TE LINDE'S
OPERATIVE
GYNECOLOGY
TO DR. GEORGE W. MORLEY

This tenth edition of Te Linde’s Operative Gynecology is dedicated to our friend, admired and respected colleague, and contributor to previous editions of this book, Dr. George W. Morley, who passed away February 20, 2005 at age 81.

The last century was filled with spectacular progress in gynecologic surgery. Through his enthusiastic teaching, writings, mentoring to hundreds, compassionate and competent care of patients in the operating room and beyond, and especially his wise leadership of almost every national organization in gynecology and obstetrics, George was an active participant and contributor to this progress. Always totally loyal to his specialty, his institution, and the truth, he was fond of saying that we see farther by standing on the shoulders of giants who have gone before us. Now, we who knew George are able to see farther, do more, and do better for those we serve by having stood on his shoulders.

Dr. Te Linde and all the editors, authors, and publishers of Te Linde’s Operative Gynecology since its beginning in 1946, are pleased and honored to dedicate this new edition to the memory of a gentle giant, George W. Morley, with our promise that the path of progress in gynecologic surgery will continue in this new century.
CONTENTS

Contributors xi
Foreword xv
Preface xvii

SECTION I  GENERAL TOPICS AFFECTING GYNECOLOGIC SURGERY PRACTICE

1  Operative Gynecology Before the Era of Laparoscopy: A Brief History  02
Gert H. Brieger

2  The Ethics of Pelvic Surgery  15
Ruth M. Farrell, Eli A. Rybak, and Edward Wallach

3  Psychological Aspects of Pelvic Surgery  26
Betty Ruth Sperr

4  Professional Liability and Risk Management for the Gynecologic Surgeon  42
Charles J. Ward

5  The Changing Environment in Which We Practice Gynecologic Surgery  62
Eric J. Butler and Edie L. Derian

6  Training the Gynecologic Surgeon  73
Robert M. Rogers, Jr.

SECTION II  PRINCIPLES OF ANATOMY AND PERIOPERATIVE CONSIDERATIONS

7  Surgical Anatomy of the Female Pelvis  82
John O. L. DeLancey

8  Preoperative Care  113
Samford M. Markham and John A. Rock

9  Postanesthesia and Postoperative Care  133
Alexander Duncan, Ira R. Horowitz, and Kenneth Kalassian

10  Water, Electrolyte, and Acid–Base Metabolism  162
Jack B. Basil

11  Postoperative Infections: Prevention and Management  190
W. David Hager and John W. Larsen

12  Shock in the Gynecologic Patient  203
Harriet O. Smith and Heather M. Greene

13  Wound Healing, Suture Material, and Surgical Instrumentation  226
Gary H. Lipscomb

SECTION III  PRINCIPLES OF GYNECOLOGIC SURGICAL TECHNIQUES AND MANAGEMENT OF ENDOSCOPY

14  Incisions for Gynecologic Surgery  246
James J. Burke II and Donald G. Gallup

15  Principles of Electrosurgery as Applied to Gynecology  280
Richard M. Soderstrom and Andrew J. Brill

16  Application of Laser Gynecology  298
John L. Marlowe

17  Diagnostic and Operative Laparoscopy  319
Howard T. Sharp, Sean L. Francis, and Ana Alvarez Murphy

18  Operative Hysteroscopy  336
Michael S. Baggish

19  Control of Pelvic Hemorrhage  371
Howard W. Jones III and William A. Rock, Jr.

SECTION IV  SURGERY FOR FERTILITY

20  The Impact of Assisted Reproductive Technology on Gynecological Surgery  398
Howard W. Jones, Jr.

21  Reconstructive Tubal Surgery  403
Victor Gomel and Elizabeth Taylor

vii
Contents

22 Endometriosis 438
   John S. Hesla and John A. Rock

SECTION V ■ SURGERY FOR BENIGN GYNECOLOGIC CONDITIONS

23 Surgical Conditions of the Vulva 480
   Ira R. Horowitz, Joseph Buscema, and Bhagirath Majmudar

24 Surgical Conditions of the Vagina and Urethra 508
   Celia E. Dominguez, John A. Rock, and Ira R. Horowitz

25 Surgery for Anomalies of the Müllerian Ducts 539
   John A. Rock and Lesley L. Breech

26 Normal and Abnormal Uterine Bleeding 585
   William J. Butler and David E. Carnovale

27 Tubal Sterilization 609
   Herbert B. Peterson, Amy E. Pollack, and Jeffrey S. Warshaw

28 Surgery for Benign Disease of the Ovary 629
   Joseph S. Sanfilippo and John A. Rock

29 Persistent or Chronic Pelvic Pain 648
   John F. Steege

30 Pelvic Inflammatory Disease 660
   Mark G. Martens

31 Leiomyomata Uteri and Myomectomy 687
   Lesley L. Breech and John A. Rock

32A Abdominal Hysterectomy 727
   Howard W. Jones III

32B Vaginal Hysterectomy 744
   S. Robert Kovac

32C Laparoscopic Hysterectomy 763
   Fred M. Howard

SECTION VI ■ SURGERY FOR OBSTETRICS

33 Management of Abortion 776
   Melissa J. Kotbke and Mani Zaiman

34 Ectopic Pregnancy 798
   Mark A. Damario and John A. Rock

35A Obstetric Problems 825
   Cornelia R. Gravas

35B Ovarian Tumors Complicating Pregnancy 842
   Cornelia R. Gravas and Lynn Parker

SECTION VII ■ SURGERY FOR CORRECTIONS OF DEFECTS IN PELVIC SUPPORT AND PELVIC FISTULAS

36A Pelvic Organ Prolapse—Basic Principles 854
   Carl W. Zimmerman

36B Site-Specific Repair of Cystourethrocele 874
   Carl W. Zimmerman

36C Paravaginal Defect Repair 882
   Bobby Shull

36D Posterior Compartment Defects 892
   Thomas M. Julian

36E Vaginal Vault Prolapse 911
   Steven D. Kleeman and Mickey M. Karram

36F The Nonsurgical Management of Pelvic Organ Prolapse: The Use of Vaginal Pessaries 936
   Rony A. Adam

