideas are the major concern. Patients may or may not be interested in coital function, further childbearing, or simply knowing that the vagina is present if social circumstances change. Some women have grown accustomed to advanced prolapse and may describe very little inconvenience related to the herniation. These people may simply want to know if the prolapse represents any threat to their longevity. Other women are very conscious of an anatomically minor prolapse or may have pain unrelated to the prolapse. The patient may have unrealistic expectations or may be ready for intervention before the physician’s operative criteria are met. In this situation, the pelvic reconstructive surgeon needs to be honest and forthright in discussing what will or will not improve after a surgery. A careful micturition, defecation, and sexual history may be invaluable in developing a treatment plan. Patients must be placed at ease and reassured during the evaluation before a full history concerning the details of pelvic functions can be obtained. Stress, urge, and neurogenic urinary incontinence may be differentiated by history. Obviously, the evaluations and treatments differ for each of these conditions. The complex topic of urinary incontinence is covered in detail elsewhere in this book. The mechanics involved in defecation are important. Determine the number of trips to the toilet and the compensatory measures necessary to complete evacuation. Fecal incontinence is a condition that patients are notoriously reluctant to discuss. This condition may or may not be due to physical damage to the anal continence control mechanism. The patient may be continuously voiding gas, liquids, and solids. Each patient may safely be presumed to desire urinary and bowel continence. Marked variation exists in patients’ sexual goals. The practitioner should learn about these goals in a respectful and nonjudgmental way. Collecting sexual function information is an art, critical to the development of a management plan. The past surgical history helps the surgeon assess the status of the patient in general and of the pelvis in particular. Specific interest should be placed on previous attempts to correct pelvic organ prolapse. Before her visit, the patient may be asked to prepare a list of previous surgeries so that none are overlooked. The route of hysterectomy and the indications for the procedure may be helpful. If previous prolapse surgery has been performed, the physician should try to obtain the operative notes. The anatomic details, type of suture used, and other details of the operative technique may help predict problems such as the likely location of anatomic distortion (previous plications) or the location of previously placed foreign bodies (e.g., meshes). Multiple previous attempts at repair may jeopardize a combination of caution and experience to achieve a successful outcome.

The medical history should be used to determine what other medical conditions exist that would likely interact with surgery or recovery. A complete pelvic reconstructive surgery may last several hours, involve significant blood loss, and require advanced vaginal and abdominal approaches. Obviously, the patient needs the physical reserve to withstand this degree of stress. Patients with morbid obesity, limited pulmonary and
cardiac function, thromboembolic risks, entrenched tobacco addiction, or limited mobility are not ideal candidates for this type of surgery. A complete list of current medications, including herbas and over-the-counter preparations, and treating physicians is also helpful.

The proper physical examination of the prolapse patient requires that the examining physician have a working knowledge of normal pelvic anatomy. Older systems for recording physical findings related to prolapse relied on subjective terms such as mild, moderate, and severe. These terms have a limited ability to accurately describe prolapse and restrict effective communication between examiners. Two systems are currently in use that encourage a complete prolapse examination and that more objectively record anatomic detail. Each of these systems has strengths and weaknesses. The Baden-Walker Halfway System is user friendly, easy to record, and maximizes the amount of detail that can be recorded in a very brief space. Proponents of this system maintain that the essence of the prolapse examination is recorded after writing six numbers and some editorial notes. Critics note that the abbreviation of detail means that some compromises are made along the way. The second system is the Pelvic Organ Prolapse—Quantification or POP-Q system. This is a more complex system incorporating more specific detail of the physical findings. Even for those clinicians accustomed to its use, the number of measurements needed requires additional time to acquire. The beauty of this system is that, theoretically, physician-to-physician variation is minimized. The POP-Q is currently used in many academic papers on the subject of prolapse. Interested physicians should become familiar with both of these systems. More important than any system is an accurate and anatomically based assessment of the patient at the time of examination.

### Baden-Walker Halfway System

The extent of prolapse is recorded using a number (0 to 4) at each of six defined sites in the vagina. There are two sites on the anterior, superior, and posterior walls of the vagina. Table 36A.10 lists the anatomic sites and the associated symptoms. The six numbers are recorded as a measure of descent. For all sites except the perineum, the hymen is used as a fixed anatomic reference point. Zero indicates normal anatomic position for a site, whereas 4 represents maximum prolapse. Between these extremes, the intervening numbers grade descent using a halfway system as illustrated in Figure 36A.9. The examination is performed with the patient straining so that maximum descent is attained. The patient may wish to stand to demonstrate maximum descent.

The perineum is graded using the familiar perineal laceration system used in obstetrics (Fig. 36A.9). The patient is asked to hold or Kegel to evaluate the amount of muscular and fascial compensatory support. Editorial comments may include the site of dominant prolapse, location of scars, palpable puckering from previous surgery, and the type of efforts necessary to demonstrate maximum prolapse. Strength of the levator contraction may be recorded as 0 to 4.

Example: 12/44/32. A dominant complete apical prolapse is noted with enterocele, significant cystocele and rectocele, and perineal attenuation to the level of the external anal sphincter. 2/4 levator strength is present. Although this type of notation encodes much information in a small space, no specific location of fascial defects is indicated.

Pelvic Organ Prolapse—Quantification System (POP-Q)

This system was developed as an effort to introduce more objectivity into the quantification of pelvic organ prolapse. For example, measurements in centimeters are used instead of subjective grades. Nine specific measurements are recorded as indicated in Figure 36A.10. Point Aa is defined as being 3 cm proximal to the external urethral meatus on the anterior vaginal wall. Point Ap is defined as being 3 cm proximal to the hymen on the posterior vaginal wall. Points Ba and Bp are defined as points of maximum prolapse excursion on the anterior and posterior vaginal walls, respectively. Measurements are recorded as negative numbers when proximal to the hymen and positive numbers when distal to the hymen. POP-Q sites C and D are identical in location to Baden-Walker sites 3 and 4 in the apical vagina. In addition, measurements of the total vaginal length, genital hiatus, and perineal body are taken. All measurements are recorded on a tic-tac-toe style grid (Fig. 36A.11). When combined with sagittal line drawings, a fairly complete picture of prolapse is attained (Fig. 36A.12). Ordinal stages of pelvic organ prolapse are then assigned from stage 0 (no prolapse) to stage V (complete prolapse) so that the outcome of cases of like magnitude may be compared.

The nine specific sites of measurement used in the Pelvic Organ Prolapse—Quantification System (POP-Q). gh, genital hiatus; pb, perineal body; tvl, total vaginal length. (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996;175:10.)

Pelvic Examination

After a general physical examination is performed, the prolapse may be evaluated. Any surgical scars on the abdomen should be correlated with the surgical history. Patients frequently forget procedures that may have an impact on the treatment plan. The physician should pay particular attention to the suprapubic region where previous incontinence procedure incisions may be located.

The pelvic examination is initiated with the patient in the lithotomy position. Hip mobility should be evaluated because adequate abduction and flexion of the thighs is required for a vaginal procedure. Thigh and buttock obesity may also be limiting factors. If exposure is limited, an extended procedure performed vaginally is not in the patient’s or surgeon’s best interest.

The labia are opened for introital inspection. Prolapse may be internal (proximal to the hymen) or external (distal to the hymen) at rest. The extent of the prolapse may change considerably if the patient is asked to strain. This difference may be especially pronounced in patients with healthy pelvic floor muscles and an undescended levator plate. These two structures may help hold a prolapse in place. The patient may give a history of a prolapse that is not apparent on examination or not as large as she describes. In such a case, the patient is examined while she is in the standing position; or she may be asked to perform the maneuvers necessary to demonstrate the full extent of the prolapse.

The dominant prolapse is considered to be the first hernia to descend or the most dependent part of a prolapse that has previously descended. Proper identification of the dominant prolapse provides key clues about where the most significant fascial damage is located. The dominant prolapse is located and replaced to examine the remainder of the vaginal vault. A large dominant prolapse often fills the urogenital hiatus and introitus, preventing incipient hernias from fully developing. Usually an anterior prolapse is easily replaced by placing a tongue blade or Ayre spatula in each anterior lateral sulcus.
If an apical transverse or lateral paravaginal defect is present, this maneuver replaces the anterior vaginal wall. If this maneuver does not reduce the hernia, a central anterior defect is likely present. A dominant posterior segment prolapse may be replaced with the posterior blade of a disjoined Sims’ speculum. A dominant superior segment prolapse may be replaced with a large cotton swab, a sponge stick, or, in advanced cases, by attaching a tenaculum to the cervix. After replacement of the dominant prolapse, the secondary sites of prolapse become more apparent. An isolated single-site prolapse is rare. The location of the cervix or hysterectomy scar helps determine the location of the dominant prolapse. Frequently displaced, either anteriorly or posteriorly, these sites are often not at the most dependent part of the prolapse. The posthysterectomy scar is commonly a transverse fibrous band that may be slightly retracted. To either side of the band are dimples in the epithelium corresponding to the location of the insertion of cardinal and uterosacral ligament remnants. Incomplete evaluation may lead to incomplete repair that results in recurrent prolapse and multiple trips to the operating room. The support structures of all vaginal segments and levels are interdependent. Complete restoration of all defects is necessary for a successful outcome.

Careful inspection of the vaginal epithelium reveals the location of rugae. The presence of these transverse folds implies that endopelvic fascia is adherent to the epithelium in that location. The lateral vaginal sulci are the location of the junction of the pubocervical and rectovaginal septa to their respective lateral arcuate attachments. The pattern of rugae and the condition of the sulci should correlate with the pattern of fascial breaks found at surgery. The vaginal epithelium should also be inspected for atrophy created by the absence of the effects of estrogen. Local or systemic administration of estrogen before surgery assists in dissection and subsequent healing. Occasionally, an external prolapse may develop pressure ulcers as a result of entrapment when the patient is sitting. These lesions must be properly evaluated to rule out malignancy.

Rectovaginal examination assists in the evaluation of the posterior and superior vaginal segments. The urogenital ligaments may be palpable immediately medial to each ischiorectal fossa, especially if the uterus is present. The uterosacral ligaments may be more easily palpated with traction placed on the cervix. Anterior displacement of the rectal examining finger toward the vagina helps to distinguish between rectocoele and enterocele. During the rectal examination, the patient is asked to strain. If an enterocele is present, it bulges down in the nonrugated vaginal epithelium proximal to the tip of the examining finger. Palpating the transversely detached proximal edge of the rectovaginal septum is possible during this maneuver. This sharp border may retract distally all the way to the perineum. Perineal descent is also evaluated at the time of rectal examination. The levator plate is immediately posterior to the rectum and should be horizontal and immovable. The perineum is evaluated last. The perineum is triangular in the sagittal plane. The base is on the rectal side, and the apex at the hymen. Perineal attenuation is very common in parous women. Apposition of the thumb of the examining hand while the index finger is in the rectum proximal to the anterior aspect of the external anal sphincter allows for evaluation of the integrity of this muscle. Voluntary contraction of the sphincter may be helpful. The S3 neurologic segment is necessary to contract this muscle and controls the ability to spread and dorsiflex the toes. If the patient cannot perform these tasks, the integrity of that neural segment is in question.

The mechanical strength of the pelvic diaphragm is directly correlated with the ability to voluntarily contract these muscles. This ability is best tested clinically with light pressure placed on the posterior vaginal wall by the examining digits. The patient may need coaching to elicit a response. This time is an excellent opportunity to instruct the patient in the importance of postvoiding Kegel exercises and perineal support (splinting) during defecation.

If muscle activity is elicited, it may be subjectively graded from 0 to 4. If no muscle activity is detected, a more formal neurologic and medical workup should be considered. Pudendal nerve motor latency studies may reveal significant neuropathies. Magnetic resonance imaging of these patients has revealed the presence of advanced muscle atrophy and muscular detachments as well. Neuropathy and myopathy erode the surgeon’s ability to correct prolapse. If the patient cannot properly move her toes and cannot contract the levator muscles, a spinal cord or central nervous system lesion must be considered.
The presence of urinary incontinence should be noted during any part of the evaluation of prolapse. In an advanced prolapse, assessment of incontinence should be conducted with the prolapse in a reduced state. A pessary or loose vaginal packing may be helpful in accomplishing this goal. Incontinence may be masked by a hypotonic bladder or reverse kinking of the urethra if a cystocele is large. Repair of a large prolapse may be followed by the appearance of urinary incontinence if the preoperative evaluation is not performed with the prolapse reduced.

When a large prolapse is present, the trigone of the bladder is often located outside the vaginal introitus. In this degree of displacement, one may deduce the location of the trigone as being directly adjacent to the location of a Foley catheter bulb. The course of the ureter in a large prolapse arcs from the superior and lateral aspect of the anterior prolapse to the area of the trigone. The ureter may often be palpated in this location. If the prolapse is chronic and advanced, hydroureter and even hydronephrosis may be present. In this circumstance, the ureters lose their cordlike consistency and are more difficult to palpate or recognize at the time of surgery. A large external prolapse makes the ureter more susceptible to surgical injury. Intraoperative placement of ureteral catheters may be helpful in such a patient. Postoperative documentation of ureteral patency is required.

A patient may present with the cervix near the level of the hymen. If no other signs of prolapse are present, the alert examiner is aware of the possibility of an elongated cervix. Sometimes surgery is not necessary in these patients. If surgery is performed, the technique of hysterectomy needs to take into consideration the elongation of the cervix. Often the para-ortic lymph nodes are enlarged in these patients.

The examiner should not underestimate the value of an examination under anesthesia to supplement information that has been gathered preoperatively. With the patient and her pelvic diaphragm relaxed, the full extent of prolapse may become more apparent. Deep structures of importance, such as the ischial spines and uterosacral ligaments, may be more easily palpated. An examination under anesthesia should be performed before initiating a prolapse surgery.

A number of ways may be used to summarize the array of clinical findings discussed in this section. My preference is to use a pelvic organ prolapse map (Figs. 36A.13 and 36A.14). Key anatomic landmarks are schematically outlined. The three-dimensional structure of the vagina is reduced to two dimensions as if the vagina were divided at the 3-o’clock and 9-o’clock positions. A Baden-Walker profile can be recorded vertically on the map with numbers placed beside the appropriate anatomic location. As seen in Figure 36A.13, fascial defects can be sketched on the map at their suspected or known location. Editorial notes regarding the prolapse can be recorded in the space provided. A POP-Q evaluation may be used as well. The pattern that is noted in Figure 36A.13 is the one most commonly seen in pelvic organ prolapse surgery; however, many variations on this theme are encountered (Fig. 36A.16). Another diagram may be drawn to indicate the exact locations of fascial defects at the time of surgery.
Pelvic Organ Prolapse: Basic Principles

Figure 36A.15. The most frequently encountered pattern of fascial damage in pelvic organ prolapse: (1) full-length right paravaginal defect; (2) transverse proximal detachment of the pubocervical septum; (3) transverse proximal detachment of the rectovaginal septum. This pattern of damage is consistent with the mechanics of a left occipitoanterior delivery. Baden-Walker vaginal support profile sites: 1, urethral; 2, vesical; 3, uterine; 4, cul-de-sac; 5, rectal; 6, perineal. PT, pubic tubercle; ATFP, arcus tendineus fascia pelvis; ATFRV, arcus tendineus fasciae rectovaginalis; IS, ischial spines; U, urethra; Cx, cervix; A, anus.

A thorough history and physical examination improves the treatment of the prolapse patient. The physical findings must be recorded in an anatomically accurate and understandable way.

Choice of Treatment

Vaginal reconstructive surgery is concerned with the return of abnormal organ relationships to a usual or normal state. There is no one site or degree of damage that must be repaired or restored; there are many and they occur in various combinations at various times of life, from different etiologic factors, varying degrees, and with varying degrees of symptoms and disability. (Nichols and Randall, 1989)

Patients with pelvic organ prolapse have highly individualized perceptions of their situation. The single most important concept in the treatment of these conditions is to understand the patient’s symptoms, concerns, and limitations related to the prolapse. Her quality of life should be of paramount concern in the decision-making process. The patient’s expectations and her ability to tolerate surgery should be expertly evaluated. The physician’s job is to educate the patient regarding options of treatment. After informed consent is given, the appropriate course of action is usually obvious to both the doctor and the patient. If the chosen course of action fails or becomes inappropriate over the course of time, the clinical evaluation and decision process can be revisited.

Nonsurgical Management

Regardless of the degree of prolapse, no surgery should be done unless the patient experiences a sufficient degree of morbidity. Most symptoms relate to quality-of-life issues. Generally, preventative measures should be the most widely applied techniques. Pelvic floor exercises, weight loss, treatment of chronic diseases, physical therapy, cessation of smoking, and estrogen therapy are all considerations in the conservative treatment of pelvic organ prolapse. These interventions have been discussed in the previous section of this chapter and should be used regardless of whether expectant management or surgical intervention is the plan. During expectant management, periodic examinations should be done to determine the status of pelvic organ support and the degree of progression. Symptoms and the ability to participate in daily activities may be reviewed to reinforce the patient’s motivation to continue preventative measures.

Pessaries are ingenious devices that have been used for a long time. They were originally the product of an age when surgery was not an option for the prolapse patient. They are available in a variety of shapes and sizes, depending on the needs of the patient. In general, the greater the degree of prolapse and the more strenuous the daily activities of the patient, the less likely it is for a pessary to be a permanent solution. As the prolapse expands, occupies the urogenital hiatus, and dilates the introitus, the pressure of the prolapse tends to expel the pessary.
A pessary may be valuable for a patient to wear to feel more comfortable during a specific activity, such as exercise. If a patient of limited activity and acute-onset advanced prolapse can be successfully fitted with a pessary, it may prevent progression and result in long-term improvement in intestinal and urinary function. Teaching patients to hold a pessary in place manually (splitting) during the process of defecation is helpful. In a patient with significant prolapse, the insertion of a pessary elevates the bladder floor and can allow for more functional and complete voiding. The utility of these devices is directly proportional to the efforts of the physician and the patient. If both parties are interested, pessaries can have a valuable place in the management of prolapse. Pessaries are more thoroughly discussed in Section F of this chapter.

### Surgical Principles and Management

The management of advanced and symptomatic prolapse is primarily surgical. In 1997, 226,000 women underwent pelvic organ prolapse surgery in the United States. This condition is one of the most common indications for major surgery. Eleven percent of all women will undergo another operation for recurrence of prolapse or a complication related to surgery. Prolapse is a high-incidence problem that commands a substantial expenditure of health care dollars. Only those patients who request relief should be considered surgical candidates. Once the decision is made to operate, quality-of-life goals need to be established. If the patient can tolerate a lengthy operation and especially if she desires costal function, a reconstructive operation should be considered. The removal of normal anatomy (form) maximizes the potential that symptoms and limitations (function) will be corrected or significantly improved. Restoration of normal anatomy automatically addresses the questions of vaginal axis, caliber, and depth. If the patient does not desire costal function, an occlusive procedure, such as colpocleisis, might be the best choice. Colpocleisis with vaginectomy has a very low failure rate, but the end does not justify the means in all patients.

Choosing the correct operation for prolapse is critical for success. The general plan for the procedures that will best correct the problems of the individual patient may be developed from details gathered during the preoperative history and pelvic examination and even the examination under anesthesia. Specific details become evident only during the intraoperative dissection. The goals of the operation are the restoration of normal form and function. Isolated areas of prolapse are uncommon. Childbirth places damaging pressure on all segments of suspension and support during the various phases of labor and delivery. Restricting an operative procedure to the repair of a single dominant or symptomatic site of prolapse simply transfers the physical stress to a different vaginal segment. An incomplete reconstruction may result in a secondary prolapse descending as a new dominant prolapse. Sometimes prolapse can return quite unpredictably. Perhaps the best known example of this phenomenon was the observation by Burch that many patients developed an enterocele after his anterior rectopexy procedure. An active search for potential and undeveloped defects should be done at the time of prolapse surgery. Site-specific repair of all segments and levels is the best insurance against failure.

The route of operation is a matter of debate. Vaginal surgery is the historical hallmark of the gynecologic surgeon. Although surgical training in vaginal techniques has eroded in recent years, a resurgence of interest in these operations is occurring. The vaginal approach requires either limited or no access to the peritoneal cavity and is surgically less stressful on the patient.

During the last three decades, a significant change has occurred in the way prolapse surgery is conceptualized and performed. Anatomically the prolapse, the reconstructive procedures have been replaced by defect-specific anatomic restorations. Several aspects of the defect-specific method favor the vaginal approach. Defect-specific defects can be best identified when the full extent of the vaginal segment to be repaired is dissected and exposed. Such dissections are only possible vaginally. The detached fascial edge of a paravaginal defect may retract across the midline to the contralateral side of the body. This retraction leaves the fascial edge in a position that is impossible to reach from the abdominal or endoscopic approach. No one questions that a paravaginal defect can be seen from the abdominal or endoscopic operative approach. A question does remain about whether the retracted fascial edge can be accessed and reattached to the white line using the abdominal or laparoscopic approach. Likewise, a proximal rectovaginal septal defect that has retracted distally to the perineum would be very difficult to find and resuspend from above. All the major support anatomic landmarks and tissues are accessible vaginally. These points include the arcus tendoecus fascia pelvis, arcus tendoecus fasciae rectovaginalis, ischial spines, ureterosacral ligaments, sacrospinous ligaments, and virtually all components of the deep endopelvic connective tissue. During childbirth, the named components of the endopelvic fascia are displaced away from the interspinous diameter. Reconstructive efforts must be centered in this diameter for a permanently successful outcome. Access to torn fascial edges is best attained by complete dissections of the vesicovaginal and rectovaginal spaces. Midvaginal lateral defects can easily be repaired by this route. Additionally, apical suspension can also be performed to complete the restoration of central pelvic organ suspension. For most primary reconstructions, the vaginal operative route is superior to any other approach. The vaginal route is used more frequently for patients with failures from previous operations. This approach is especially useful when a previous operation did not use the defect-specific approach and did not include the use of permanent sutures for critical support sites.

The discussion and opinions in the previous paragraph do not preclude the use of abdominal and laparoscopic techniques for certain problems in pelvic reconstructive surgery. Procedures to correct stress urinary incontinence are discussed extensively in Chapter 37. Anterior urethropexy approached through the prevesical space with a suprapubic incision or laparoscopic technique has some advantages when compared with a suburethral sling urethropexy. No iatrogenic paravaginal defect is necessary during anterior urethropexy, for example. Such defects are made with pubovaginal sling procedures of all types. Some intentionally created defects are larger than others. To spend time and effort to reconstruct the pubocervical fascia anatomically from white line to white line and then to destroy part of the paravaginal support intentionally to allow passage of the sling material into the prevesical space does not make good sense. The primary prevesical space approach avoids this destructive necessity. Kelly-Kennedy plications and paravaginal repairs have been shown to be ineffective as incontinence procedures. New minimally invasive sling operations represent an effective totally vaginal operation to cure stress urinary incontinence. Vaginal incontinence operations that avoid iatrogenic paravaginal damage and an abdominal or laparoscopic incision are ideal.
Pelvic Organ Prolapse: Basic Principles

The abdominal approach is useful in some cases of prolapse in which one or more previous pelvic support operations have failed. Abdominal sacral colpopexy is an option in this situation. Colpopexy may be useful in a circumstance in which considerable scar is present from previous surgery. For example, consider a patient with a previous aggressive distal plication and a proximal support failure. Significant fibrosis would be necessary to access the proximal fascial structures necessary to repair the prolapse. A rescue abdominal sacral colpopexy may more easily and effectively correct the prolapse. Occasional patients whose support has failed following a site-specific operation with permanent suture may also benefit from this operation. Abdominal/sacral colpopexy is not a site-specific operation; however, it provides substantial proximal support and protects vaginal length.

During a prolapse surgery, the surgeon may determine that adequate support or repair is not attainable through the primary approach. No harm is done in using a combined approach. If support is not satisfactory after a vaginal procedure, an abdominal sacral colpopexy can be done at that time. Conversely, a vaginal examination should be performed after an abdominal sacral colpopexy to determine if the vaginal axis, caliber, and depth have been restored to an acceptable state. The patient with proper informed consent would likely prefer a combined procedure to subsequent surgery.

Suture selection for pelvic reconstitution has changed with the realization that prolapse surgery is really a series of herniorrhaphies. No surgeon would consider performing a repair of an inguinal or ventral hernia with absorbable suture. In the days of distal plications, the use of absorbable suture was common. Today, fascial defects are repaired with permanent suture. In an attempt to compromise, some surgeons use delayed absorbable sutures. They reason that the suture material is not needed after healing has been accomplished. However, evidence exists in the hernia literature to support the use of anything other than permanent suture for these repairs. Monofilament and polyfilament sutures are acceptable. Monofilament sutures occasionally erode and cause an unpleasant whisker effect in the vagina. If erosion occurs, the suture can be removed. My choice of suture is interwoven braided polyester for fascial repairs. This suture is affordable and easily tied, has no sharp end, and infrequently causes a reaction or erosion.

All prolapse patients should be carefully evaluated for concomitant vaginal, uterine, adnexal, pelvic, or abdominal disease. Coexisting pathology may change the operative approach selected for correction of prolapse. Orthopedic problems and obesity must be factored into the decision-making process because adequate surgical access is important. Young patients with uterovaginal prolapse may request preservation of their fertility. Unless the problem is severe, these patients should be advised to complete their childbearing so that a definitive operation can be performed. Ring-type pes-saries may provide temporary relief. They permit intercourse and may be worn at the discretion of the patient during exercise or strenuous activity and on other occasions. A unilateral sacrospinous ligament fixation with the uterus in place may be beneficial and does not prohibit subsequent vaginal childbirth. Various abdominal or endoscopic uterine suspensions may also be considered. In general, retention of the uterus when a significant degree of prolapse is present compromises the long-term operative result. The cervix limits access to the structures of the paracolpium that are necessary to achieve proper proximal suspension of the vaginal vault. At the same time, removal of the cervix creates an inherent defect in the proximal anterior vaginal wall. The posthysterectomy vault prolapse is in many instances a result of this cervical defect. Care must be taken to compensate for this weakness at the time of hysterectomy. This area is the location of the pericervical ring whose proper attachments are so important to normal vaginal suspension. No totally anatomic method to close this space exists. To achieve a satisfactory result it is easier at hysterectomy than at subsequent posthysterectomy repair. Plication of the cardinal ligaments and McCall’s culdoplasty are necessary components of hysterectomy cuff repair.

Various grafts, bolsters, and synthetic meshes can be valuable tools in prolapse surgery. For example, in a posthysterectomy prolapse, a small piece of foreign material used to bolster the weak area left by the absence of the cervix may decrease the amount of anatomic distortion needed to support the apical anterior vaginal wall. These materials are useful and necessary in abdominal sacral colpopexy. The overzealous use of grafts and meshes is unnecessary and may predispose to the annoying problems of exposure and erosion. Procedures that require the use of foreign materials to compensate for absent fasciae should be viewed with suspicion. Even in an advanced prolapse, the fascia is present in most cases. Fasciae, unlike muscles, do not atrophy. They may be retracted and scarred but are available for dissection and reattachment if the surgeon is trained in the proper techniques. Bolstering of site-specific repairs is acceptable. At no time should bolsters, grafts, and meshes be used as a substitute for meticulous surgical technique. Foreign materials should be used to strengthen anatomically restorative repairs.

Complications occurred in 15.5% of prolapse surgeries performed in the United States in 1997 (Table 36A.11). The majority of these complications can be addressed in the operating room. Gynecologic surgeons have been well trained to irrigate inside the abdomen. The same principles are applicable when operating vaginally. In the operating room after the surgical prep and draping are completed, a vaginal lavage rinses the vagina of nonadherent viscus while negative suction at frequent intervals also helps to prevent infection. Irrigation as described and prophylactic antibiotics greatly help reduce the incidence of postoperative infection. A vaginal pack may help initial adherence of the vaginal epithelium to the endopelvic

Pelvic organ prolapse affects a patient’s quality of life. Any principles of hernia repair should be followed in prolapse. Pelvic reconstructive surgeries should be designed to restore anatomy, physical diagnosis, reconstructive surgical techniques, and good medical care will yield the best results.

**BEST SURGICAL PRACTICES**

- Pelvic organ prolapse affects a patient’s quality of life. Any decision regarding treatment of prolapse should ultimately be made with significant input from the patient.
- A careful physical examination documenting the defects in pelvic supportive structures is useful in selecting the appropriate treatment to correct the anatomic defect responsible for the patient’s symptoms and physical exam findings.
- Pelvic reconstructive surgeries should be designed to restore maximally the normal biomechanical support and suspension of the central pelvic organs. This concept is called anatomic-specific repair of pelvic support defects. Restoration of normal anatomy maximizes the potential for normal urination, intestinal, and sexual functions.
- Principles of hernia repair should be followed in prolapse surgery. Use of permanent suture is standard. Judicious use of meshes, bolsters, and grafts may be indicated; however, these products should be used to enhance rather than replace sound surgical technique.
- Complex pelvic surgery and dissection into the deep pelvic spaces require that ureteral patency be documented before leaving the operating room.

Burke MM. Fine L. Surgery for corrections of defects in pelvic support and pelvic fistulas. P298. Surgery for Corrections of Defects in Pelvic Support and pelvic Fistulas. The pelvis is a busy place anatomically. The deep dissections necessary for the correction of prolapse predispose the patient to injury to adjacent structures. Development of proper surgical planes helps to minimize the potential for such injuries. Vascular injuries are usually immediately apparent and can be corrected during the operation. Intestinal and urinary injuries are often more subtle. The surgeon should not conclude the operative procedure without some reassurance of the integrity of these structures. Cystoscopy is a valuable skill that should be used by the pelvic support surgeon. A high rectal examination may suffice for intestinal reassurance unless damage is suspected higher than the examination extends.
Preoperative and postoperative care is discussed elsewhere in this text. Early ambulation and thrombosis prophylaxis are particularly important in the usual prolapse patient. The patient should be at sexual pelvic rest for approximately 6 weeks. The patient may be quite anxious about sexual activity. Sexual rehabilitation may require time, reassurance, and the helpful advice of the physician. Straining to void and defecate should be minimized. The act of perineal splinting postoperatively helps to protect the perineum from downward displacement during defecation. Lifting should be restricted to those things that can be accomplished with available strength in the shoulders, back, and hips.
The care of patients with pelvic organ prolapse can be equally challenging and rewarding. Attention to the details of surgery, bowel, and urinary control may reduce pain and other symptoms.

CHAPTER 36B ▪ SITE-SPECIFIC REPAIR
OF CYSTOURETHROCELE

CARL W. ZIMMERMAN

DEFINITIONS

Arcus tendineus fascia pelvis or white line—A thickening of the parietal fascia of the pelvic sidewall along a line between the ischial spine and pubic tubercle. Along this line, the pubocervical septum attaches to the pelvic sidewall.

Cystocele—A defect within the central pubocervical septum that allows the floor of the bladder to descend. Cystoceles are normally caused by transverse apical defects in the pubocervical septum.

Paravaginal defect—A lateral defect at or near the attachment of the pubocervical septum to the arcus tendineus fascia pelvis. Paravaginal defects create a direct connection between the vesicovaginal space and the paravesical space on the affected side of the patient.

Pericervical ring—The collar of strong connective tissue surrounding the cervix. This is the central support of the vaginal apex to which the cardinal and uterosacral ligaments as well as the anterior pubocervical ligaments and fascia and posterior rectovaginal septum are attached.

Pubocervical septum—A component of the endopelvic fascia composed of fibroelastic connective tissue. This septum separates the vaginal epithelium and the bladder. Defects in the pubocervical septum are associated with anterior vaginal compartment failure.

The anterior compartment of the vagina extends from the pubic symphysis anteriorly to the posterior aspect of the cervix. The lateral boundaries are the white lines or arcus tendineus fasciae pelvis. The anterior vaginal compartment separates the bladder from the lumen of the vagina. Support of the bladder is the function of the pubocervical septum that is part of the deep endopelvic connective tissue. In the anatomically normal woman, the epithelium of the anterior vaginal wall firmly adheres to the pubocervical septum, creating rugae. Rugae are responsible for the finely ridged texture of the vaginal wall. The linear attachment of the pubocervical septum to the white line forms the anterior lateral sulci of the vagina. In the standing woman, the proximal two thirds of the anterior vaginal segment is nearly horizontal. In the lithotomy position, the anterior vaginal wall is oblique, with the apical portion inferior. The cervix and its surrounding ring and ligaments compose the proximal portion of the anterior vaginal segment. As a result, the pubocervical septum is shorter than the rectovaginal septum by the diameter of the cervix. In the absence of the cervix, an inherent defect is present that cannot be repaired in a completely reconstructive fashion. Compensating for the absence of the cervix at the time of hysterectomy is possible by using careful techniques of cuff repair. The failure to correct anatomically for the absent cervix in the posthysterectomy prolapse patient leads to many problems. The correction of the connective tissue defect left by the absence of the cervix is one of the most challenging problems in pelvic reconstructive surgery. Labor and delivery apply intense pressure to all components of vaginal support and suspension. During descent, flexion, internal rotation, and extension, specific stresses are focused on the pubocervical septum before external rotation and expulsion of the fetus. The damage that results from the passage of a baby through the obstetric axis of the pelvis is the nidus for symptomatic prolapse of the anterior vaginal segment. The named anatomic components of anterior prolapse are cystocele, urethrocele, paravaginal defects, and uterine procidentia. Prolapse may occur without childbirth; however, this clinical circumstance is the exception rather than the rule. Other etiologic factors are normally required for the development of pelvic organ prolapse. These factors include time, age, repeated pelvic stresses, and lack of estrogen.

For most of the 20th century, the assumption was made that during childbirth, gradual attenuation of the endopelvic fascial support structures occurred. Howard Kelly of Baltimore championed this concept. His influence was considerable, and, as a result, surgical repair of a cystocele with anatomically distorting midline anterior plications became the standard of care. The Kelly–Kennedy plication was used to correct the perceived attenuated and stretched support of the bladder and anterior vaginal wall. This method of prolapse correction has been shown to have an unacceptable failure rate and has not proven to be a satisfactory treatment for urinary incontinence.

This procedure is seldom used today by pelvic reconstructive surgeons.

In 1909, George White of Georgia noted that the repair of lateral anterior vaginal wall support was sufficient to correct cystocele. His observation remained largely unknown to mainstream gynecologic surgeons until the 1960s. Beginning with observations by Burch and others, the significance and importance of the lateral support of the anterior vagina began to emerge. Burch initially performed his anterior urethropexy using the white line as the ventral attachment point. He quickly abandoned the white line in favor of the more substantial Cooper's ligament. Subsequently, the importance of paravaginal defects in anterior vaginal relaxation has gradually become more and more apparent. Paravaginal defects are created when the pubocervical septum is separated laterally from the arcus tendineus fascia pelvis. A paravaginal defect is a connection between the vesovaginal space and the paravesical space. A trampoline analogy is useful in illustrating the difference between central and paravaginal defects. A central defect would result from a tear in the fabric of the trampoline. A lateral or paravaginal defect is analogous to unhooking the fabric from the side frame of the trampoline. Either defect results in a failure of the support of the trampoline. The correction of
lateral defects is now considered to be a necessary component of anterior vaginal reconstruction. In most patients, paravaginal and apical transverse defects are responsible for anterior vaginal prolapse.

A Kelly–Kennedy plication procedure bunches connective tissue in the midline. This operation actually places more stress on paravaginal defects by pulling the detached edge of the pubocervical septum farther away from the pelvic sidewall. Pelvic surgeons have learned how to identify fascial defects. To visually distinguish between the visceral fascia of the bladder wall and the pubocervical septum is possible. The bladder wall is red, distensible, and highly elastic. The pubocervical septum that is part of the deep endopelvic connective tissue is whiter in color, stands out as a separate layer, and, when closely examined, has a coarse fibrous texture. During dissection, if the surgeon irrigates with saline, the color distinction between the visceral fascia of the bladder wall and the pubocervical septum becomes even more apparent.

In the 1970s, A. Cullen Richardson and colleagues of Georgia formally described specific breaks in the deep endopelvic connective tissue (Fig. 36B.1). His observations have been confirmed by others, and these defects are described by their location and direction. For location, the terms distal, proximal, central, and lateral are used. For direction, the terms transverse and longitudinal are used. Anatomically specific terms improved the description of fascial defects. In older literature, for example, lateral defects were termed displacement cystoceles, and central defects were termed distention cystoceles.

The next major conceptual step occurred after the biomechanical observations of DeLancey (see Figs. 36A.7 and 36A.8). He recognized that each portion of the vagina relies on a different biomechanical mechanism to preserve normal anatomy. The proximal one third of the vagina is suspended by the structures of the paracolpium, primarily the uterosacral ligaments (see Fig. 36A.8). The middle one third of the vagina is supported by lateral attachments to the pelvic sidewall at the arcus tendineus fasciae pelvis. The distal one third of the anterior vagina fuses with the relatively immovable urogenital diaphragm. These concepts become very important in site-specific repairs.

Any operation that does not account for the normal attachments at all three DeLancey levels is likely to fail. Specifically, the proximal extent of the operation should extend to the inter-spinous diameter and include proximal suspension of the pubocervical septum. The lateral extent of the operation should ensure bilateral attachments of the pubocervical septum to the parietal fasciae of the pelvic sidewalls at the white lines. Each lateral attachment should include the entire length of the white line from the ischial spine to the pubic tubercle. Distally, the integrity of the connection between the pubocervical septum and the urogenital diaphragm should be assured. The only way to achieve these goals is a full-length and full-width dissection, followed by a meticulous correction of fascial defects. After the surgeon becomes practiced at detecting these separations, the reattachment becomes a relatively straightforward exercise in reconstruction.

**EVALUATION OF THE PATIENT WITH A CYSTOCELE**

Cystoceles are common in parous women, and most are asymptomatic. If they are large enough or accompanied by incontinence, the patient will seek surgical relief. Prevention and physical therapy were discussed in the previous section of this chapter. Incontinence is a major presenting symptom in women affected by pelvic support defects. Cystocele and paravaginal repair may improve the symptoms; however, these surgeries do not represent a cure for incontinence. The correction of anterior vaginal defects does play a major role in the treatment of incontinence. Cystocele and paravaginal defects should be corrected at the time of incontinence procedures to improve long-term
The normal anatomy of the pubocervical septum (see Table 36A.6) and perirectal ring (see Table 36A.8) has been described. Operative goals of anterior vaginal reconstruction are summarized in Table 36B.1. A full-length and full-width dissection of the anterior vaginal wall is necessary. If each operative goal is not satisfied, the long-term success of the surgery is jeopardized.

The patient’s legs are carefully positioned in adjustable stirrups before the surgery to avoid peripheral neuropathy, joint stress, and femoral fracture. No rotational stress should be present at the hip or knee. Ideally, the angles of the hip and knee should be 90 degrees. If extended, a line connecting the foot and knee should intersect with the contralateral shoulder. Compromises in position may be needed in patients with obesity, limitations of motion, inadequate joint mobility, or other orthopedic problems. The vaginal operative approach may not be ideal in patients whose physical limitations prevent adequate operative exposure.

The procedure begins with a lavage of the vaginal vault to remove nonadherent bacteria. Irrigation at intervals throughout the procedure serves the same purpose as irrigation during abdominoplasty. An anterior midline vaginal incision begins the surgery. If a concomitant hysterectomy is performed, the anterior midline of the vaginal cuff may be used as the starting point for the anterior vaginal wall incision. This maneuver ensures adequate proximal surgical access. In the posthysterectomy patient, the initial incision is made immediately anterior to the hysterectomy scar (Fig. 36B.2). The hysterectomy scar is usually visible as a transverse fibrous band with lateral dimples that signify the location of the remnants of the uterosacral ligaments. The midline incision is extended distally to the plane where the pubocervical septum fuses with the urogenital diaphragm. The goal of the anterior vaginal incision is to allow separation of the epithelium from the underlying deep endopelvic connective tissue (Fig. 36B.3). The plane of dissection is continued laterally in each direction to the pelvic sidewall. Separating the deep endopelvic connective tissue from the undersurface of the vaginal epithelium facilitates the dissection. This separation should begin immediately lateral to the line of incision. Once the correct dissection plane is established, the space is avascular and opens to blunt dissection (Fig. 36B.4). According to Uhlenthal, this plane of dissection is the part of the vesicovaginal space that is below the pubocervical septum. Gynecologic surgeons seldom enter the portion of the vesicovaginal space between the pubocervical septum and the visceral fascia of the bladder. Complete development of the vesicovaginal space allows access to all structures necessary for anterior vaginal reconstruction, except for the prevaginal space that is needed for urethropexy.

**SURGICAL TECHNIQUE**

The site-specific correction of anterior vaginal defects depends on access to all normal support structures. Complete restoration of the pubocervical septum and of the attachments of the perirectal ring is the surgical goal. The normal anatomy of the pubocervical ring is the surgical goal. The normal anatomy of the perirectal ring is the surgical goal. The normal anatomy of the perirectal ring is the surgical goal.
A dominant anterior posthysterectomy prolapse is grasped with two Allis clamps. Notice the hysterectomy scar posterior to the clamps. The initial anterior incision will be made in the crease between the clamps.

The vesicovaginal space is developed by separating the endopelvic connective tissue from the vaginal epithelium.

Demonstration of the avascular vesicovaginal space.

The arcus tendineus fascia pelvis or white line extends from the ischial spine to the pubic tubercle. In the lithotomy position, the distal end of this structure is approximately 60 degrees above the horizontal plane. The white line may be visible to the surgeon. This structure is the fascial white line, not the arcus tendineus levator ani or muscular white line. The easiest place to palpate the white line is adjacent to its terminus at the ischial spine. Once a suture is placed around the white line and is under slight tension, the entire length of the structure is often palpable. Before initiating a paravaginal repair, the ischial spines must be palpable and accessible at the proximal extent of the dissection.

After the completion of dissection, an inspection may be started for fascial defects (Fig. 36B.5). The visceral fascia of the bladder is red, muscular, and distensible. It has very little tensile strength. The pubocervical septum is whitish, fibrous, strong, and in a different plane than the underlying visceral fascia. Irrigation with saline causes the subtle color difference between the visceral fascia of the bladder and the pubocervical fascia to become more obvious. Careful inspection reveals the presence of fascial edges. These edges are not smooth but are ragged and often beveled or splayed. If the full thickness of the most obvious portion of the fascial edge is grasped with an Allis clamp, the entire length of the defect may become visible (Fig. 36B.6). The fascial edge may retract away from the pelvic sidewall and create a wide paravaginal defect. In an advanced or chronic prolapse, the fascial edge may retract to the contralateral side of the midline.

The ability to recognize fascial defects is acquired during careful dissection and observation. The exact pattern of fascial damage cannot be determined until dissection is completed in the operating room. The most common pattern of anterior fascial damage is a full-length patient right paravaginal defect and a transverse proximal separation of the pubocervical septum from the pericervical ring (see Fig. 36A.15). This pattern of fascial damage is consistent with the physical stress associated with the most common fetal presentation, left occipitoposterior...
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

FIGURE 36B.5. Initial identification of the ragged edge of the pubocervical septum. The central Allis clamp is grasping the fascial edge. The right paravaginal defect can be seen in the upper left portion of the incision.

FIGURE 36B.6. After all secondary adhesions are released, the fascial edge is much more apparent when grasped by Allis clamps. A full-length right paravaginal defect is seen with the pubocervical edge retracted to the midline of the body.

position, at the time of delivery. The effects of the dynamics of a typical labor on pelvic support anatomy are described in Section A of this chapter. A left paravaginal defect or bilateral paravaginal defects may be encountered. The key to successful repair is the ability to visually distinguish between the visceral fascia of the bladder wall and the pubocervical septum.

After all the secondary adhesions are freed, the edge of the fully mobilized pubocervical septum should precisely extend to the desired reattachment point: the fascial white line. Paravaginal sutures should connect the arcus tendineus fascia pelvis and lateral edge of the pubocervical septum. The placement of all sutures on a given side should precede tying. Commonly, between three and eight sutures are required for each paravaginal defect. Placement of the paravaginal sutures should begin proximally in the area adjacent to the ischial spine and proceed distally until the defect is completely closed (Figs. 36B.7, 36B.8, and 36B.9). If one accepts the premise that these defects are hernias, absorbable sutures have no place in their correction. Zero-gauge braided polyester is a useful suture; it is a soft and pliable product that is easily tied and not prone to erosion. Anatomic repairs restore the normal axis, caliber, and depth of the vagina and do not distort the anatomy of the vagina (Fig. 36B.10). The absence of anatomic distortion reduces the tension on the sutures and decreases the likelihood of suture erosion.

First, repair the largest lateral defect, and then check the contralateral side to see if the contralateral paravaginal attachment is intact. Checking the proximal portion of the contralateral paravaginal attachment is especially important because closure of the first lateral defect may increase the separation of the pubocervical fascia from the opposite pelvic sidewall, making the defect more apparent. After lateral reattachment has

FIGURE 36B.7. A 0-gauge interwoven braided polyester suture is placed through the right white line adjacent to the ischial spine (left-handed surgeon).
FIGURE 36B.8. The 0-gauge interwoven braided polyester suture from Fig. 36B.7 is passed through the detached edge of the pubocervical fascia to complete the most proximal paravaginal suture. The visceral fascia of the bladder wall is avoided to minimize the potential for urinary injury (left-handed surgeon).

FIGURE 36B.9. Four paravaginal sutures have been placed to completely close the right paravaginal defect. These sutures have been placed between the proximal edge of the pubocervical septum and the remnants of the hysterectomy scar to close the proximal transverse cystocele.

FIGURE 36B.10. After the sutures in Fig. 36B.9 are tied, the pubocervical septum is restored to its normal anatomic location.

FIGURE 36B.11. A 0-gauge interwoven braided polyester suture is placed in the left white line. This suture will be one of the anchor sutures for the interlocked polyester fiber graft shown in Fig. 36B.12.
been completed, central defects should be repaired. The most common central defect is a proximal transverse separation of the pubocervical fascia from the cervix or hysterectomy scar. Occasionally, a central defect may be encountered, which is in the configuration of an inverted "V" (see Fig. 36A.16). This type of central fascial defect is not commonly associated with paravaginal defects.

When all fascial defects are repaired, the pubocervical septum assumes its normal configuration with the distal end 60 degrees above the horizontal plane. The restoration of normal anatomy should always be in the mind of the site-specific surgeon. When fascial defects are properly identified, dissected, and repaired, the pubocervical fascia will be in the correct anatomic position as a hammock supporting the bladder with firm attachment to the pelvic sidewalls.

Proximal attachment of the pubocervical septum is the most difficult problem in anterior vaginal reconstruction. After paravaginal and central defects have been repaired, the transverse proximal edge of the pubocervical septum remains unattached. Normally, the proximal edge of the pubocervical septum connects with the pericervical ring, pubocervical ligaments, and the anterior portion of the cardinal ligaments. After hysterectomy, the normal proximal connections of the pubocervical septum are interrupted by removal of the cervix. No completely anatomic method exists to compensate for the absence of the cervix and to close the defect created by its absence.

If a hysterectomy is a part of the prolapse procedure, corrective measures can be taken to compensate for the absence of the cervix during the surgery. Plication of the cardinal ligaments across the midline and a McCall’s culdoplasty with a permanent suture will close the cervical defect. Following this plication, the proximal edge of the pubocervical septum is attached in a site-specific fashion to the anterior aspect of the cardinal ligaments. Careful attention to vaginal cuff support and closure is the most important part of a hysterectomy from the perspective of prolapse prevention.

In the posthysterectomy patient, the closure of the proximal anterior defect and the subsequent attachment of the proximal pubocervical septum are more difficult. The cardinal ligaments and uterosacral ligaments are key anatomic landmarks that are difficult to identify or mobilize during a posthysterectomy anterior vaginal dissection. Attachment of the pubocervical septum to the hysterectomy scar with permanent suture may provide sufficient support. The hysterectomy scar can mimic the function of the pericervical ring, especially if a concomitant vaginal suspension or colpopexy is performed during the same surgery. Placement of a bolster may be necessary when identifiable structures provide insufficient support. The surgeon may select from a variety of bolsters or mesh products for this part of the reconstruction. I generally use an acceptable biomaterial or a permanent interlocked polyester fiber mesh for this portion of the operation. No definitive evidence exists to show superiority of any specific bolster or graft. The surgeon should choose wisely and never substitute a foreign material for biomechanically sound surgical technique. I do not recommend the use of an extruded polytetrafluoroethylene graft in this area.
Site-Specific Repair of Cystourethrocele 881

The repair of anterior vaginal wall defects has undergone a largely conceptual revision. Anatomically distorting midline plications have been replaced by anatomically restoring operations that resemble herniorrhaphies. Anatomic landmarks define the extent of the components of the surgery. Permanent suture is used for support attachments. Anatomic restoration allows maximum potential for normal urinary, intestinal, and sexual function in the patient. To paraphrase the biological adage: function follows form.

BEST SURGICAL PRACTICES

- Site-specific techniques should be used to restore the anatomy of a prolapsed anterior vaginal segment.
- The pubocervical septum must be dissected completely so that specific fascial defects can be identified and repaired.
- Cystoceles are typically due to apical transverse defects in the pubocervical septum. Central defects in the pubocervical septum are not common or typical.
- The pubocervical septum is shorter than the rectovaginal septum by a length equal to the diameter of the cervix. Complete restoration of the anterior vaginal segment must take into consideration the defect left by the absence of the cervix.
- A cystocele may be due to detachment of the trampoline-like pubovesicle septum from the proximal attachment to the pericervical ring, from the lateral attachments to the white line, or from its distal attachment to the pubic ramus. It can also result from a central tear in the septal fascia itself. Each and every defect must be evaluated and repaired to provide a long-term successful result.

CHAPTER 36C ■ PARAVAGINAL DEFECT REPAIR
BOBBY SHULL AND PAUL M. YANDELL

DEFINITIONS

Arcus tendineus fascia pelvis—The white line of the pelvic sidewall. This thickening of the pelvic sidewall fascia extends from the ischial spine posteriorly to the pubic tubercle anteriorly. It is the site of lateral attachment of the pubocervical fascia.

Paravaginal defect—When the pubocervical fascia becomes detached from, or torn just medial to, its lateral attachment to the arcus tendineus fascia pelvis (white line).

Pubocervical fascia—A trapezoid-shaped fascia that provides support for the anterior vagina under the bladder. It is attached superiorly to the pericervical ring, distally to the pubic ramus, and laterally to the arcus tendineus fascia pelvis (white line).

HISTORY

In 1909, George R. White quoted Ahlfelt, who said, “the only problem in plastic gynecology left unsolved by the gynecologist of the past century [the 19th century] is that of permanent cure of cystocele.” Three years later, in 1912, White reviewed the current theories regarding the etiology of cystocele: overstretched and thinning of the vaginal wall and other supports of the bladder, which allow the bladder to descend in the form of a hernia; stretching of the firm attachment of the bladder to the uterus; and stretching of the ligamentous suspension of the bladder. He rejected each of these theories and also described his autopsy findings regarding the dissection of the anterior vaginal segment. One year before Howard Kelly's report on midline plication of the anterior segment, he discussed vaginal paravaginal repair for the management of certain types of cystocele; however, his theory and recommendation for surgical management did not gain widespread acceptance.

In 1923, Victor Bonney described the “periurethral wedge” that he found attached “to the subpubic angle, the rami of the pubes, and the edges of the levatores ani” and the association between this wedge and the mechanism of continence. Bonney suggested a retroperitoneal repair of the loosened periurethral wedge in the treatment of incontinence. In 1961, Burch reported his experience with colposuspension. He attached the paravaginal fascia to the white line of the pelvis in his first seven patients. Subsequently, he chose Cooper's ligament as the point of fixation. In the next decade, Richardson and colleagues published a “new” and controversial look at pelvic relaxation and its relationship to fascial defects.

ANATOMIC CONCEPTS AND PHYSICAL FINDINGS

Stimulated by the work of Richardson and Baden, we have found it valuable to consider that isolated defects in the anterior compartment not only do occur but must be properly identified and specifically repaired to offer the best opportunity for cure of anatomic and functional symptoms of the anterior vaginal segment. The pubocervical fascia is a trapezoid, part of which was described by Bonney more than 70 years ago. The fascia or fibromuscular tissue of the anterior vagina fuses with the perineal membrane distally, is attached to the arcus tendineus fasciae pelvis from a point just posterior to the pubic ramus to a point just anterior to the ischial spine bilaterally, and is attached to the cervix or to the vaginal cuff and base of the broad ligament and cardinal-uterosacral ligaments (Fig. 36C.1).

There are four clinically identifiable areas in which defects in this support are likely to occur:

■ Laterally, where the pubocervical fascia attaches to arcus tendineus fascia pelvis (paravaginal defect)

■ Transversely, in front of the cervix where the pubocervical fascia blends into the periurethral ring of fibromuscular tissue, or in the case of a woman who has had a hysterectomy, at the vaginal cuff (transverse defect)

■ Centrally, in the area immediately anterior to the vaginal mucosa in between the lateral margins of the pubocervical fascia (midline or central defect)

■ Distally, where the urethra perforates the urogenital diaphragm

These isolated defects may occur in combination, requiring the surgeon to identify and repair each defect individually. The clinical evaluation provides clues about the site of the fascial defect. The examination should be performed with the woman in the lithotomy position and the physician using only the posterior blade of the speculum. The patient is asked to strain or bear down maximally while the physician observes the landmarks of the anterior vagina. It is difficult to recognize an abnormal examination without having an understanding of normal. In a woman with normal support and no functional symptoms, there is minimal descent of the urethra and urethrovesical junction on straining. There are lateral sulci in the anterior vagina at the site of attachment of the pubocervical fascia to the arcus tendineus fascia pelvis that extend from the back of the pubic bone to a point just anterior to the ischial spine (Fig. 36C.2). The anterior vaginal wall is normally about a centimeter shorter than the posterior vaginal wall. There are usually rugae in the epithelium overlying the urethra and bladder.

In a woman with paravaginal loss of support, one or both lateral sulci will be lost. Observations by DeLancey have shown...
that defects occur with equal frequency on the left and right sides and are associated with hypermobility of the urethra and urethrovesical junction. When the support defect is predominantly paravesical, the support for the bladder is also poor. Loss of paravaginal support can also be detected during use of the bivalve speculum when the clinician finds that the sides of the vaginal walls collapse through the open sides of the bivalve speculum, obscuring view of the cervix or vaginal apex.

Baden and Walker have recommended the use of a curved ring forceps to elevate the lateral aspects of the anterior vagina to their normal points of attachment along the pelvic sidewall. The curved arms of the ring forceps are directed laterally and posteriorly toward the ischial spines as the patient bears down. When this lateral elevation corrects the support defect, the diagnosis of a paravaginal defect can be made (Fig. 36C.3). If the patient continues to have a bulge of tissue through the open arms of the forceps, she either has a midline loss of support or a combined midline and lateral loss of support. Imaging studies such as magnetic resonance imaging and ultrasound provide details not only about connective tissue support in the pelvis but also about muscle integrity.

Women with complete eversion of the anterior vaginal segment must, by definition, have not only paravaginal loss of support for the urethra, urethrovesical junction, and bladder but also loss of support for the transverse portion of the pubocervical fascia. The eversion may occur in association with procidentia or posthysterectomy vaginal prolapse (Fig. 36C.4). In our own practice, management of the prolapsed anterior vaginal segment is technically the most challenging dilemma because it may require correction of a complex set of problems, including urinary incontinence; incomplete bladder emptying; impaired intravaginal intercourse; symptoms of prolapse, such as pressure, fullness, and a sense of things falling out; or any combination of these. Successful management of prolapse of the anterior vagina should ultimately result in correction of the poor support, maintenance or enhancement of the ability to have intravaginal intercourse, and maintenance or enhancement of urinary continence. A particularly difficult challenge is the patient with complete eversion of the vagina. Vaginal and abdominal operations for the treatment of vaginal vault prolapse are usually successful in suspension of the vaginal cuff. However, a 1992 study found a 15% to 25% incidence of postoperative urinary incontinence and a 15% incidence of persistent or recurrent cystocele.

**OPEN RETROPUBIC TECHNIQUE**

Paravaginal defects can be surgically repaired through an open retropubic incision, through a vaginal retropubic incision, or laparoscopically. We use the open retropubic repair primarily in the treatment of women who have genuine urinary incontinence associated with paravaginal defects. The operation can
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

be performed with or without hysterectomy. If hysterectomy is performed, we prefer the intrafascial technique and incorporate the cardinal uterosacral ligaments into the angles and the pubocervical and rectovaginal fascia to minimize the occurrence of postoperative enterocoele formation. In women with a preoperative enterocoele and prior hysterectomy, we repair the enterocoele in association with the paravaginal defect repair. The paravaginal repair is performed after completion of the hysterectomy or culdoplasty. The patient’s legs are in low leg holders, and she is draped so that there is access to the abdomen as well as to the vaginal canal. A Foley catheter drains the urinary bladder. We prefer a low transverse abdominal incision made about one finger breadth cephalad to the symphysis pubis. The incision is carried to the anterior sheath of the rectus fascia, which is incised sharply. The rectus muscles are reflected laterally. The transversalis fascia is separated from the superior ramus of the pubic bone, and the space of Retzius is entered immediately medial to the superior ramus of pubis on each side. The loose areolar tissue can easily be dissected away from pubic bone by use of either the index finger or a pair of long tissue forceps. The bony landmarks in the pelvis are identified by palpation. The symphysis pubis, the midline landmark, is almost always convex. The pubic bone extends laterally and gently curves posteriorly. The next palpable landmark is the obturator neurovascular canal, which can be felt along the inferior border of the superior ramus of pubis. A set of larger veins that course between the anterior surface of the urethra and back of the pubic bone can also be the source of considerable bleeding. When they obstruct the dissection or interfere with the operative repair, they should be clipped with silver clips and divided sharply to fall out of the operative field. After the proper cleavage plane has been established, a fluffed-up 4-inch piece of gauze should be placed in the space to rest on the anterior surface of the vagina. Then a small or medium malleable ribbon retractor should be used to hold the bladder and urethra medially while the remaining landmarks are identified by direct visualization. To minimize bleeding, the bladder should never be reflected off of the anterior surface of the vagina. The vessels in the bladder generally course medially to laterally across the operative field. The vessels in the vagina generally course anteriorly to posteriorly. We dissect both the left and the right sides of the space of Retzius before beginning any of the operative repair. We find it helpful to use the long extension for the electrocautery in case it is necessary to cauterize bleeding points.
The operating surgeon stands on the patient’s side opposite to his/her dominant hand. Suturing away from the urethra and bladder to decrease the chance of urologic injury requires backhanding the sutures when sewing at the side of the table on which the surgeon is standing. We prefer to use round tapered needles and 2-0 nonabsorbable suture for the repair. A long needle driver such as is used in chest surgery allows one to reach even the deepest portion of the retro-pubic space without having a hand directly in the operative field.

Paravaginal defects can occur in one of three different ways (Fig. 36C.6):

1. The entire arcus may remain attached to the pelvic sidewall with the pubocervical fascia breaking away from the arcus (Fig. 36C.6).

FIGURE 36C.4. A: Physical findings in the standing patient who has prolapse of the anterior segment (1) as well as uterine prolapse (2). B: Posthysterectomy prolapse of the anterior vaginal segment (1), vaginal cuff (2), and enterocele (3). (From Shull BL. Clinical evaluation of women with pelvic support defects. Clin Obstet Gynecol 1993;36:939.)

FIGURE 36C.5. The key anatomic landmarks in the space of Retzius in a woman with normal findings. (From Shull BL. How I do abdominal paravaginal repair. J Pelvic Surg 1995;1:43.)
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

2. The arcus may pull away from the side of the pelvis but remain attached to the pubocervical fascia (Fig. 36C.6C). 3. The arcus may split, with a portion of it remaining attached to the sidewall and a portion tearing away but remaining attached to pubocervical fascia (Fig. 36C.6D).

In any circumstance, the goal of the operative repair is to reattach the pubocervical fascia to the arcus tendinous fascia pelvis, as well as to the fascia overlying the obturator internus muscle.

The easiest point of identification of the white line is near its insertion at the back of the pubic bone. Using a pair of tissue forceps to grasp the white line and place it on tension makes it easier to identify the remainder of the white line as it courses toward the ischial spine. The smooth white fibromuscular tissue of the pubocervical fascia is always medial to the white line. The most dependent portion of the operative field is the perivesical space adjacent to the ischial spine. Any bleeding results in the collection of blood in that space; therefore, we prefer to initiate the repair near the vaginal apex while the field is quite dry.

The nondominant hand is placed into the vaginal canal to elevate the perineal raph and perivesical tissue to its site of normal attachment along the white line. The first suture is placed near the apex of the vagina through the perivesical portion of the pubocervical fascia. When permanent sutures are used, one should avoid penetration of the vaginal epithelium. If the needle is placed at a right angle to the fibromuscular tissue, it is easier to retrieve and place it through the white line and obturator internus fascia at a point 1 to 2 cm anterior to its origin at the ischial spine. The suture is securely tied with a series of four knots and the excess trimmed. We prefer to place the next suture at the opposite end of the repair through the pubocervical fascia near the distal portion of the urethra. The needle is regrasped and placed through the white line near its origin from the back of the pubic bone. The suture is similarly secured with four knots and the excess cut. At that point, the two extreme ends of the repair have been performed (Fig. 36C.7A). The pubocervical fascia and white line stand out on relief, making it easier to determine the placement of subsequent sutures.

I prefer to place the remaining sutures sequentially beginning proximal to the apical stitch. About four to six sutures are required for each side. In some patients, the vascular supply to the vagina is so generous that it is impossible to avoid suturing through or around a vessel. When each suture is tied as placed, significant bleeding is rarely a problem. Bleeding becomes a problem, however, if a needle is placed through a vein and the needle is removed without tying the suture down. Bleeding can also be a problem if one chooses to dissect the bladder or urethra off of the anterior surface of the vagina. When the sutures have all been placed on one side, the suture line adjacent to the urethra and urethrovesical junction is about horizontal to the floor (Fig. 36C.7B). The suture line from the urethrovesical junction to the apex of the vagina angles gently posteriorly. The same sequence of sutures is repeated on the opposite side (Fig. 36C.7C). We have used this repair for hundreds of patients over 14 years and have not left a drain in the space of Retzius in a single patient.

In patients who undergo a retropubic repair only, my goal is to dismiss them on the same day the procedure is performed. In these patients, we inject the incision site with a short-acting local anesthetic agent before making the incision and with a longer-acting local anesthetic agent when the wound is closed. When the patient is fully awake and can ambulate, the indwelling Foley catheter is used to empty the bladder fully. Next, the bladder is filled retrograde with 300 mL sterile saline and the catheter is removed. The patient is allowed to void. If she voids more than 150 mL, she is dismissed without a catheter; if not, she is dismissed doing intermittent clean self-catheterization (ICSC). For the last 7 years, all our patients with retropubic repair only have been dismissed on the same day of surgery.

In patients who have more extensive surgery and are admitted overnight, the same catheter management is used the morning following surgery after the patient has breakfast. In the exceptional patient who cannot perform ICSC, either a family member is taught to perform the catheterization or the patient is dismissed with a Foley catheter to closed drainage. A few days later, the patient returns for retrograde filling and a test of bladder function.
Some surgeons who treat vaginal eversion by sacral colpopexy have begun to incorporate the paravaginal repair as a part of the total vaginal reconstruction. After completion of the sacral colpopexy, the paravaginal repair is performed as previously described. Others perform a combined Burch procedure and paravaginal repair in association with a sacral colpopexy. After the sacral colpopexy is completed, the sutures adjacent to the urethra and the urethrovesical junction are placed through the Cooper’s ligament, as is done in the modified Burch colposuspension. The perivesical

FIGURE 36C.7. A: A patient with bilateral paravaginal defects. The repair has been started on the left with sutures at the two extremes of the defect. B: The repair is complete on the left side. C: Both sides are repaired. (From Shull RL. How I do abdominal paravaginal repair. J Pelvic Surg 1995;1:43.)
loss of support is then repaired with a series of paravaginal sutures.

VAGINAL RETROPUBIC TECHNIQUE

The vaginal approach to the paravaginal repair is particularly helpful in women whose primary symptom is pelvic organ prolapse without significant urinary incontinence. The vaginal approach requires greater technical skills than does the open retropubic repair. It has a limited use for the general gynecologic surgeon. The angle of the subpubic arch is the most important factor affecting access to the retropubic space. In a woman with a subpubic arch that admits three or more finger breadths, several retractors can easily be placed in the retropubic space, making the vaginal approach technically possible. In a woman with prolapse of the anterior segment and a narrow subpubic arch, I prefer a combination approach, managing the defects that can be handled appropriately through a vaginal incision and completing the retropubic repair through a transabdominal incision.

In the vaginal approach to paravaginal repair, the following steps are used. The patient's legs are placed in high leg holders, and the bladder is drained before the initiation of the surgical procedure. All segments of the vaginal canal area are thoroughly evaluated to confirm the fascial defects. The anterior vaginal segment is examined, specifically to observe loss of lateral sulci, lack of rugation of the epithelium along the base of the bladder, and elongation of the cardinal-uterosacral ligament pedicle, and the ligament itself can be palpated as it courses posterior and medial to the ischial spine. Nonabsorbable sutures are used to initiate the culdoplasty. Regardless of the technique used for the hysterectomy, the cardinal-uterosacral ligament pedicles are clamped, divided, and tagged to be used later for support of the vaginal apices. A cross-clamp, cut, and tie technique is used to perform the hysterectomy. The cardinal-uterosacral ligament pedicles are clamped, cut, and tied to facilitate placement of subsequent sutures. A cross-clamp, cut, and tie technique is used to perform the hysterectomy. The cardinal-uterosacral ligament pedicles are clamped, cut, and tied to facilitate placement of subsequent sutures. The obliteration of the para-rectal space, making the vaginal approach technically possible. In a woman with prolapse of the anterior segment and a narrow subpubic arch, the bladder is drained before the initiation of the surgical procedure. All segments of the vaginal canal area are thoroughly evaluated to confirm the fascial defects. The anterior vaginal segment is examined, specifically to observe loss of lateral sulci, lack of rugation of the epithelium along the base of the bladder, and elongation of the cardinal-uterosacral ligament pedicle, and the ligament itself can be palpated as it courses posterior and medial to the ischial spine. FIGURE 36C.12. The suture in the arcus tendineus fasciae pelvis near the pubic bone is also sewn into the lateral margin on the pubocervical fascia periurethrally and into the undersurface of the vaginal epithelium at the site of the marking suture at the urethrovesical junction. (From Shull BL, Benn SJ, Kuehl TJ. Surgical management of prolapse of the anterior vaginal segment: an analysis of support defects, operative morbidity, and anatomic outcome. *Am J Obstet Gynecol* 1994;171:1429.)
The goal of the operative repair of a paravaginal defect is to reattach the pubocervical fascia to the arcus tendineus. The patients are ambulated and fed an oral diet on the afternoon or evening of the day of surgery. The transurethral catheter management is the same as for an abdominal repair. If the patient can void spontaneously with a residual volume of less than 150 mL, no further catheterization is required. If she cannot, she is taught ICSC and is dismissed with instructions to continue ICSC until she can spontaneously void 150 mL or more and has a postvoid residual volume of 150 mL or less.

### SUMMARY

There are several ways to approach the management of paravaginal defects of the anterior compartment. In a woman with genuine urinary incontinence as a primary symptom, an open retropubic paravaginal repair may provide excellent relief. However, a valid criticism is that this procedure has not been subjected to the rigorous preoperative and postoperative urodynamic testing used for the Burch colposuspension and the Marshall-Marchetti-Krantz procedure. Reports by Richardson and associates and Shull suggest that paravaginal repair is efficacious in the management of genuine urinary incontinence in properly selected patients. Our clinical impression, documented by longitudinal follow-up of our patients, is that women with uncomplicated urinary incontinence, urethral hypermobility, a positive provoked full-bladder stress test, and lateral loss of support—as well as women with no incontinence but paravaginal defects and cystocele—are candidates for paravaginal repair. Colombo and associates performed a randomized comparison of the Burch procedure and abdominal paravaginal repair for urinary incontinence and reported that the Burch procedure was superior for the treatment of urinary incontinence. The patients who underwent a paravaginal repair resumed spontaneous voiding more quickly. However, the potential disadvantages include an opportunity for repair of isolated defects in the pubocervical fascia to the apex of the vagina, a posterior axis for the vaginal canal, and anterior support loss. In patients who have no significant urinary incontinence but who have prolapse of the anterior vaginal segment with paravaginal defects, the vaginal paravaginal repair is attractive because there is less manipulation of the bowel, avoidance of an abdominal incision, and decreased adverse effects on pulmonary function. However, the potential disadvantages include the greater technical difficulty of the repair and the unknown effects of extensive anterior dissection on bladder innervation and durability of the repair. Our clinical impression is that attention to suspension of the transverse pubocervical defect, which is present in all patients with significant paravaginal defects, is of paramount importance in decreasing the risk of recurrent anterior compartment and apical prolapse. A recent retrospective study by Morse did not find that adding vaginal paravaginal repair to midline pubocervical placation and apical support was superior in terms of anatomy or quality of life outcomes.

### BEST SURGICAL PRACTICES

- The goal of the operative repair of a paravaginal defect is to reattach the pubocervical fascia to the arcus tendineus...
Paravaginal Defect Repair

Using an open retropubic technique, the bony landmarks of the pelvis are identified by palpation; then tissue forceps are used to develop the space between the pelvic sidewall fascia and the bladder and urethra. Care is taken to avoid venous bleeding in this area.

After the white line and the lateral edge of the pubocervical fascia have been identified, a series of interrupted 2-0 permanent sutures are placed about 1 to 2 cm apart to reapproximate the fascial edge to the white line of the pelvic sidewall fascia.

When a transvaginal approach is used, the retropubic space is opened and cleared back to the ischial spine and the important landmarks visualized as with an anterior retropubic approach. Starting near the ischial spine, a series of sutures are placed in the white line and held with the needles in place. Then, in reverse order, starting with the most distal suture, a bite is taken in the edge of the pubocervical fascia and the undersurface of the vaginal mucosa. The process is repeated, advancing deeper into the pelvis until the highest suture is placed. The sutures are then tied, starting with the one closest to the vaginal introitus and proceeding to the vaginal apex. The vaginal mucosa is then closed in the midline.

An indwelling catheter is not used. If patients cannot void spontaneously, they are taught self-intermittent catheterization. They are given a regular diet as desired. If no other surgery has been done, they may be discharged later the same day or the next morning.

Posterior vaginal compartment (posterior compartment, posterior vaginal wall, posterior segment)

DEFINITIONS

Anal manometry—A test that uses a pressure-sensitive catheter to measure pressures generated in the anal canal and at the anal sphincter.

Defecography—A fluoroscopy study to assess anatomy by watching the patient evacuate radiopaque dye. It outlines urogenital hood, enterocele, rectoceles, and rectovaginal septum.

Endopelvic fascia—The term used to describe in general all the supporting tissues of the pelvis.

Enterocele, rectoceles—The terms historically used to describe protrusion of the vaginal apex with enteric contents or a bulge in the posterior vaginal wall, respectively.

Genital hiatus—The central opening in the pelvic floor through which passes the urethra, vagina, and rectum.

Pelvic floor dysfunction—An all-encompassing term to describe any or all of the patient's symptoms that may be related to pelvic organs. The most common symptoms in the posterior compartment will be those of a mass, the inability to begin emptying or incomplete emptying of the rectum, rectal incontinence, and discomfort or pain. No physical finding on examination is directly related to the degree of patient inconvenience.

Perineal body—A confluence of connective tissue of the bulbocavernous muscles, transverse perineal muscle, pelvic membrane, anal sphincters, and anchoring sites to the pubic rami, and ischial tuberosities that together make up a central tendinous insertion on the perineum. It is shaped like a pyramid, with the base on the perineum, and extends cephalad 2 to 5 cm to join the rectovaginal septum.