37 Stress Urinary Incontinence 942
   Alfred E. Bent

38 Operative Injuries to the Ureter 960
   Paul Underwood, Jr.

39 Vesicovaginal Fistula and Urethrovaginal Fistula 973
   G. Rodney Meeks and Ted M. Roth

40 Anal Incontinence and Rectovaginal Fistulas 994
   Michael P. Aronson and Raymond A. Lee

SECTION VIII ■ RELATED SURGERY

41 Breast Diseases: Benign and Malignant 1030
   Victoria L. Green

42 The Vermiform Appendix in Relation to Gynecology 1084
   Barry K. Jarnagin

43 Intestinal Tract in Gynecologic Surgery 1097
   Kelly L. Melpus

44 Nongynecologic Conditions Encountered by the Gynecologic Surgeon 1131
   James R. Dolan and Michael D. Moen

SECTION IX ■ GYNECOLOGIC ONCOLOGY

45 Malignancies of the Vulva 1151
   Mitchel S. Hoffman

46 Cervical Cancer Precursors and Their Management 1208
   Howard W. Jones III

Foreword

Once again, the editors, authors, artists, and publishers have collaborated to produce a completely updated revision of Te Linde’s Operative Gynecology, the most widely read textbook on this subject in the world. It has been translated into several foreign languages, and the eighth edition was the first to be translated into Chinese. This textbook is essential to the care of women with gynecologic disease.

There is a long history of publication of classic textbooks by distinguished members of the faculty of the Department of Gynecology and Obstetrics at Johns Hopkins. The list includes William Obstetrics and notable literary works of Kelly, Cullen, Novak, Wharton, Everett, Woodruff, Howard and Georgeanna Jones, Rock, and others. Many of these textbooks have been carried on in succeeding editions in the last 100 years. By describing and emphasizing “the Hopkins way” of caring for patients, these books have had great influence on the practice of gynecologists and obstetricians. Te Linde’s Operative Gynecology is a prime example of this Hopkins tradition.

In the first edition in 1947, Dr. Te Linde wrote only about gynecologic operations that he had personal experience with, and advised subsequent editors to do the same. Since then, the subject of gynecologic surgery has become so large that it is no longer possible for any one or two gynecologic surgeons to be masters of the entire field, partly the result of development of subspecialties in gynecologic surgery. Therefore, it has been necessary to include authors other than the Hopkins authors who also qualify as experts in various aspects of the subject. The current edition includes 75 authors. This has resulted in a more complete national and even international presentation. This venerable textbook includes not only the usual and customary problems in gynecology that may require surgery for relief, but also the special, difficult, complicated, and unusual problems encountered occasionally.

The last century saw spectacular advances in the surgical treatment of gynecologic diseases. Consider that a tumor as common as uterine leiomyomata was a lethal disease in some women when the 20th century began. Because of the heroic surgical innovations of Howard Kelly and Thomas Cullen and others at Johns Hopkins and elsewhere, women who live in countries where modern gynecologic surgery is practiced no longer endure long suffering or die of this benign tumor. Similarly advances have also been made in the management of cervical cancer, endometriosis, ectopic pregnancy, pelvic infections, uterine prolapse and vaginal relaxations, urinary incontinence, fistulas, infertility, congenital anomalies, etc. Throughout the century, progress in gynecologic surgery was chronicled by many textbooks. For example, Kelly’s Operative Gynecology was the helpful companion of gynecologic surgeons in the first half of the 20th century, and Te Linde’s Operative Gynecology served a similar function in the second half.

In addition to the scholarly work of the authors of chapters, one must also pay tribute to the brilliant artwork that has accompanied and explained the text. Originally, in Dr. Kelly’s Operative Gynecology, the highest standard was set by the close collaboration, often in the operating room, between Dr. Kelly and his choice of Max Brodel as his personal artist. Their work together produced many masterpieces that are still outstanding teaching aids today. Brodel started the Hopkins School of Art in Medicine, and many of the graduates of this school, especially Leon Schlossberg, have contributed to every edition of Te Linde’s Operative Gynecology and other texts. One cannot underestimate the value of their work in teaching gynecologic surgery. Because of the numerous illustrations, Te Linde’s Operative Gynecology could qualify as an atlas of surgical technique, but it is much more.

Although an important part of the education and training of the gynecologic surgeon, Te Linde’s Operative Gynecology cannot alone teach technical skills or substitute for spending years at the elbow of a seasoned, wise, and experienced mentor working in a proper health care facility, both of which are a necessary minimum in creating and maintaining an environment in which gynecologic surgery can be studied and learned and practiced. Proper technical skills are important in the successful performance of even the simplest operation. However, the most serious mistakes in the practice of gynecologic surgery may be made by those who know “how,” but have not learned “when” and “why.” The ability to perform a large number of gynecologic operations with a low morbidity and mortality rate, although desirable, is not ipso facto evidence that gynecologic surgery is being practiced correctly. The gynecologic surgeon must first study and understand the basic-science aspects of female reproductive organ function and the pathology, clinical manifestations, and psychosocial aspects of gynecologic disease. It takes time to evaluate patients properly, some more so than others. This may be difficult in a busy gynecologic practice, but it is necessary in order that proper recommendations can be made for or against surgery. And, after one chooses the right patient for operation, one must choose the right operation for the patient. It is a mistake to do an abdominal hysterectomy when a vagi- nal hysterectomy would have significant advantages. One must select from a variety of operations available, and the one that most properly fits the needs of the individual patient depends upon many variables. It is a serious mistake to know only one operation and do it on every patient regardless of the circumstances. And remember always the admonition of John Burch that the golden rule of pelvic surgery is the conservation of useful
function—for example, the conservation of normal ovaries at the time of hysterectomy in most premenopausal women.

When indicated, alternatives to surgical therapy should be offered. As an advocate for patients and as a guardian of professional integrity and responsibility, gynecologic surgeons must insist on working in a proper health care environment, evaluate the results of care carefully, and change indications for surgery and surgical techniques as warranted and based on valid data. New methods and innovations in surgical therapy must be subjected to proper analysis before adopted as standard practice. Arrangements should be made for long-term follow-up to determine the results of treatment. As Dr. Te Linde was fond of saying, “Never take a young gynecologic surgeon’s opinion about the value of a new operation because he/she has not yet been able to follow patients long enough.”

Although the decision to operate may at times seem complicated, it can be simplified. According to Dr. J.M.T. Finney, there are only three valid reasons to operate:

■ To save life (as in ruptured ectopic pregnancy, cervical cancer, etc.)
■ To relieve suffering (as in pain from endometriosis, urinary incontinence, etc.)
■ To correct significant anatomical deformities (as in uterine prolapse, Meyer-Rokitansky-Kuster-Hauser Syndrome, etc.)

Now, modern gynecologic surgery can offer a fourth reason to operate:

■ To allow the creation of life (as in tubal reconstructive surgery, various in vitro fertilization operations, etc.)

This is an indication that is unique to gynecologic surgery and a great gift to humankind.

If, in making the decision to operate, one cannot fit the patient into one of these categories, perhaps the decision is wrong and needs review, and even review by a consultant.

*Te Linde’s Operative Gynecology* will help the gynecologic surgeon learn the important details of performing procedures correctly. More importantly, it will help the gynecologic surgeon learn how to evaluate patients correctly. Today, such great emphasis is placed on learning to use new technology and new instruments that basic fundamentals of clinical evaluation of the patient care are forgotten or ignored. The greatest improvements in the practice of gynecologic surgery will come from listening to the patient rather than mastering new technology. In my judgment, the absolutely most important chapter ever written about gynecologic surgery is Chapter 3 on Psychosocial Aspects of Pelvic Surgery, written first by Dr. Malcolm Freeman and now by Dr. Betty Ruth Speir. This chapter should be required reading for anyone practicing gynecologic surgery.

And what of the future? Gynecologic surgery is a dynamic field of medicine, always changing to benefit the health of women by curing or alleviating the symptoms of gynecologic disease. We can expect exciting new developments in the 21st century, although it will be difficult for the next century to exceed the fantastic progress made in the last century. Gynecologic surgery will change and benefit because the future of biomedical science is wide open. Incredible discoveries in the past 50 years will inevitably effect gynecologic surgery, discoveries including massive improvements in technology, new and better vaccines, stem-cell research, DNA research, nanoscience, etc. We can look forward to new developments such as the implantation of a tissue-engineered product which, once implanted, slowly disappears while the host replaces it with his or her own tissue. The knowledge and skills required of gynecologic surgeons will be completely different by the end of the 21st century.

In the current tenth edition, each chapter is well written, well illustrated, easy to read and understand, and comprehensive yet specific, with the most modern, up-to-date information. It is hard to imagine a more thorough review of gynecologic surgery. It is also hard to imagine anyone who plans to learn, practice, and teach gynecologic surgery without this textbook. It can be used as a ready reference, a ready consultant with ease. It can be considered as a partner or companion in practice.

All who contributed to this new edition of Te Linde’s deserve our congratulations for a job well done. It will be a great help to those who work to improve and maintain the quality of life for women.

*John D. Thompson, MD*
The rapid pace of the introduction of new surgical techniques for the treatment of gynecologic disease has required the timely revision of *Te Linde’s Operative Gynecology*. Until 1992 the text was revised every 7 to 9 years. Since then the interval to revision has significantly shortened to 4 to 5 years due to the rapid advances in the field of surgery. Dr. Richard Te Linde wrote the first edition. Today up to 72 contributors have shared their personal insights and surgical approaches for the treatment to improve the health of women. *Te Linde’s Operative Gynecology* has been, and hopefully will continue to be, a major influence in maintaining and improving the quality of gynecologic surgery.

The tenth edition of *Te Linde’s Operative Gynecology* presents the basic, sound principles for established gynecologic surgical technique. Major advances in the field of education of the gynecologic surgeon and the changing environment in which we practice gynecologic surgery are presented. John Deutsh, P. L. Malone, Leon Schlossburg, and others have contributed excellent medical illustrations throughout the last 10 editions. We appreciate the new medical illustrations prepared by Jennifer Smith in Chapters 17, Diagnostic and Operative Laparoscopy; 19, Control of Pelvic Hemorrhage; 23, Surgical Conditions of the Vulva; 32A, Abdominal Hysterectomy; 32C, Laparoscopic Hysterectomy; 34, Ectopic Pregnancy; 35A, Obstetric Problems; 36C, Paravalvaral Defect Repair; 36D, Posterior Compartment Defects; 37, Stress Urinary Incontinence; 43, Intestinal Tract in Gynecologic Surgery; 50, Pelvic Exenteration; and 51, Surgical Reconstruction of the Pelvis in Gynecologic Cancer Patients; and by Joe Chovan in Chapter 18, Operative Hysteroscopy. The addition of color to the text offsets important figures and tables.

In view of the major focus on best surgical practices in surgical specialties, we have introduced a new section in each chapter that discusses the major take-home points. These best surgical practices present the opinion of the authors. Each clinical situation is unique, and readers should exercise their professional judgment accordingly. The information presented in the best practices is educational in nature and not a set of guidelines for use in any given situation. The authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of this or any other information in this book and make no warranty, expressed or implied, with respect to the contents of the publication.

Also new to this edition are definitions, which have been added as a part of the introduction of each chapter. The self-test questions in the Appendix have been revised and will allow the reader to “self test” after reviewing a specific topic. Perhaps more importantly, the editors have added for the first time a DVD of several surgical procedures previously introduced as “surgery in the retroperitoneal space,” with accompanying text. Hopefully this will be a regular feature of future editions and will add an appreciation of the “Art of Surgical Techniques.”

The authors wish to sincerely thank all the contributors and gratefully acknowledge the assistance of Barbara Schmidt, Lynne Black, Patsy Shepard, and the Lippincott Williams & Wilkins editorial team of Sonya Seigafuse, Ryan Shaw, Nicole Dernoski, Mark Flinders, and Rosanne Hallowell for their attention to details and hard work in the preparation of this book. As always, we are deeply indebted to those authors and editors who have labored to write the previous editions of this text. The current edition would not exist without their dedication. We owe a sincere debt of gratitude to Drs. Richard W. TeLinde, Richard F. Mattingly, and John D. Thompson.

SECTION I  GENERAL TOPICS AFFECTING
GYNECOLOGIC SURGERY PRACTICE
CHAPTER 1 OPERATIVE GYNECOLOGY BEFORE THE ERA OF LAPAROSCOPY: A BRIEF HISTORY

GERT H. BRIEGER AND HOWARD W. JONES, Jr.

Gynecology, spelled gynaecology, is defined by the Oxford English Dictionary as “that department of medical science which treats of the functions and diseases peculiar to women.” The word was first used as such in the middle of the 19th century. In 1867, gynecology represented the physiology and pathology of the nonpregnant state. Although most histories of gynecology trace its roots back to antiquity, the field of medicine we call by that name today really has had a fairly recent origin. The successful removal of an ovarian tumor by Ephraim McDowell in 1809 was as rare an event as it was a spectacular one. In the preceding centuries, the history of gynecologic surgery was closely tied to the history of general surgery, and the obstacles that had to be overcome were the same. Infection, hemorrhage and shock, and pain were all effective barriers to any but emergency surgical procedures in the days before anesthesia.