Perineal descent—A bulge in the perineum with straining to below the ischial tuberosities. The total lack of muscular attachment allows the examiner to easily pull the perineum caudally, even against voluntary resistance by the patient.

Posterior colporrhaphy—The operation that divides the epithelium of the posterior vaginal wall and sews together the underlying tissues of the posterior vaginal wall in the midline (plackets), often from the vaginal apex to the perineal body. It is the oldest common operation to repair dysfunction thought to have an anatomic cause related to the posterior vaginal wall.

Posterior vaginal compartment (posterior compartment, posterior segment)—The posterior vaginal compartment encompasses the dorsal wall of the vagina and its supporting structures and therefore extends from the uterosacral and cardinal ligament attachments of the vagina at the perineal connective tissue ring to the perineal body.

Rectovaginal septum (RVS) or fascia of Denonvilliers—The connective tissue immediately dorsal to the epithelium of the posterior vaginal wall. It is not a histologically distinct structure but rather a confluence of connective tissue that supports and attaches the posterior vaginal wall to the underlying rectum, lateral levator muscle, and perineal body.

Site-specific defect—An anatomic discontinuity in the pelvic connective tissue network that allows the pelvic surgeon to identify and repair a specific break in the connective tissue network of the pelvis.

Uterosacral ligaments—The posterior thickenings of the network of endopelvic connective tissue that extend separately from the midsacrum to the 5- and 7-o'clock positions on the posterior vaginal wall.

With improved understanding of female pelvic floor anatomy and pathophysiology has come change in the gynecologist's treatment of disorders of the posterior vaginal compartment, referred to throughout the remainder of this subchapter as posterior compartment. The current concepts used by pelvic reconstructive surgeons are well described by Carl Zimmerman in Chapter 36A. For a better understanding of this subchapter, the reader is advised to read that material before this one.

Students and practitioners interested in pelvic floor dysfunction should no longer consider patient symptoms that seem to be related to the posterior vaginal wall as being caused by a rectocele and curable with posterior colporrhaphy. Leaders in gynecologic surgery are trying to abandon the concept of rectocele and replace it with terms describing specific anatomic defects (site-specific defects).

ANATOMY IN RELATION TO PELVIC REPARATIVE SURGERY

The vagina is a hollow, pliable tube about 9 cm long anteriorly and 11 cm long posteriorly. The caudal 3 cm of the posterior vaginal wall is held in place by connective tissue attachments to the perineal body and ischiopubic rami. The midvagina attaches laterally to the connective tissue covering the medial portion of the ischial. The levator muscle covering fuses laterally to the obturator internus fascia and ultimately to the bony pelvic sidewall. The connective tissue immediately dorsal to the epithelium of the posterior vaginal wall is called the rectovaginal septum or the fascia of Denonvilliers. The rectovaginal septum is not a histologically distinct structure but rather a confluence of connective tissue that supports and attaches the posterior vaginal wall to the underlying rectum. The upper vagina attaches to the uterosacral ligaments on the posterior pericervical connective tissue ring and anterior to pubocervical connective tissue. The uterosacral ligaments

892
are mainly smooth muscle, nerves, blood vessels, and some connective tissue. In the standing position, the uterosacral ligaments are almost vertical in orientation, suspending the vagina as these ligaments fan out in the retroperitoneal space into a broad attachment bilaterally over the second, third, and fourth bony sacral segments. The cephaladmost posterior compartment is continuous with the apical vaginal compartment. The apical compartment consists of the cervix, located on the anterior vaginal wall, with its attachments to the pubocervical connective tissue anteriorly, the cardinal ligaments laterally, and the uterosacral ligaments posteriorly. The fusion of the cephalad margins of the connective tissue surrounding the cervix and upper vagina make up the pericervical connective tissue ring (Fig. 36D.1).

In posterior segment reparative surgery, the uterosacral ligaments are the major support structure. The contiguity of the connective tissue of the uterosacral ligaments with the connective tissue of the rectovaginal septum and perineal body are the suspensory mechanism holding the vagina in its normal anatomic position.

The Vaginal Axis: The Pelvic Valve Mechanism

The distal one third of the vagina in the standing individual ascends almost vertically, then angles 120 degrees dorsally in its upper two thirds. This angulation is caused by connective tissue attachments that tether the vagina over the midline levator plate. Held in this position, the vagina will not move caudally through the opening in the pelvic floor called the genital hiatus. If the connective tissue supports do not hold the vagina in this position, the genital hiatus will not be a closed valve but rather a portal for descent of the bladder, uterus, and rectum when intrapelvic/abdominal pressure increases. Current thinking hypothesizes that the pathologic changes in the position of the vagina and contiguous organs, called urogenital or genital prolapse, results from breaks, attenuation, and/or loss of function in supporting tissues and mechanisms.

Surgery can often correct pathologic anatomic changes and resultant symptoms (pelvic floor dysfunction). When surgery is selected as the treatment, the goal becomes the restoration of the anatomic relationships by either repairing connective tissue supports or by creating a compensatory support mechanism. Although a simple concept, historically, operations did not emphasize repairing an entire connective tissue network, but were incorrectly thought of as organ specific (cystocele, enterocele, rectocele, etc.). Operations were artificially thought of as reinforcing attenuated tissues surrounding organs in contact with the vagina.

In truth, the support for the pelvis is not from ligaments and fascia but a network of connective tissue that intertwines as it surrounds organs. In surgical repair of the female pelvic organ prolapse, the gynecologist uses portions of the entire network of connective tissue, trying to restore the continuity that was lost in those tissues surrounding and supporting the uterus, bladder, vagina, and rectum. The terms cystocele, rectocele, enterocele, urethrocele, and perineocele do not aid in

**FIGURE 36D.1.** The network of pelvic connective tissue. The cephalad posterior compartment is continuous with the apical vaginal compartment at the pericervical connective tissue ring. The pericervical connective tissue (PCT) ring is the area around the cervix where there is anteriorly pubocervical connective tissue, laterally the cardinal ligaments (C.L.), and posteriorly the uterosacral ligaments (USL), which fuse with the rectovaginal septum (RVS), which continues caudally to fuse with the perineal body (PB). The connective tissue network is a continuous structure. It is this network (A) that tethers and supports the vagina in its normal axis (B) over the levator ani muscle (LA).
understanding the loss of continuity of the connective tissue network. They are not site specific. For many surgeons, the gynecologic conditions traditionally referred to as enterocoele and high rectocele are two separate entities. To the experienced pelvic surgeon, they are the same anatomic defect—detachment (loss of continuity) between the rectovaginal septum and uterosacral ligaments. Later descriptions in this discussion will not describe defects or their repair as isolated phenomena, but will try to integrate what are epiphenomena.

**PATIENT SELECTION AND SURGICAL PREPARATION**

**History**

Every surgical procedure should begin, first and always, by determining who would benefit from the operation. In our experience, symptoms of posterior compartment defects include (i) a sensation of fullness or heaviness in the vagina or pelvis made worse by activities that increase intraabdominal pressure, like lifting, exercise, or standing for long periods of time; (ii) bulging mass that increases in prominence with increased activity or as the day progresses; (iii) difficulty initiating stool evacuation from the rectum and anal canal, often accompanied by splinting of stool (placing a finger in the vagina to push stool out the rectum); (iv) feeling of incomplete stool evacuation; and (v) discomfort with intercourse, generally described by the patient as feeling like an obstruction is present.

The examiner should pay special attention to the description of patient symptoms. The sensation of fullness may be accompanied by low back discomfort or pulling, but a posterior compartment defect should not be assumed to be a common cause of low back pain. Difficulty eliminating stool should not be confused with constipation or delayed intestinal transit. When a patient has a history of dry, hard stool, infrequent bowel movements, or bowel movements that alternate between constipation and diarrhea, it is unlikely that an operation will improve this patient's symptoms. Patients with stool incontinence or continuous leakage (sergeage) or fecal staining or who have difficulty recognizing when stool is present in the rectum are more likely to have a disruption of the anorectal sphincter mechanism, prolapse of the rectum, a neurologic dysfunction, an anatomic bowel lesion, poor hygiene, or impaction than an anatomic defect of the posterior compartment. The patient who splints stool by pressing on the perineum or lateral to the rectum often has a perineal support defect rather than a defect of the rectovaginal septum.

Sexual dysfunction has many causes, but seldom is it related solely to an anatomic defect of the posterior segment. Dryness, irritation, burning, or pain in the vagina with intercourse, especially at the introitus or confined to the apex, is more likely an infection, genital atrophy, pelvic pathology, or vulvodynia. Discomfort the patient describes as an obstruction to perineal penetration is the symptom produced by a bulging posterior vaginal wall from retained stool.

**Examination**

Pelvic examination can be used to diagnose most posterior compartment defects in a manner that allows the examiner to identify a site-specific defect in the continuum of the pelvic connective tissue network. Knowing the underlying anatomic defect allows the surgeon to plan surgery to repair a specific defect. Most defects can be detected during examination with the patient in the dorsolithotomy position. Some examiners recommend that the patient be examined in the standing position with the examiner kneeling on the floor. In the occasional patient in whom I have not been able to find the vaginal compartment defect in the dorsolithotomy position, I have done this—but with limited success.

When a defect cannot be identified, it has been more helpful to us for the examiner to instruct the patient to get up from the examining table, strain on the toilet, perform isometric lifting, or perform whatever maneuver she feels exacerbates her symptoms. The examiner leaves while the patient does this and returns to re-examine after the provocative maneuvers have been completed. If I still cannot find an anatomic defect, the patient leaves the clinic, performs whatever activity brings on the problem and returns for examination later in the day or on another day when symptoms or findings are most prominent.

I find the following examination sequence, a modification of that described by Ruden and Walker, essential to diagnose defects and plan treatment. The examination consists of: (i) providing retraction for exposure of the area of the vaginal compartment to be examined; (ii) asking the patient to strain; (iii) determining descending part of the vagina and degree of descent; (iv) simulating normal support using a ring forceps to reduce the defect; and (v) asking the patient to strain again with the ring forceps in place to see if this manual assistance (which simulates surgical repair) corrects the anatomic defect. In general, there are five defects, which may occur alone or in any combination, that the examiner can identify in the posterior compartment: (i) detachment of the rectovaginal septum from the uterosacral/pericervical connective tissue ring; (ii) central or lateral defects in the midvaginal portion of the rectovaginal septum; (iii) detachment of the rectovaginal septum from the perineal body; (iv) disruption of the perineal body; and (v) disruption or attenuated external anal sphincter (Fig. 36D.2).

To diagnose defects of the posterior compartment, the patient is asked to bear down, and the vaginal introitus and perineum are inspected. A bulging mass at the posterior introitus is part of a posterior compartment defect, most often above the external anal sphincter. If straining produces more than 2 cm of perineal descent or the perineum descends beyond the ischiorectal tuberosities or the anus becomes the most caudal (dependent) portion of the perineum, there is a perineal body defect (disruption of the perineal body); most often a disruption of the distal rectovaginal septum from the perineal body and/or transverse perineal muscle detachment from the central tendon of the perineum.

**Detachment of the Rectovaginal Septum**

To improve visualization, the posterior blade of a Graves speculum elevates the anterior vaginal wall. Lack of posterior vaginal wall rugae indicates the underlying connective tissue is detached from the surface epithelium. Often this lack of rugae begins at the top of an episiotomy scar.

The patient strains, and if on straining, posterior vaginal wall descent occurs, there is a posterior compartment defect. If the placement of the posterior speculum blade to the vaginal apex completely reduces the descent, it is likely that the vaginal support defect is apical, involving what has been referred to as an anterior enterocoele. This defect is a perirenal sac containing small bowel, most often adherent to the posterior bladder wall. This defect is most commonly found after a colposuspension procedure.

If the defect is still present, the ring forceps are used to support the posterior vaginal fornix toward the hollow of the...
Posterior Compartment Defects

There are five general ways to describe defects by site in the posterior compartment. They may occur alone or in any combination. All must be identified for successful reconstruction: (1) detachment of the rectovaginal septum from the uterosacral/pericervical connective tissue ring, (2) central or lateral defects in the midvaginal portion of the rectovaginal septum, (3) detachment of the rectovaginal septum from the perineal body, (4) disruption of the perineal body, and (5) disruption or attenuation of the external anal sphincter.

Sacrum. If on straining, this maneuver reduces the mass in total, the defect is a detachment of the cephalad rectovaginal septum from the uterosacral ligaments. If the mass still bulges, the speculum blade should be placed on the anterior vaginal wall to the apex and the ring forceps on the posterior vaginal wall to the apex, and both are slowly withdrawn. If slow withdrawal immediately produces a bulge that enlarges as the two instruments are withdrawn, there will be a peritoneal sac with small bowel or omentum in addition to detachment of the rectovaginal septum.

As a second maneuver, the presence of this sac can be confirmed on bimanual examination. The examiner inserts one index finger in the patient's rectum and the other index finger in the vagina. The sac can be felt to slide between the examining fingers. As a third maneuver, the rectal examining finger can be inserted as high into the rectal canal as possible, and the examiner determines whether his/her finger enters the bulge. If the mass is rectum alone; if it does not, there is a bowel-containing sac (enterocele) or the very rare entity of sigmoidocele. As mentioned before, there is no anatomic difference between a lack of support of the vaginal apex, traditionally called an enterocele, and the posterior compartment defect referred to as a high rectocele. Both defects result from the rectovaginal septum being detached at the cephalad portion of the pericervical connective tissue ring at the uterosacral ligaments.

Central and Lateral Defects in the Rectovaginal Septum

The midportion of the rectovaginal septum at the posterior cul-de-sac (pouch of Douglas) contains little connective tissue. The rectovaginal septum (thickened connective tissue), therefore, is not palpable centrally between the attachments of the uterosacral ligaments. About 4 cm from the apex, the connective tissue of the rectovaginal septum becomes palpable and extends to the introitus where the last 2 or more centimeters is contiguous with the perineal body.

Detection of tears or detachments of the rectovaginal septum may be done both in the office and at the time of surgery by the examiner placing a finger in the patient's rectum and sweeping widely from lateral to medial along the entire rectovaginal septum (Fig. 36D.3). When the examiner's finger palpatates the defect, the digit can be seen to enter the defect, lifting the posterior vaginal wall at the defect site. Lateral defects are detachments of the rectovaginal septum from the levator fascia; central defects are breaks in the rectovaginal septum. Repeating this maneuver in the operating room is essential to find and fix defects in a site specific manner.

Detachment of the Rectovaginal Septum from the Perineal Body

The examiner's index finger is gently moved upward from the external anal sphincter toward the vaginal introitus. If there

External anal sphincter

FIGURE 36D.3. Detection of tears or detachments in the rectovaginal septum can be done both in the office and at surgery. The examiner places a finger in the patient's rectum and sweeps widely from lateral to medial along the entire rectovaginal septum. The examining finger palpates the defect and can be seen to enter the defect, lifting the posterior vaginal wall. Lateral defects are detachments of the rectovaginal septum from the medial levator fascia, central defects are openings in the rectovaginal septum.

Disruption of the Perineal Body

The rectal examining finger applies traction against the rectal side of the perineum with the examiner pulling toward him/herself. If the perineum is very distensible and can be brought several centimeters caudally while offering little or no resistance when the patient is asked to tighten the perineal muscles, this is perineal descent. Palpating the perineum with the examiner's thumb against the ipsilateral index finger in the patient's rectum often shows that the only palpable structures seem to be the rectal wall and the perineal skin. In the patient with an intact perineal body, the perineal body is largely connective tissue and can be felt as a substantial pyramidal shaped body, 2 to 4 cm wide at its caudal margin and extending cephalad 2 to 5 cm between the vagina and external anal sphincter (Fig. 36D.4).

ADJUNCTIVE TESTING

When symptoms and physical findings are consistent with an anatomic defect, no adjunctive testing is needed before surgery for the patient with a posterior compartment disorder. Adjunctive testing including anal manometry, anal sphincter ultrasound, defecography, electrophysiologic studies, and colonic motility studies have all been reported in these patients in various studies. Anal manometry is used to measure the functional length of the anal canal and the sensation and pressures generated in the anal canal and anal sphincter. Manometry techniques are not standardized, and there is some debate as to what the limits of normal are. Its usefulness may be in identifying patients suspect for bowel storage diseases rather than as a routine diagnostic test.

Defecography is a fluoroscopic study done after ingestion or insertion of radiopaque contrast material. It can be used to outline the anatomy of a rectocecle or identify an occult enterocele, sigmoidocele, peritoneocele, rectal intussusception, rectal prolapse, and paradoxical contracture of the puborectalis muscle during defecation. Studies have shown that interpretation of defecography has a roughly 80% interobserver reliability. Proponents argue that defecography improves the diagnostic ability for the practitioner. There are no studies showing that defecography changes clinical outcomes by changing nonsurgical or surgical management.

Electrophysiologic studies of bowel function (electromyography and nerve conduction velocity), especially those measuring individual muscle response, have generally been abandoned by physical therapists and gastroenterologists.
because of the tests’ inability to measure clinically significant parameters. For example, the differences in pudendal nerve latency studies do not directly relate to patient symptomatology or suggest that one type of treatment or procedure is better. The study has some ability to predict the likelihood of surgical success in patients undergoing external anal sphincteroplasty. Imaging with dynamic ultrasound and magnetic resonance imaging seem to show an even greater diagnostic ability to delineate anatomy than defecography.

Ultrasound for the diagnosis of anal sphincter defects offers diagnostic help for the clinician uncertain as to whether patient symptoms relate to a sphincter defect. For a rectocele, it has the same limitation as other radiologic testing. These techniques and the management of anal incontinence are discussed in Chapter 40.

To summarize diagnosis, a competent, site-specific-directed exam allows the clinician an opportunity to assess the posterior compartment from the retroperitoneum to the perineum. Imaging and electrophysiologic testing is of limited value in a patient with an indeterminate history and confirmatory physical findings. To routinely add adjunctive diagnostic testing cannot be recommended in everyday practice. Adjunctive testing should rely on the judgment of the clinician. Most of the testing is not cost-efficient, nor has it been shown to improve long-term outcome. For the midposterior compartment (rectocele)—the most common problem the practicing gynecologist will face—defecography parameters, such as size, poor evacuation, barium trapping, and intussusception, have no prognostic value.

It should also be emphasized that an anatomic defect diagnosed either by history and examination or on imaging and physiologic testing often shows no correlation with the degree of patient symptomatology. Large anatomic defects may cause the patient no problem; small ones may be very symptomatic. It should also be stressed that it is up to the clinician to decide how much evaluation and treatment is needed. If the clinician cannot do so, consultation should be obtained. The asymptomatic posterior compartment defect needs neither testing nor treatment.

**ALTERNATIVE THERAPIES TO SURGERY**

When a posterior compartment defect has been diagnosed and the patient seeks relief from the symptoms, the clinician should have a working knowledge of how to manage those symptoms with nonsurgical alternatives. In the case of posterior compartment defects, a pessary may be tried when the symptom is thought to be secondary to a mass lesion. While no pessary is specifically designed for mass lesions in the posterior compartment, those that occupy a larger space within the vagina are most helpful in my own practice—the doughnut, inflatable tampon, and intrasutural, have no prognostic value.

It should also be emphasized that an anatomic defect diagnosed either by history and examination or on imaging and physiologic testing often shows no correlation with the degree of patient symptomatology. Large anatomic defects may cause the patient no problem; small ones may be very symptomatic. It should also be stressed that it is up to the clinician to decide how much evaluation and treatment is needed. If the clinician cannot do so, consultation should be obtained. The asymptomatic posterior compartment defect needs neither testing nor treatment.

**SURGERY FOR POSTERIOR COMPARTMENT DEFECTS**

**Preoperative Counseling**

Preoperative counseling entails explaining surgical risks, benefits, and nonsurgical alternatives to the patient. Risks from repair of apical and posterior compartment defects are usually low, but this differs by the route the surgery is performed and the defect repaired. The always-present risks of infection, bleeding, and injury to bladder or bowel vary with the surgical approach taken; whether it is laparotomy, laparoscopic, transvaginal, or transrectal; whether it is simply fixing a detached or torn septum versus a repair that may need to involve bowel resection when rectal intussusception or external prolapse of rectal mucosa is present; or whether graft materials will be necessary.

The most common symptoms reported to the gynecologist are stool retention and discomfort, and the most common defect will be a detatchment or tear of the midrectovaginal septum. A review of the literature shows that there are really very few reports of the long-term success of “rectocele” repair. Studies with a year or more follow-up show success rates of 50% to 80% for treating obstructed defecation, with most tending toward the more favorable of those figures. Failure rates seem to be highest in patients with anismus or other physiologic dysfunction before surgery. The rate of persisting dyspareunia after standard posterior colporrhaphy is quoted as 15%, a figure few share with prospective surgical candidates.

**Preoperative Preparation**

When performing an operation with even a small risk of entering large or small bowel, many surgeons prefer that the stool be evacuated from the rectum and a single dose of preoperative antibiotic be given. Evacuating the rectal vault with a preoperative phospho-soda enema or an oral osmotic agent is at the discretion of the surgeon who must consider the risk for causing bacterial contamination and subsequent infection for the surgery being performed. If antibiotics are to be given, they should be chosen as for any operation and given as a single intravenous dose with enough time between administration and the time of incision to ensure adequate serum levels. I check the vaginal pH; if elevated, I do a saline mount to check for bacterial vaginosis and treat with an appropriate regimen.

**Positioning, Lighting, and Visualization**

For transabdominal repair of the posterior compartment either by laparotomy or laparoscopy, the patient is placed in the low atrophy, lack of lubrication, or suggesting a change in sexual activity or position. Discomfort exacerbated by activity or prolonged standing can often be alleviated with a pessary. The use of a pessary before considering surgery may be a good diagnostic test to indicate how likely surgery is to help. If the pessary relieves discomfort, surgery is more likely to be beneficial. If it does not, surgery may not be the answer.

Physical therapy and biofeedback have both been shown to improve symptoms from pelvic organ prolapse, especially early stages of pelvic organ prolapse. Its greatest role may be in the treatment of paradoxical contractions of the pelvic floor with attempted defecation and anismus.
lithotomy position by most gynecologists to allow access to both the abdominal and vaginal fields. For transrectal repair, colorectal surgeons usually place the patient in a jackknife (ven-
tral lithotomy) or kneeling position (using a surgical stool) to optimize exposure to the perineum and anus. I perform nearly all posterior compartment repairs with the patient in the high
dorsolithotomy position with the feet placed in candy-cane stir-
rups. Many surgeons prefer heavily padded leg rest-type stir-
rups that do not allow for as much flexion at the hip and pro-
vide support at the calf and plantar aspect of the foot, believing that these stirrups have less chance of injury from positioning. Positioning injury has never been a problem for me in thou-
sands of vaginal repair operations. I feel that candy-cane stirrups allow better visualization and access by assistants. The opera-
tor will be seated centrally, and the assistant, either one or two, will stand or sit (their preference) on each side of the operator.

For transvaginal repair of the posterior compartment in my practice, the vaginal and abdominal fields are steriley pre-
pared. I prefer a plastic drape placed to catch fluid from the cystoscopy that will be part of nearly all our pelvic reparative surgery. The anus is left undraped so that it is accessible for in-
traoperative rectal examination to aid in defect identification and the placement of our sutures to close fascial defects. I will change the intrarectal examining glove when going from rec-
tum to vagina. Although evidence is insufficient to support or refute this technique, some habits die hard. A drape that comes with a finger cot that allows intrarectal examination during surgery without contamination of the examiner's glove is also available.

Exposure is maintained using mainly self-retaining retrac-
tors. A Martin arm is attached to the table to which is affixed a small Drayer retractor that elevates the anterior vaginal wall. A disposable plastic retractor that is a variation of the figure-
of-eight–shaped (larger half placed toward the floor) Scott and White retractor is used along with commercially available metal hooks that come attached to stretchable plastic stays that slide into grooves on the two rings of the figure-eight retractor. I use self-retaining retractors for several reasons: (i) the expo-
sure is superior to that available when using an examination; (ii) only my hands are directly in front of the wound, making it easier to see and operate; (iii) the countereversion from this retractor and the ability to move the eight stays facilitate sharp dissection, which is almost exclusively what I use during the operation; (iv) this system frees the assistant to aid in the operation and mobility to better see the operation (for learning purposes); and (v) self-
retaining retractors never complain, fall asleep, or get called to leave the emergency department or labor and delivery—also big advantages! When used correctly, this setup allows the surgeon to operate with a single scrub assistant without difficulty.

We routinely use a dilute solution of vasopressin, 10 units in 30 mL of normal saline, injected into each compartment to a volume of 8 to 10 mL. I find that this chemical tourniquet controls the minor oozing of blood that often detracts from the operation.

Operative Technique

When only the rectovaginal septum is operated on, an incision is made transversely at the junction of the perineal skin and posterior vaginal wall epithelium. If mesh is to be used, I try to lift up the vaginal epithelium without dividing it, or dividing it cephalad only far enough to include the disrupted area. If a repair is performed, the vaginal epithelium is dissected from the underlying con-
nective tissue in the relatively avascular plane just beneath the epithelium. Dissecting in this plane helps identify the layer that

will allow us to see the underlying connective tissue of the recto-
vaginal septum. Some operators try to dissect the “good stuff” from the underside of the vaginal epithelium. If the tissue that is freed by dividing the epithelium is joined side to side, it covers the true defects(s) rather than allowing the operator to identify them. The space over the rectovaginal septum is opened from the introitus, cephalad to the yellow adipose tissue of the cul-de-sac peritoneum, and the position of the vasa deferentia and the levator and obturator fascia on the pelvic sidewall.

When multiple defects are present in the rectovaginal sep-
tum, I usually correct them in the following order: (i) perineal body, (ii) midrectovaginal septum, and (iii) uterosacral liga-
ment attachments to the rectovaginal septum. To identify these intraoperatively, the operator places an index finger in the pa-
tient's rectum, and defects are identified with a combination of visualization and palpation similar to that performed during of-
fice examination (Fig. 36D.3). It is easier to identify posterior compartment defects intraoperatively with the vaginal epithel-
rium dissected free from the underlying rectovaginal septum. The operator advances the examining finger from the perineal-
vaginal junction cephalad to find detachment of the rectovagi-
nal septum at the perineal body, then sweeps laterally to me-
dially on each side of the septum from the levator-obturator junction, and finally palpates and visualizes the vaginal apex.

Once identified, these defects are closed by direct approxima-
tion of the disrupted connective tissue with interrupted su-
tures directly along the configuration of the tear. When pa-
tient tissues look healthy and seem strong, but just torn, I use 0-polyglycolic acid or polyglactin 910 suture (both de-
layed absorbable) on a CT-1 or CT-2 needle. These sutures maintain 50% tensile strength at 2 weeks; therefore, successful repair relies on a normal patient healing response. When tis-
ue healing may not be optimal, I use nonabsorbable, tig-
nergagenerated, suspected connective tissue compromise, repeat-procedure pa-
tients), I close the defects with a permanent suture, such as a coated (polybutylate or silicone), 00-braided, polyester suture on an MO-7 needle. Our needles are swaged on with controlled release, making them easy and quick to use. The CT-2 and MO-7 needles are small, tapered and heavy gauge with a 3/8 curve and fit into small spaces with the ability to penetrate dense tissues. My thinking of the use of peritoneal repair is that tissue of lesser quality may stay joined together better with a longer period of assisted approximation. Tissue suture purchases are as deeply into the connective tissue of the rectovaginal septum as possible, avoiding the rectal lumen with assistance from the rectal examining finger.

When the surgeon has a single assistant, the operator grasps each edge of the torn rectovaginal septum after identification with an Allis clamp, starting at the location where the sepa-
ration is most obvious. Marking with the Allis clamp allows the surgeon to remove the finger from the rectum when closing the defect. Once the most obvious area of the defect is brought together, the defect on either side becomes easier to see, making subsequent tissue purchases similarly easier to place.

I do not use running closures to approximate connective tissue defects. Running closure bunches up tissue and makes for a poorer “fit” that may compromise the vaginal caliper.

When closed as described above, the repair is less likely to form the palpable tissue “bridges,” often a source of complaint af-
ter traditional midline plication repairs. The reason for tissue bridging with traditional posterior colporrhaphy is that some suture purchases make as deeply into the connective tissue of the rectovaginal septum as possible, avoiding the rectal lumen with assistance from the rectal examining finger.

When multiple defects are present in the rectovaginal sep-
tum, I usually correct them in the following order: (i) perineal body, (ii) midrectovaginal septum, and (iii) uterosacral liga-
ment attachments to the rectovaginal septum. To identify these intraoperatively, the operator places an index finger in the pa-
tient's rectum, and defects are identified with a combination of visualization and palpation similar to that performed during of-
fice examination (Fig. 36D.3). It is easier to identify posterior compartment defects intraoperatively with the vaginal epithel-
rium dissected free from the underlying rectovaginal septum. The operator advances the examining finger from the perineal-
vaginal junction cephalad to find detachment of the rectovagi-
nal septum at the perineal body, then sweeps laterally to me-
dially on each side of the septum from the levator-obturator junction, and finally palpates and visualizes the vaginal apex.

Once identified, these defects are closed by direct approxima-
tion of the disrupted connective tissue with interrupted su-
tures directly along the configuration of the tear. When pa-
tient tissues look healthy and seem strong, but just torn, I use 0-polyglycolic acid or polyglactin 910 suture (both de-
layed absorbable) on a CT-1 or CT-2 needle. These sutures maintain 50% tensile strength at 2 weeks; therefore, successful repair relies on a normal patient healing response. When tis-
ue healing may not be optimal, I use nonabsorbable, tig-
nergagenerated, suspected connective tissue compromise, repeat-procedure pa-
tients), I close the defects with a permanent suture, such as a coated (polybutylate or silicone), 00-braided, polyester suture on an MO-7 needle. Our needles are swaged on with controlled release, making them easy and quick to use. The CT-2 and MO-7 needles are small, tapered and heavy gauge with a 3/8 curve and fit into small spaces with the ability to penetrate dense tissues. My thinking of the use of peritoneal repair is that tissue of lesser quality may stay joined together better with a longer period of assisted approximation. Tissue suture purchases are as deeply into the connective tissue of the rectovaginal septum as possible, avoiding the rectal lumen with assistance from the rectal examining finger.

When the surgeon has a single assistant, the operator grasps each edge of the torn rectovaginal septum after identification with an Allis clamp, starting at the location where the sepa-
ratio
The reason for tissue bridging with traditional posterior colporrhaphy is that some suture purchases include each side of the torn rectovaginal connective tissue and some do not. When “hits” and “misses” occur, bridges are produced. A: Defect that begins below the cul-de-sac. B: The result of a repair that starts too high and uses wide midline suture purchase. C: Results from narrow midline purchases. D: Site-specific repair.
defect), bridges are less likely to be formed. Tissue bridges, especially near the vaginal apex, also occur when the surgeon pulls together the lateral connective tissue at the most cephalad portion of the vagina, failing to consider that the central portion of the posterior vaginal septum ends 4 cm from the most cephalad portion of the uterosacral ligaments and upper levator fascia. If this cephalad attachment is in place, the repair is complete.

Reattachment of the Rectovaginal Septum to the Uterosacral Ligaments

Detachment of the cephalad rectovaginal septum from the uterosacral ligaments is diagnosed visually by recognizing a large protrusion at the uppermost vagina (Fig. 36D.6A). Before the vaginal epithelium is opened, the cephalad detachment can be seen as the site on the intact vaginal epithelium where the vaginal rugae end, the epithelium becomes smooth, and the bulge ends at the distal portion of the defect, indicating there is no connective tissue beneath the epithelium to tether it. This site where the detached central rectovaginal septum can be found, interestingly enough, often coincides with the cephaladmost portion of the scar from a repaired episiotomy, perhaps explaining why episiotomy prevents low rectocele formation.

Once the vaginal epithelium is opened and dissected free, the bulge becomes more prominent, and the cephalad rectovaginal septum is readily apparent at the caudalmost portion of the bulge, where its edges can be grasped (Fig. 36D.6B). Pulling the rectovaginal septum cephalad at its lateral margins with forceps simulates reattachment of the rectovaginal septum to the uterosacral ligaments and reduces the upper defect (“high rectocele”). When the sutures from the ipsilateral uterosacral ligament are placed into the corresponding side on the cephalad rectovaginal septum and tied, the bulge will be reduced in total (Fig. 36D.6C). If difficult to see, this defect can be accentuated by using the rectal examining finger to gently pull caudally from the vaginal apex. The examining finger will feel the detached upper margin of the midrectovaginal septum. Reattaching the vaginal apex to the uterosacral ligaments has been routinely recommended in every textbook description of hysterectomy for many years to avoid descent of the vaginal apex postsurgery. Yet for nearly 100 years, midline plication has been used by many gynecologists as the main operation to treat descent of any part of posterior vaginal compartment, including the apex. Because the uterosacral ligaments also support the posterior vaginal apex, repair of the posterior compartment should ensure that the rectovaginal septum is suspended. The two most common techniques for doing this at the time of transvaginal repair of the posterior compartment are the McCall culdoplasty and the uterosacral ligament suspension.

The original McCall culdoplasty, described in Chapter 37 of this text, consisted of rows of internal and external sutures. Internal sutures close the posterior cul-de-sac by approximating the cephalad portion of the uterosacral ligaments at a level high in the posterior cul-de-sac. The external sutures pass from the vaginal lumen through the epithelium of the lateral vaginal apex into the open peritoneal cavity (from hysterectomy or at the time of enterocele repair). The suture purchases then are swept laterally to incorporate the uterosacral ligament on the ipsilateral side, sewn across the peritoneum of the cul-de-sac, through the contralateral uterosacral ligament, and out through the cul-de-sac peritoneum, upper vaginal wall, and into the vaginal lumen on the contralateral side, approximating the distal uterosacral ligaments and drawing the cul-de-sac and uterosacral ligaments together.
The McCall operation has been successful as an operation for prophylaxis against enterocele formation and descent of the vaginal apex after surgery; a reparative procedure for vault prolapse, and as a rescue operation for recurrent vault prolapse after failed apical suspension surgery. Disadvantages of this operation are entrapment or kinking the ureters, difficulty identifying the uterosacral ligaments, and narrowing of the cephalad vagina.

Recently, many gynecologic surgeons have changed from the McCall culdoplasty to using the uterosacral ligaments for both primary reattachment as a prophylactic measure at the time of hysterectomy and as a reparative technique for posthysterectomy apical compartment prolapse. The most important step in uterosacral ligament suspension, and often the most challenging part of this operation, is identifying the uterosacral ligaments. Identification of the uterosacral ligaments can be done in three ways:

- When the posterior cul-de-sac peritoneum is open with the examiner’s finger in the patient’s rectum, tension applied on the ipsilateral cul-de-sac, the surgeon directly palpates the uterosacral ligament from its disrupted attachment at the vagina to near the sacrum. This technique is usually combined with palpation of the ureter against the lateral pelvic sidewall to make sure both structures are free.

- The uterosacral ligament is identified anatomically by its position just medial and deep to the ischial spine and by placing a suspension stitch just medial to the ischial spine. This method offers several disadvantages in my opinion. First, the uterosacral ligament is not clearly identified. Second, the placement of the suture at the level of the ischial spine will suspend the vaginal vault no higher than the ischial spine. Some patients’ vaginal length is well above this level, and repairing the vault in this manner causes it to droop downward. Third, a deep blind purchase with needle and suture into this tissue may offer support, much like the prespinous fascial suspension described by Meeks and colleagues, but can be placed directly into the body of the ligament at any level. The higher the placement, the farther the ligament is from the ureter. By placing the suture directly into the body of the ligament and always placing the suture from lateral to medial, the surgeon is certain the ureter, which is always lateral to the uterosacral ligament, is not harmed.

- Transrectal Identification of the Uterosacral Ligament by Palpation

I use this technique to identify the uterosacral ligament for several reasons.

- When not using mesh, the 2-0 braided polyester sutures for these stitches to maintain suture integrity for this vital support function. Delayed absorbable suture will have lost most of its tensile strength by the third postoperative week, which is about 2 months short of the time it takes to form maximum tissue strength after an operation. When not using mesh, the 2-0 braided polyester sutures are tied after the assistant grasps the corresponding site of placement on the vagina and approximates this to the uterosacral ligament it will join. This takes the tension off the suture as it is tied and serves as a check to see how the repair fits the patient. In nearly all cases, this satisfactorily elevates the vaginal cuff and closes the connection of the genital hiatus and pelvis. The anterior and posterior vaginal walls are approximately central with delayed absorbable suture. The McCall operation has been successful as an operation for prophylaxis against enterocele formation and descent of the vaginal apex after surgery; a reparative procedure for vault prolapse, and as a rescue operation for recurrent vault prolapse after failed apical suspension surgery. Disadvantages of this operation are entrapment or kinking the ureters, difficulty identifying the uterosacral ligaments, and narrowing of the cephalad vagina.

Recently, many gynecologic surgeons have changed from the McCall culdoplasty to using the uterosacral ligaments for both primary reattachment as a prophylactic measure at the time of hysterectomy and as a reparative technique for posthysterectomy apical compartment prolapse. The most important step in uterosacral ligament suspension, and often the most challenging part of this operation, is identifying the uterosacral ligaments. Identification of the uterosacral ligaments can be done in three ways:

- When the posterior cul-de-sac peritoneum is open with the examiner’s finger in the patient’s rectum, tension applied on the ipsilateral cul-de-sac, the surgeon directly palpates the uterosacral ligament from its disrupted attachment at the vagina to near the sacrum. This technique is usually combined with palpation of the ureter against the lateral pelvic sidewall to make sure both structures are free.

- The uterosacral ligament is identified anatomically by its position just medial and deep to the ischial spine and by placing a suspension stitch just medial to the ischial spine. This method offers several disadvantages in my opinion. First, the uterosacral ligament is not clearly identified. Second, the placement of the suture at the level of the ischial spine will suspend the vaginal vault no higher than the ischial spine. Some patients’ vaginal length is well above this level, and repairing the vault in this manner causes it to droop downward. Third, a deep blind purchase with needle and suture into this tissue may offer support, much like the prespinous fascial suspension described by Meeks and colleagues, but can be placed directly into the body of the ligament at any level. The higher the placement, the farther the ligament is from the ureter. By placing the suture directly into the body of the ligament and always placing the suture from lateral to medial, the surgeon is certain the ureter, which is always lateral to the uterosacral ligament, is not harmed.

- Transrectal Identification of the Uterosacral Ligament by Palpation

I use this technique to identify the uterosacral ligament for several reasons.

- With the examiner’s finger in the patient’s rectum, tension is applied toward the examiner using an Allis clamp on the ipsilateral cul-de-sac (Fig. 36D.7). The surgeon can trace by direct palpation the uterosacral ligament in almost all patients from its disrupted attachment at the vagina to near the sacrum, allowing suspension of the vagina as high as is appropriate based on the length of the vagina to be suspended.

- The uterosacral ligament has characteristic features by palpation; it is very dense, strong, mobile, about the caliber of a pencil, and tracks dorsal and medial to the lateral margin of the mid sacrum.
Detachment of the Rectovaginal Septum from the Perineal Body

The caudalmost portion of the rectovaginal septum must be reattached to the perineal body. This defect can easily be felt and seen during rectal examination. The detachment is almost always transverse and right at the level of the perineal body (Fig. 36D.8A). It is closed with interrupted sutures to approximate the two structures (Fig. 36D.8B).

Disruption of the Perineal Body (Perineal Descent Syndrome)

The posterior compartment cannot be repaired completely unless there is a perineal body to which the rectovaginal septum can be attached. I often see disruption of the perineal body presenting as a “failed rectocele repair.” The patient still has the symptom of incomplete emptying of stool and often splints the perineum or lateral to the anus to evacuate stool, rather than splinting through the vagina. On examination with the patient bearing down, there may be little or no posterior compartment descent above the vaginal introitus, but the perineum descends, and on palpation, the examiner feels nothing at the perineal body other than rectal mucosa and perineal epithelium.

This posterior compartment defect cannot be repaired by making a small V-shaped incision at the perineum and sewing the skin and superficial connective tissue together or by sewing together the insertions of the bulbocavernous muscles at the perineum. I have found that the operation performed in this manner often includes a crown stitch, which pulls together the left and right margins of the introitus and results in a ridge. The ridge at the time of intercourse acts like a speed bump and causes dyspareunia. I see this condition several times each year, occurring after perineoplasty and episiotomy repair. I would advise against the crown stitch as a technique to either reduce the caliber of the introitus or lengthen the vaginal canal.

Repair of the perineal body requires reapproximation of the structures that attach at the central tendon of the perineum: the rectovaginal septum, the lateral dorsal bulbocavernous muscle insertions, the transverse perineal muscle, and the external anal sphincter. The attachments of the perineal body to the inferior pubic rami, ischial tuberosities, and coccyx have always been intact in these patients and require no revision, only a central disruption exists.

To begin the repair, a midline incision from the posterior introitus to the external anal sphincter is made. The skin overlying the perineum is widely dissected until the remnants of the transverse perineal muscle can be seen. Wide deep purchases of these muscles and any overlying connective tissue are taken and tied to approximate these muscles. Most of the time, three to five sutures (2-0 polydioxanone) are required. With the laxity of the perineum, these muscles are generally approximated. I will imbricate these muscles with a second layer of interrupted sutures to reinforce the repair. The repair may seem “thick” at this point in the operation, but it will not be as thick at the 6 weeks examination after surgery. I will then make sure the external anal sphincter is attached to the most dorsal portion of the perineal repair with interrupted sutures and that the bulbocavernous muscles are attached at the ventral and lateral margins of the reapproximated perineal body. When this operation is done correctly, a rectovaginal examination will allow the examiner to feel the pyramid-shaped perineal body, which will now be about 5 cm long and 3 cm thick at its base.

Vaginal/Perineal Closure

It is common for the gynecologic surgeon to “trim excess vaginal epithelium,” then close the vaginal epithelium as a midline structure, but I have gotten away from this technique to closing...
the vaginal epithelium as one would a skin graft. I tack down the undersurface of the lateral margins of the detached vaginal epithelium from apex to perineum, then move medially and put in a second row. This allows the epithelium to be used to cover the repair as it fits, rather than just amputating vaginal epithelium and closing with a running midline suture. It eliminates much dead space and makes a better fit with less trimming and more reattachment of epithelium.

Authorities in the past have written that closing this dead space does not allow the vagina to physiologically “slide” one layer over another. There is no evidence to show that this “sliding” phenomenon really takes place. Certainly if one has done enough second and third operations after failed prolapse surgery, one can attest to the fact that the vaginal epithelium may be densely adherent without much movement to facilitate dissection in previously operated areas. Even in the patient who has never been operated on, the caudalmost 4 or 5 cm of the vagina seldom demonstrate a facile cleavage plane and certainly does not slide. The connective tissue from the perineal body is densely intertwined; it is not until several centimeters cephalad does it separate easily.

Densely intertwined; it is not until several centimeters cephalad does it separate easily during the dissection of the vaginal wall that it separates easily from underlying connective tissue.

Mesh Placement at the Time of Apical Posterior Compartment Repair

In my practice, the most common circumstance for using mesh in posterior compartment repair is suspending the apical compartment and reattaching the rectovaginal septum to the uterosacral ligaments. These two reattachments, traditionally referred to as repair of a posterior enterocele and repair of a high rectocele, are thought of as separate operations; but in my experience, they are the same.

In repairing these defects, a peritoneal sac containing small intestine, omentum, or sigmoid colon is often found. I isolate this sac by dissecting it free from the surrounding tissues. The sac is opened; the omentum, small bowel, or sigmoid colon is packed out of the sac into the abdominal cavity with a tail suture and the opposite long side to the caudal uterosacral suture. When tied, they close the space at the top of the apical compartment (Fig. 36D.9D). The remaining edges of the ellipse are sewn into the underlying connective tissue to make sure that the mesh lies flat. Within 2 weeks after surgery, native tissue will infiltrate the mesh, and the mesh will be firmly fixed in place.

Laparoscopy and Laparotomy in the Treatment of Posterior Compartment Defects

Transabdominal uterosacral ligament suspension is enjoying a resurgence as the gynecologic surgical community remembers what it seems to have once forgotten: Suspension of the vagina is an important part of vaginal reconstruction, especially after hysterectomy. Reattachment of the uterosacral ligaments to the vaginal vault at hysterectomy has long been described as a preventative measure against vault prolapse and enterocele formation. When the posterior cul-de-sac was considered to be deep, enterocele was prevented by sewing the posterior cul-de-sac closed with either sequential or concentric purse-string sutures placed from the caudal posterior cul-de-sac to the level of the uterosacral ligaments, incorporating peritoneum over the sacrum (Moschowitz procedure), if necessary, or by closing the cul-de-sac by sewing the posterior vaginal wall from its most caudal to most cephalad position to the rectum back to front in parallel rows (Halban culdoplasty). Little data exist measuring the success of these procedures, but they should be fundamentally sound.

Most transabdominal procedures suspend the vaginal apex, but do not deal effectively with the distal one half of the vagina or perineum. With the increasing use of laparoscopic surgery, more surgeons are repairing all compartments of the pelvic floor, including the posterior compartment with laparoscopic techniques. Sacrocollpopexy operations use main synthetic mesh grafts to suspend the vaginal apex from near the sacral promontory.

Most surgeons will use a synthetic mesh graft fashioned with a central trunk attached to anterior and posterior limbs. The anterior limb is sutured to the anterior vaginal wall dorsally...
to the freed bladder, and the posterior limb is sutured to the posterior vaginal wall where it has been freed from overlying peritoneum or rectum. The posterior mesh limb can be used to correct posterior compartment defects near the apex and generally caudally to the midvagina. Traditionally, surgeons secure each mesh limb with four to six permanent sutures from the midvagina to the vaginal apex. To correct the most caudal defects, including detachment and/or disruption of the perineal body, surgeons extend the posterior mesh limb to the perineum to perform \textit{sacrocolpopereiopexy}. In addition to being a
21-letter word, this operation is thought to hold the entire pos-
terior compartment from the perineum to the sacrum in place.

Other pelvic reparative surgeons have used a combined transabdominal sacrocoploprectomy with transvaginal repair to
place the extended posterior mesh limb. Some surgeons will
do the sacrocolpoperineopexy to the midvagina and then oper-
ate through a transvaginal approach, keeping the surgical fields
separate to fix the anterior compartment of the posterior defects.
The number of reports of sacrocolpoperineopexy is limited. Some
reports indicate that there is an increased incidence of infection with combined abdominal-perineal procedures using
mesh.

**COMPLICATIONS**

**Intraoperative Bleeding**

To prevent excess bleeding, I use several techniques. The in-
jection of a dilute solution of vasopressin, 10 units in 30 to
50 mL of normal saline, injected into the area to be dissected
immediately before the incision decreases blood loss by about
one third, helps clear the operative field of blood for about
75 minutes, and facilitates identification of planes by its hy-
drodissection effect. Although it was once thought that the use
of vasoconstrictor (chemical tourniquets) increases the like-
lihood of delayed hemorrhage and increases the incidence of
postoperative infection, several recent studies have shown the
opposite.
The use of sharp dissection, rather than blunt dissection,
allows better identification of surgical planes and the small
vessels. To control bleeding sites, I use cautery sparingly and
rely heavily on fine 3-0 and 4-0 sutures on a small caliber needle
for vessels. To control bleeding from a particular site, I often pack
the small area first with thrombin-soaked oxidized cellulose,
then a small sponge over this, and work in another area rather than
chase bleeding. Small bleeding areas will stop on their own after
this, and I save time (and blood loss) by completing the remain-
der of the operation while allowing the troublesome ooze to be
controlled by packing and thrombin.

Sometimes bleeding from the connective tissue of the recto-
vaginal septum can be most effectively controlled by using the
vaginal epithelial layer as a bolus. We do not sew directly into
the rectovaginal septum, but place sutures through the vaginal
epithelium into the septum where bleeding occurs and pass the
suture back through the vaginal epithelium. This allows the
vaginal epithelium to be tied down on top of the bleeding site,
using it as an extra tissue bolster to tamponade the bleeding.

**Injury to the Rectum**

In anticipation of injury to the rectum, many gynecologic sur-
groups will prepare the bowel or at least the distal bowel with
purgings regimens, laxatives, or enemas. Although this is com-
monly done by many gynecologic surgeons for operations in
which the incidence of rectal injury is estimated at 1% to 2% of
all cases, it is no longer a routine for obstetricians to use en-
emas before vaginal delivery, in which lacerations of the rectal
sphincter and wall are estimated to be 5% of cases.

I do not prep the bowel. I give a single preoperative antibi-
otic dose, evacuate the distal rectum digitally in the operating
room at the time of exam under anesthesia, and repair any rec-
tal injury during surgery by irrigating it, closing it in layers,
and having patients use the same stool-softening regimen as I
would for any vaginal reparative surgery. It is interesting that
the gynecologic surgeon is concerned with entering the rectum
and the colorectal surgeon with entering the vagina. Each sees
the area that is “not their own” as a contaminated area to be
avoided at all cost. Both the posterior repair and the very few rectal
complications, it shows us how tradition precludes evidence.

**Ureteral Injury**

Operations on the posterior compartment may be complicated
by ureteral injury. I do cystoscopy after the administration of
intravenous indigo carmine dye for nearly all of our vaginal
reparative surgery cases, both to teach residents how to do it
and because the literature shows some series with very high
rates of unrecognized ureteral compromise after gynecologic
surgery. In all my years of reparative surgery, I have had only
one procedure complicated by ureteral compromise, which was
resolved by removing the McCall culdoplasty sutures. How-
ever, I do feel cystoscopy is so simple and reassuring that all
gynecologists should be able to perform this safety check after
every pelvic support operative procedure.

When I cannot demonstrate flow of intravenous indigo
carmine dye from a ureter, I give a small dose of furosemide. If
unsuccessful, I have retrograde catheters passed. If a catheter
can easily be passed 10 cm up from the ureter orifices, injury is
unlikely. If the ureteral stent cannot be passed, which is seen in
about half the cases of vaginal eversion, retrograde dye studies
can be performed in the operating room and patency confirmed
radiographically.

**The Surgically Small Vagina**

During surgery, vaginal caliber and depth should be assessed af-
after each part of the procedure, whether performed on the an-
terior, apical, or posterior compartment. One of the advantages
of site-specific repair is that it seldom results in tissue bridging,
vaginal shortening, or reduction of vaginal caliber. When any
of these are encountered, there are a number of options avail-
able to the surgeon. In the case of bridging, the defect should be
rechecked to make sure that the fascial edges are approximated
along the defect. If the defect has been closed in a site-specific
manner and the vagina still contains palpable bridges, the re-
pair needs to be taken down and either redone or a graft placed
where the bridging exists. Graft material may be an autograft,
allograft, xenograft, or synthetic graft.

In taking down the repair, the operator needs to determine if
the true defect has been closed along lines of tissue breaks.
If it has not, it can be closed along these lines, and bridging
should be eliminated.

Placing a graft to alleviate bridging requires removing the
surfaces causing the bridging and identifying the edges of
the defect that is not being adequately closed; this results in
the pulling together of the tissues involved in the bridge (Fig.
36D.10A). The defect in the rectovaginal connective tissue is
measured and the graft cut to a shape slightly larger than the
defect left from bridge removal. For a small defect, I cut a full-
thickness skin graft from the thigh or buttock from skin that has
been sterilely prepared within the surgical field (Fig. 36D.10B).
In harvesting the graft, I follow Langer’s lines and choose a site
that will not be under pressure during sitting. The graft harvest
site is closed with fine absorbable suture and covered with a
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

FIGURE 36D.10. Placing a graft to alleviate bridging in the repair requires removing the sutures causing the bridging (A). If the defect is too large to close with site-specific tissue, the defect is measured and a full-thickness dermal graft cut to a shape slightly larger than the defect (B). Follow Langer’s lines, and choose a donor site that will not be under pressure during sitting. The graft harvest site is closed with fine absorbable suture and the graft sewn down, overlapping slightly the edges of the posterior compartment defect in the rectovaginal septum (C).

Using a Graft to Reinforce Posterior Compartment Repair

When native connective tissue or support structures are thought to be of insufficient strength to provide adequate repair, the decision may be to augment or reinforce the entire repair with a graft. In choosing a reparative material, I searched the literature and decided on polypropylene mesh. Since 1988, I have used polypropylene mesh as a reparative material in the posterior compartment in more than 400 cases; including anterior and apical vaginal compartment repairs, in more than 1,500 cases. Polypropylene mesh is preferred because it is readily available in many sizes, soft, easy to shape and handle, relatively inexpensive compared with other graft materials, and consistently strong. It should be realized that in many patients, polypropylene mesh undergoes 10% to 15% shrinkage after placement.

The downside of polypropylene mesh is that it exhibits erosion in 2% to 15% of patients. In my own experience, erosion is twice as likely in the posterior compartment as in the anterior or apical compartment for reasons unknown. Erosion occurs as two types. The first is a simple mesh exposure, usually consisting of small (<1 cm) area. The patient is often asymptomatic but may present with spotting, granulation tissue, pain, or discharge. The second type of erosion presents with a rejectionlike reaction, with an exaggerated inflammatory response associated with a foul-smelling discharge, sometimes pain, and, on exam, a large area of exposure (2 or more cm).

In the case of minimal mesh exposure, the small area can be trimmed in the office with no anesthetic or local anesthesia. I have used scissors and forceps, large Tischler biopsy forceps with colposcopic guidance, or the carbon dioxide laser to trim or remove small areas of erosion. The removal sites in these cases usually heal spontaneously. Mesh erosion characterized by large exposure and/or foul-smelling discharge or pain is treatable only by completely removing the mesh.
When true infection is present, which is rare, the mesh can often be removed with little or no dissection.

I have found conservative treatment with cautery, antibiotics, and/or vaginal estrogen cream to be of little value in treating either type of erosion, despite some reports in the literature. I also have patients with small areas of asymptomatic erosion who declined treatment and have had stable mesh exposure for years without problem.

Removing Redundant Cul-de-Sac

When not using mesh, if there is redundant posterior cul-de-sac after placing the 2-0 braided polyester sutures in the uterosacral ligaments and closing the peritoneum, I remove the redundant cul-de-sac. I perform a Torpin culdoplasty, excising only the redundant central portion (Fig. 36D-11A) by placing two Kocher clamps across the diamond-shaped redundancy, excising the
The surgical repair of a posterior compartment defect by a colorectal surgeon is generally transanal or transperineal with the patient in a flexed, ventral lithotomy or jackknife position, often with the patient’s knees on a shelf and the body bent forward at the waist onto the operating table. Many colorectal surgeons excise excess anal mucosa over the protruding portion of the rectum and close the resulting defect with purse-string or suture placed horizontal to plicate the rectal wall. There are some reports of closure with a stapling device. These operations are often combined with a levatorplasty, which detaches the medial portions of the levator muscles together in the midline ventral to the rectum. This ventral position is considered to be nonanatomic by many gynecologists but is used to create a compensatory defect. In colorectal surgery, the repair of a defect at the vaginal apex (enterocele) is repaired transabdominally, using a sling to support the viscera or resection of the segment of bowel that is prolapsing in the enterocele, similar to the way rectal prolapse through the anus would be repaired. A Cochrane metaanalysis concluded the transvaginal approach to repair of the posterior vaginal compartment was more effective than the transanal approach. The transanal approach also seems to be associated with a higher incidence of dyspareunia and dyschezia than the transvaginal approach. The site-specific transvaginal repair seems to have the lowest association with postprocedural dyspareunia.

Alternative Methods for Repair of Posterior Compartment Defects

Transvaginal Midline Plication of the Connective Tissue of the Posterior Compartment

Transvaginal midline plication of the connective tissue of the posterior compartment is historically known as posterior colporrhaphy. The operation was described about 50 years ago, and it is still performed today, much as it has always been done. Midline colporrhaphy is performed by dissecting the overlying vaginal epithelium from the underlying endopelvic fascia of the rectovaginal septum and sewing the endopelvic fascia together in the midline. This was the only posterior repair operation performed by gynecologists for many years and was done with relatively fine-caliber, rapidly absorbable, chromic gut suture. The results were initially reported and continue to be reported as effective in many series at reducing the midline bulging of the posterior wall. But posterior colporrhaphy does not appear to be an operation to correct obstructed or incomplete defections in more than 40% to 50% of cases in some series. It has also been associated with dyspareunia in as many as 15% of patients in some series. The technique is a central plication of the rectovaginal fascia, beginning as cephalad as possible, while avoiding the muscular layer of the vagina or rectal wall. This avoidance of the “true wall” of either organ is to prevent bunching of those tissues, which is associated with bridging of the connective tissue and resulting dyspareunia. By careful suture placement starting as cephalad as possible in the rectovaginal connective tissue, it was hypothesized that the surgeon closed only the fascial layer and left the vagina and rectum free to “slide” in loose areolar tissue during intercourse. In my experience, there is no connective tissue located at the cephalad posterior vaginal wall for several centimeters, and the posterior colporrhaphy causes bridging in most cases unless site-specific repairs are performed. Posterior colporrhaphy does not eliminate obstructive defecation because it does not anchor either the proximal or distal rectovaginal septum to the urogenital ligaments or perineal body, leaving what amounts to a reinforced wall of a still-prolapsing organ. When combined with central amputation of the “excess” vaginal wall for midline closure and continuation of a crown stitch joining the dorsalmost portions of the bulbocavernous muscles and/or the perineal skin, the approximation causes central narrowing of the vagina and a speed bump of perineal skin that partially obstructs the vaginal entrance.

Colorectal Surgeons’ Approach to the Posterior Compartment Defect

The surgical repair of a posterior compartment defect by a colorectal surgeon is generally transanal or transperineal with the patient in a flexed, ventral lithotomy or jackknife position, often with the patient’s knees on a shelf and the body bent forward at the waist onto the operating table. Many colorectal surgeons excise excess anal mucosa over the protruding portion of the rectum and close the resulting defect with purse-string or suture placed horizontal to plicate the rectal wall. There are some reports of closure with a stapling device. These operations are often combined with a levatorplasty, which detaches the medial portions of the levator muscles together in the midline ventral to the rectum. This ventral position is considered to be nonanatomic by many gynecologists but is used to create a compensatory defect. In colorectal surgery, the repair of a defect at the vaginal apex (enterocele) is repaired transabdominally, using a sling to support the viscera or resection of the segment of bowel that is prolapsing in the enterocele, similar to the way rectal prolapse through the anus would be repaired. A Cochrane metaanalysis concluded the transvaginal approach to repair of the posterior vaginal compartment was more effective than the transanal approach. The transanal approach also seems to be associated with a higher incidence of dyspareunia and dyschezia than the transvaginal approach. The site-specific transvaginal repair seems to have the lowest association with postprocedural dyspareunia.

Buttock incision sites

Mesh sutured to posterior vaginal wall

Peritoneum closed at vaginal apex

FIGURE 36D.12. A graft, most commonly polypropylene or porcine dermis, is placed over the entire posterior compartment. Introduced through small incisions 2 to 3 cm lateral and dorsal to the anus, a tunneling device is brought up through the buttocks into the ischiorectal space to a level just caudal to the ischial spine. The vaginal wall is penetrated at this point, the tunneling device is threaded with the arm of a precut mesh, and the sling arm is drawn back to the buttock. This is repeated on the opposite side. The central graft is large and can be trimmed so that it attaches to just the apex or to the entire posterior compartment below the opened epithelium. The central graft is sewn into place, and the epithelium closed over it.

then pulls on the mesh arm, and the mesh elevates whatever portion or portions of the posterior compartment to which it is attached. At this point, the mesh can be anchored to the underlying connective tissue of the posterior vaginal wall from apex to perineum and the vaginal wall trimmed and closed or just closed. The mesh arms are trimmed so that they retract back into the subcutaneous tissue of the buttock. Early reports of these large mesh repairs come from outside the United States and appear to be favorable, but long-term results are not yet available at the time of this writing, especially from surgeries done within academic centers.

BEST SURGICAL PRACTICES

- The reparative operation for the posterior compartment should be tailored to fit the needs of the patient.
- Assessing the needs of the patient begins with history and physical examination to determine symptoms and anatomic site-specific defects. Some operations may be better suited to a given patient based on symptoms and findings.
- Understanding of the anatomy and pathophysiology of pelvic organ prolapse has changed and as a result, so has the way we perform surgery to repair it. The gynecologist now in practice will have to learn new surgical techniques to provide the best care possible for patients.
- Site-specific examination of the posterior vaginal compartment from the uterosacral ligaments to the perineum is used to formulate the surgical plan. The surgeon who goes to the operating room with one operation that he/she can perform probably will not be entirely pleased with the long-term results, and neither will the patients.
- Midline plication of the posterior vaginal compartment, or the traditional posterior colporrhaphy, does not anchor either the most cephalad or distal portions of the vagina. Failure to anchor the vaginal apex leads to descent of the apex; failure to anchor the distal vagina may lead to perineal descent syndrome.
- Approximately 20% of posterior vaginal wall repairs are now being performed with augmentation by a graft, with polypropylene mesh being the most common graft material. Although not without complications (exposure, infection, pain, dyspareunia), the use of graft material in gynecologic surgery is likely to become the standard of care for repeat procedures after failed pelvic organ prolapse surgery. Each graft material has its limitations, but gynecologic surgeons will need to become familiar with at least one type of material to use.

Bibliography

Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

Our understanding of pelvic prolapse and the treatment thereof has changed in recent years. It was formerly taught that prolapse resulted from attenuation or stretching of endopelvic fascia. Richardson and colleagues challenged this theory by introducing the concept of discrete breaks in endopelvic fascia. More recently, Richardson and colleagues described apical enterocele as a separation of pubocervical fascia from recto-vaginal fascia. This allows peritoneum of an enterocele sac to be in direct contact with vaginal epithelium. Kleeman and colleagues described the microscopic anatomy of the posterior vagina in cadavers without prolapse. Figure 36E.1 shows a microscopic horizontal section of the upper third of the vagina. Identification of all layers fails to reveal a discrete fascial layer. Despite this controversy, the theory proposed by Richardson helps our overall understanding of vaginal support.

DeLancey divided the support of the vagina into three levels. This concept is helpful in understanding normal anatomic relationships and appreciating why certain repairs may work in some patients and not in others. Level I support defects are apical defects caused by loss of support of the uterosacral ligaments, paracolpium, and pararectum; Level II: disruption of the normal lateral attachments of the midvagina; and Level III: lower vaginal defects in the perineal body or fusion of the distal urethra to the pubic bone.

Levels of support defects (according to DeLancey classification)—Level I: apical defects caused by loss of support of the uterosacral ligaments, paracolpium, and parametrium; Level II: disruption of the normal lateral attachments of the midvagina; and Level III: lower vaginal defects in the perineal body or fusion of the distal urethra to the pubic bone.

Pully stitch—Often used to attach the vaginal apex to the sacrospinous ligament. The suture is passed through the ligament (or other tissue where the final knot is to be located). One end of the suture is then passed through the vaginal apex (or other tissue that is to be approximated or “pulled” next to the first pass). The suture in the vaginal apex is tied with a half hitch. The two free ends of the suture are now tied, and as the knot is tightened down, the vaginal apex is pulled up to the sacrospinous ligament, and the two tissues are then approximated. The pulley stitch reduces the risk of cutting through the tissue as the knot is tightened.

Sacrospinous ligament—A strong ligament that runs within the coccygeus muscle from the ischial spine to the sacrum.

DEFINITIONS

EEA sizer—One of a series of metal instruments that are used primarily to evaluate the size of the end-to-end anastomosis staple instrument that is appropriate for a given patient. It is also an excellent instrument for distending and manipulating the vaginal apex from below, allowing the abdominal surgeon to easily feel the vagina and dissect against a firm surface (see Fig. 36E.14).

Many operations have been described for suspending the vaginal vault and securing the prolapsed vaginal vault in a significant number of patients. The ultimate goal of pelvic reconstructive surgery is to restore anatomy, maintain or restore visceral function, and maintain or restore normal sexual function. It is extremely important to determine preoperatively whether lower urinary tract dysfunction, sexual dysfunction, and defecatory dysfunction exist. Urinary dysfunction may be masked in patients with advanced pelvic organ prolapse by obstructing or kinking the urethra. Thus, reductive maneuvers aimed at simulating what surgery will accomplish should be used in the hope of identifying those patients who will require an antiincontinence procedure in conjunction with their pelvic reconstructive surgery. It is also important to initiate local estrogen therapy preoperatively in patients who have urogenital atrophy.

Many operations have been described for suspending the prolapsed vaginal vault. There is no general consensus on what is the best procedure. The procedure that the surgeon ultimately chooses is influenced by many factors, including the comfort and skill of the surgeon performing the operation, whether the prolapse is primary or recurrent, the patient's age, state of health, anticipated outcome, sexual activity, and overall state of the tissues. We believe it is important for the surgeon to have a variety of operative approaches available for the individual patient. We prefer to approach most cases transvaginally, reserving abdominal sacral colpopexy for patients who have failed a previous vaginal approach, have a foreshortened...

FIGURE 36E.2. Levels of support. DeLancey’s biomechanical levels: level I, proximal suspension; level II, lateral attachment; level III, distal fusion. (From DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. Am J Obstet Gynecol 1992;166:1717.)

vagina, or in whom a compensatory procedure with the insertion of mesh is necessary to obtain a long-term durable repair. We believe the vaginal approach to pelvic prolapse has the advantage of decreased operative time, decreased incidence of adhesion formation, and quicker recovery time. Obliterative procedures including partial Le Fort colpocleisis and colpectomy; colpocleisis can be used in elderly fragile patients who are no longer sexually active.

VAGINAL PROCEDURES TO SUSPEND THE VAGINAL APEX

McCall Culdoplasty

Several operations have been described and used by surgeons for vaginal vault suspension with correction of concurrent enterocele. McCall (in 1957) described his technique of surgical correction of enterocele at the time of vaginal hysterectomy. He used several nonabsorbable sutures to obliterate the enterocele (internal McCall sutures) by approximating both uterosacral ligaments and several bites of posterior peritoneum together. Delayed absorbable sutures were then inserted through the full thickness of the posterior vagina just lateral to the midline, passed through each uterosacral ligament and back out the posterior vaginal wall. Additional external sutures are placed as required by the amount of prolapse. The internal sutures are then tied, and the external sutures are tied after the vaginal cuff is closed. This simple procedure obliterates the cul-de-sac, supports the vaginal apex, and lengthens the posterior vaginal wall (Fig. 36E.3). McCall originally reported on 45 cases and stated there was no incidence of enterocele recurrence.

FIGURE 36E.3. McCall culdoplasty. Two internal sutures (permanent) and one external suture (delayed absorbable) have been placed. (From Baggish MS, Karram MM. Atlas of pelvic anatomy and gynecologic surgery. New York: Saunders, 2003.)
Several modifications of McCall’s technique have been described, most notably the modified endopelvic fascia repair, which was popularized and reported on from the Mayo Clinic. A wedge of vaginal mucosa is removed from the anterior and posterior vaginal wall. This narrows the vault when closed and allows easier access to lateral supports of the vagina (i.e., cardinal and uterosacral ligaments and perirectal fascia). The enterocele sac is then dissected free and excised at the neck. The ureters are identified by palpation bilaterally. One to three internal McCall’s sutures are placed as described above. After these sutures are placed and tagged, modified external McCall sutures are placed by passing delayed absorbable sutures through the posterior vaginal wall and peritoneum, through remnants of uterosacral and cardinal ligaments on the patient’s left. Several bites of peritoneum overlying the rectosigmoid are taken, and then the right perirectal fascia and uterosacral are incorporated into the suture. Last, the suture is passed back out through the posterior vaginal wall. The number of internal and external sutures placed depends on the size of enterocele and redundancy of the upper vagina (Figs. 36E.4 and 36E.5). A 1998 article by Webb reported on 660 women who underwent primary repair of vaginal vault prolapse. Follow-up was available on 514 of the 660 women. Eighty patients (11.5%) reported a “bulge” or “protrusion” at the time of questioning. Eighty-two percent (385 patients) responded that they were very satisfied or somewhat satisfied with the operation. The most common operative complication was laceration of bowel or rectum in 16 patients (2.3%). Four patients (0.6%) suffered ureteral complication. Three of these were from obstruction, and one developed a ureterovaginal fistula. Nine patients (1.3%) had a vault hematoma, and four (0.6%) had a cuff abscess or infection. Fifteen patients (2.2%) sexually active women reported dyspareunia.

To perform sacrospinous ligament fixation, it is imperative that the surgeon be familiar with the anatomy of the sacrospinous ligament complex and of the pararectal space. Obtaining adequate exposure can be difficult, and vascular complications, when encountered, may be life-threatening. The sacrospinous ligament is a cordlike structure that exists within the body of the coccyx muscle. The sacrospinous ligament attaches medially to the sacrum and coccyx and attaches laterally to the ischial spine. The complex is collectively called the coccygeus-sacrospinous ligament complex (CSSL). The CSSL is best identified by palpating the ischial spine and tracing the fingerlike ligamentous structure medially and posteriorly to the sacrum (Fig. 36E.6). The pudendal nerve and vessels pass directly posterior to the ischial spine. The sciatic nerve lies superior and lateral to the sacrospinous ligament. Superior to the ligament lies the inferior gluteal vessels and the hypogastric venous plexus (Fig. 36E.7). To avoid trauma to these structures, it is important to place the fixation sutures two fingers medial to the ischial spine. The apex of the vagina is grasped with two Allis clamps so the extent of the prolapse can be assessed. The vagina is then reduced to the sacrospinous ligament. Most surgeons prefer to use the sacrospinous ligament opposite their dominant hand; that is, the right-handed surgeon uses the right sacrospinous ligament, although some surgeons prefer to perform a bilateral fixation. Marking sutures can be used to identify the intended vaginal apex throughout the operation. It may be necessary to choose a different fixation point than the original vaginal cuff scar. This is best illustrated in a patient with a foreshortened anterior segment and a large enterocele. In this case, the
new fixation point would be moved to an area over the enterocele. It is equally important to access the anterior and posterior segments of the vagina and the genital hiatus. If the patient requires an anterior vaginal wall repair or an antiincontinence procedure, this should be performed in conjunction with the sacrospinous fixation.

A posterior vaginal incision is made and extended to the vaginal apex. Almost always an enterocele sac is present. The enterocele sac should be mobilized off the posterior vaginal wall up to its neck; the sac is then opened and the peritoneum excised. The defect is then closed with purse-string sutures.

The next step is entry into the perirectal space. The rectal pillar separates the rectovaginal space from the perirectal space. A window must be created through the rectal pillar, which is best accomplished by blunt dissection just lateral to the enterocele sac over the ischial spine. The window can also be created with the tips of scissors, a tonsil clamp, or a hemostat. The window should be gently enlarged to accommodate the vagina. The sacrospinous ligament can then be palpated by palpating the spine and moving the fingers dorsal and medial. It may be necessary to use blunt dissection to remove excess tissue from the CSS.

Once the window has been created and the ligament is identified, a retractor (Breisky-Navratil or Heaney) is used to displace the rectum medially. Great care must be taken to avoid raking the retractor over the anterior surface of the sacrum and causing damage to presacral nerves and vessels. When using the right sacrospinous ligament, the middle and index finger of the left hand are placed on the medial surface of the ischiial spine.

Then, under direct vision, the tip of the long-handled ligature carrier (Fig. 36E.8) penetrates the sacrospinous ligament two fingers medial to the ischial spine. There should be considerable resistance as the carrier is pushed through the body of the ligament. If no resistance is felt, then the carrier either passed in front of or around the ligament. The ligament can be grasped with an Allis clamp or Babcock to isolate the tissue away from vessels and nerves. After the suture has been passed, the fingers of the left hand are withdrawn. The sutures are then grasped with a nerve hook. A second suture is placed in a similar fashion approximately 1 cm medial to the first. If the surgeon doesn't desire a second passage, the suture can be cut in the midline, and each end of the cut loop can be paired with its respective free suture. If a good purchase of tissue has been taken, the surgeon should be able to gently move the patient with traction of the suture.