"The history of gynecology," Howard Kelly wrote in 1912, "seems to me more full of dramatic interest than the evolution of any other medical or surgical specialty." Himself an accomplished historian of medicine, among his many other skills, Kelly noted that, "It was, notably, anesthesia which accomplished historian of medicine, among his many other skills, Kelly noted that, "It was, notably, anesthesia which enabled the operator to discriminate between malignant and non-malignant growths." Here, in a nutshell, we have the landmarks of much of the history of gynecology of the last 150 years. Ann Dally was correct when she noted that until recently, much of what has been written about the history of gynecology was written by gynecologists themselves, who picked their own heroes. With the rise of the new history of women and the social history of medicine since the 1970s, a much more balanced view has emerged.

There are many ways to approach the history of a medical and surgical specialty such as gynecology. The usual practice in textbooks that make an attempt to include some history is to tell the story in terms of who discovered what and who did which operation first. These facts are of interest but hardly constitute the history of the field. Besides the surgical operations of gynecology, the techniques devised, and the instruments to carry them out, there is much to be learned from the changing picture of diseases and their diagnoses; from the professionalization of the field, including the societies, journals, and textbooks that have been created; and from the education required to master the science and practice of operative gynecology. It is in these terms, rather than in tracing simply the great ideas and their creators, that this historical introduction proceeds.

Any major medical textbook can itself serve as a convenient window through which we can see history unfold.

Robert Hahn has vividly described the changing world view of obstetrics by examining the succeeding editions of William's Obstetrics since its first edition in 1903. Likewise, the 50 years that have elapsed since the first edition of Richard Wesley Te Linde's Operative Gynecology provide an equal opportunity to describe the major developments in the companion field of gynecology.

BARRIERS TO SURGICAL PROGRESS

In ancient times, the lack of real anatomic knowledge was a barrier to the development of surgery. It is sometimes said that because the ancient Egyptians had effective techniques for the eversionation of bodies for mummification, they must have had a good knowledge of the body. However, removal of the internal organs during the embalming process was performed by technicians who did not concern themselves with the structure of the bodies they were preparing.

Anatomy was pursued in Alexandria during the Hellenistic period, but it had few, if any, practical applications until a later time. By the end of the 13th century, anatomic dissection again became more common, but often it was limited to one or two public dissections a year or the study of animals. Surgeons were responsible for the few autopsies that were performed to determine the cause of death. This was especially important if a crime was suspected or drowning had to be established.

Soranus, the Roman physician and writer who practiced in the reign of the Emperors Trajan (98–117) and Hadrian (117–138), is perhaps best known for his text entitled Gynecology. This book is somewhat mistitled because it is mostly devoted to what we would call obstetrics. Soranus wrote about prenatal and postnatal problems, as well as those associated with delivery itself. This ancient text has been translated and has an excellent introduction by Owsei Temkin. Recently, it has been reissued in a paperback edition.

Although Soranus's Gynecology still makes interesting reading, it hardly qualifies as an early text on the subject of operative gynecology. However, like other physicians of his time, Soranus clearly noted that the best midwife was one who was trained in all branches of therapy; “... for some cases must be treated by diet, others by surgery, while still others must be cured by drugs.”

Although there were instances of anatomical study in earlier times, we generally begin the story with the work of Andreas Vesalius and the publication of his De humani corporis fabrica in 1543. Before this time, anatomic knowledge was not tied
to the teaching and practice of medicine. The tradition of the
surgeon-anatomists, of whom Vesalius was a stellar example,
culminated in the late 18th century with the work of the En-
grish surgical teacher John Hunter (1728–1793) and his older
brother William (1718–1783). It was William's classic book
about the gravid uterus with its detailed engravings that shed
new light on the structures of the female pelvis.

In the 19th century, for all types of surgery, the problems of
pain, hemorrhage, and infection had to be solved before op-
erations could be undertaken safely. The problems of surgical
dressings and postoperative infections were generally a matter
of trial and error. The Scottish surgeon and gynecologist Sir
James Simpson (1811–1870) urged his surgical colleagues
to perform their operations on the kitchen tables of their patients
to avoid the dangers of hospital infections, or “hospitalism” as
it came to be called.

In the 1840s, the Hungarian obstetrician Ignaz Semmelweis
(1818–1865) showed clearly that puerperal fever could be pre-
vented by disinfecting the hands of doctors before they exam-
nined their patients during the course of delivery. Despite good
statistical evidence, his method of washing hands in chlori-
nated lime solution was not widely adopted. In fact, it met
with outright resistance from most physicians. In this coun-
try, the Harvard anatomist and writer Oliver Wendell Holmes
(1809–1894) met similar disbelief and resistance when he sug-
gested in 1842 that it was the physicians themselves who were
performing the dreaded puerperal infections to their patients.

In the middle 1860s, Joseph Lister (1827–1912), while
working in Glasgow, began experimenting with carbolic acid, a
phenol derivative, to clean the instruments, sutures, and dress-
ings he was using in his operations. He based his work on an
understanding of the germ theory of disease, which was then
just in its infancy as a major theory of disease causation. Lister
had been able to demonstrate the importance of preventing the
germs present in the air or on instruments and sutures from enter-
ing the wound, which would prevent the formation of the hereto-
fore much desired laudable pus. Lister, too, met much opposition to his method
of antisepsis. Partly because of the frequent changes in the sys-
tem he was developing, which made it difficult for others to
follow him, and because of the inadequate understanding of
the germ theory by most surgeons, it took nearly two decades
for antiseptic surgery to become routine. In Lister's case, as was
also true for Holmes and Semmelweis, some of the resistance
undoubtedly stemmed from the fact that doctors never like be-
ing told that what they are doing is actually causing harm to
their patients.