In 1987, Miyazaki described a new technique for passing a suture through the sacrospinous ligament using a specially designed ligature carrier (Miya hook) (Fig. 36E.9). The proposed advantage of this technique is that it is safer and easier because the ligature carrier penetrates the sacrospinous ligament under direct palpation and is then passed downward into the safe perirectal space.

To use the Miya hook, the right middle finger tip is placed on the sacrospinous ligament, two fingers breadth medial to the ischiial spine and just below the superior margin. The Miya hook is held closed in the left hand and slid along the palmar surface of the right hand. The point of the hook then comes to rest just beneath the tip of the right middle finger. The handles
are threaded through a free needle, sewn into the full thickness two ways for the surgeon to attach the sutures to the vagina. Once the surgeon has the two sutures through the sacrospinous ligament, the vaginal vault can then be suspended. There are several other instruments have been designed to pass the suture through the ligament. These include the Laurus needle driver and Nichols-Veronikis ligature carrier (Fig. 36E.10). A nerve hook is then used to retrieve the suture. Several other instruments have been designed to pass the suture through the ligament. These include the Laurus needle driver and Nichols-Veronikis ligature carrier (Fig. 36E.10). Once the surgeon has the two sutures through the sacrospinous ligament, the vaginal vault can then be suspended. There are two ways for the surgeon to attach the sutures to the vagina. The first is to use a pulley stitch. The free end of the suture is threaded through a free needle, sewn into the full thickness of the fibromuscular layer on the undersurface of the vagina (excluding the epithelium), and then tied by a half hitch. Traction on the free end of the suture pulls the vagina directly onto the ligament. A square knot is then used to fix the suture in place. Generally, when using this technique, permanent suture should be used.

The second technique can be used if the vagina is thin or of greater vaginal length is desired. This technique involves passing each end of the sutures through the full thickness of the vagina using 1-0 or 2-0 absorbable suture. The upper portion of the posterior vaginal wall should be closed with interrupted or running 3-0 absorbable sutures before tying the colpopexy sutures (Fig. 36E.11). If the colpopexy sutures are tied before the posterior wall is closed, the visibility of the vault is reduced, and the colpopharynx sutures are much more difficult to place.

The vagina should come into contact with the sacrospinous ligament, especially if absorbable sutures are used. A suture bridge can predispose to recurrent prolapse because a strong scar will not form before suture absorption. After the colpopexy sutures are tied, a posterior colpopharynx and perineorrhaphy is done. The vagina is then packed with moist gauze for 24 hours.

The overall results from sacrospinous fixation have been good. In 1997, Sae and Karram reviewed the literature on sacrospinous suspension, and of the 1,137 patients available for follow-up, 36 (3%) had recurrent vault prolapse. Ninety-six (8%) had anterior wall prolapse, and 25 (2%) had posterior wall prolapse. Some authors have not. Smilen and colleagues in 1998 compared patients with anterior vaginal wall defects undergoing anterior colpopexy. Many authors have conducted randomized trials evaluating sacrospinous fixation have been reported. Benson and colleagues in 1998 reported higher success rates with abdominal sacral colpopexy than sacrospinous fixation, and Maher and associates reported similar success rates. It has been our experience that this operation does distort the vagina posteriorly and leaves the anterior segment vulnerable to recurrent prolapse. Table 36E.1 reviews published results of sacrospinous ligament suspension.

Complications can occur, and the more common complications are disclosed here. It is important to do frequent rectal examinations during this procedure to make sure that no inadvertent proctotomy has occurred. If evidence of suture penetration is evident, the offending suture should be removed and replaced. Lacerations should be closed in a standard two-layer fashion. Hemorrhage can result from injury to the hypogastric veins, inferior gluteal vessels, and internal pudendal vessels. Injury can occur from overzealous dissection or inappropriate needle passage through the sacrospinous ligament. If bleeding does occur initially, pressure should be applied to the bleeding area. Continued bleeding should be addressed with suture ligations and hemoclips. Because this area is difficult to approach transabdominally, every effort should be made to control bleeding transvaginally. An improperly placed retractor or insufficient assistance can cause damage to the presacral vessels by raking the tip over the bony sacrum. Stress urinary incontinence may occur postoperatively and is probably the result of weakening of the posterior urethrovaginal junction. It is important that all patients have
adequate evaluation for potential stress incontinence. This is best done by preoperatively performing a stress test in the standing position with reduction of the prolapse.

A patient who reports severe postoperative gluteal pain that runs down the posterior surface of the affected leg most likely has a pudendal nerve injury. Sutures that are placed too close to the ischial spine risk injury to the pudendal nerves and the sciatic nerve. If the patient has evidence of nerve injury, she should immediately undergo reoperation with removal of those sutures impinging on the nerve. New colpopexy sutures should be placed either more medial on the same side, or the opposite sacrospinous ligament can be used.

In our experience, approximately 10% to 15% of patients have transient moderate to severe buttock pain on the side of the sacrospinous suspension. It is usually self-limiting and resolves by 6 weeks postoperatively. Reassurance and anti-inflammatory agents are all that are necessary.
Vaginal stenosis can occur if too much vaginal tissue is re- moved before closing the vaginal incision. An aggressive posterior repair can also cause a constriction ring. If a constriction ring is present while the patient is still under anesthesia, it should be addressed at that time. The colporrhaphy sutures can be removed or lateral-relaxing incisions can be made in the vagina.

High Uterosacral Ligament Suspension with Fibromuscular Vaginal Wall Reconstruction

In 1976, Richardson introduced a new approach to the management of enterocele and vault prolapse. The concept maintains that the endopelvic fascia that surrounds the vagina does not attenuate but breaks at specific points. The reconstruction aims to eliminate the enterocele by using principles of abdominal hernia surgery. This involves identifying the fascial defect, reducing the enterocele sac, and closing the fascial defect. In addition, the vagina is resuspended to its original level I support (the uterosacral ligaments).

Two Allis clamps are used to grasp the vaginal apex. With traction on the Allis clamps, the vaginal epithelium overlying the enterocele is incised. The enterocele sac is then dissected up to the neck of the hernia. The sac is opened, and the cul-de-sac is palpated for adhesions and any unsuspected pathology. If adhesions are present, they should be carefully taken down. The excess peritoneum is excised. A Heaney retractor or Deaver is then placed anteriorly. The abdominal contents are carefully packed away with moist laparotomy sponges. The retractor is withdrawn and then replaced so as to elevate the sponges and abdominal contents out of the pelvis, exposing the cul-de-sac (Fig. 36E.12).

Two Allis clamps are then placed where the remnants of uterosacral ligaments are believed to be, usually the 5-o’clock and 7-o’clock positions. It is sometimes necessary to trim excess vaginal mucosa to facilitate good traction on the uterosacral ligament. With tension on the Allis clamp directed outward, the pelvic sidewalls are palpated. The ischial spine is palpated transperitoneally, and an attempt is made to palpate the ureter. If the uterosacral ligament is difficult to find, the Allis clamp can be repositioned. The ureter is usually found 2 to 5 cm ventral and lateral to the ischial spine. The ureter is best found by applying pressure to the pelvic sidewall with the tip of the index or middle finger and sweeping from an anterior superior to a posterior inferior position.

Initially two or three delayed absorbable sutures are passed through the uterosacral ligament on each side around the level of the ischial spine. The distal remnants of the uterosacral ligaments are plicated across the midline with two to three permanent sutures. Tying of these sutures obliterates any redundant cul-de-sac. The previously placed delayed absorbable sutures are passed through the full thickness of the posterior vaginal wall. The sutures are then tied down, elevating the vault into the hollow of the sacrum. It is imperative to perform cystourethroscopy to evaluate ureteral integrity.

There are three reports to date on the results of high uterosacral ligament suspension. In 2000, Shull and colleagues reported on their experience with 298 patients. Thirty-five

</table>

*Subjective assessment based on telephone interview or questionnaire; objective assessment based on findings from pelvic examination.

*Cure rate applies to vaginal vault support only; does not include support defect at other site.

*Extrapolated from text.

*Includes 11 patients whose uteri were preserved.

*Includes 33 patients with anterior vaginal wall defects, three vaginal vault prolapses, and eight posterior vaginal wall relaxations.

From Sze EHM, Karram MM. Vaginal operations to correct vaginal vault prolapse: a review. Obstet Gynecol 1997;89:466.

(12%) had evidence of an anterior wall defect in the form of cystocele or urethrocele. However, 25 of these defects were noted to be only grade 1. Eleven (4%) patients subsequently developed posterior wall defects. In all, 18 patients (13%) had development of one or more support defects; however, 24 of these were grade 1 only. Two patients required another surgery for recurrent prolapse.

In 2000, Barber and colleagues reported their series of 46 patients, of whom 39 were available for long-term follow-up. Of note is that 19/26 anterior wall, 5/7 apical, and 13/21 posterior wall defects were designated as stage I. Three patients required another surgery for recurrent prolapse.

In 2001, Karram and colleagues reported on 202 patients. One hundred and sixty-eight patients were available for follow-up either by phone or office visit. Eighty-nine percent of patients indicated that they were happy or satisfied with the procedure. The reoperation rate was 5.5%. In 2006, Silva and colleagues reported on 72 patients who underwent uterosacral vault suspension. Two patients (2.8%) had stage II recurrence of apical prolapse with a mean follow-up of 5.1 years. These results are summarized in Table 36E.2.

**Complications** included hemorrhage with subsequent transfusion or bowel and bladder injury. The most common complication of this procedure, however, is ureteral injury or kinking. Karram and colleagues reported a 2.4% risk. Barber and colleagues reported an 11% risk, and Shull and colleagues reported a 4% risk. It is imperative that intraoperative cystoscopy be done to ensure ureteral patency. If ureteral spill is not observed, then the suspension sutures on that side should be cut and removed and the ureter reevaluated. Often, the suture can be replaced using a more medial placement into the uterosacral ligament complex.
**FIGURE 36E.12.** Uterosacral ligament suspension with fascial reconstruction. A: Apex of vagina is grasped with two Allis clamps. B: Enterocele has been entered and nonabsorbable sutures have been passed through the uterosacral ligaments at the level of the ischial spines. C: Sutures have been tied across midline, creating a firm ridge to which the vagina will be anchored. D: Absorbable sutures are used to suspend anterior and posterior vaginal walls with their fascia to uterosacral ligaments. E: Tying of these sutures suspends the vagina into the hollow of the sacrum and restores the continuity of the endopelvic fascia of the anterior and posterior vaginal walls. (From Walters MD, Karram MM. *Urogynecology and reconstructive pelvic surgery.* 2nd ed. St. Louis: CV Mosby; 1999.)
Iliococcygeus Fascia Suspension

In 1963, Linton described bilateral fixation of prolapsed vaginal vault to iliococcygeal fascia on three patients with inadequate uterosacral ligaments. In 1993, Shull and colleagues reported using this technique to treat 42 women. Their approach was to identify all fibromuscular vaginal wall defects preoperatively. Before iliococcygeus suspension, any anterior compartment defects are fixed. A cul-de-sac repair may be undertaken to shorten and approximate the uterosacral ligaments. Cuff suspension and posterior colporrhaphy are approached by excising a diamond-shaped section of tissue from the perineum and introitus. The vaginal epithelium is then freed from the rectum and rectovaginal fibromuscular vaginal wall, and the dissection is carried laterally to the levators and cephalad to the cuff. The iliococcygeus muscle is identified lateral to the rectum and anterior to the ischial spine. The surgeon then uses the nondominant hand to press the rectum down and medially. A suture is placed just anterior to the ischial spine. Both ends of the suture are then passed through the ipsilateral vaginal apex. The same procedure is repeated on the patient's opposite side. If delayed absorbable suture is used, it should be passed through the full thickness of the vagina. If nonabsorbable suture is used, a pulley stitch similar to that described by Shull and colleagues and by Meeks 13 years earlier to shorten and approximate the uterosacral ligaments by sewing the serosa of the sigmoid to the lateral peritoneum. The appropriate amount of graft material is cut, and sutures are placed through the graft and tied. The benefit of the EEA sizer is that penetration into the vagina is easily detected by the tactile sensation of the needle on the metal sizer. The sutures are then placed through the mesh and tied down. In 1997, Cundiff and colleagues recommended extending the mesh to the perineum. We generally extend the mesh approximately halfway down the posterior wall. We also place two to four pairs of 0 nonabsorbable suture on the anterior aspect of the vagina and attach a separate piece of mesh. This anterior mesh is sewn to the posterior mesh just proximal to the vaginal apex. Other potential configurations have also been described. A Moschowitz or Halban procedure is then done to obliterate the cul-de-sac. To expose the presacral area, the rectosigmoid is then reflected to the left. The bifurcation of the aorta is then reflected to the left. The course of the ureters and the uterine artery is then followed. The right ureter is identified and retracted laterally. The peritoneum over the sacral promontory is opened and carried down over the anterior surface of the sacrum. With the peritoneum reflected, the middle sacral artery and vein are identified. The left common iliac vein and artery are then identified. Any adhesions are then released by the surgeon's hand or with scissors. The peritoneum reflected, the middle sacral artery and vein are identified. The left common iliac vein and artery are then identified. Any adhesions are then released by the surgeon's hand or with scissors. The peritoneum is then dissected free laterally. Three to five pairs of 0 nonabsorbable suture are placed on the posterior aspect of the vagina about 1.5 to 2 cm apart. The suture incorporates the full thickness of the vaginal wall without entering the vaginal lumen. If the vagina is thin, imbricating sutures can be used to increase its thickness. The benefit of the EEA sizer is that it penetrates into the vagina is easily detected by the tactile sensation of the needle on the metal sizer. If the vagina is thin, imbricating sutures can be used to increase its thickness. The benefit of the EEA sizer is that it penetrates into the vagina is easily detected by the tactile sensation of the needle on the metal sizer.

Suspension of the vagina to the sacral promontory or into the hollow of the sacrum with an intervening mesh has been shown to be an effective treatment for vault prolapse. The patient is placed in Allen stirrups and is prepared and draped. Alternatively, the patient could be placed in the frog-leg position. Either position allows access to the vagina during the operation. We generally use an EEA sizer for manipulation, although a sponge stick may also be used. A three-way Foley catheter is used to drain the bladder. A laparotomy incision is made via a low transverse or vertical midline approach. Most laparotomy sponges are then used to pack the bowel into the upper abdomen. Any adhesions should be carefully taken down. The course of the ureters and the cul-de-sac should be identified and palpated. If the patient has a uterus, a hysterectomy should be done first and the cuff closed.

The vagina is then elevated using an EEA sizer (Fig. 36E.14). The peritoneum is then dissected off the anterior vaginal wall. The peritoneum on the posterior aspect of the vagina is incised in the midline and carried down into the cul-de-sac. The peritoneum is then dissected free laterally. Three to five pairs of 0 nonabsorbable suture are placed on the posterior aspect of the vagina about 1.5 to 2 cm apart. The suture incorporates the full thickness of the vaginal wall without entering the vaginal lumen. If the vagina is thin, imbricating sutures can be used to increase its thickness. The benefit of the EEA sizer is that it penetrates into the vagina is easily detected by the tactile sensation of the needle on the metal sizer.

The sutures are then placed through the mesh and tied down. In 1997, Cundiff and colleagues recommended extending the mesh to the perineum. We generally extend the mesh approximately halfway down the posterior wall. We also place two to four pairs of 0 nonabsorbable suture on the anterior aspect of the vagina and attach a separate piece of mesh. This anterior mesh is sewn to the posterior mesh just proximal to the vaginal apex. Other potential configurations have also been described. A Moschowitz or Halban procedure is then done to obliterate the cul-de-sac. To expose the presacral area, the rectosigmoid is then reflected to the left. The bifurcation of the aorta is palpated, and again the right ureter is identified and retracted laterally. The peritoneum over the sacral promontory is opened and carried down over the anterior surface of the sacrum. With the peritoneum reflected, the middle sacral artery and vein are identified. The left common iliac vein and artery are also prone to injury and should be identified. A subperitoneal tunnel can be created into the cul-de-sac by blunt and sharp dissection. The graft can then be placed retroperitoneally. Alternatively, the graft can be placed over the previous culdoplasty and can then be extraperitonealized by sewing the serosa of the sigmoid to the lateral peritoneum of the cul-de-sac.

Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

The vagina is elevated with an EEA sizer. The peritoneum over the vagina is opened, exposing the muscular portion of the vaginal wall (inset). (From Baggish MS, Karram MM. Atlas of pelvic anatomy and gynecologic surgery. New York: Saunders; 2001.)

The vagina is inspected and evaluated for any remaining defects. Usually a posterior colporrhaphy and a perineoplasty are also required. Although the exact indications for abdominal sacral colpopexy are controversial, many surgeons use it as their primary surgery for all cases of posthysterectomy vault prolapse. Because of the increased operative time and longer time to recover, we generally use the abdominal approach for young patients with advanced prolapse, patients who have previously failed a vaginal approach, have a shortened vagina, or who have other coexisting conditions that predispose to continued marked increases in intraabdominal pressure and therefore possible subsequent failure.

It has been shown by multiple investigators that abdominal sacral colpopexy is a durable and strong surgical correction for vaginal vault prolapse. Excellent results have been reported by many clinics. Benson and colleagues randomized patients with prolapse to abdominal sacral colpopexy versus bilateral sacrospinous ligament fixation. They found superior results with abdominal sacral colpopexy. The reoperation rate was 33% in the vaginal group and 16% in the abdominal group. Optimal results were obtained in only 29% of the vaginal group and 58% of the abdominal group. The time of operation was longer for the abdominal group. Lo and Wang also reported higher success rates with abdominal sacral colpopexy than sacrospinous fixation, and Maher and associates reported similar success rates.

Overall, the long-term results from sacral colpopexy have been very good. Addison and colleagues reported three recurrent prolapses after sacral colpopexy. In two patients, the synthetic mesh had separated from the vaginal wall, and in the third patient, the posterior vaginal wall ruptured distal to the attachment of the mesh. The authors believed that failures can be minimized by performing meticulous culdoplasty and securing the mesh to the culdoplasty with permanent sutures to prevent the dissection of an enterocele. They also recommended attaching the mesh to the vagina at multiple sites. Long-term follow-up is summarized in Table 36E.3.

Intraoperative complications are unusual, and injury to bowel, bladder, ureter, and infection, as with all abdominal surgery, have been described. Hemorrhage, especially from presacral vessels, can be life-threatening. Hemostasis can be difficult because damaged presacral vessels tend to retract beneath the bony surface. Sutures, hemoclips, and bone wax should be used initially. If these measures fail, then sterile thumbtacks can be employed. These stainless steel thumbtacks should be placed on the retracted bleeding vessel.

The most common long-term complication has been erosion of synthetic mesh. Kohli and colleagues in 1996 reported an incidence of 7%. Removal of the eroded mesh can be done via an abdominal or vaginal route. We have had good success removing the mesh via the vaginal route. With the patient prepped and draped, as much of the mesh as possible is exposed. The mesh is cut as high as possible and removed. The vaginal edges are then trimmed and closed in layers.

**High Uterosacral Ligament Suspension**

The vaginal approach of vaginal suspension to the uterosacral ligaments has been described. The same concept can also be used in an abdominal approach. After the abdominal wall has been opened and the bowel has been packed away, the remnants of the uterosacral ligaments are identified and tagged.
FIGURE 36E.16. Attachment of the mesh to the sacrum. Closure of the peritoneum over the mesh is shown in the inset. (From Baggish MS, Karram MM. Atlas of pelvic anatomy and gynecologic surgery. New York: Saunders, 2001.)

with suture near the ischial spine. The ureters are identified bilaterally. The enterocele is then addressed by obliteration of the cul-de-sac. The peritoneum over the vaginal apex is then opened, and the endopelvic fibromuscular vaginal wall is identified and reapproximated to form a continuous covering of endopelvic fibromuscular vaginal wall over the vaginal epithelium. Nonabsorbable sutures are then used to suspend the vagina with the now intact endopelvic fibromuscular vaginal wall to the uterosacral ligaments (Figs. 36E.17 and 36E.18).

Results for the abdominal approach to high uterosacral suspension should be similar to those for the vaginal approach.

There are, however, no long-term studies available. Complications are similar to those for the vaginal approach.

LAPAROSCOPIC APPROACH TO VAGINAL SUSPENSION

The techniques and concepts described earlier can also be approached via laparoscopy. The laparoscopic approach to the patient for positioning, port placement, and equipment is described elsewhere. The laparoscopic approach to these

procedures requires patience, attention to detail, and the realization that there is a steep learning curve. It is our belief that the operation and subsequent outcomes should not be compromised for the purpose of having achieved the operation by this approach. Therefore, the surgical measures taken to achieve the underlying concepts should not be significantly altered or changed.

ABDOMINAL VERSUS VAGINAL APPROACH TO PELVIC PROLAPSE

Expert opinion differs as to the most appropriate approach to pelvic organ prolapse. There are two randomized controlled trials that evaluate the best approach to prolapse repairs. Benson and associates demonstrated the abdominal sacral colpopexy was more likely to result in an optimal outcome as compared with the vaginal approach using sacropinous fixation. The vaginal group also underwent urethral urethropexy for stress incontinence. Previous authors have shown that retroversion of the vaginal axis predisposes to recurrent anterior vaginal wall prolapse. Maher and colleagues compared abdominal sacral colpopexy to unilateral sacropinous fixation and found them to be equally effective in the treatment of posthysterectomy vault prolapse. Data from both studies suggest the vaginal route to be safer and require less operative time. It is important to note that in both studies, the authors are in fact comparing a combination of procedures, and this must be taken into account when evaluating this data. It is our opinion that no one surgical approach is appropriate for all patients. Surgeons must be adept at multiple approaches and procedures to effectively care for all patients.

ROLE OF HYSTERECTOMY IN PROLAPSE REPAIRS

Hysterectomy with repair of pelvic support defects is standard practice for most parts of the world. However, more attention has been placed on uterine preservation when undergoing surgery for prolapse repairs. This is probably due to concerns about bowel, bladder, and sexual function following removal of the uterus and the improvement of conservative measures to treat menometrorrhagia. Three studies by Maher and associates, Hefni and colleagues, and van Brummen and associates failed to show a decrease in prolapse recurrence if hysterectomy was performed. There is no evidence that suggests routine hysterectomy improves the outcome of prolapse surgery, and there...

OBLITERATIVE PROCEDURES

Le Fort Partial Colpocleisis

At times, a patient may be sufficiently bothered by uterovaginal or vault prolapse but they are poor candidates for major reconstructive surgery because of their overall medical condition. An obliteratorive procedure may then be a good approach for these women. A Le Fort procedure is an option if the patient has her uterus and is no longer sexually active. The rate of postoperative urinary stress incontinence has been reported to be as high as 30% after this procedure, and, because the uterus is retained, it will be difficult to evaluate any future uterine bleeding or cervical pathology. Therefore, endometrial biopsy and Papanicolaou smear must be done before surgery.

The procedure is started by placing the cervix on traction to evert the vagina. The vaginal mucosa is injected with 0.025% Marcaine with 1:200,000 epinephrine just below the epithelium. A Foley catheter with a 30-cc balloon is placed in the bladder for identification of the bladder neck. A marking pen or scalpel is used to mark out the areas that are to be denuded both anteriorly and posteriorly. The area should extend 2 cm proximal to the tip of the cervix to 4 to 5 cm below the external meatus. A mirror image on the posterior aspect of the cervix should also be marked out. The previously marked areas are removed by sharp dissection. The surgeon should leave the maximum amount of fibromuscular vaginal wall behind on the bladder and rectum. Hemostasis is an absolute must (Fig. 36E.19). The cut edges of the anterior and posterior vaginal wall are sewn together with interrupted delayed absorbable sutures. The knot should be turned into the epithelium-lined tunnels that were created bilaterally. The uterus and vaginal apex are...
Elevated vaginal apex by EES sizer
Complete obliteration of cul-de-sac with facial reconstruction

FIGURE 36E.18. Longitudinally placed nonabsorbable sutures are passed through the ridge of uterosacral ligaments, down the cul-de-sac to the edge of the rectovaginal fascia, into the vaginal vault, and finally, through the edge of pubocervical fascia. Tying of the sutures (inset) elevates the apex of the vagina to the uterosacral ligaments and reapproximates the pubocervical fascia with the rectovaginal fascia. (From Baggish MS, Karram MM. Atlas of pelvic anatomy and gynecologic surgery. New York: Saunders; 2001.)

Vaginal Vault Prolapse

Gradually turned inward. After the vagina has been inverted, the superior and inferior margins of the rectangle can be sutured. A plication of the bladder neck should be routinely performed because of the high incidence of postoperative stress incontinence. Also, because there is no real support to the repair, an aggressive perineorrhaphy should be done to narrow the introitus.

In general, about 90% of patients have relief of symptoms and have good anatomic results. Complete breakdown and recurrence can be expected in 2% to 5% of patients. Results are summarized in Table 36E.4.

Early postoperative complications include hematoma and infection. These patients typically have other medical problems that may need to be addressed. Goldman and colleagues in 1985 reported on late postoperative complications from a modified Le Fort procedure in 118 patients. Ninety percent of patients had good anatomic results, whereas 83% had relief of symptoms. Two percent to 5% had recurrence of their prolapse, 10.2% developed incontinence or worsening of their incontinence, and 1.8% had late vaginal bleeding.

Colpectomy and Colpocleisis

<sup>a</sup>Number of patients with recurrent prolapse who underwent surgical repair/number of patients with recurrent prolapse.

<sup>b</sup>Extrapolated from text.

NA, Not available.

at a minimum, a colpectomy and colpocleisis can be done to treat the prolapse.

To perform this operation, the vaginal mucosa is completely excised from the underlying endopelvic fibromuscular vaginal wall. A series of purse-string sutures are used to invert the prolapse and endopelvic fibromuscular vaginal wall (Fig. 36E.20). Once the prolapse is reduced, a posterior colpoperineorrhaphy and levatorplasty is done. Von Pechmann and colleagues reported two cases of rectal prolapse following total colpocleisis in a total of 92 patients. The authors also reported that hysterectomy done at the time of colpectomy was associated with a statistically significant decrease in hematoctrit and increase in transfusion requirement. Results are listed in Table 36E.4.

CONCLUSION

Our understanding of the anatomy and concepts of pelvic organ prolapse and its treatments are constantly evolving. This evolution will and must continue to facilitate our understanding of the complex and varied etiologies of pelvic organ prolapse. Surgical treatments must restore both anatomic and functional derangements. This evolution will also provide insight into preventive measures for women at risk for pelvic organ prolapse and pelvic floor dysfunction. We, as pelvic surgeons, must continue to evaluate and apply new principles and techniques to established surgical dictums. There must be continued research, education, and a thoughtful, honest comparison of long-term surgical outcomes if we are going to continue to improve our care to a growing number of afflicted but active patients.

BEST SURGICAL PRACTICES

- The ultimate goal of pelvic reconstructive surgery is to restore anatomy, maintain or restore visceral function, and maintain or restore sexual function.
- The McCall culdoplasty and its various modifications are the most commonly used transvaginal techniques to suspend the vaginal apex. Approximately three delayed absorbable sutures are used to plicate the uterosacral ligaments. The Mayo Clinic technique excises a wedge of posterior and anterior vaginal wall, and any enterocele that is present, and includes both the uterosacral and cardinal ligaments for support.
For significant vaginal prolapse, the sacrospinous ligament fixation is a very useful technique. Shoulders should be very familiar with the anatomy and experienced with the procedure because injury to the pudendal nerve or vessels can cause sensory injury or life-threatening hemorrhage.

Abdominal sacral colposcopy is a very useful technique if an abdominal approach is indicated for other reasons (adnexal mass) and is preferred by some surgeons for the treatment of recurrent prolapse after a prior surgical failure. We prefer to support the vagina to this longitudinal ligament of the sacrum using synthetic mesh, which is secured to the anterior and posterior vaginal walls with 0 nonabsorbable sutures.

Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

Pelvic organ prolapse—Downward displacement of structures that are normally located adjacent to the vaginal vault.

Pelvic Organ Prolapse Quantification (POP-Q) scale—A coring system used to quantify pelvic organ prolapse; see Chapter 36A.

Pessary—A device inserted into the vagina for correction of pelvic organ prolapse.

Splenling—A maneuver that assists with elimination of urine or feces, usually used in cases of pelvic organ prolapse.

Stress urinary incontinence—Leakage of urine with any maneuver that increases intraabdominal pressure (such as a cough or sneeze).

The surgeon who treats patients with pelvic floor defects should also be familiar with the nonsurgical management of these disorders. Although pelvic organ prolapse prevalence has been and continues to rise steadily, pessary use has previously fallen out of favor, with renewed interest having been noted only recently. Vaginal pessaries have been used for the treatment of not only genital prolapse but also urinary incontinence, uterine retroversion, cervical incompetence, and, more recently, local administration of estrogen. Various shapes and sizes allow a variety of pelvic floor defects to be adequately managed without the need for surgery. Although modern pessaries have been used for a long time with an abundance of expert opinion and case reports in the literature, rigorous investigations of these modalities is severely limited, as concluded in a recent Cochrane review. This chapter reviews the available data on pessary use for pelvic organ prolapse, some of the more commonly used pessary types and their proper fitting, subsequent follow-up, and potential complications.

By the end of the 16th century, various pessaries of brass and waxed cork were used for uterine prolapse. The late 17th century saw a considerable number of medical therapies and pharmaceutical concoctions promoted for the treatment of genital prolapse, which persisted even into the 18th century. In the mid-19th century, the American Medical Association documented 123 different pessaries. As the safety of surgical procedures has improved and concerns of adverse consequences of pessaries reported, there has been a tendency during the mid-20th century to use pessaries less often in favor of corrective surgery. Modern pessaries are primarily made of silicone, rarely of latex rubber or acrylic. These materials have completely replaced the old Bakelite and hard-rubber types used previously. Silicone is advantageous because it is inert, does not absorb secretions or odors, is flexible yet sturdy, and can be autoclaved for resterilization.

The primary indication for fitting a pessary is the nonsurgical relief of symptoms associated with pelvic organ prolapse. This ideally should be achieved without introduction or worsening of urinary incontinence and with minimization of the risk of vaginal mucosal abrasion, erosion, and bleeding. Additionally, pessaries are used for the alleviation of stress incontinence and will be discussed in more detail in Chapter 37.

Surveys demonstrate that 87% to 98% of gynecologists and/or urogynecologists prescribe pessaries in their practice. Among members of the American Urogynecologic Society (AUGS), 77% of those responding offered pessaries as first-line therapy for pelvic organ prolapse, whereas 12% offered them only to women who are not considered good surgical candidates or those who refused surgery. Among a randomly drawn survey of American College of Obstetricians and Gynecologists (ACOG) members, 20% of gynecologists prescribed pessaries only to patients deemed poor surgical candidates. Some advocate pessaries in patients who have prolapse-related vaginal and/or cervical ulcerations and for mucosal hypertrophy. In the AUGS survey, those who described themselves as gynecologists or urologists (as opposed to urogynecologists or...
obstetrician–gynecologists) were more likely to offer pessaries only to patients who are poor surgical candidates. Those in practice for more than 20 years were found to be less likely to use pessaries as a first-line management option, preferring to limit their use to nonsurgical patients. In the ACOG members survey, physicians with a self-reported special interest in urogynecology prescribed pessaries more often than those who did not proscribe such an interest, and female physicians were more likely to prescribe pessaries than their male counterparts.

**PESSARY USAGE: PATIENT PERSPECTIVE**

Only a few recent studies have focused on the efficacy and impact on quality of life that pessaries provide for patients. A cross-sectional study in which all new patients seen in a referral practice were counseled regarding their options found that older patients were 10% more likely to choose a pessary rather than surgery as their initial management option for prolapse. Ring pessaries were used in 74% of these 73 patients, and the rest were Gellhorn pessaries. At 2-month follow-up, they found significant resolution of the symptoms of feeling a bulge, pelvic pressure, vaginal discharge, and need for splinting to void or effect a bowel movement. Urinary symptoms of stress incontinence and urge incontinence improved in 45% of patients, and voiding difficulties improved in 53%. On the other hand, de novo stress incontinence occurred in 21% of patients with a pessary. Overall, 67 of the 73 women were “very satisfied” or “somewhat satisfied” for a 92% satisfaction rate among those with a successful pessary fitting. Even using an intent-to-treat analysis, 67% of the original 100 women who were fitted for a pessary reported being satisfied. Of the patients who were sexually active before pessary use, 90% were able to continue to have sexual intercourse. Those who could not were the ones fitted with a Gellhorn rather than ring pessary.

A retrospective analysis found that women who wore a pessary for prolapse were more likely to continue than those who wore a pessary for incontinence. They also found that women who reported themselves as sexually active were more likely than those who were not sexually active to continue pessary use regardless of the indication. Age, parity, menopausal status, and previous surgical history were not found to be predictors of pessary continuation.

A small retrospective observational study suggests that 1 year following pessary use, pelvic organ prolapse did not worsen, as evaluated by Pelvic Organ Prolapse Quantification (POP-Q) measurements with Valsalva. The study found that in 4 of 19 (21%) patients, their prolapse improved, and the rest remained unchanged.

**SUCCESS AND RISK FACTORS FOR FAILURE**

In a prospective study by Wu and colleagues, among 110 women who opted for and were fitted for pessaries as first-line therapy, 81 (74%) were successfully fitted. Characteristics associated with initial failure of pessary fitting included younger age, higher parity, a history of pelvic surgery, and stress incontinence. The degree of pelvic organ prolapse did not predict failure of initial fitting, neither did hormone replacement or the adequacy of the perineal body. In this study, the initial pessary used was a ring or a ring with support in the vast majority of cases (95%), with a cube pessary used for the remaining patients. No differences were noted in efficacy between these different pessary types.

Clemens and colleagues prospectively observed 100 patients who were fitted with ring (with support) or Gellhorn pessaries, with an initial pessary fitting success rate of 94%. However, this declined to 73% when evaluated 2 weeks later. Short vaginal length (≤ 6 cm) and a wide introitus (4 finger breadths) were associated with failure of pessary fitting. The degree of prolapse, genital hiatus size, and presence of vaginal atrophy were not associated with failure. The same group followed a subset of this cohort—67 women who were satisfied at their 2-month follow-up—for a full year. At the 1-year follow-up, 43 patients (64%) continued with pessary use, whereas 16 elected surgery.

Mutone and colleagues, in a retrospective study of 407 patients, reported a lower pessary fitting success rate of 41% when evaluated 3 weeks after the initial fitting. Characteristics associated with failure in this study included prior hysterectomy or surgery for prolapse. There was no association with the type or degree of pelvic organ prolapse. In a retrospective study of 101 patients, Saluk and colleagues reported discontinuation rates using primarily the Gellhorn pessary. The following are the categories reported of the reasons for discontinuation: inconvenience or inadequate relief of symptoms (40%), difficulty in removal (23%), discomfort (13%), patient requesting surgery (13%), pessary fell out (6%), and inability to urinate (5%).

**CLINICAL EVALUATION**

The patient with pelvic floor dysfunction requires careful evaluation by history and physical examination as outlined in Chapter 16A. Important considerations are assessment of symptoms attributable to prolapse, including pelvic pressure or discomfort, a sensation that something is falling out or protruding, voiding and defecatory symptoms, and urinary incontinence. The clinical evaluation should be aimed at investigating and quantifying the specific pelvic support defects present in terms of anterior, posterior, and apical compartments. The POP-Q scale is a validated and widely accepted measure of the degree of pelvic organ prolapse and includes a measure of vaginal length. Testing for occult stress urinary incontinence by provocative maneuvers with the prolapse reduced using a femoral (or high) speculum helps identify patients who may suffer from urinary leakage associated with pessary use. This may be helpful in the counseling of such a patient and perhaps in choosing a pessary with better support of the bladder neck to prevent such an undesirable outcome.

Evaluation of the vaginal mucosa to assess estrogen status is necessary. The concern for pessary-associated erosion and ulceration in the atrophic vagina leads the vast majority of surveyed AUGS members (94%) to recommend concurrent estrogen replacement therapy in the absence of contraindications. Wu and colleagues reported that the incidence of vaginal abrasions increased as the vaginal epithelium exhibited more atrophy. Furthermore, those that experienced vaginal abrasions were more likely to discontinue pessary use. In my experience,
use of vaginal estrogen therapy is the preferred method to treat and prevent vaginal atrophy.

**TYPES OF PESSARIES**

There have been hundreds of pessaries described throughout the ages. Currently, however, fewer than 20 pessary types are used for prolapse. Some types have been further modified for the nonsurgical management of stress urinary incontinence by increasing support to the bladder neck (Fig. 36F.1).

Of responding AUGS members, 78% tailored their choice of pessary type to the specific pelvic support defect. Of the members who reported using the same pessary for all types of prolapse, the ring was the most commonly used. Most respondents (59%) considered a weak pelvic diaphragm—whereas only 44% considered a prior hysterectomy—as important in the choice of pessary, generally favoring a space-occupying rather than supportive pessary in each of these circumstances. The supportive pessaries were defined as those that were deprived by a spring mechanism (ring, Gehrung, lever-type pessaries) and thought to be supported by the symphysis pubis. The space-filling pessaries were defined as supported by the creation of suction between the pessary and the vaginal walls (e.g., cube) or by providing a diameter larger than the genital hiatus (donut, InflatoBall, Shaatz) or by both mechanisms (Gellhorn). Although these categories clearly simplify the analysis of data, such a functional classification has not been studied. It is unclear whether the mechanistic differences inferred by such a classification are indeed valid.

Surveys show that the ring pessary is the most commonly used, both among physicians who tailor their pessary choice based on the support defects present and those who use the same pessary for all types of prolapse. It is unclear whether this choice is related to perceived efficacy or issues related to ease of management, patient acceptability, the patient’s ability to remove the pessary, or other considerations.

**Ring Pessary**

The hinged spring circumference of the silicone-coated ring pessary allows for its compression in one direction, which makes for ease of insertion. These pessaries are similar in appearance to the contraceptive diaphragm and thus may be more familiar and acceptable to some patients. It is recommended that once inserted behind the symphysis pubis, the ring be turned 90 degrees because it collapses only along a single axis. The ring with support may provide additional support to a mild anterior vaginal defect and prevents the rare complication of an incarcerated herniated cervix through the open ring. The ring pessary is amenable for self-removal and insertion by the patient. It may be worn during coitus.

**Donut Pessary**

The silicone donut-shaped pessary may be used for higher degrees of prolapse. It is supported by the levator muscles and fills the upper vagina completely. It is, therefore, considered appropriate for the management of uterovaginal and vaginal vault prolapse. Insertion through the introitus is in the vertical plane, and the pessary is turned to a horizontal plane when inserted beyond the levator muscles. It tends to be difficult for patients to remove this type of pessary by themselves. Coitus is not usually possible with this type of pessary.

The InflatoBall is a variant of the donut pessary. Made out of latex rubber, it can be easily inserted and removed when deflated. When inflated by use of a manual pump, it sits above the levator plate much like the donut pessary, with the valve stem tucked in the vagina (Fig. 36F.2). Because it is made out of latex and therefore absorbs secretions and odors, the InflatoBall should be removed and cleaned every 1 to 2 nights and reininserted in the morning. This pessary’s use is contraindicated with a history of latex allergy.

**Gellhorn Pessary**

The Gellhorn pessary is useful in patients with severe degrees of uterovaginal or vaginal vault prolapse. Support derives from the base that sits above the levator plate and the stem that rests on the distal posterior vaginal vault mucoperiostum (Fig. 36F.3). An adequate perineal body is considered by some important for the effectiveness of this pessary, whereas others believe that suction from the concave base contributes to its support.
highly unlikely that patients will be able to remove and reinsert this pessary. The Gellhorn pessary does not allow comfortable coitus because of its shape.

**Shaatz Pessary**

The Shaatz has a shape similar to that of the Gellhorn but has no stem. This may facilitate coitus in some patients. Self-management of this pessary is possible.

**Cube Pessary**

The concave walls of the cube pessary create suction and adhere to the vaginal sidewalls. This characteristic results in effective support for severe uterovaginal or vaginal vault prolapse but can potentially cause ulceration and erosion of the vaginal mucosa. It is, therefore, recommended to remove this pessary nightly. This is achieved by inserting fingers between the pessary and the vaginal walls to release the suction and grasp the pessary itself (not the string) before pulling it out of the vagina.

**Gehrung Pessary**

The arch-shaped Gehrung pessary has a pliable metal frame that allows the pessary to be shaped to the patient’s dimensions. The heels of the pessary rest on the lateral aspects of the posterior vagina, with the distal arch positioned behind the symphysis pubis (Fig. 36F.4). This underutilized pessary is effective in managing anterior and mild posterior compartment defects. Its shape makes this pessary somewhat difficult to insert but also allows for intercourse.

**Lever Pessaries**

All lever pessaries in use today are modifications of the original Hodge pessary. The Smith modification is designed to fit a narrow pubic arch, whereas the Risser fits the wider pubic arch.
arch. The major function of these pessaries is the management of a retrodisplaced uterus. It has been proposed in the treatment of mild anterior and/or posterior compartment defects, as well as for cervical incompetence during pregnancy. When placing a lever pessary in a patient with uterine retrodisplacement, the uterus must be first manually anteverted. Lever pessaries can be worn during intercourse and may be self-managed.

Incontinence Pessaries

Many of the previously described pessaries have undergone additional modification to manage concurrent stress urinary incontinence. This usually involves the addition of a knob that is positioned under the urethra at the level of the bladder neck to help prevent its descent and facilitate temporary compression of the urethra with effort. These pessaries and the Introl device, which is solely designed for treatment of stress incontinence, often result in discontinuation. In a study by Alnaif and Drutz, douching or Trimo-San gel (Cooper Surgical) and does not usually result in discontinuation. If, however, such an erosion or serious abrasion is diagnosed after pessary insertion but was not present before, the erosion is probably related to pressure from the pessary.

COMPLICATIONS

Most commonly, a discharge and odor develop with continued wearing of a vaginal pessary. This is often treated with periodic douching or Trimo-San gel (Cooper Surgical) and does not usually result in discontinuation. In a study by Alnaif and Drutz, bacterial vaginosis was found four times more commonly in pessary users. Mucosal erosion and abrasions of the vagina and/or cervix are more common with cube and Gelhorn pessaries. They are
also more likely in patients who do not remove and reinsert their own pessary, as well as women with untreated vaginal atrophy. Recurrent erosions despite multiple attempts at pessary fitting with an adequately estrogenized vagina should prompt discontinuation of this mode of therapy. Pessary incarceration within the vagina with formation of vaginal adhesions has been described. Removal is facilitated by application of estrogen cream for several days.

Although rare, serious complications have been reported, mainly with the pessary that has been neglected, sometimes for many years. These complications include infections, fistulas, and even complete erosion with transmigration of the pessary into the bladder or the rectum. Herniation and incarceration of the cervix and even small bowel through neglected ring pessaries have been described. Unilateral and bilateral hydrocele with urosepsis and uremia have also been reported.

Chronic irritation associated with prolonged, uninterrupted pessary use has been associated with vaginal cancer. The literature comprises case reports that preclude the assumption of a causal relationship between pessary use and vaginal cancer. It appears to be more likely in the patient with a pessary neglected for many years and perhaps with older pessaries made of rubber. Pessaries used in practice today are primarily made of inert medical grade silicone, which may further reduce the risk of vaginal cancer.

**SUMMARY**

Although vaginal pessaries have been used throughout the millennia, their use has not been intensely studied. They remain a useful alternative either as initial management or reserved for those patients who are otherwise not candidates or do not desire surgery. This requires frank discussion with the patient regarding potential risks and benefits of all the proposed management options before she makes a decision. Pessary types may, at the discretion of the physician, be chosen for specific pelvic support defects. Although follow-up regimens may be individualized, adequate follow-up and treatment of vaginal atrophy are important to prevent the minor and major complications that can be associated with pessary use. The available evidence suggests that most patients who wish to proceed with pessary use as initial management can be successfully fitted.

**BEST SURGICAL PRACTICES**

- Nonsurgical management of pelvic organ prolapse should be considered in all patients with symptomatic prolapse.
- Indications for insertion of a pelvic pessary include symptomatic prolapse, urinary incontinence, uterine retroversion, or cervical incompetence.
- When using a pessary, care should be taken to avoid worsening stress urinary incontinence after placement.
- Intent to continue vaginal intercourse does not preclude use of a pessary.
- Evaluation of the vaginal mucosa should be performed before pessary placement. Atrophic vaginitis can increase the risk of pessary complications.
- Choice of pessary is highly individualized and will be guided by the type and severity of prolapse, desire to have intercourse, and the practitioner's preference.
- Patients should be followed closely after pessary placement and should be examined at regular intervals. Patients should be asked about vaginal bleeding, malodorous discharge, pain, voiding difficulty, or symptoms of a urinary tract infection.
- At each follow-up visit, the pessary should be removed and the vagina and cervix inspected for signs of erosion or abrasion. Suspicous vaginal lesions should be biopsied.
- Common complications of long-term pessary use include discharge and mucosal irritation or abrasion. Erosions or abrasions can often be addressed by local estrogen treatment or a change in pessary type.
- Serious complications of pessary use are usually only seen in patients with neglected pessaries and can include infection, fistulas, complete erosions, or incarceration.

CHAPTER 37 ■ STRESS URINARY INCONTINENCE
ALFRED E. BENT

DEFINITIONS

Cystometrography—Tests of bladder function, including bladder sensation, capacity, and compliance. These tests may be simple clinical evaluations of bladder filling and emptying or may involve electronic measurement of bladder, urethral, and intraabdominal pressures.

Hypermobile stress incontinence—Stress incontinence caused by loss of anatomic support of the urethra and bladder base.

Intrinsic sphincter deficiency—Urinary incontinence that is due to dysfunction of the urethral sphincter mechanism.

Stress urinary incontinence—Voluntary leakage of urine from the urethra caused by increased intraabdominal pressure (coughing, straining, etc.).

Urodynamic stress incontinence—Involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction.

Urinary incontinence is a condition that affects 30% to 40% of older American women, with the majority afflicted with stress urinary incontinence (SUI). Conservative therapy helps a large number of these patients but cures relatively few. Surgical approaches for SUI have become more and more common, large number of these patients but cures relatively few. Surgical approaches for SUI have become more and more common, and have moved to delivery through minimally invasive surgical techniques. The purpose of this chapter is to detail the required evaluation before surgical intervention, then describe the surgical procedures used most effectively, along with the indications, results, and complications.

Stress urinary incontinence is defined by the International Continence Society as a condition defined by urodynamic observations associated with characteristic signs or symptoms. Urodynamic stress incontinence is defined as the involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction. Under the category of lower urinary tract symptoms, SUI is a storage disorder for which the characteristic symptom is the involuntary leakage of urine on effort or exertion, or on sneezing or coughing. The sign of SUI is the observation of involuntary leakage from the urethra synchronous with exertion or effort, such as sneezing or coughing. Current terminology refers to the condition described by both symptoms and urodynamic findings.

Stress incontinence has been divided into hypermobile stress incontinence, caused by anatomic defects, and intrinsic sphincter deficiency, with incontinence resulting from a poorly functioning urethra. This separation has become less distinct with time. SUI may include a wide spectrum of varying degrees of disruption of normal anatomy causing hypermobility or, somewhat paradoxically, scarring and fixation of these same tissues. Urethral sphincter function may be minimally altered so as not to be discernable on testing, or it may be severe. Most experts in the field are of the opinion that there is a contribution of each kind of dysfunction in most patients. The development of SUI has been attributed to a number of causes, with childbearing thought to be a dominant role in altering structural function (Table 37.1).

INITIAL EVALUATION

In 1996, the Agency for Health Care Policy and Research published its consensus guidelines for the evaluation and management of urinary incontinence. These recommendations from a panel of experts include the following: a thorough history (including voiding diary), physical examination, postvoid residual, and urinalysis.

More recently, the 3rd International Consultation on Incontinence held in Monaco (June 19–21, 2004) has published a series of management algorithms, including one for women with incontinence. The basic evaluation includes history; urinary symptom assessment, including a frequency-volume chart and questionnaire; assessment of quality of life and desire for treatment; cough stress test; urinalysis; assessment of voluntary pelvic floor contraction; and assessment of postvoid residual urine.

INITIAL MANAGEMENT

The recommendations for initial management do not require detailed testing, but treatment is based on a presumptive diagnosis of SUI. The first-line therapies commence with lifestyle interventions, which include weight reduction, smoking cessation, and dietary and fluid modification. Estrogen deficiency requires treatment followed by reassessment. Supervised pelvic floor muscle training and bladder training are recommended. The key word here is supervised. Patients will not and cannot manage the proper therapy on their own. An appropriate duration of therapy is 8 to 12 weeks before reassessment for further treatment. Vaginal support devices can be included in the treatment options, depending on availability of the product, ability of the patient to manage the product, patient acceptance, and cost. In Europe, there is drug therapy available in the form of a dual serotonin and noradrenalin reuptake inhibitor, which has well-documented efficacy in large placebo-controlled drug studies.

EVALUATION BEFORE SURGERY

The American College of Obstetricians and Gynecologists Practice Bulletin issued in 2005 describes the evaluation of patients with symptoms of SUI. In addition to a focused history and
In the patient who has symptoms that are mixed (stress and movement greater than 30 degrees from horizontal with strain)

- Q-tip test or imaging
- Residual urine determination

Consultation on Incontinence recommended urodynamics to diagnose the type of incontinence. Urethral function testing may be helpful in some patients. Guidelines for operating on bladder function, including cystometry and cystourethroscopy, function blood tests are indicated. Office evaluation of bladder function also is used as a less invasive intervention for SUI in certain patients. A comprehensive listing is provided in Table 37.3. This reflects a combination of the alteration of techniques and approaches of established and effective procedures and the introduction of newer technologies and materials. In today’s surgical practice, it is well established that performing an anterior repair or Kelly plication for the treatment of SUI is standard compared with more effective procedures. This procedure was described in the 19th century; although it remains a recognized therapy for central defect cystocele, the most current international recommendation for use in patients with stress incontinence is in women who prefer to sacrifice some chance of becoming continent for a reduced chance of complications.

More than 200 procedures have been described in the literature for the treatment of stress incontinence (Table 37.3). This reflects a combination of the alteration of techniques and approaches of established and effective procedures and the introduction of newer technologies and materials. In today’s surgical practice, it is well established that performing an anterior repair or Kelly plication for the treatment of SUI is standard compared with more effective procedures. This procedure was described in the 19th century; although it remains a recognized therapy for central defect cystocele, the most current international recommendation for use in patients with stress incontinence is in women who prefer to sacrifice some chance of becoming continent for a reduced chance of complications. Because of significant recurrence rates at even 1 and 2 years of follow-up, long-needle procedures—such as the Pey- era, Stamey, or Raz procedures—are not recommended. Currently, the two primary forms of surgery for SUI are retropubic urethropexy and sling procedures. Injection of urethral bulking agents also is used as a less invasive intervention for SUI in certain patients. A comprehensive listing is provided in Table 37.3, but the procedures presented in detail will be those in current widespread use.

**Retropubic Urethropexy**

The gold-standard surgical treatment of SUI in patients with a mobile bladder neck and normally functioning urethra has been accomplished through a retropubic approach using either

The endopelvic fascia can then be identified (Fig. 37.2). The anatomic landmarks and points of attachment of a Foley catheter bulb, and it may be marked with hemoclips if desired. The bladder is retracted to expose the bladder. Following exposure of the bladder dome to locate the bladder neck by direct vision for exact suture placement at the bladder neck. Sutures are placed at the bladder neck and usually at least one set at the bladder neck and the second set at midurethra (Figs. 37.4 and 37.5). One or both arms of each suture are sutured into the pubocervical fascia or fibromuscular layer of the vagina. Permanent sutures are placed on either side and 2 cm lateral to the urethra into the endopelvic fascia (avoiding full thickness), one set at the bladder neck and the second set at midurethra. Permanent sutures are placed at either side of the urethra in a paraurethral location quite close to the urethra (Fig. 37.8). Bilateral permanent sutures are placed at the bladder neck and usually at least one set is placed just distal to this. These sutures are attached to the fibrocartilage of the symphysis pubis. Some surgeons open the bladder dome to locate the bladder neck by direct vision for exact suture placement at the bladder neck.

The aim of both procedures is to reestablish the intraabdominal location of the proximal urethra and urethrovesical junction, and to minimize descent of the bladder neck or urethrovesical junction, thus allowing normal pressure transmission to this crucial area during times of increased intraabdominal pressure. Cure rates for these procedures range from 83% to 90% at 1 to 5 years and greater than 70% at 10 years. These procedures can be performed in concert with an abdominal hysterectomy or alone through a retropubic approach without opening the peritoneal cavity. Minilaparotomy techniques allow incisions as small as 5 cm to accomplish the suspension.

Laparoscopic Burch urethropexy became very popular in the mid-1990s. The approach could be either intraabdominal or extraperitoneal, and numerous modifications to the original Burch procedure were described, including using only two sutures; substituting mesh; or using tacks, anchors, and other tools to elevate the bladder neck. These variations significantly lowered cure rates as compared with traditional open urethropexy. Placement of four permanent sutures identical to an open procedure, though, has yielded similar 1- and 2-year cure rates as an open Burch (93% and 89%, respectively). In a prospective randomized trial of 62 laparoscopic and 28 open Burch procedures followed by urodynamics at 1 year, the cure rates were 93% for the laparoscopic and 88% for the open group. However, the more recent introduction of tension-free tape procedures made the use of laparoscopic Burch markedly less frequent, and it is now generally performed only with other intraabdominal reconstructive surgery.

Another procedure in the category of a retropubic approach is the paravaginal defect repair, first described by White in 1909. This procedure is for correction of lateral defect cystocele and not for treatment of SUI. The paravaginal defect repair, first described by White and revealed with Richardson and Shull. However, this procedure is for correction of lateral defect cystocele and not for treatment of SUI.

When performing a Burch retropubic urethropexy, the paraurethral tissue is exposed either with a “daisy sponge” (three 4 × 4 sponges on a sponge stick) or by using a moist sponge and narrow retractor. The best instrument for this is a Miyazaki all-purpose lighted retractor. The paraurethral areas may be cleared of fat that overlies the pubocervical fascia (fibromuscular layer of the vagina). The pubocervical tissue is elevated with a vaginal finger, and the overlying rectus muscles are mobilized medially and superiorly away from the site of suture placement using a small dissecting sponge or “peanut” (Fig. 37.3). The large veins in this area are avoided, if possible, but may require control with suture, hemoclips, or cautery. The most important aspects of the development of the retro-
Stress Urinary Incontinence

Tension-free Midurethral Slings

Tension-free slings are surgical procedures using a polypropylene mesh to support the midurethra without tension, a technique first described by Ulmsten and colleagues. Long-term follow-up has been reported with cure rates of approximately 85%. The original technique uses a retropubic approach, but the transobturator approach is fast becoming the most common tension-free sling technique performed worldwide for primary SUI. The appeal of a tension-free midurethral sling is that it is an effective, minimally invasive technique using local anesthetic and intravenous sedation in a day-surgery setting.

Many products are now marketed for this type of sling (Table 37.4). Some surgeons fashion their own sling from polypropylene soft mesh and place it without the aid of specially devised needles and kits. The manufactured products have a protective plastic sheath, allowing easy movement and adjustment of the sling under the urethra (Fig. 37.9).

The anesthetic for the procedure is injected as a solution of lidocaine hydrochloride diluted to 0.25% (1/4%) strength. Because the approximate maximum safe dose is 30 mL of a 1% solution, the 0.25% (1/4%) solution will provide 120 mL. Epinephrine may be used in the mixture, and with an original concentration of 1/100,000, the dilution ends up as 1/400,000. Alternatively, bupivacaine HCl may be used for local infiltration. The maximum dose of bupivacaine is 225 mg.
FIGURE 37.3. Dissection of bladder medially to expose endopelvic fascia. The finger of the vaginal hand elevates the vagina while the instrument pushes medially against the finger.

with epinephrine and 175 mg without epinephrine. In the traditional tension-free tape, 30 mL of solution is injected suprapubically on each side to include skin and subcutaneous tissues, rectus fascia, tissue immediately adjacent to the symphysis pubis, and endopelvic fascia. Then 20 mL of the solution is placed bilaterally by a vaginal approach, extending laterally from the midline into the endopelvic fascia and under the descending pubic rami. Five to 10 mL is placed under the midurethra. A 1- to 2-cm incision is made under the midurethra. For traditional tension-free tapes, a 2 cm tunnel is made with Metzenbaum scissors at a 45-degree angle toward the descending pubic rami on each side. A rigid

catheter guide is placed in a 18 French catheter; this is placed into the urethra and directed laterally to the side on which the surgeon is working so as to deviate the bladder to the opposite side. The delivery needle with detachable handle is placed into the tunnel by an initial lateral direction, then directed toward the ipsilateral shoulder while the opposite-hand index finger guides the needle under the descending pubic ramus. The needle hugs the pubic ramus as the endopelvic fascia is penetrated, and then is advanced until the tip appears suprapubically (Fig. 37.10). The needle tip is passed just through a 5-mm skin incision, and the detachable handle is removed and placed on the needle passer for the other side. The tape is passed on the opposite side, and the handle removed. Cystoscopy is performed after each pass, or, alternatively, after both passes have been made. If there is no bladder perforation, the needles are advanced and pulled completely through the suprapubic area while viewing the bladder with the cystoscope. The needles are removed from the sling device. The sling with protective sheath is tightened over a number 8 Hegar dilator or other instrument. A clamp is positioned to grasp only the plastic sheath, and, while tension is maintained on the Hegar dilator to prevent the sling from becoming too tight, the plastic sheaths are gently pulled free from the mesh. The excess sling arms are cut flush to the skin surface. The vaginal and skin incisions are closed. The sling is not sutured to any underlying tissue, and the composition of the mesh allows tissue ingrowth to fix the sling in place. A Foley catheter is placed; or, alternatively, the patient may go to recovery without a catheter. A voiding trial is initiated in the recovery room; if the patient does not pass, she performs self-catheterization, or a Foley catheter is placed overnight. The catheter is removed by the patient the following morning, and she comes to clinic for assessment of voiding function.

The abdominal approach commences with the same vaginal dissection. A catheter guide is usually not used. The abdominal needle passer is passed through a small incision on either side of the midline just above the symphysis pubis and is guided along the back of the symphysis until it passes under the descending pubic ramus and comes into contact with the vaginal finger. It is guided into the vaginal incision similar to needle suspension procedures, such as Stamey, Raz, and Pereyra. Cystoscopy is performed to ensure the needle passers have not penetrated the bladder. The mesh is attached to the needle passers and pulled from the vaginal incision through the retropubic space to the abdominal site. The remainder of the procedure is the same as the vaginal route. Complications are similar to tension-free
FIGURE 37.10. Insertion of vaginal tension-free tape. A: Vaginal guidance of needle under descending pubic ramus along back of symphysis. B: Pressure over skin of abdomen to allow needle to penetrate abdominal skin. C: Both needles passed through retropubic space and resting on abdomen. (With permission: Klutke J, Klutke C. The promise of tension-free vaginal tape for SUI. Contemporary Urology Archive. 2000; October: Figures 4, 6, and 7.)

Vaginal tape (TVT) except for fewer described severe problems with vascular or bowel injury. Bladder perforation occurs with equal frequency.

The most serious complications after the first 500,000 cases of TVT procedures are shown in Table 37.5. There were seven deaths from that group, which included five after undiagnosed bowel perforation, one from uncontrolled bleeding in the retropubic space in a woman with a bleeding disorder, and one after a bowel perforation in which no additional information could be obtained. Major vascular injury may be prevented by using universal Allen stirrups. The insertion needle must not stray laterally. Smaller venous channels are frequently penetrated and are managed by pressure for 5 minutes or placement of a vaginal pack. Moderate bleeding may be controlled by a Foley catheter with 50 mL in the balloon to tamponade the bleeder against a pack in the vagina. Occasionally, a retropubic space hematoma will develop, but it is self-limited, and the usual treatment is observation. Bladder perforation occurs 2% to 4% of the time and is usually managed by withdrawal and reinsertion of the needle. When this occurs, a Foley catheter is recommended for 1 to 2 days, and antibiotic coverage provided. Bladder perforation may be prevented by infiltration of the dilute local anesthetic in large volume amounts, keeping the bladder empty, and directing the bladder away from the operative site with the rigid catheter guide. Bowel perforation may be prevented by imaging prospective patients who have had prior retropubic surgery and who may have bowel adherent in the cul-de-sac in close proximity to the retropubic area.

Frequent delayed complications include voiding dysfunction, urgency, and urinary tract infection (Table 37.6). About half of patients will void by the time of discharge from day surgery, and most are voiding well by the following day. There is a 2% to 5% persistent urinary retention rate, and these patients require sling revision. This is best performed in the first 4 to 6 weeks after surgery before advanced scarring around the mesh. The tape has usually migrated somewhat proximally along the urethra and needs to be exposed by sharp dissection, then loosened or cut to allow retraction of the mesh away from the underside of the urethra. Continence is maintained in most patients, and the release of the sling allows normal voiding in most cases. Urinary tract infection may be prevented by preoperative antibiotics, but there is still a 7% to 8% incidence of urinary tract infection in the first 2 months postoperatively. Urgency with some urge incontinence occurs in 10% to 12%; although time resolves a lot of this, a number of patients require medical intervention. Release or loosening of the sling may help resolve severe urgency symptoms. Mesh erosion is a delayed complication, occurring in 1% of patients, and usually is managed by excision of the exposed mesh and resuture of the vagina.

The transobturator approach (TOT) theoretically has safety factors that may make it preferable to the original TVT.

A nationwide analysis of complications associated with the tension-free vaginal tape.

approach. It is placed more horizontally and should interfere with voiding even less than a TVT. Local infiltration of dilute lidocaine or Marcaine is carried out along the tracks of needle passes. There are two basic types of transobturator surgeries for stress incontinence. One is an outside-in technique, which emphasizes speed, safety, and ease of placement. The vaginal incision needs to be large enough to insert a finger to reach to the ischiopubic rami, and the thumb of the same hand grasps the outline of the rami in the genitofemoral fold between labium majus and the thigh. A point in the groin fold level with the clitoris is selected and a 5-mm incision made on each side. The needle passer is inserted perpendicularly and guided by the finger until it penetrates the obturator membrane (Fig. 37.11). The needle is then rotated under the pubic ramus, and the vaginal index finger guides it into the vaginal incision. The tightening of the sling is the same as the TVT.

The inside-out TOT starts with local infiltration of dilute anesthetic. The incision may be slightly smaller than the outside-in TOT. Scissor dissection proceeds on one side until the obturator membrane is penetrated with the scissor tips. A metal winged guide is placed into the defect in the obturator membrane. The needle passer is placed along the direction of the winged guide and then rotated while the handle is moved inferiorly to a vertical position. The needle passer exits 1 cm lateral to the groin fold about 2 cm superior to the urethral meatus and parallel to the clitoris. The tape is retrieved, and tightening follows the same pattern as with the technique described above. The same-day patient attempts to void in recovery; if unsuccessful, she uses self-catheterization or has a Foley placed overnight.

The transobturator tape does not have a retropubic passage and therefore avoids the major complications of retropitoneal vascular injury, bowel injury, and bladder perforation. Because of the horizontal placement for TOT, the incidence of postoperative voiding dysfunction is considered to be less, though no large randomized trial has definitively shown this (Fig. 37.12). There remains the possibility of damage to the obturator vessels and nerve during passage of the needle, but this can be avoided by following the procedure as described. There have been isolated reports of bladder perforation, and it may still be appropriate to carry out cystoscopy with urethral inspection at the end of the procedure, especially in women with significant prolapse. There are still the same complications of bleeding, hematoma, dysuria, urgency, and bladder infections as with TVT. Abscess formation in the ischiorectal fossa has been reported, but it is very uncommon. Occasionally, there is persisting groin pain or irritation with movement.

The tension-free sling is thought to work by forming a solid buttress under the midurethra, allowing the mobile bladder neck to descend and rotate with increased intraabdominal pressure, and compress the urethra against the sling. Most efficacy reports are in the 85% range for both TVT and TOT procedures, and this can safely be quoted to patients in preoperative discussion.

![Figure 37.11. Transobturator tension-free tape (TOT) approach.](image1)

![Figure 37.12. Comparison of retropubic and transobturator placement of TVT and TOT.](image2)
When the tension-free tape procedures are done in conjunction with other pelvic floor surgery, it does not seem to matter as to the order in which things are done. The tape can be laid in position initially and then the rest of the procedures completed and the tape tightened at the end of the case. If there is a lot of bleeding from dissection for the tape, this can cause some delay and interference with the rest of the case. The other way is to do the other procedures first and then place the tape at the end. Any anterior vaginal wall dissection should not extend closer than 2 cm to the urethral meatus, thus leaving room for the tape dissection. If a colposuspension is performed, the tape has to be placed before obliterating the anterior wall.

Suburethral Slings

The concept of placing a material under the urethra and suspending it to the abdominal tissues was introduced as early as 1907 when Giordano used gracilis muscle transposed beneath the bladder neck. Gorebell (1910) used pyramidalis muscles transposed through the space of Retzius, and first Frangenheim (1914) and then Stoeckel (1917) described using a strip of anterior abdominal fascia with the pyramidalis muscles. Price (1933) harvested fascia lata, which he passed beneath the urethra and then retroperitoneally, and attached it to the anterior rectus fascia on either side of the midline. This technique and its modifications became known as the Gorebell-Stoeckel-Frangenheim procedure, or fascia lata sling, but the named surgeons never used fascia lata. Aldridge (1942) used strips of rectus fascia from a transverse abdominal incision, passed them retroperitoneally, and secured them beneath the urethra. McGuire and Lytton (1978) described a sling procedure using rectus fascia supported by sutures extending through the space of Retzius, and first to the rectus fascia. This procedure and its modifications are referred to as a rectus sling.

The sling acts like a hammock under the bladder neck to both elevate the urethrovesical junction into an intraabdominal location and to provide partial compression of the urethra. These techniques differ from the modern tension-free procedures because the ends of the sling or suspending sutures are fixed to the rectus fascia. During periods of increased abdominal pressure, the abdominal wall moves outward and the sling is drawn upward. This compresses the urethra and increases intraurethral resistance. Variations of the sling procedure in which the ends of the sling are attached to an immovable tissue (Cooper’s ligament or bone anchors in the pubic symphysis) do not allow upward displacement of the sling and urethra during straining. In these operations, the sling is thought to create a secure platform of urethral support. Increases in intraabdominal pressure press the urethra downward against the sling, thereby compressing the urethra from both above and below. It is this compression of the urethra that is believed to lead to increases in urethral resistance and a resolution of stress incontinence. However, the potential for excess compression of the urethra also contributes to the most common complications of the sling procedure: voiding dysfunction.

The intervening 100 years have provided time for development of many materials and techniques for sling surgery. The autologous tissues have included rectus fascia, fascia lata, vagina, gracilis muscle, round ligaments, pyramidalis muscle, and rectus muscle. Because of additional operative time and morbidity to harvest autologous materials, many substitute and rectus muscle. Because of additional operative time and morbidity to harvest autologous materials, many substitute and rectus fascia is harvested at the time of repair with fascia lata composing most of the active use. Allograft fascia materials have been in use for more than 25 years but have to be harvested, processed and distributed by tissue banks regulated by the American Association of Tissue Banks. Xenograft materials are mostly porcine dermis and bovine pericardium.

Surgeons who prefer an autologous sling use either rectus fascia or fascia lata. Rectus fascia is harvested at the time of a suprapubic incision by excising a strip of rectus fascia and closing the residual defect. A 4- to 5-cm incision easily allows harvest of a fascial strip 2 cm wide and 8 to 10 cm long (Fig. 37.13). A fascial closure suture is placed beyond the harvest site on both sides and a strip of rectus fascia developed medially from each side. The graft is wrapped in saline-soaked gauze or placed in an antibiotic solution. The fascia is mobilized sharply off the underlying muscle to avoid tension in the closure. The rectus fascia is cleared of fat just above the symphysis pubis on either side to allow for fixation of the sling.

Alternatively, fascia lata may be harvested from the lateral aspect of the thigh (Fig. 37.14) using a Masson stripper or a Crawford fascial stripper. Alternatively, the fascia may be excised directly. The Masson stripper comes in 1-cm and 2-cm sizes and can remove a strip up to 3 cm in width and 20 cm long. The Crawford stripper can remove a strip 1 cm wide and 20 cm long. Harvest is accomplished with the patient supported leaning to one side and the leg positioned on a pillow (Fig. 37.15). The illiotibial fan of fascia is palpated over the lateral thigh near the knee. A vertical or transverse incision is made 2 to 3 cm above the knee over the fascia and the fascia lata cleaned with a gauze-tipped finger. Two incisions are made in the fascia, 1.5 to 2 cm apart, and the fascia lata transected 3 to 4 cm superior to its attachment into the lateral condyle of the femur. The distal 4 to 5 cm of fascia is mobilized with sharp dissection and the free end threaded into the Masson or Crawford fascial stripper and held firmly with straight Kocher clamps. The fascia is freed superiorly from attachments by passing a long forceps (handle end) over the superior and inferior surfaces of the fascia. The stripper is then advanced parallel to the fascia lata fibers, toward the greater trochanter of the hip (Fig. 37.16). The Masson stripper has an inner and outer component, and the outer...
sheath is disengaged and advanced briskly or turned over the inner portion, which severs the fascia at the uppermost area of the leg. The Crawford stripper requires a pulley action to advance a cutter at the end of the instrument to cut the fascial strip. The 1-cm-wide strip obtained with the Crawford stripper requires a second pass to get a second strip of a full-length sling is desired, and the two are sutured together, overlapping in the center 2 or 3 cm, to make that area thicker as well as wider. The open technique requires two vertical incisions separated by an intact skin area at least the size of each incision. The fascia lata is dissected free from the muscle underneath, and elevation of the skin bridge allows dissection to the higher incision. The fascia is cut 2 to 3 cm wide, and the uppermost end is severed to procure the strip. The fascial defect is not closed, but a pressure dressing is usually applied, and the skin may be closed with a subcuticular suture.

Sling length has varied in the many procedures described. A patch sling is several cm in length, but the tails of the sling do not perforate the endopelvic fascia into the retropubic space. The patch is suspended by permanent sutures and allows harvest of small amounts of tissue, but there is little in situ scar- ring and fixation of the fascial material. A full-length sling passes underneath the urethra, through the endopelvic fascia and retropubic space, all the way to the point of fixation, where it is secured with sutures. Usually the fixation point is rectus fascia. A half sling (7 cm length or more) extends into the retropubic space through the endopelvic fascia and is attached by sutures secured to the tails to suspend the material to the appropriate fixation site, usually the rectus fascia. This has become the most common sling length when using autol- ogous materials. A full-length sling extends all the way to the fixation site, rectus fascia, or Cooper's ligament, where it is attached.

The abdominal dissection is performed through a 4- to 5-cm incision (unless the patient is obese) usually placed 2 cm above the symphysis pubis, but not in the crease of the panniculus. The fascia is cleared of fat and subcutaneous tissues at sites 2 cm above the symphysis and 2 cm lateral to the midline, where the sling arms or sutures will be passed through the fascia. If an instrument is used to grasp the sling or suture tails (as opposed to a needle passer technique using Pereyra or Stamey needles), then a small 0.5- to 1-cm incision is made in the full-thickness rectus fascia. If rectus fascia has been harvested, the remaining lower margin of fascia is cleared of fat and subcutaneous tissue.