Lister encountered a great deal of opposition, particu-
larly in his own country. Lawson Tait (1845–1899), an active
and polemical gynecologist who settled in Birmingham, was
strangely opposed to Lister's system of antisepsis. Tait paid
much attention to general cleanliness when he was operating,
and he actually achieved quite good results. However, his older
colleague, Spencer Wells (1818–1887) of London, was a de-
voted follower of the antiseptic system in his many ovarian
operations, perhaps because he had a clear grasp of the role
of microbes. In 1864, the year before Lister began using car-
bonic acid in Glasgow and 3 years before he published his first
results, Wells published a paper in the British Medical Jour-
nal entitled “Some Causes of Excessive Mortality after Surgi-
cal Operations.” Wells clearly described the recent work on
germs by Louis Pasteur (1822–1895) in France. There is no
definite proof that Lister was aware of the paper, but it is hard
to imagine that he did not know what was appearing in the
national medical journal. Thus, gynecologists probably had a
much greater hand in the development of safe surgery in the
last century than is usually acknowledged.

BEGINNINGS OF GYNECOLOGIC-
SURGERY IN 19TH-CENTURY
AMERICA

Opening the abdominal cavity to remove extrauterine pregnan-
cies was successfully accomplished several times in the later
19th century but did not become routine until the advent of
anesthesia and antisepsis. Ephraim McDowell (1771–
1830) (Fig. 1.1) made surgical history with his successful re-
moval of a large ovarian cyst in his patient Jane Todd Crawford,
who in 1809 rode 60 miles to her doctor's house in Danville,
Kentucky, to undergo an untreed operation without any assur-
ance of care and without the benefit of anesthesia. Although
McDowell is often referred to as a backwoods physician, he
was in fact a well-trained surgeon. His Edinburgh training
probably gave him confidence in his diagnosis and courage to
attempt a surgical cure rather than have his patient face certain
death from her relentlessly growing tumor. During his study
tour in Scotland, he probably heard that in the previous cen-
tury, the popular surgical teacher John Hunter had suggested
such an operation, believing that “women could bear spaying
just as well as did animals.”

The drama of McDowell's case is best described in the words
of the surgeon himself:

In December, 1809, I was called to see a Mrs. Crawford, who had
for several months thought herself pregnant. She was affected with
pains similar to labor pains, from which she could find no relief.
So strong was the presumption of her being in the last stage of
pregnancy, that two physicians, who were consulted on her case,
requested my aid in delivering her. The abdomen was considerably
enlarged, and had the appearance of pregnancy, though the inclina-
tion of the tumor was to one side, admitting of an easy removal to
the other. Upon examination, per vagina, I found nothing in the
uterus, which induced the conclusion that it must be an enlarged
ovarium. Having never seen so large a substance extracted, nor
heard of an attempt, or success attending any operation, such as
this required, I gave to the unhappy woman information of her

FIGURE 1.1. Ephraim McDowell (1771–1830). One of the earliest
abdominal surgeons.
dangerous situation. She appeared willing to undergo an experiment, which I promised to perform if she would come to Danville... With the assistance of my nephew and colleague, James McDowell, M.D., I commenced the operation, which was concluded as follows: Having placed her on a table of the ordinary height, on her back, and removed all her dressing which might in any way impede the operation, I made an incision about three inches from the musculus rectus abdominis, on the left side, continuing the same in nine inches in length, parallel with the fibres of the above named muscle, extending into the cavity of the abdomen. The patient, which were a good deal constricted, which we ascribed to the resting of the tumor on the horn of the saddle during her journey. The tumor then appeared in full view, but was so large that we could not take it away entire. We put a strong ligature around the fallopian tube near to the uterus; we then cut open the tumor, which was the ovarium and fibrous part of the fallopian tube very much enlarged. We took out fifteen pounds of a dirty, gelatinous looking substance. After which we cut through the fallopian tube, and extracted the sack, which weighed seven pounds and one half. As soon as the external opening was made, the intestines rushed upon the table; and so completely was the abdomen filled by the tumor, that they could not be replaced during the operation, which was terminated in about twenty-five minutes. We then turned her upon her left side, so as to permit the blood to escape; after which, we closed the external opening with the interrupted suture, leaving out, at the lower end of the incision, the ligature which surrounded the fallopian tube. Between every stitches we put a strip of adhesive plaster, which, by keeping the parts in contact, hastened the healing of the incision. We then applied the usual dressing, put her to bed, and prescribed a strict observance of the antiphlogistic regimen. In five days I visited her, and much to my astonishment found her engaged in making up her bed. I gave her particular caution for the future; and in twenty five days, she returned home as she came, in good health, which she continues to enjoy.

McDowell’s patient long outlived her surgeon. He did not publish his feat until 1846, by which time he had performed several more oophorotomies. McDowell is sometimes cited as a pioneer of early abdominal, unwitting as it was in his case. If his first patient had not recovered so well, her failure would surely have been blamed on rising too early from her bed after such extensive surgery. McDowell also did not mention the intense drama of this Christmas day operation. When the townsfolk of Danville heard about his plan, they were incensed. They gathered in a tense group outside his house, with a rope slung over a tree, ready to lynch the surgeon if his “experiment” proved a failure. McDowell certainly had the nature of a true pioneer.

T. G. Thomas, in his 1876 centennial review of obstetrics and gynecology, reported that Alexander Dunlap of Springfield, Ohio, claimed he did his first ovarian operation in 1843. Dunlap said he sent the report of this case to a medical journal, which sent it back to him saying that they “could not publish the case of such an unjustifiable operation.”

By 1876, Thomas wrote, “It is to estimate the amount of good this operation has bestowed upon humanity. Practised today in every civilized country in the world, yielding the statistics of seventy to seventy-five per cent of recoveries, and daily being improved in its various steps, it may well be regarded as one of the greatest surgical triumphs of the century.”

In the middle decades of the 19th century, another American surgeon working in the South helped to popularize gynecologic surgery by another set of pioneering feats. James Marion Sims (1813–1883) told the dramatic tale of his development of a successful technique to repair vesicovaginal fistulas in his widely read autobiography The Story of My Life, which was published the year after his death (Fig. 1.2). He described his repeated attempts to achieve a permanent closure of these fistulas in a few of his young slave-women patients. Sims began his experiments in 1845 and continued them for 4 years. In these preanesthesia and preantisepctic days, Sims produced remarkable results. He had had no experience in pelvic surgery, and in fact claimed that he disliked it. It was his custom to turn away patients with pelvic disorders, referring them to other doctors in his Alabama neighborhood. Many of his planter friends owned slaves, some of whom suffered from vesicovaginal fistulas as a result of traumatic births. These wounds were considered incurable and made the young women unacceptable for household work. After several entreaties to help one of his planter friends who had such a slave, Sims began with a small group of women, operating on some of them repeatedly over the course of 4 years. Sims’s many failures only increased his determination to succeed. The colleagues who at first assisted him at the operations abandoned him, and his friends, he claimed, begged him to give up what was considered to be a hopeless effort. He trained other young slave patients to assist him, and on his 29th operation on one of the patients, he finally succeeded. In reviewing his work in 1852, Sims did cite several successful cases by other American surgeons between 1839 and 1849. He claimed originality for:

1st. for the discovery of a method by which the vagina can be thoroughly explored, and the operation easily performed (the Sims, or lateral position). 2nd. For the introduction of a new suture apparatus, which lies imbedded in the tissues for an indefinite period without danger of cutting its way out, as do silk ligatures. 3rd. For the invention of a self-retaining catheter, which can be worn with the greatest comfort by the patient during the whole process of treatment.