The retropubic space may be opened, especially in cases in which there has been previous retropubic surgery. If necessary, the bladder can be opened at the dome to facilitate sharp dissection of the bladder away from the sidewall of the pelvis. In this technique, a finger can be placed through the abdominal incision reaching to the level of the endopelvic fascia. The vaginal dissection commences with an inverted U or 2-cm midline incision along the anterior vaginal wall. The epithelium is dissected off the fibromuscular layer laterally until access through the endopelvic fascia is readily available beneath the descending pubic ramus. The epithelial flap may be left thick to protect against poor healing of the vaginal epithelium over the sling material. The fibromuscular layer does not need to be plicated unless extra thickness is desired under a synthetic sling or there is a central anterior vaginal wall defect. Sharp dissection to the level of the pubic ramus allows easy access to perforate the endopelvic fascia sharply or bluntly,
FIGURE 37.16. Harvesting fascia lata. With the fascial end secured by Kocher clamps, the stripper is slowly advanced parallel to the fascia lata fibers, shearing off a long strip of fascia.

FIGURE 37.17. Perforation of the endopelvic fascia to open the space of Retzius and mobilize the periurethral tissues.

FIGURE 37.18. Passage of sling material through the space of Retzius from vaginal to abdominal site. Rectus fascia partial sling with attached sutures. (With permission: Brubaker L. Suburethral sling procedures. Operative Techniques in Gynecologic Surgery 1997;2:48.)

directing the instrument or finger toward the ipsilateral shoulder (Fig. 37.17). Some surgeons do not enter the retropubic space when placing a sling. Others use a finger to guide an instrument or needle pass from the abdominal to the vaginal incision, and this is the recommended technique. The instrument is directed through the abdominal incision and directed toward the back of the symphysis pubis. A finger placed in the vaginal dissection reaches to the retropubic space to meet the advancing clamp or needle to minimize the distance of blind passage (Figs. 37.18 and 37.19). Cystoscopy ensures bladder integrity and ureteral function. The sling is sutured to the pubocervical fascia under the mid-to proximal urethra to prevent movement from the placement site. A Foley catheter bulb marks the bladder neck. Historically, the position of the sling was bladder neck and proximal urethra (Fig. 37.20). With the introduction of the tension-free tape procedures at the midurethra, a number of surgeons have also moved traditional suburethral sling placement more distally to override the midurethra. A broad-based sling is considered preferable to a narrow band of material.

The most common fixation site is rectus fascia (Fig. 37.21). The arms of the sling or suspending sutures may be secured together loosely over the rectus fascia without actually being sutured to the fascia. Cooper’s ligament can also be used to support the sling arms. Bone anchors allow alternative fixation to a solid structure, although there is no evidence that weak rectus fascia attachment is a cause of procedure failure. The sutures or sling tails are placed through the fascia and tied with 1 to 3 finger breadths between the tissues and the sutures or sling. The object is to leave the sling loose.
FIGURE 37.19. Passage of fascia lata strip through space of Retzius. Under guidance from the surgeon’s hand in the vaginal incision through the endopelvic fascia into the space of Retzius, a clamp is passed from the abdominal incision to the vaginal incision. The end of the fascia is grasped and retrieved to the abdominal site.

Bladder drainage techniques include suprapubic catheter, Foley catheter, or intermittent self-catheterization. Most often, a Foley catheter is left overnight and then removed the following day, allowing the patient the opportunity to void. Postvoid residual urine determinations are measured by bladder scan or catheterization; if voiding is not adequate, the Foley catheter may be reinserted or self-catheterization used. There is no uniform residual urine determination considered normal, but it should be less than 200 mL, with a reasonable voided amount equal to or two times greater than the residual amount.

Hospital length of stay is variable but often is only 1 day. Patients should avoid strenuous exercise and heavy lifting for 3 months. Intercourse and vaginal inserts should be avoided until there is good vaginal healing. There is no need to restrict showers or shallow tub baths.

Complications (Table 37.7) are addressed before surgery by use of preoperative antibiotics to prevent infection and use of compression stockings or heparin to prevent deep venous thrombosis (DVT). Early mobilization and use of an incentive spirometer help avoid DVT and respiratory problems. The
usual intraoperative complication of surgery is bleeding. Large veins under the descending pubic ramus may be avulsed during the vaginal portion of the procedure, and there are often vessels on the medial side of the vaginal dissection into the retropubic space. The latter ones can be isolated and cauterized or sutured, but the ones under the pubic ramus are best controlled by pressure, completion of the procedure, and placement of a vaginal pack. Large vessels of the pelvis are seldom penetrated by instruments or sling. The sling may be passed through the bladder and may have to be removed and repassed. On rare occasions, the sling or a suprapubic catheter may be placed through a portion of bowel, and recognition of this complication can be delayed. Temperature elevation is rare but may be caused by atelectasis, pneumonia, and hematoma in the early postoperative period. Cystitis, pyelonephritis, bowel injury, and wound infection are not usually obvious for a few days. Voiding function and possible bladder overdistension must be monitored carefully.

Short-term complications include continued voiding difficulty, bladder infection, and overactive bladder symptoms. A wound seroma or infection may occur at either the abdominal incision site or at the fascial harvest site. If a significant hematoma has occurred in either the abdominal incision or retropubic space, abscess formation may follow. Vaginal healing may be compromised by delayed healing of the anterior vaginal wall, oozing or bleeding from the suture sites, and failure of the incision to close properly over the sling. Long-term complications include voiding dysfunction, overactive bladder symptoms, and procedure failure. If the patient is unable to void at all, the sling may need to be incised. The occurrence of a vaginal erosion is usually a delayed event with synthetic materials, and this area of incomplete healing can be difficult to resolve.

The cure rate for sling procedures is more than 80% for all procedures, primary and repeat. Traditional suburethral sling procedures have long-term durability, effectiveness in cases with impaired urethral sphincter function or restricted mobility of the bladder neck, and applicability to primary cases with minimal risk of complications.

Periurethral Bulking Procedures

The major impetus for use of periurethral bulking in the United States came in 1993 when the U.S. Food and Drug Administration approved the use of Contigen®. This was followed in July 1994 by Medicare’s approved payment for the service based on a number of criteria. These criteria were altered in 1996 and included the presence immobility of the bladder neck, as well as a leak point pressure less than 100 cm of water. The ideal patient is one who meets the above criteria with a fixed bladder neck (Q-tip straining angle 40 degrees or less), who is medically compromised and/or elderly, and in whom an operative intervention may offer too much risk. Also, some patients prefer to use a less invasive technique. There are still little data on effectiveness of minimally invasive midurethral slings in patients who have a scarred bladder neck; although a traditional suburethral sling has a very good cure rate, it is invasive and is associated with greater risk and complications.

The ideal material is biocompatible, nonimmunologic, and hypoallergenic. It should be inexpensive and easy to inject, and it should not migrate. Materials approved for use or in studies are shown in Table 37.8. Methods of injection include periurethral, transurethral through the cystoscope, or transurethral using an injector device that fits in the urethra. The ideal setting for injection is the office or clinic. No preoperative sedation is
required. The injection is performed in a sterilized field by using no-touch technique.

**Periurethral Injection**

The patient empties her bladder and is placed in lithotomy position. Local anesthestia using 0.5 to 1.0 mL of lidocaine hydrochloride is injected 0.5 cm on either side of the urethral meatus (Fig. 37.22). Under endoscopic guidance, lidocaine 1% solution is injected parallel to the urethra in small amounts until the proximal urethra is reached and the needle or injection can be seen distending an area 1 cm distal to the bladder neck. The syringe with lidocaine is replaced with a syringe of bulking agent, and the material is injected until the entire syringe has been injected or there has been adequate effect noted with urethral bulking. The process is repeated on the opposite side, but the second side is more difficult to inject because of the distortion caused by the initial injection (Fig. 37.23).

**Transurethral Injection**

The transurethral method is best accomplished using a cystoscope with a 12-degree or 25-degree lens. The sheath has no fenestration, and the operating channel allows the passage of a disposable injection needle with a guide or a reusable needle. Alternatively, a spring-loaded mechanism is favored by some operators. The needle is prefilled with lidocaine 1% solution, the syringe with bulking material is attached, and the cystoscope with injection needle retracted is placed into the bladder. The bladder neck is identified, and the scope is withdrawn to visualize the proximal urethra. The usual injection sites are 3 and 9 o’clock, but this can be varied depending on user preference and number of injection sites selected (up to four). The injection needle is advanced into the urethra submucosa approximately 2 cm distal to the bladder neck (Fig. 37.24), and the injection of material is preceded by the small amount of local anesthetic solution. The needle is advanced 1 cm, and the bulking material is injected. The injection needle is flushed with lidocaine at the first site, and then the second site is selected.

A pressure system is required for transurethral injection of Macroplastique. Injection needles vary in diameter according to the ease of injection of the selected material. An insertion device is available for Macroplastique and for Zuidex. Transurethral injection is facilitated without

FDA, U.S. Food and Drug Administration.

visualization of the injection site. The device has four angled ports for four needles; after measurement of the urethral length, the device is inserted into the urethra to allow placement of the material at the desired submucosal depth in the mid-to-proximal urethra. The efficacy reports are still in early stages, and the more traditional injection techniques are the current recommendation.

After injection, the patient may have urethral burning that lasts for only part of a day and can be controlled with phenazopyridine (Pyridium). Antibiotics are prescribed for 1 to 2 days after injection because the rate of urinary tract infection is high. The patient attempts voiding after the injection, and she should be prepared to stay in the clinic area for 1 to 2 hours to allow the initial swelling from the injection to diminish. If the patient is unable to void or she has a high residual urine, she either needs to be instructed in self-catheterization or have a small catheter (8 to 10 French Foley) placed, using no more than 5 mL in the balloon. Patients should be called or seen the day following the injection to be sure there is no continuing problem. At follow-up, assessment is made for voiding function, urinary tract infection, and swelling at the injection site. Effectiveness is assessed, and overactive bladder symptoms are managed as appropriate.

One or two injections may be required to obtain a satisfactory result; if there is no improvement at that point, additional injections are not indicated. The success rate is generally quoted to be about 70%. Most injections last 6 months to 2 years and then have to be repeated. There is no limit to the number of injections provided that improvement occurs after each injection and lasts a reasonable period of time. There is no advantage of any particular bulking agent, and selection is usually based on operator experience, ease of injection, cost, and availability of the product.

**ARTIFICIAL URINARY SPHINCTER**

The ultimate treatment of urinary incontinence secondary to intrinsic sphincter deficiency is implantation of an artificial urinary sphincter. The device consists of a small inflatable cuff, a pump (which usually is implanted within one of the labia...
majora), and a reservoir, which is placed in the abdomen beneath the fascia (Fig. 37.25). The cuff is placed around the bladder neck and proximal urethra usually through a combined vaginal and abdominal approach. After allowing 6 weeks for healing to take place, the cuff is inflated to compress the urethra. Once inflated, the cuff maintains urethral closure until the patient needs to void. The patient deflates the cuff by squeezing the labial pump, moving fluid from the cuff into the reservoir. After voiding, the cuff automatically reinflates from the reservoir over 1 or 2 minutes and remains closed until the pump is reactivated.

There are a number of complications related to artificial urinary sphincter, including cuff erosion, infection, and device failure. The device is not indicated as a primary treatment for SUI and should only be inserted by an experienced surgical team working in an isolated and controlled operative environment.

SUMMARY

The surgical management of SUI has developed over almost 100 years. Only recently have randomized controlled trials been conducted, and new procedures are often introduced with little long-term efficacy or complication risk data. One of the problems has been the numerous modifications surgeons like to make on other procedures, thus producing yet another new approach.

More recently, instrument manufacturers have introduced a multitude of new instruments and new tape materials for the tension-free midurethral tape procedures with very little clinical data to support their safety or efficacy, much less any comparison with older, established procedures or equipment. The basic evaluation of incontinence includes history, physical examination, measurement of postvoid residual urine, and urinalysis. Preoperative assessment may include a measure of urethral mobility, 24-hour voiding diary, cough stress test, symptom questionnaire, and cystometry. Long-term data indicate the Burch colposuspension and tension-free tapes have similar cure rates. Anterior repair, needle procedures, and paravaginal repairs are not indicated for SUI.

BEST SURGICAL PRACTICES

- There are two types of SUI: hypermobility (or anatomic) and intrinsic sphincter deficiency. Most patients have elements of both causes for their incontinence but in varying degrees for each.
- Evaluation before surgery for SUI includes history, physical examination, pelvic examination, voiding diary, symptom questionnaire, residual urine determination, Q-tip test for urethral mobility, and urinalysis. If there is any concern regarding symptoms or prior procedure failure, then cystometrics and cystoscopy should be performed.
- The approach for primary SUI is a tension-free midurethral sling, Burch retropubic urethropexy, or other suburethral sling.
- The approach for recurrent SUI and a scarred bladder neck is most often a suburethral sling.
- The tension-free vaginal tape procedures have revolutionized surgery for stress incontinence, bringing it into the realm of minimally invasive day surgery. The principles for tension-free slings are to place them at the midurethra without tension. There are numerous brands, but the essence is a polypropylene mesh sling, 1 cm in width, placed by insertion needles and small incisions. Cystoscopy is recommended to assure there is no bladder injury. There are suprapubic as well as transobturator techniques without obvious proven advantages of one kind over another. The cure rates are all close to 85%. The procedures may be combined with other pelvic floor reconstructive surgery. Complications are minimal and include voiding dysfunction, overactive bladder, and mesh erosion.
- Standard suburethral slings are best performed with harvested autologous materials, either rectus fascia or fascia lata. The vaginal dissection should allow minimal blind passage from the vaginal to the abdominal site. Fixation is loosely accomplished to rectus fascia so as to avoid voiding dysfunction.
- Periurethral bulking has a place in medically compromised or elderly patients, especially for those with severe incontinence and minimal mobility of the bladder neck, i.e., Q-tip test <40 degrees straining.

CHAPTER 38  ☐ OPERATIVE INJURIES TO THE URETER
PAUL UNDERWOOD, JR.

DEFINITIONS

Cystotomy—Incision into the urinary bladder.

Spatulate—To incise the cut end of a tubular structure longitudinally and splay it open to allow creation of an elliptical anastomosis of greater circumference than would be possible with conventional transverse or oblique end-to-end anastomoses.

Ureteroureterostomy—Restoration of the continuity of the urinary tract by anastomosis of the upper segment of a partially destroyed ureter to a segment of ileum, the lower end of which is then implanted into the bladder.

Ureteroureterostomy—Establishment of an anastomosis between the two ureters or between two segments of the same ureter.

Ureteroneocystotomy—An operation whereby a ureter is implanted into the bladder.

Ureteral injuries have been recognized as a potential complication of gynecologic surgical procedures since the inception of our discipline. Over the years, numerous unique surgical modifications of procedures have been offered with the specific intent of decreasing the probability of ureteral injury. Despite these efforts, ureteral injury remains a very real complication of abdominal-pelvic surgery in the female patient, affecting as many as 1.79% of women taken to the operating theater for pelvic surgery, although the accepted incidence is about 0.35%. The risk depends on the procedure performed and the skill and experience of the surgeon. Therefore, it is important to the gynecologic surgeon to be cognizant of ways to minimize the occurrence of these potentially disastrous complications, as well as facile in the diagnosis and management of such an injury should it occur.

The goals of this chapter are to (a) outline the functional anatomy of the ureter and illustrate how this leads to the ureter being in harm’s way during gynecologic surgery, (b) review the unique issues surrounding ureteral injury during the performance of specific groups of gynecologic surgical procedures, and (c) summarize the basic principles of injury avoidance and, should injury occur, recognition and management.

FUNCTIONAL ANATOMY OF THE URETER

When viewed in cross section, the ureter can be divided into distinct layers: the lumen with transitional epithelium; the mucosa—the muscular layer—which is made up of longitudinal, circular, and spiral smooth muscle fibers; and the adventitia, which contains an intercommunicating network of blood vessels. The peritoneum lies over the ureter, making it a completely retroperitoneal structure (Fig. 38.1).

In normal adults, the ureter is between 25 and 30 cm in length from the renal pelvis to the trigone of the bladder. By convention, the ureter is divided into the abdominal and pelvic segments by the pelvic brim; each of these components if approximately 12 to 15 cm in length.

The abdominal ureter runs along the ventral surface of the psoas muscle and posterior to the ovarian vessels to the level of the pelvic brim. The right ureter lies slightly lateral to the inferior vena cava and descends into the pelvis over the common iliac artery at approximately the site of the latter’s bifurcation. On rare incidences, the right ureter can be over the vena cava; therefore, if one is performing a paraaortic node sampling, the ureter must be identified before removing any nodes. The left ureter runs lateral to the aorta and posterior to the inferior mesenteric artery, ovarian vessels, and colon. The left ureter mirrors the right at the pelvic brim, entering the pelvis over the bifurcation of the left common iliac artery. The left ureter often is obscured by the sigmoid colon at the pelvic brim (Fig. 38.2). There is little variance between the positions taken by the pelvic ureters. They descend into the posterior lateral pelvic lateral to the sacrum and immediately ventral to internal iliac (hypogastric) artery. The ureters then deviate medially and course medial to the internal iliac artery and its anterior branches. The ureters subsequently pass beneath the uterine artery (often referred to as uterus under the bridge). At this point, it is approximately 1.5 cm lateral to the cervix, and this is the site of entrance into the paracervical tissues. The ureters pass through this paracervical tissue often referred to as “the tunnel” of the cardinal ligament/interior bladder pillar (also referred to as the web or the tunnel of Wertheim). Once through this tunnel, the ureter travels medially and anteriorly over the vaginal fornix to enter the trigone of the bladder.

When inflammatory or adhesive changes are not present, the ureters can usually be visualized through the peritoneum from the pelvic brim to this parametrial tissue. Once the ureters have entered this tunnel, they cannot be easily seen or palpated; if identification is required, they must be mobilized out of this tissue. Although the peristaltic activity that occurs in the normal ureter may be helpful in its identification, it is not uncommon that the ureter, following any degree of trauma, will have transient paralysis. Therefore, the skill of definitely identifying the ureter is based on its anatomy, not its motion. The ureter is unique in that it has a “snap” feeling when passed between one’s fingers. This may be helpful in massively obese women with poor exposure. This “snap” will also permit one to follow the ureter to the tunnel without actually exposing it. Having defined the general anatomy of the ureter, one must appreciate
Operative Injuries to the Ureter

that there is a significant degree of interpatient variability, even in the pelvis that is free of inflammatory, infectious, neoplastic, congenital, or postsurgical changes. Direct visualization of the ureter is the only sure way to know its location in any given patient.

The ureter obtains blood supply from every vessel that it transverses (Fig. 38.3). The small vessels that nourish the ureter are interconnected by a lush network of anastomosing arcades within the adventitial sheath. It is this vigorous and multi-origin blood supply that helps to make the ureter resistant to devascularization, even when it has been stripped of the surrounding ureteral sheath. Yet, although the ureter may be relatively difficult to devascularize, such injuries can occur and are more likely to happen if one fails to remember the origin of the blood supply, as illustrated in Figure 38.3. Cephalad to the pelvic brim, the blood supply enters from the medial side; therefore, dissection and mobilization should be carried out from the lateral aspect of the ureter. The inverse is true below the pelvic brim.

### URETERAL INJURY

Thompson, in preceding editions of this text, listed six types of operative ureteral injuries, which are shown in Table 38.1. Other authors have proposed that avulsion and stretch injuries also be listed as separate types, although these two categories are included under “transaction” and “ischemia,” respectively.

All of these injuries can and do occur, although relatively infrequently, during the performance of gynecologic surgical procedures. Additionally, angulation and ischemia can be the sequelae of nonsurgical processes (e.g., broad ligament cervical myomas and radiation therapy, respectively). The specifics as to how these injuries occur and, more importantly, how they can be best avoided are discussed in subsequent sections of this chapter. Ureteral injuries most commonly occur at one of five different locales, as illustrated in Table 38.2.

### GENERAL PRINCIPLES OF PREVENTION AND MANAGEMENT

It is extremely important to be cognizant of the settings in which a ureteral injury is more likely to occur. Several common elements associated with ureteral injury are listed in Table 38.3. Among the clinical diagnoses that put the ureter at increased risk during gynecologic surgery are severe endometriosis; large fibroids, especially lower uterine broad ligament or cervical fibroids; large adenexal masses; dense adhesions; ovarian cyst adherent to peritoneum; residual ovarian syndrome; lacerations at cesarean section; and radical cancer surgery. There are no data supporting the belief that preoperative intravenous pyelogram, computed tomography, or prophylactic ureteral stint placement decreases the probability of a ureteral injury.

The most important way to prevent ureteral injury is for the surgeon to constantly and unequivocally know where the ureter is located at all times. Not only is this supported by all of the references in this chapter, but also by my personal experience. Often when we are called to assist a colleague in an operation in which a ureteral injury has occurred, it is evident that the surgeon did not know where the ureter was and, therefore, clamped, ligated, incised, or transected it. When...

### TABLE 38.3

**URETERAL INJURY ASSOCIATED WITH GYNECOLOGIC SURGERY: “MOST COMMONS”**

| Most common site: Pelvic brim near the infundibulopelvic ligament |
| Most common procedure: Simple abdominal hysterectomy |
| Most common type of injury: Obstruction |
| Most common “activity” leading to injury: Attempts to obtain hemostasis |
| Most common time of diagnosis: None: 50-50 split between intraoperative and postoperative |
| Most common long-term sequelae: None |

dissecting a ureter from its location, try to stay outside the adventitial sheath. This will decrease the probability of devascularization and subsequent ischemia. This cannot always be accomplished, particularly in those settings in which there is a malignancy, significant scarring and fibrosis that accompany endometriosis, or prior pelvic radiation. However, because of its rich longitudinal blood supply, the ureter usually survives. Finally, when using instruments that transmit energy to the tissues (e.g., electrocoagulation, whether monopolar or bipolar, argon beam coagulator or laser), the surgeon should know the zone of thermal injury for that instrument at that power setting. Although the mean distance of thermal damage with most of these instruments is approximately 2 mm, it may be as much as 5 mm; therefore, the use of such energy sources near the ureter has the potential for unrecognized injury and delayed necrosis.

Every obstetrician and gynecologist performing pelvic surgery must know how to enter the retroperitoneal space and identify the ureter. Starting at the round ligament, cut the peritoneum lateral to the ovarian vessels to the colon at the pelvic brim (Fig. 38.4). There is nothing one can injure or cause to bleed in this zone. Bluntly dissect the ovary and its vessels medially to enter this posterior retroperitoneal space. The large vessels and pelvic sidewall will be lateral and easily identified by palpation and visualization. The ureter will be seen adhered loosely to the medial peritoneum. It always crosses over the iliac artery at this pelvic brim just where the internal iliac artery arises. Gently caress the ureter with the sucker or pickups, and it will further identify itself with a peristaltic movement. In massively obese women with poor exposure, place your index finger in this retroperitoneal space and your thumb outside the peritoneum. The ureter can be identified by a distinct “snap” or “click” between one’s fingers. Once identified, the ureter can easily be followed by using blunt dissection with a right angle clamp all the way to the uterine artery. Between the uterine artery and bladder, it can usually be followed by the palpation and “snap” technique previously described.

### SPECIFIC HIGH-RISK PROCEDURES FOR URETERAL INJURIES

**Laparoscopy-Associated Ureteral Injuries**

Ureteral injuries at the time of laparoscopy are very uncommon, occurring in approximately 0.3% to 0.4% of all cases. Laparoscopic ureteral injuries are unique when compared with

![FIGURE 38.4. The initial step for ureteral identification is clamping and cutting of the round ligament. The loose areolar tissue is dissected and the ureter identified on the medial leaf of the broad ligament peritoneum.](image_url)
open injuries from two potentially complicating realities. First, these injuries are more likely to be the result of a thermal injury than incision, transaction, or encroachment/ligation. Second, ureteral injuries in association with laparoscopy are more likely to be diagnosed 2 to 5 days after the surgery. This delay in diagnosis decreases the probability of a successful immediate primary repair and increases the risk of a long-term complication. The ureter is most commonly injured during laparoscopic hysterectomy when the uterine vessels are stapled or electrocoagulated. Another common site of injury is when the infundibulopelvic ligament is transected. When performing laparoscopic surgery near the pelvic wall or cul-de-sac, it is imperative to know the location of the ureter. Extreme caution should be used with cautery or laser near or over the ureter. It can usually be seen and followed through the peritoneum; but when not visible, it should be identified retroperitoneally and followed down to the site of operative interest. When primary injury is recognized, laparoscopic repair can be successfully performed by an experienced laparoscopist.

**Complex Adnexectomy**

Ureteral injury at the time of complex adnexectomy is worthy of specific comment because (a) it is in this setting that the ureter is commonly injured, and (b) these injuries can be avoided by using the retroperitoneal approach as previously described.

Every obstetrical or gynecological surgeon must be able to quickly and safely enter the retroperitoneum. This surgical skill is necessary to (a) access the pelvic vessels for the purpose of establishing hemostasis and (b) use the retroperitoneum as an adhesion- and pathology-free “space” in which to operate. Access is obtained most commonly for the latter purpose. Entrance into this retroperitoneal space in the pelvis is safe, easy, and extremely useful as previously described. Once this retroperitoneal space (which continues deep into the pelvis as the pararectal space) has been developed, the ureter should be visible on the medial leaf of the broad ligament.

If an adnexal mass is adherent to the medial leaf of the broad ligament or pelvic peritoneum overlying the ureter, the ureter can safely be dissected laterally from the peritoneum. Once the ureter has been mobilized and is out of harm’s way, resection of inflamed, scarred, or fibrotic peritoneum with the overlying adherent mass can safely be performed (Fig. 38.5). There are rare instances when it is impossible to mobilize the ureter from the pathology. In this setting, the surgeon must decide whether to leave a little tumor or endometriosis on the ureter, risking subsequent obstruction, or resect a segment of ureter and repair accordingly.

**Abdominal Hysterectomy**

Ureteral injury during resection of an adnexal mass usually results from surgical trauma to the ureter between the level of the pelvic brim to the tunnel of Wertheim. When discussing ureteral injuries associated with the performance of an abdominal hysterectomy, the focus of our attention is on where the ureter enters the tunnel under the uterine artery, lateral to the uterosacral ligaments, until the ureter terminates in the bladder. When performing an abdominal hysterectomy for benign disease, there are two situations that are particularly high risk for a ureteral injury: (i) a lower uterine segment or cervical fibroid protruding into the broad ligament or (ii) bleeding from pedicles, especially at the vaginal corners.

With a broad ligament fibroid, the ureter can be anterior, lateral, or posterior to the fibroid. The clamp, cut, suture technique around the fibroid is too dangerous for injury. I prefer a myomectomy by an incision adjacent to the uterus or cervix. One can do this with no risk of ureteral injury by staying within the myometrial capsule of the fibroid. Bleeding may occur, but once the fibroid is out, bleeding is easily controlled by clamping adjacent to the uterus. In the rare case when this is impossible, the entire course of the ureter must be identified before clamping or cutting.

Bleeding from the pedicles or vaginal angle should be controlled by a “superficial” 3-0 suture. One should place the
Operative Injuries to the Ureter

suture very superficially so that it cannot be around the ureter, which is “very close” once the tissues have retracted. It is that deep suture that gets the ureter. To avoid ureteral injury, an “intrafascial hysterectomy” technique was used in the past. In this technique, a plane within the myometrium of the lower uterine segment and cervix is developed once the uterine vessels have been ligated. This technique is illustrated in Chapter 32A. It is rarely used today because it results in increased blood loss; however, it theoretically reduces the risk of injury to the distal ureter.

If one is fearful that the ureter is ligated or injured on one side, it is easy to answer the question. Find the ureter at the common iliac artery, place it on stretch, and insert a 21-gauge “butterfly” needle into its lumen—just like an IV. Inject 5 to 10 cc methylene blue stained saline directly into the lumen of the ureter. If the ureter is intact, blue stain is seen in the Foley catheter verifying an open ureter. If the ureter has a leak, blue stain will be seen in the pelvis. If the ureter enlarges and no blue stain is seen in the Foley, the ureter is ligated and needs appropriate repair. I have done this many, many times and never seen a complication secondary to it.

Cesarean Hysterectomy

I feel this special situation is worthy of comment, even though it is relatively uncommon. The location of the ureter is a frequent cause of intraoperative consultations to advanced pelvic surgeons during the course of cesarean hysterectomy, which is often bloody and where distorted anatomy is almost always present. An easy way to avoid ureteral injuries is to simply perform a supracervical hysterectomy; however, some surgeons find this a suboptimal choice. Therefore, in addition to the techniques outlined to this point, a hysterectomy incision can be extended caudally toward the cervix (Fig. 38.6). This permits the relatively easy placement of the forefinger into the endocervical canal and upper vagina, allowing tactile as well as visual guidance for the cervical-vaginal junction. With your finger in place, it is simple to identify where to place a clamp adjacent to the cervix.

Vaginal Hysterectomy

Ureteral injury during a vaginal hysterectomy is remarkably uncommon because of traction on the cervix, which pulls the uterus farther from the ureter. However, a culdoplasty frequently is part of the reconstructive phase of the procedure, and this places the ureter at risk. There are maneuvers that can be taken to minimize the probability of injuring a ureter. Palpatory ureteral identification via the vaginal approach is one useful step (Fig. 38.7). Another technique is placing an Allis clamp on the vaginal cuff in the area of the uterosacral ligament and...
Bladder Neck Suspension and Pelvic Organ Prolapse

Ureteral injury during retropubic repair most often affects the distal ureter. As Wiper and Walters have stated, this injury can occur during three distinct parts of performance of the procedure: (a) vigorous dissection of the space of Retzius and the periretreal tissues, (b) high elevation of Burch colposuspension sutures, and (c) paravaginal defect repair performed in combination with the Burch procedure. An additional way that the ureters could be injured is by excessive lateral mobilization of the bladder, which exposes the actual dorsal surface of the bladder in the vicinity of the trigone, bringing the ureter into the operative field.

There are specific steps that can be taken to avoid such injuries. Dissection into and through the space of Retzius should be done under direct visualization, remaining as close to the symphysis pubis as possible. The amount of dissection that occurs over the lateral paravaginal tissues should be kept to the minimal amount needed to guarantee accurate and appropriate placement of the sutures. Marked lateral mobilization of the bladder off of the underlying vagina potentially exposes the ureters. The urethrovesical junction must not be elevated as high as possible. Unquestionably, this can cause kinking not only of the urethra but also the ureters in certain patients.

Ureteral injury at time of surgical correction of pelvic organ prolapse is relatively common. The method of ureteral injury may result from direct ligation or, more likely, from kinking as the redundant tissues are plicated. Many surgeons who specialize in this type of surgery recommend that cystoscopy with intravenous indigo carmine be routinely performed during these procedures to check for ureteral integrity.

Radical Pelvic Surgery

Of all the groups of surgical procedures performed, those performed for the treatment of cancers affecting the female reproductive tract are the most likely to involve either intentional ureteral surgery or have the highest risk of an associated ureteral injury. It is very important to differentiate between an intentional ureteral ligation and one that is unintended or accidental. Intentional cutting of the ureter or entry into the bladder may be an integral part of performing many of the most important operative procedures in the radical pelvic surgeon’s armamentarium. The MD Anderson type IV radical hysterectomy, a total or anterior pelvic exenteration, and resection of a fixed pelvic sidewall mass that involves the ureter may require that the redundant tissues be plicated. Many surgeons who specialize in this type of surgery recommend that cystoscopy with intravenous indigo carmine be routinely performed during these procedures to check for ureteral integrity.

How common are ureteral injuries in association with radical pelvic surgery? The largest volume of data addresses ureteral injuries at time of traditional Wertheim or MD Anderson type III radical hysterectomies. Angioli and Penalver, in their excellent review combining the major modern series, reported that there is an average rate of ureteral injury of just more than 1% with a concomitant rate of bladder injury that is similar. Interestingly, as noted, these rates have been consistent over time and among different surgical groups during the last quarter century. There is a growing international experience with the performance of radical vaginal trachelectomy as fertility-sparing treatment for women with FIGO stage IA1 to IB1 cervical cancer. The cumulative English-language data demonstrate that the rate of ureteral injuries in this setting is about the same as with radical abdominal hysterectomy, although rates of bladder injury are somewhat higher. In contrast to these relatively low rates of ureteral injury, when a radical resection is performed following therapeutic radiation therapy, there is an associated risk of ureteral dysfunction of approximately 30%.

The incidence of ureteral injury at the time of a simple transvesical hysterectomy as part of the treatment of endometrial cancer is low and similar to that when hysterectomy is performed for nonmalignant disease. Ureteral injuries in association with lymph node dissections, sampling, or when performing “radical” oophorectomies are remarkably uncommon when those injuries that occur near the entrance to and through the tunnel of Wertheim are excluded from the data. The reader is referred to the appropriate chapters within this text for more details concerning ureteral injury and its prevention during surgery for gynecologic malignancies.

DIAGNOSING URETERAL INJURY

In most instances, the symptoms and findings associated with an intraoperative ureteral injury that are not appreciated at the time of surgery are subtle and may be overlooked. Signs and symptoms such as unilateral cramping, flank pain, unexplained temperature elevation, ascites, peritoneal fluid collection, and unusual delay in return of bowel function (ileus) should lead one to consider an investigation into the integrity and function of the ureter, depending on the degree of suspicion of the surgeon. From a laboratory perspective, relatively inconsequential rises in serum creatinine (as little as 0.8 mg/dL) may be related to unilateral ureteral ligation. In contrast, it is unlikely that specific urinary tract symptomatology—such as the frank draining of urine from a drain, vagina, or abdominal incision—would be ignored. In all instances, when a patient reports a watery vaginal discharge following a hysterectomy, urinary tract injury must be investigated. A ureteral fistula may be suspected if there is urine leakage from the vagina; however, a bladder or urethral fistula is more common, depending on the type of surgery. Several simple tests can differentiate between a ureteral and bladder fistula. The bladder is filled with 200 cc saline stained with 1 to 3 cc methylene blue. If blue fluid comes out of the vagina, there is a bladder injury. If the watery discharge does not stain, inject 3 cc indigo carmine intravenously. If within 5 to 10 minutes the fluid turns blue, a ureteral fistula is present. If neither procedure results in blue drainage fluid, check the creatinine level of the fluid. If it is the same as serum levels, the drainage is peritoneal fluid or lymph. If it is urine, the creatinine level will be higher. These simple, rapid tests will usually answer the problem.

If there is any significant degree of suspicion that a ureteral injury has occurred, further evaluation must be

Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

pulling upward to make the uterosacral ligament taut. With a finger inside the cuff, the uterosacral ligament should be palpated. This technique allows identification of both the ureter and the uterosacral ligament so that the culdoplasty sutures can be placed correctly and safely.

Ureteral injury at time of surgical correction of pelvic organ prolapse is relatively common. The method of ureteral injury may result from direct ligation or, more likely, from kinking as the redundant tissues are plicated. Many surgeons who specialize in this type of surgery recommend that cystoscopy with intravenous indigo carmine be routinely performed during these procedures to check for ureteral integrity.

How common are ureteral injuries in association with radical pelvic surgery? The largest volume of data addresses ureteral injuries at time of traditional Wertheim or MD Anderson type III radical hysterectomies. Angioli and Penalver, in their excellent review combining the major modern series, reported that there is an average rate of ureteral injury of just more than 1% with a concomitant rate of bladder injury that is similar. Interestingly, as noted, these rates have been consistent over time and among different surgical groups during the last quarter century. DIAGNOSING URETERAL INJURY

In most instances, the symptoms and findings associated with an intraoperative ureteral injury that are not appreciated at the time of surgery are subtle and may be overlooked. Signs and symptoms such as unilateral cramping, flank pain, unexplained temperature elevation, ascites, peritoneal fluid collection, and unusual delay in return of bowel function (ileus) should lead one to consider an investigation into the integrity and function of the ureter, depending on the degree of suspicion of the surgeon. From a laboratory perspective, relatively inconsequential rises in serum creatinine (as little as 0.8 mg/dL) may be related to unilateral ureteral ligation. In contrast, it is unlikely that specific urinary tract symptomatology—such as the frank draining of urine from a drain, vagina, or abdominal incision—would be ignored. In all instances, when a patient reports a watery vaginal discharge following a hysterectomy, urinary tract injury must be investigated. A ureteral fistula may be suspected if there is urine leakage from the vagina; however, a bladder or urethral fistula is more common, depending on the type of surgery. Several simple tests can differentiate between a ureteral and bladder fistula. The bladder is filled with 200 cc saline stained with 1 to 3 cc methylene blue. If blue fluid comes out of the vagina, there is a bladder injury. If the watery discharge does not stain, inject 3 cc indigo carmine intravenously. If within 5 to 10 minutes the fluid turns blue, a ureteral fistula is present. If neither procedure results in blue drainage fluid, check the creatinine level of the fluid. If it is the same as serum levels, the drainage is peritoneal fluid or lymph. If it is urine, the creatinine level will be higher. These simple, rapid tests will usually answer the problem.