The new “suture apparatus” used silver wire. This provided the breakthrough needed for the successful repair of vesicovaginal fistulae. Sims used silver in many of his other operations. In a 10th anniversary lecture at the New York Academy of Medicine in 1857, Sims somewhat immodestly told his august audience that the use of silver suture was one of the great achievements of 19th-century surgery. Sims wrote and spoke frequently about his development of a successful procedure for the definitive care of vesicovaginal fistula, but never more eloquently than in his Anniversary Address in November

FIGURE 1.2. James Marion Sims (1813–1883).
1857, in which he described his work with silver sutures over the previous 12 years. The audience included several past presidents of the academy and most of the distinguished colleagues at the Woman’s Hospital. After four years of fruitless effort, Sims proclaimed a new dawn on 21 June 1849. Since that day, he claimed, he had used no other suture in any of his surgical work.

It is worth noting that Sims’s early patients—the slave women of Montgomery, Alabama, and the poor Irish servant girls who were predominant patients of the Woman’s Hospital in New York—were equally vulnerable, so it is not hard to see why some recent historians have been very critical of Sims and his contemporaries. Yet with the advent of anesthesia and the use of antisepic techniques, such surgery became increasingly routine. The repair of vesicovaginal fistulas and the removal of ovaries for a wide variety of indications were the beginning of the field of operative gynecology as it is known today. The story is, of course, not purely an American one. The English, French, and German contributions were important and can be found in any general history of medicine or of obstetrics and gynecology. In 1876, Sims became president of the American Medical Association, and in the same year, he and others founded the American Gynecological Association.

Even with the advent of effective and relatively safe anesthesia after 1846, it was several decades before surgeons were ready to increase the number of their operations. At midcentury and during the Civil War in the 1860s, surgery was generally confined to amputations after accidents, hernia repair when the intestine became incarcerated in the hernia sac, thus threatening life; an occasional ligation of a major vessel for aneurysm; and cystotomy for bladder stones. Therefore, Sims, operating in the 1840s, was truly a pioneer.

Also pioneers in the field of gynecologic surgery by mid-century were the Atlee brothers of Lancaster, Pennsylvania. They rediscovered oophorectomy, which was also being done in England by the 1860s, and were among the early leaders who performed myomectomy for fibroid tumors of the uterus.

Of semantic interest is the changing terminology for ovarian operations between 1843 and 1883, with 64 recoveries and only 14 deaths. Thus, he validated McDowell’s work of the previous 12 years. The audience included several past presidents of the academy and most of the distinguished colleagues at the Woman’s Hospital. After four years of fruitless effort, Sims proclaimed a new dawn on 21 June 1849. Since that day, he claimed, he had used no other suture in any of his surgical work.

Ovariotomy, often used imprecisely to refer to removal of the ovary, actually was first used in that way in the 1830s by James Simpson and other British gynecologists. Ovariotomy means to cut into the ovary for removal of a cyst or tumor. In the 1870s, gynecologists such as Edmund Peaslee of New York, in his book on ovarian tumors, stated that oophorectomy was a more precise and distinctive term for removal of the ovary.

John Light Atlee (1799–1885) actively practiced medicine and surgery in New York—were equally vulnerable, so it is not hard to see why some recent historians have been very critical of Sims and his contemporaries. Yet with the advent of anesthesia and the use of antisepic techniques, such surgery became increasingly routine. The repair of vesicovaginal fistulas and the removal of ovaries for a wide variety of indications were the beginning of the field of operative gynecology as it is known today. The story is, of course, not purely an American one. The English, French, and German contributions were important and can be found in any general history of medicine or of obstetrics and gynecology. In 1876, Sims became president of the American Medical Association, and in the same year, he and others founded the American Gynecological Association.

By the 1880s, the specialty of gynecology, or the science of women, as some historians have called it, was well on its way to being established as one of the subdivisions of medical labor. Ornella Moscucci, in her perceptive history of gynecology in Britain, quotes the eminent surgeon from Birmingham, Lawson Tait, in his aptly entitled book of 1889, Diseases of Women and Abdominal Surgery:

The great function of woman’s life has for years made her the subject of specialists, male and female, the obstetrician. The subsidiary relations of her special organs and the special requirements of her physique, based upon these, have necessitated the establishment of another class of specialist, the gynecologist.

The growth of interest in women’s diseases began long before the 19th century. In the Renaissance, for instance, the publication of a large, encyclopedic work entitled Gynaecia, by Gaspar Wolf (1532–1603), and later similar collections represented what had been written since antiquity. The mere existence of such texts, however, does not mean that much attention was given to the treatment of women, except as it related to childbirth.

Any discussion of the treatment of women’s diseases since the latter half of the 19th century must take into account a
variety of interpretations of women’s role in society and both professional and lay views of women's health. Historical as-
sessments in our own time have contributed to the further-
ing of interest in the issues of women's health. Today's dis-
cussions are best understood in the light of their historical
roots.

Historians of the family and the role of women in the
19th century have written much about the separate spheres for
women and the cult of domesticity in which there was a rigid
distinction between the home, where it was thought women
belonged, and the economic world outside. Thus, the "cult of
true womanhood," as historians have called it, made sharp dis-
tinctions between women's place in the family and the working
world of men. As the social role of women was increasingly de-
dined, they were, in a sense, held hostage in the home. Women
were judged by the male world and themselves according to
four cardinal virtues: piety, purity, submissiveness, and domes-
ticy.

To these social distinctions between men and women were
added the biologic differences. The biologic notions of women
in the 19th century ranged widely, but they included the idea
that women were not only physically weaker than men (al-
though morally superior), but inherently diseased or patho-
logic. Their cyclical physiology was believed to make women
unsuitable for sustained work or learning. Feminist historians
of recent times have taken doctors of an earlier era to task for
casting women as frail creatures entirely dependent on their
biology, destined to be kept from the male world of education,
politics, the professions, and any but domestic work. As Or-
nella Moscucci points out, however, the medical ideas about
the social destiny of women were far more complex than has
been assumed.

On both sides of the Atlantic, the view of Victorian
women was influenced by the writings of eminent physicians.
In Boston, a Harvard Medical School professor, Edward H.
Clarke (1820–1877), wrote a book in 1873 entitled Sex in Edu-
cation; or, A Fair Chance for the Girls. This book was widely re-
viewed and discussed. Similarly, Henry Maudsley (1835–1918)
in England, an influential psychiatrist and medical teacher, also
wrote about the supposed harm of higher education on the
physiologic development of postpubescent girls. Clarke's book,
which has become known as a uterine manifesto, clearly set the
brain and the uterus in opposition. Higher education, Clarke
claimed, might be good for developing the intellect, but that oc-
curred at the expense of the reproductive organs, thus dooming
the woman to a state of stunted womanhood and lifelong in-
validism.

Sex in Education went through 17 printings and editions in
the space of a few years. Because of its popularity and notoriety,
it is worth citing one of Clarke's case reports:

![Figure 1.4](image-url)

FIGURE 1.4. This famous illustration of “the touch” in
a gynecologic examination is from a 19th-century French
text frequently used in America. Note the avoidance of eye
contact between doctor and patient and the dress shielding
the woman’s body from view. (From: Wertz WR, Wertz
WC. Lying-in: a history of childbirth in America, expanded
with permission.)
Miss D—went to college in good physical condition. During the four years of her college life, her parents and the college faculty required her to get what is popularly called an education. Nature required her, during the same period, to build and put in working order a large and complicated reproductive mechanism a matter that is popularly ignored—shoved out of sight like a disgrace. She naturally obeyed the requirements of the faculty, which she could see, rather than the requirements of the mechanism within her, that she could not see. Subjected to the college regimen, she worked four years in getting a liberal education. Her way of work was sustained and continuous, and out of harmony with the rhythmic periodicity of the female organization. The stream of vital and constructive force evolved within her was turned steadily to the brain, and away from the ovaries and their accessories. The result of this sort of education was, that these last-mentioned organs, deprived of sufficient opportunity and nutriment, first began to perform their functions with pain, a warning of error that was unheeded; then, to cease to grow; . . . And so Miss D—spent the few years next succeeding her graduation in conflict with dysmenorrhea, headache, neuralgia, and hysteria.

Many writings in the 1870s and 1880s attempted to refute the medical notions of physicians such as Clarke and Maudsley. In this country, Mary Putnam Jacobi (1842–1906), a physician and future champion of women in higher education and the professions, submitted a prize-winning essay that refuted Clarke’s contentions that work by the brain interfered with uterine function and the menses. In Britain, the pioneer woman-physician Elizabeth Garrett Anderson (1836–1917) claimed that it was boredom that caused the medical symptoms of middle-class women, not higher education.

By the middle of the 19th century, even the use of the speculum as a diagnostic instrument stirred controversy. The speculum was known to the ancients, but it fell into disuse by the early modern period. Early in the 19th century, Joseph Re- camarier (1774-1832) reintroduced it in Paris, and soon the speculum was routinely used in treating inflammatory disease. It was also used in the routine examination of prostitutes in France and England.

In the Victorian climate of concern about women and their diseases, as well as their moral sensibilities, vaginal examinations were not routine. When they were performed, great efforts were made to preserve the patient’s privacy and dignity, as the accompanying illustrations show (Figs. 1.4 and 1.5). A battle over the morality of the use of the speculum also ensued. The speculum, opponents of its use believed, could lead to sexual stimulation and sexual excesses. The term “speculum rape” was used in the debates over the Contagious Disease Acts in England in the 1860s.

Meanwhile, the surgeons went about debating the advisability of oophorectomy. One of the most prominent proponents of ovarian surgery for symptoms not just associated with demonstrable ovarian disease was an American surgeon named Robert Battey (1828–1895) of Georgia. In 1872, he removed the ovaries of a 32-year-old woman who had claimed invalidism for 16 years. Battey reported that his patient was cured after the bilateral oophorectomy. (Cured of what remains the intriguing question.) In succeeding years, the Battey operation became popular with some surgeons. Battey himself tried a vaginal approach to the ovaries but soon reverted to abdominal section. He advocated bilateral removal of the ovaries, whether or not they revealed any sign of disease, to ameliorate menstrual difficulties or psychological symptoms.

With historical examples such as the Battey operation, it is no surprise that feminist historians today level charges of male physicians’ exploitation of their female patients. One of the most drastic charges claimed that most of the gynecological surgery of the late 19th century was a calculated plot against women, a tacit conspiracy between insecure husbands and anxious gynecologists.

Ann Douglas, a literary historian and feminist, was one of the earliest to invoke the notion of a conspiracy of male physicians to subject their female patients to mutilating, harmful, and unnecessary surgery. She simply dismissed 19th-century doctors as ignorant because they did not receive the kind
of medical training we have now come to take for granted. However, because the physician of 1870 did not yet have the understanding of physiology or pathology physiology enjoyed by his colleagues a century later, calling most earlier doctors ignorant, callous, or worse was not warranted.

Those with a less conspiratorial view of history have shown that other views of both husbands and male physicians existed in the late part of the last century. The economist Thorstein Veblen, for instance, believed that nonworking wives served as status symbols for their husbands rather than as threats or temptations to eager surgeons.

Women learned and taught surgery, including gynecologic procedures, at the Women’s Medical College of Pennsylvania from its founding in 1850. But it is also fair to say that there were few women actively practicing gynecologic surgery until well into this century. A notable exception was Mary Dixon Jones of Brooklyn, who by the 1890s had won respect from her male colleagues. Her story has recently been told by Regina Morantz-Sanchez, whose observations of Dixon Jones’s career help us to understand how a woman made it in a man’s world. Morantz-Sanchez, in her book about the liberal trial of Dixon-Jones in the early 1890s, charts the development of gynecologic surgery as a specialty. Dixon-Jones was unusual because she was a successful woman surgeon, but also because she was on the cusp of the developments in gynecology and its evolution from a field that viewed women in their social as well as their biological roles to a 20th-century surgical specialty that concentrated on the pathology of diseased organs and the most appropriate and effective surgical techniques.