If there is any significant degree of suspicion that a ureteral injury has occurred, further evaluation must be
undertaken expeditiously. If there is concern of ureteral ligation, a noninvasive renal ultrasound showing hydronephrosis or hydroureter is fast, inexpensive, and accurate. In the past, these investigations began with the performance of an intravenous pyelogram. However, in the modern era, urinary tract imaging is usually done by computer tomography (CT) scan. The CT scan with contrast can give the same information regarding the integrity and function of the renal collecting system while offering the advantage of identifying urinomas, strictures, or changes in the postoperative anatomy of the surrounding structures. When the serum creatinine is elevated, intravenous contrast can cause significant renal damage, so a contrasted CT scan in contraindicated in these circumstances. A renal/proximal ureter ultrasound would be preferable in this situation.

**MANAGEMENT OF URETERAL INJURY**

It is an oversimplification to state that every specific type of ureteral injury can be managed by a specific and universally applicable way. Unique variables among patients play an important role in deciding which approach is best for a given setting. Nevertheless, general guidelines and techniques may be helpful. General recommendations for the management of ureteral injuries identified at the time of surgery are outlined in Table 38.4.

One of the most controversial issues regarding the management of ureteral injuries diagnosed in the postoperative period is how long one should wait before attempting repair. Some form of immediate intervention must be undertaken no matter what type of injury has occurred. If there is an obstruction without intraperitoneal or retroperitoneal leakage of urine, an immediate attempt at ureteral stent placement should be undertaken. It is important to appreciate that the higher the grade of obstruction, the less likely that a retrograde stent can be placed successfully. In those instances in which a retrograde stent cannot be placed, a percutaneous nephrostomy must be immediately carried out. A percutaneous nephrostomy usually cannot be done under fluoroscopic guidance by the interventional radiologist without too much difficulty. Any delay in relieving an obstruction into the bladder. If successful, larger catheters can then be passed over the guidewire. Finally, a double-J stent with one end in the bladder and the other in the real pelvis can be left in place for 6 to 8 weeks until the sutures responsible for the ureteral obstruction have dissolved. If the obstruction is too similar recommendation that a percutaneous nephrostomy be performed. Once drainage of urine has been reestablished by the nephrostomy stent, the next decision is whether surgical intervention should be undertaken. Some believe that for those women with high-grade obstructions, an attempt at surgical débridement or performance of the appropriate repair as described later in this chapter (which is unlikely to be successful) should be undertaken as soon as can be scheduled. Once the nephrostomy is functioning well, this is not an emergency; therefore, most believe that a workup to localize the site of obstruction or leakage should be completed, the patient stabilized, and any appropriate consultation obtained. If diagnosed immediately postoperatively, the best chance of healing with primary repair is reoperation within 24 to 48 hours. However, most injuries are diagnosed later, and edema, necrosis, and tissue reaction reduces the possibility of immediate successful primary repair and dictates delayed repair. By waiting several weeks, the postoperative inflammatory changes will resolve making repair easier.

In those instances in which there is no major degree of obstruction and the obstruction is not the result of a “permanent” agent (metal clip or suture), or when only a ureteral leak occurs, a period of watchful waiting may be tried in the hope of avoiding surgical intervention entirely. If there is a ureteral leak, delay is advised only if a ureteral stent can be placed that stops the leakage.

If a ureteral leak has been identified postoperatively and the leak has developed in the setting of prior pelvic radiation, then an aggressive attempt at percutaneous nephrostomy diversion should be undertaken. A period of many months should be allowed to pass before reevaluating the patient radiographically to determine whether the leak has spontaneously healed. Although it is less likely that spontaneous closure will take place, the complex and risky nature of surgical correction in the radiated pelvis demands, in the patient’s best interest, that the maximal attempt for spontaneous healing be allowed before any attempt at surgical repair. The site of ureteral repair should incorporate a functional blood supply. Therefore, the success of an ureteroureterostomy is very low. Thus, one time an ureteroureterostomy above the irradiated pelvis is indicated. Omental wrap at the anastomotic site will improve blood supply.

**Ureteral Ligation**

Complete ureteral ligation can occur, but it is much more common that the ureter will be angulated or kinked by the placement of a suture that is either within the pararectal tissue or partially placed through the ureter. If kinked, which is probably much more common than has been recognized, the first management approach would be to attempt to pass a ureteral catheter. This may be done via the classic approach from below, but in recent years, a percutaneous nephrostomy can be done by the interventional radiologist. The dilated renal pelvis, which results from the distal ureteral obstruction, often simplifies the percutaneous nephrostomy. Once the nephrostomy tube is in place, contrast can be injected to see if even a small trickle of dye gets past the obstruction into the bladder. If there is no opening, an attempt is made to pass a thin guidewire through the nephrostomy tube, down the ureter, and past the obstruction into the bladder. If successful, larger catheters can be passed over the guidewire. Finally, a (double-J) stent with one end in the bladder and the other in the real pelvis can be left in place for 6 to 8 weeks until the sutures responsible for the ureteral obstruction have dissolved. If the obstruction is too
We recommend. First, the surgeon should be assured that the resection drain (Fig 38.8). There are two major modifications that recommended method of repair. The rules regarding perforation of the ureteroureterostomy are the same as for the repair of the primary subtotal transaction: a limited number of sutures should be trimmed to an appropriate length that is neither too long and redundant or too short so that there is tension on the anastomoses. The edges of the distal ileal segment are pulled through an incision in the dome of the bladder and sutured to the bladder mucosa with 3-0 delayed absorbable sutures placed via another incision in the bladder done. A series of 2-0 delayed absorbable sutures are then used to secure the serosa of the bowel to the outside serosa and muscularis of the bladder.

We strongly favor cystotomy. Performing a ureterostomy when one is not required produces an unnecessary site for stenosis or a leak. Cystoscopy requires additional time, instrumentation, repositioning, and reparing of the patient if she has not been placed in the dorsal low-lithotomy position from the beginning of the case. Opening the dome of the bladder in an extraperitoneal (preperitoneal via the space of Retzius) fashion is easy, safe, and efficient. We prefer the use of a no. 7 French double-J ureteral stent over a guidewire. The use of a right-angle clamp to manipulate the wire makes placement quite easy. The cystotomy is closed in two layers of absorbable suture: (a) the urothelium and (b) the detrusor muscle in a running Lembert technique.

Partial Ureteral Transsection
Repair of a partial transaction (buttonhole) is probably the easiest and fastest of all the ureteral injuries to manage. Because the ureterotomy already has occurred, if it is believed a stent is needed, it can be placed up and down through the ureterotomy. If it is a small hole, a stent is not necessary. The ureter is repaired using small, absorbable interrupted sutures. Excessive suture placement should be avoided. It is uncommon that more than two or three individual sutures are needed. Unless there is distal obstruction or the ureter has been devascularized, healing is usually rapid and complete. Additional suture placement does not increase the probability of adequate watertight closure and simply increases the probability of infection, ischemia, and scar formation. A closed suction drainage should be placed at the base of the repair.

Total Transsection
Uncomplicated Upper and Middle Thirds
A transaction of the ureter in its upper or middle thirds occurs in association with the performance of a paraaortic lymph node dissection or colonic resection. When the type of injury occurs, an end-to-end ureteroureterostomy over a ureteral stent is the recommended method of repair. The rules regarding perforation of the ureteroureterostomy are the same as for the repair of the primary subtotal transaction: a limited number of sutures using small-gauge absorbable sutures are placed over a ureteral stent, and the site of the repair is drained using a closed suction drain (Fig 38.8). There are two major modifications that we recommend. First, the surgeon should be assured that the ureteroureterostomy is completely tension free. Extra length of the ureter can be obtained by either mobilizing the kidney or mobilizing the distal ureter. The latter is usually preferable. Second, we recommend that both ends (proximal and distal) of the ureteroureterostomy site be spatulated. When the spatulating incision is made, care must be taken to assure that the blood vessels running in the ureteral sheath are not transected. If this occurs, the advantages of increasing the lumen size at the site of the ureteroureterostomy are probably offset by the possibility of a devascularization injury and subsequent sloughing of the site of repair. The vessels in the ureteral adventitial sheath usually can be visualized. Of course, the spatulation should be done on opposing sides of the proximal and distal ureter so as to facilitate a watertight seal.

Complicated Upper and Middle Thirds
By convention, complicated upper- and middle-third ureteral injuries are those in which one has resected a sizable segment of the ureter, and it can not be brought together in a tension-free fashion using either proximal or distal mobilization techniques as described. Although there are really two ways to effect repair (transureteroureterostomy and ureteroureteroneocystotomy), most argue against the performance of the first technique. By definition, this places both urinary drainage systems with injuries and, therefore, at risk. For this reason, transureteroureterostomy has generally been abandoned and remains of historical interest only. Therefore, it is ureteroureteroneocystotomy, in the form of an ureteroileal interposition, that most call standard for management of such an injury.

Ureteroileal interposition is a relatively easy procedure to perform. A healthy and mobile segment of the distal ileum is identified and the vascular arcades assured to be adequate for viability. We prefer to perform this resection using linear stapling devices. The ileum is repaired with a side-to-side stapled anastomosis before the performance of the ureteral repair. Once the bowel has been reanastomosed and packed off, the proximal end of the isolated loop of ileum is opened and all metal staples excised. A ureteral-ileal end-to-side anastomosis is performed over a ureteral stent or infant feeding tube. The ureter is spatulated, and the full thickness of the ureter is pulled through a hole made in the antimesenteric wall of the ileal segment. The full-thickness ureter is splayed open inside of the ileal segment using a small-gauge suture. In addition, the seromuscular portion of the ureter is attached to the serosa of the ileal segment so that the intra-ileal anastomosis is completely tension free. Unless a “pigtail” stent is used, the stent must be fixed with a catgut suture to the bowel lumen to prevent expulsion by normal ureteral peristalsis. After the proximal ureteroureteral anastomosis is completed, the patent lumen of the proximal end of the ileal segment is closed. Either PGA staples (our preference) or a two-layer hand-sewn technique can be used. Closing the ileum with metal staples is not an acceptable option because of the potential for stone formation on the permanent foreign body that is exposed to urine. The distal end of the ileal segment is then opened and the staple line removed. The distal end of the ileal segment and ureteral stent are then inserted directly into the bladder. The outermost ileal segment should be trimmed to an appropriate length that is neither too long and redundant or too short so that there is tension on the anastomoses. Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas
FIGURE 38.8. A: The ends of the ureters are trimmed obliquely and spatulated. B: Fine delayed-absorbable sutures are used to approximate the ends of the ureter. C: The anastomosis is done over a double-J or pigtail stent. A suction catheter is placed retroperitoneally at the site of anastomosis.

(Fig. 38.9). This “ileal conduit” may be secured to the psoas muscle fascia to minimize tension on that bowel segment mesentery and potential tension on the proximal ureteroneoanastomosis that may result from the effect of gravity when the patient is in an upright position. The ureteral stent should remain in vivo for at least 6 weeks. A cystoureterogram to identify any persistent occult leaks is recommended before removing the stent.

Lower Third of Ureter

Following a ureteral transaction within 6 cm of the ureterovesical junction or at the time of any resection of the lower third of the ureter, there must be a serious concern that vascularity of the distal remaining ureteral segment has been seriously compromised. Usually, it is possible to mobilize the bladder and do a direct ureteroneocystostomy so that there is no reason to take a risk with a possibly compromised distal ureter. The standard for repair in these situations has become the ureteroneocystostomy over a ureteral stent. A psoas hitch may be necessary for the ureter to reach the bladder. As with the performance of the ileal interposition, this is not a technically difficult procedure. There is a very high probability of a successful outcome if a meticulous focus on surgical technique is maintained. The first step in performing the ureteroneocystostomy is to tie off the distal segment of the ureter that is still attached to the bladder. Because the lumen of the remaining distal ureter is not in contact with the sutures, a permanent material can be used for the ligation. If a psoas hitch is required, the entire ventral surface of the bladder is freed from its areolar attachment in the retropubic space. This facilitates mobilization of the bladder toward the proximal ureter and can be done with no functional risk for the bladder as long as the dorsal lateral blood supply is left intact. Once the bladder has been fully mobilized, a cystotomy in the bladder dome is performed. The cystotomy incision should be at 90 degrees to the direction desired to elongate the bladder. After the ureterostomy has been done, the incision is then closed at right angles to the way it was opened (the two ends of the incision are closed together as the middle of the closure and the middle of the incision becomes the end of the closure). This will elongate the bladder toward the shortened ureter helping to avoid tension on the ureteral anastomosis. The ureteroneocystostomy is performed using the same technique for anastomosis as described in the discussion of the ileal interposition procedure. The site where the ureter should be drawn into the bladder usually is self-evident. We attempt to place this attachment on the posterior aspect of the bladder dome, some distance from the trigone so as to minimize any potential stenosis or injury to the contralateral ureteral orifice. Using direct tactile and visual guidance, with the primary...
surgeon’s finger in the bladder, the ventral-lateral aspect of the bladder is attached to the psoas muscle tendon. We prefer to attach the bladder directly to the psoas tendon using two separate permanent sutures. The sutures are attached to the bladder wall without entering the bladder lumen. Therefore, the bladder is elongated toward and approximated to the psoas tendon (Fig. 38.10). Many inexperienced surgeons are amazed at the degree of elongation that can be obtained and the length of the ureterovesical gap that can be bridged if there has been a thorough bladder mobilization in the retropubic and paravesical spaces. The ureter is stented, and the bladder is closed in two layers. The site of the ureteroneocystostomy is drained. Our preference is to remove this drain within the first 2 to 3 days once we are certain that no leak has occurred. The bladder is drained for 10 days and ureteral stent left in place for 6 weeks.

**SUMMARY**

Ureteral injuries can be expected, and, although unpleasant, they are a reality in the life of the active gynecologic surgeon. The vast majority of these misadventures can be avoided by constant reflection on the location of the ureter and meticulous attention to optimal surgical technique. Should ureteral injury occur, an optimal outcome is the result of accurately diagnosing the type of injury and its location; protecting the kidney by nephrostomy, retrograde stenting, or prompt reoperation; and, finally, by correcting the ureteral injury by appropriate surgical or nonsurgical techniques.

**BEST SURGICAL PRACTICES**

- The pelvic surgeon must always be aware of the location of the ureters in relation to the operative field.
- The most common sites of ureteral injuries are within the cardinal ligament where the ureter crosses under the uterine artery, in the tunnel of Wertheim, in the intramural portion of the ureter dorsal to the infundibulopelvic ligament near or at the pelvic brim, and lateral on the pelvic sidewall above the uterosacral ligament.
Abdominal hysterectomy is the most common gynecologic surgery resulting in operative injury to the ureter. The two high-risk areas for ureteral injuries during abdominal hysterectomies for benign disease are lower-uterine-segment or cervical tissues protruding into the broad ligament or bleeding from pedicles, especially at the vaginal corners.

Postoperatively signs and symptoms of ureteral injury include unilateral hematuria, flank pain, unexplained temperature elevation, ascites, retroperitoneal fluid collection, and unusual delay in return of bowel function.

A test to differentiate between bladder and ureteral fistulae is instillation of 200 cc saline stained with 1 to 3 cc methylene blue into the bladder. If blue fluid is visualized from the vagina, it is a bladder injury. If the discharge does not stain, inject IV 5 cc indigo carmine. If within 5 to 10 minutes the fluid turns blue, it is a ureteral fistula. If neither stains, the drainage may be peritoneal fluid or lymph.

Complete or partial ureteral ligation at the same time of hysterectomy results in an optimal outcome. The standard repair following ureteral transection within 6 hours consists of ureteroneocystostomy. An unusual delay in return of bowel function.

Distant anastomosis is performed by appropriate surgical or nonsurgical treatment: stenting, or prompt reoperation; and, finally, by correcting the cause of accurately diagnosing the type of injury and its location; protecting the kidney by nephrostomy, retrograde ureteral catheterization, and finally by correcting the adverse outcomes.
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

CHAPTER 39 ■ VESICOVAGINAL FISTULA AND URETHROVAGINAL FISTULA

G. RODNEY MEEKS AND TED M. ROTH

DEFINITIONS

Interposition graft—Placement of tissue to enhance tissue bulk or vascularity in an effort to enhance success of repair.

Latzko repair—A vaginal technique for repair of a vesicovaginal fistula at the apex of the vagina that includes partial colpocleisis.

O’Conor repair—An abdominal technique for repair of vesicovaginal fistula that uses cystotomy, separation of the vagina and bladder, excision of the fistula tract, and layer closure of the bladder and vagina.

Urethrovaginal fistula—An abnormal communication between urethra and vagina.

Vesicovaginal fistula—An abnormal communication between bladder and vagina.

Although it is difficult to accurately gauge the incidence of genitourinary fistulae in the United States, the majority result from gynecologic surgery, specifically total abdominal hysterectomy, urogynecologic procedures, radiation therapy, or complications of parturition. Prolonged obstructed labor remains the most common cause of destruction of the urethra and base of the bladder in developing countries, where good medical care is limited. When a fistula becomes symptomatic depends on its cause, location, and size. Differences of opinion have developed regarding timing and route of repair; however, success of fistula repair ultimately depends on a surgeon’s experience, judgment, and appropriateness of technique.

HISTORICAL SURVEY

Vesicovaginal fistulae (VVF) have occurred since the beginning of recorded time. Professor Derry, of the medical faculty at Fonsal I University in Egypt, discovered a large VVF in the mummy of Henhenit, a lady in the court of Mentuhotep of the Eleventh Dynasty who reigned about 2050 B.C. He found the pelvis was considerably contracted in the transverse diameter, and there was a through-and-through tear of the perineum. The Kahun papyrus, which refers back to 2000 B.C. and generally is thought to contain the earliest gynecologic references, and the Eber’s papyrus, from about 1500 B.C., make no mention of VVF. The Talmud, likewise, fails to give any evidence of a VVF. The Eleventh Dynasty who reigned about 2050 B.C. He found the pelvis was considerably contracted in the transverse diameter, and there was a through-and-through tear of the perineum. The Kahun papyrus, which refers back to 2000 B.C. and generally is thought to contain the earliest gynecologic references, and the Eber’s papyrus, from about 1500 B.C., make no mention of VVF. The Talmud, likewise, fails to give any evidence of a VVF. The Talmud, likewise, fails to give any evidence of a VVF. The Talmud, likewise, fails to give any evidence of a VVF.

In 1663, Hendrik Von Rooinhuyzen published his Medico-Chirurgical Observations about the Infirmities of Women. His innovations for the management of VVF included proper exposure with a speculum, marginal denudation of the fistula, and approximation of the demuded edges with “stitching needles made of stiff swan’s quills.” No figures or postoperative results were presented. Posthumously published in 1752, Johann Fatto described the first reported cures using Von Roninhuysen’s technique.

A new era in the surgical treatment of VVF occurred in the 19th century. In 1834, de Lamballe was the first to emphasize tension-free closures. He also noted that newly acquired fistulae without evidence of induration at the edges might be cured by prolonged catheterization alone. De Lamballe also made attempts to cure VVF with pedicle flaps from labia, buttocks, and thighs. Simon of Darmstadt, a colleague of de Lamballe, suggested transverse colpocleisis in those cases that defied previous attempts at closure. Although this procedure was fraught with complications, partial colpocleisis was later espoused by Latzko to cure posthysterectomy fistulae.

In 1832, Marion Sims published his classic work, which formally established the technique of VVF repair. His contribution to this endeavor is recognized by the recent republication of his original paper. Although many of his innovations were not new, he attained greater success than anyone else, and his personality helped in bringing public attention to the treatment of women’s diseases. Although Sims’s only innovation was the use of silver wire suture, he standardized and defined the surgical principles of vesicovaginal repair that are used to this day. The ethics surrounding Sims’s seminal work have recently been reviewed. The fact that his original subjects were slaves leads to a question of ethical treatment of women who had minimal, if any, personal autonomy. It is generally believed that Sims was trying to enhance the lives of these women and was in concert with accepted mores.

As laparotomy became safer, many surgeons developed abdominal techniques for VVF repair. Trendelenburg, in 1881 to 1890, described opening the bladder suprapubically, freeing the bladder wall, and closing the defect. Masionnaire and Mackenrodt independently described separating the bladder from the vaginal mucosa and suturing each as an individual layer. These principles remain foundations for modern closure techniques.

In 1896, Kelly described a vaginal method of closing a large bladder defect. The bladder is freed away from the cervix to the level of the visceral peritoneum and closed. He also advocated the use of preoperative ureteral catheterization to minimize risk of ureteral injury, a technique first championed by Pawlik in 1882. By 1906, when Kelly described a suprapubic route for
repair of VVF, at least 12 different surgical approaches had been detailed.

In 1942, Latzko described, in detail, the principles of his transvaginal operation, based on the work by Simon, which is considered by some to be the gold standard for the surgical management of posthysterectomy VVF. Latzko reported that 29 of 31 cases of VVF treated by his method of partial colpocleisis were cured. The outcomes are impressive considering that the majority of these patients had antecedent radical abdominal hysterectomy for cervical cancer.

**ETIOLOGY/EPIDEMOIOLOGY**

The etiology of urogenital fistulae may be categorized as congenital or acquired, the latter being associated with childbirth, gynecologic surgery, malignancy, and radiation therapy. When VVF occurs in childhood, antecedent events include penetrating trauma, retained or neglected foreign bodies, and genitourinary surgery. Congenital VVFs are extremely rare, and most coexist with other congenital urinary tract abnormalities. In one small series, seven of nine were associated with other genitourinary malformations. This chapter focuses on acquired VVF.

Much of the literature consists of retrospective case series and reflects the experience of a particular surgeon or fistula center. During a 15-year period of review, 103 women with genitourinary fistulae were seen at the Mayo Clinic (of whom 280 underwent surgical repair). Of the 190 patients with vesicovaginal fistulae, gynecologic surgery was responsible for 145 (82%) of the fistulae, 19 (11%) were from obstetric procedures, 15 (7%) followed treatment for malignant disease, and 5 (3%) were from trauma. Similarly, Goodwin and Scardino found 74% of their cases to be of gynecologic origin, 14% of urologic origin, and 12% from radiation injury.

Culture and geography are reflected in the frequencies and etiologies of VVF. In England, Kelly found that 95% of the VVF occurred with nonobstetric causes. In contradistinction, obstructed labor caused 98% of the VVF in Nigeria. In developing countries, obstetric trauma remains the leading cause of VVF. Most often the inciting event is prolonged and obstructed labor, which results in pressure necrosis. Intestinal stenosis secondary to female circumcision, cephalopelvic disproportion (from inadequate pelvic dimensions associated childbearing at a very early age), an android pelvis, malnutrition, orthopedic disorders including rickets, and hydrocephalus contribute to dysstocia. Fistulae may be caused by the misuse of forceps, destructive instruments used to deliver stillborn infants, or surgical abortion. Symphysiotomy and the postpartum use of intravaginal caustic agents also have a role. A large series of VVF details 1,443 cases in northern Nigeria between 1969 and 1980. Eighty-three percent resulted from prolonged, obstructed labor, and 13% resulted from gishiri cuts, a traditional tribal practice of cutting the anterior vagina with a razor blade to treat a variety of conditions, including obstructed labor, infertility, dyspareunia, backache, and goiter. Only 1% of fistulae in this study were associated with antecedent surgery.

The need to continue to implement health education programs in underdeveloped countries has been emphasized. So serious is the problem that a National Task Force on VVF was formed in Nigeria in 1990. The purpose of the task force is to advocate for women's medical and surgical services. In this population, there can be grave social consequences of VVF, including divorce, poverty, depression, and societal isolation. Premature childbearing as a result of early adolescent marriage continues to be epidemic in Africa. In sub-Saharan Africa, nearly 50% of the women are married by age 18, many by age 15 or younger. A recent case-control study from Oguna and Ekwepe in Kano, Nigeria, found that promiscuous girls who married during early adolescence were more likely to experience VVF than those who married at an older age. Uneducated women and those married to men who were unskilled laborers were 14 times more likely to sustain a VVF than their cohorts. In contrast, Hible and Ward, in a study considering that the majority of these patients had antecedent radical abdominal hysterectomy for cervical cancer.
Many of the techniques advocated to reduce the incidence of fistulae are directed toward protecting the bladder during hysterectomy. The base of the bladder rests on the anterior lower uterine segment. Suture of 2-0 or 3-0 caliber is most commonly recommended. However, suture material that does not always correlate with the absolute dose and distribution of radiation, or with the patient's weight or age; this suggests that some women are more sensitive to radiation therapy than others. Healthy tissues of the anterior vaginal wall tolerate radiation doses as high as 8,000 rads. Fistulae may appear during the course of radiotherapy (usually from necrosis of the tumor itself) or remote from completion of therapy. Endarteritis obliterans progresses during the first 2 years and may lead to ischemic changes that result in the delayed occurrence of a fistula. In planning repair, recurrent malignancy must be excluded with biopsies of the fistula margins. Because of decreased vascularity of the adjacent tissue, healing is impaired, and techniques incorporating revascularization must be considered when planning repair of a radiation-induced fistula.

There are “fascinoma” case reports of VVF caused by vaginal foreign bodies, forgotten pessaries, direct trauma from masturbation or automobile accidents, tuberculosis, schistosomiasis, bladder calculi, endometriosis, syphilis, and lymphogranuloma venereum, as well as from idiopathic congenital causes. Approach to management cannot be generalized in these situations. Carcinoma is visualized in these situations. Isolated reports in the literature may help guide management of these unique problems.

Urethrovaginal fistulae are uncommon and usually occur after surgery for urethral diverticulum, anterior vaginal wall prolapse, or urinary incontinence, and after radiation therapy. In these cases, the most common causes include tissue ischemia, problems related to healing, or radiation necrosis. Operative vaginal delivery also is a risk factor for the development of a urethropelvic fistula. Pressure necrosis, resulting in a urethrovaginal fistula, can occur with a prolonged indwelling transurethral catheter. Urethrovaginal fistulae also may be congenital, although these are extremely rare. Vesicovaginal and vesicourethral fistulae are rare. They are usually complications of cesarean section. The clinical presentation may be similar to VVF, with urine egressing through the vagina. The examination fails to reveal a vaginal fistula, however, and rarely urine trickles down through the os. Cyclic hematuria (menouria) is common. An abdominal approach with interposition graft is favored for repair, using the techniques for VVF.

**PREVENTION**

Because the trigone overlies the upper one third of the anterior vagina, it is unlikely to be injured because dissection at this level is rarely done. The bladder injury associated with suprapubic cystotomy is rare because bladder dissection is minimal. Tancer and colleagues reported no VVF in their review of 1,000 consecutive suprapubic cystotomies. Tancer, in a review of a series of 151 ureteral fistulae, found that 91% of the fistulae occurred after gynecologic procedures. Total hysterectomy was the most common antecedent procedure (n = 110), resulting in a vault fistula. Seventy percent occurred in the absence of factors that typically place the patient at risk. Based on these VVF formations, Tancer recommended modifications on avoiding injury to the bladder during total abdominal hysterectomy. These include the use of a two-way indwelling catheter, sharp dissection to isolate the bladder, an extraperitoneal cystotomy when the dissection is difficult, retrograde filling of the bladder when injury is suspected, and repair of an overt bladder injury only after mobilization of the injured area. Retrograde filling of the bladder also may help define the border of a bladder otherwise distorted or displaced by prior surgery or a lower uterine segment biopsy.

An intravesical technique for removing the cervix at hysterectomy also may protect the bladder. The vesicocervical space must be completely developed, and the bladder must be thoroughly mobilized inferriorly and laterally. Before the cardinal ligament pedicles are developed and before the anterior vagina is incised, an inverted “T” or “V” incision is made in the pubocervical fascia. The fascia is separated from the cervix and upper anterior vagina. The exposed vaginal epithelium can be entered directly. In theory, the bladder has been mobilized from the site of entry into the vagina and is less likely to be compromised because it rests on the dissected fascia. Constant traction of the uterus cephalad and gentle caudad traction on the bladder allows placement of clamps and sutures without injuring the bladder. In a recent review of 867 women who underwent infracervical abdominal hysterectomy, there was a bladder injury incidence of 0.4%. This compares with a 1% rate of bladder injury during total abdominal hysterectomy. Because there are no prospective clinical trials comparing these techniques, conclusions are impossible.

**CYSTOTOMY AND REPAIR**

The principles and technique of repairing a cystotomy are the same regardless of the inciting event. The margins of the wound should be delineated carefully to assess the extent of injury and prevent injury to the ureters. The closure is started slightly below the poles of the defect. Closure may be accomplished with interrupted or continuous sutures. The authors prefer to leave the sutures long at the poles to help with orientation and subsequent suture placement. Choice of suture for repair of the urinary tract has been based on calcius formation. When a permanent suture penetrates the urothelium, it creates a nidus for encrustation and stone formation. Although numerous studies show that permanent sutures should be avoided, a clear choice among available absorbable suture has not evolved. Indeed, the risk of stone formation seems to be equivalent for chromic catgut, polyglaftin, polydioxanone, and polyglyconate. Polyglaftin also has been touted by its manufacturer as an option for urinary tract repair, but data to support this use is limited. Therefore, the suture of choice for VVF repair and other urinary tract surgery is physician dependent. Suture of 2-0 or 3-0 caliber is most commonly recommended. A point of contention is whether the bladder mucosa...
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

FIGURE 39.1. Closure of cystotomy associated with total abdominal hysterectomy. The bladder mucosa is closed with a continuous delayed-absorbable suture. The suture may invert the mucosa or may be through and through the mucosa. A second row of suture is placed in the musculofascial layer of the bladder to support the initial layer. The bladder peritoneum may be sutured over the operative site to protect it from postoperative pelvic cellulitis to further prevent leakage into the vagina. The edge of the bladder peritoneum also may be sutured to the anterior vaginal cuff.

should be penetrated with the suture or if the sutures should be placed so as to entropion the edges of the wound. Benefits of the former include ease of suture placement and possibly improved hemostasis of the wound edges. The possibility of stone formation secondary to foreign body reaction is a drawback to “through-and-through” suture placement. Subsequent rows of continuous or interrupted sutures are placed in the musculofascial tissues to imbricate initial layers. If cystotomy occurs at the time of laparotomy in addition to the repair, a flap of peritoneum or omentum may be mobilized for further buttressing (Fig. 39.1). A watertight closure is assured by instilling 200 cc of sterile baby’s formula or dilute methylene blue via a transurethral catheter. Ureteral patency, integrity of the bladder repair, and hemostasis may be assessed with cystoscopy. Decisions regarding postoperative drainage of cystotomies depend on the extent of the injury, factors that may delay healing, and the security of the closure. Following cystotomy at the time of vaginal hysterectomy or intraperitoneal injuries, the bladder is drained for 7 to 10 days. If the injury occurs extraperitoneally, the bladder may be drained for as little as 2 days. Before removing the catheter, some advocate obtaining a cystogram to evaluate the integrity of the bladder.

Although in theory, intraoperative recognition and repair may avert the formation of a VVF, Tancer noted more than 21% of patients formed a VVF despite immediate repair of intraoperative cystotomy at the time of hysterectomy.

CLINICAL PRESENTATION OF A FISTULA

The most common presenting feature of a VVF is continuous leakage of urine from the vagina. When VVF follows gynecologic surgery, urinary leakage is most commonly recognized in the first 10 days after operation and less commonly, between the 10th and 20th postoperative days. Rarely does incontinence develop later. In the case of posthysterectomy VVF, onset of symptoms and early diagnosis may be delayed by postoperative vaginal cuff edema. In rare cases, it may be difficult to distinguish urine loss secondary to a VVF and other forms of urinary incontinence.

The size and location of the fistula determines the degree of leakage. Patients with small fistulae may void normal amounts of urine and notice only slight position-dependent drainage.
In the case of a larger VVF, urine is encountered immediately; a speculum is inserted into the vagina to facilitate inspection. For a pelvic examination, a transurethral catheter is placed and a urinary tract fistula. With the patient in lithotomy position, tests traditionally have been performed to evaluate patients for urethrography with contrast medium. Imaging ureteral anatomy, and determining the adequacy of renal function from the cervical os. Vaginal fluid may be collected for vesicocervical fistula. Only rarely is urine seen actually coming from the vaginal apex. Small volumes of drainage may be associated with regular voiding raises the possibility of a small VVF or one that only leaks intermittently. Small fluid drainage associated with regular voiding raises the possibility of a small VVF or one that only leaks intermittently. Large vaginal encrustations are seen with fistula secondary to neglected vaginal foreign bodies. This constant leakage of urine may make the patient a social reisure; disrupt sexual relations; and lead to depression, loss of self-esteem, and insomnia. Steady incontinence of urine leads the majority of patients to use a variety of protective methods, including rubber sheets to protect bedding, diapers or rubber pants to protect clothing, and continence pad products.

Kush and associates examined the records of 12 patients who had VVF develop after total abdominal hysterectomy. Most of the patients had excessive postoperative abdominal pain, distention or paralytic ileus, or both. Hematuria and symptoms of bladder irritability were also noted in women who suffered a fistula. A prolonged, postoperative fever and increased white blood cell count occurred more often in the fistula group. The clinical features described are seen with an unrecognized bladder injury resulting in intraperitoneal extravasation of urine.

**EVALUATION OF A VESICOVAGINAL FISTULA**

Even though a diagnosis is obvious in many patients, a thorough urogynecologic investigation is mandatory, especially to rule out coexistent fistulae. In a series of 43 patients with VVF, Goodwin and Bricker found 12% to have an associated ureterovaginal fistula. Lee and associates found 10 of 53 patients (19%) with ureterovaginal fistulae also had a separate VVF. An evaluation begins with a history and physical examination facilitated by use of a speculum, good lighting, and positioning. A history of large-volume vaginal leakage with no voided urine suggests a sizable defect, whereas lesser vaginal fluid drainage associated with regular voiding raises the possibility of a small VVF or one that only leaks intermittently. Small volumes of drainage may be associated with a vesicoureterine or vesicovaginal fistula. Only rarely is urine seen actually coming from the cervical os. Vaginal fluid may be collected for measurement of urea concentration to confirm that it is urine as opposed to peritoneal fluid or ascites. Urethral and ureteral anatomy and determining the adequacy of renal function from the vaginal apex during and after voiding suggests a ureterovaginal fistula. These fistulae usually are easily distinguished. Other cases may require a retrograde catheter. In such cases, a vesicovaginal fistula is confirmed by filling the bladder with contrast medium. Dye flowing into the vagina demonstrates the fistula. Dye may be slowly rotated, partially closed, and slowly withdrawn to see if dye begins to leak into the vagina as the speculum blades are repoised. If dye is seen in the vagina, a tampon is inserted, and the patient is asked to sit up and ambulate for 15 or 20 minutes. With the patient on the examining table, if dye still stains the end adjacent to the vaginal apex, a small VVF probably is present. If the distal end of the tampon near the vaginal introitus is blue, urethral integrity may be compromised. If the tampon is wet with urine, but not blue, a ureterovaginal fistula is likely. The patient's symptoms of vaginal fluid leakage may result from leakage of urine from the ureter with pooling in the vagina and subsequent loss of this urine from the vagina when the patient changes position or moves about.