Morantz-Sanchez nicely illustrates this evolution of gynecology by framing the developments by the textbooks of Thomas Addis Emmet and J. C. Skene of the 1880s, still using the language of women as “other” than men, with the 1909 text of Howard Kelly and Charles Noble, Gynecology and Abdominal Surgery, in which there is no discussion of women’s social roles because the focus is on surgical technique. Thus, the language of medicine can be used to trace the changes in medicine itself.

THE RELATION BETWEEN SURGERY AND GYNECOLOGY

The complex relation between general surgery and gynecology played a continuing role in the professional definition of gynecology as a 20th-century specialty. Moreover, several important contributions to surgery, such as chloroform anesthesia, rubber gloves, and early amputation, were influenced by gynecologists as well as surgeons. The latter two items are discussed subsequently.

By 1905, the Chicago gynecologist Franklin H. Martin (1857–1935) was convinced that the three closely allied fields—surgery, gynecology, and obstetrics—were making sufficient progress to warrant a new journal. There was a shared feeling, Martin wrote in the opening editorial of Surgery, Gynecology, and Obstetrics, “...that the field of the three allied specialties represented by its title is not over-cultivated, and that there is already a place for a creditable magazine representing in one publication these three divisions of surgery.”

Another of the founding editors of the journal, the gynecologist J. Clarence Webster, wrote a provocative editorial in the first issue on “The Future of Gynecology.” Webster firmly laid the ground for general surgery as a specialty. Webster assured his readers that contrary to what some had claimed, much advance had occurred in the preceding decades, and, moreover, “...it is very evident that almost all the important advances have resulted from the work of men who have given their entire energies to the specialty. At the present day the leading authorities everywhere are those who still limit their attention to this sphere of work.”

In a programmatic statement to the American Gynecological Society in 1920, Robert L. Dickinson (1861–1950) contended that gynecologists promote surgery. “But if we be just surgeons, by surgeons we may be displaced.” In this presidential address to the society, Dickinson claimed that gynecologic procedures constituted one-fourth of all surgery, but this hardly accounted for the extent of the field, “...since operation is needed by less than one-tenth of the patients that come to the doctor for ailments peculiar to women (childbearing not included).” It was true, of course, that for much of the preceding century, gynecology was a medical rather than a surgical discipline, often taught in medical schools as part of the course on diseases of women and children.

In the early decades of the 20th century, the professional battles between the general surgeons (who increasingly dominated the field of abdominal surgery) and the gynecologists (who wished to lay claim to the same territory) waxed and waned. Dr. Howard Longyear of Detroit noted in 1917 that general surgeons tended to scorn the area of the pelvis, whereas this area was being increasingly perfected by gynecologists. These surgeons wanted to move upward in the body from surgery of the female genitalia and the pelvis to the abdomen. Longyear also noted that the Sims operation for vesicovaginal fistula did more to establish operative gynecology as a specialty than did any other single procedure or development.

The complex relations between surgery and gynecology also can be traced by following the name changes in the American Medical Association specialty section. In 1903, at its founding, it was called Section on Obstetrics and Gynecology. From 1912 until 1936, it was called Section on Obstetrics, Gynecology, and Abdominal Surgery. Then the name was changed once again, dropping the abdominal surgery component.

One area of joint progress forged by surgeons and gynecologists was the introduction of the use of rubber gloves, which helped to expand the work of all surgeons. The idea of using some form of protective covering for the surgeon’s hands occasionally appeared in the medical literature in the early decades of the 19th century, but it was not until the end of the century that some of the associates of Dr. William S. Halsted (1852–1922) at the Johns Hopkins Hospital in Baltimore began to use gloves routinely. About two decades after their introduction, Dr. Halsted recalled the story:

In the winter of 1889 and 1890— I cannot recall the month—the nurse in charge of my operating room complained that the solutions of mercuric chloride produced a dermatitis of her arms and hands. As she was an unusually efficient woman, I gave the matter my consideration and arranged an interview with John Goodyear, President of the Goodyear Rubber Company to make as an experiment two pair of thin rubber gloves with gauntlets. On trial these proved to be so satisfactory that additional gloves were ordered. In the summer, on my return to town, the assistant who passed the instruments and threaded the needles was also provided with rubber gloves to wear at the operations. At first the operator wore them only when exploratory incisions into joints were made. After a time the assistants became so accustomed to working in gloves that they also wore them as operators and would remark that they
Gynecologists were also closely involved in the form of post-operative care we have now come to take for granted: early ambulation after surgery. With the change from 2 or 3 weeks of enforced bed rest after surgery to active ambulation within a few hours of the operation, we have improved recovery, shortened hospital stays, and reduced costs, as well as postoperative complications. But like all new techniques or practices, early rising after surgery did not win rapid acceptance.

Ephraim McDowell's patient in 1809 not only was ambulant early, but also engaged in physical tasks such as making her own bed. Her surgeon clearly was not pleased with her activity, which was not in keeping with customary and usual practices of the day.

What we call early ambulation was not found again in the medical literature until the very last year of the 19th century, when Emil Ries, a professor of gynecology in Chicago, published a landmark paper, which soon disappeared from view. It was rediscovered four decades later. Ries noted in his 1899 paper that he wanted to change treatment radically by freeing patients from “... many unsightly and disagreeable features of convalescence following vaginal and abdominal surgery.” Ries found that his patients could be fed and allowed out of bed much sooner than was the usual custom. “Very soon I found,” he wrote, “that the period for which it was advisable to confine such cases to bed could be counted by hours instead of days, so that of late I have allowed my patients to get up within twenty-four to forty-eight hours and to leave the hospital four to six days after their vaginal celiotomy.” These patients, Ries also noted, did not have the listlessness or muscular weakness that was usually seen after 2 or 3 weeks in bed.

In the preoperative preparation of his patients, Ries also went against the usual custom of completely emptying the bowel. Most textbooks, he said, claimed that early action of the bowels helped to prevent peritonitis. However, in most patients with an empty intestinal tract, regular movements did not resume after they were eating a regular diet. Ries maintained that cause and effect were confused because it was not movement of the bowels that prevented peritonitis, but freedom from inflammation that allowed the bowels to move.

At the meeting of the Southern Surgical and Gynecological Society in Baltimore in 1906, H. J. Boldt described 384 cases of early ambulation that he had accumulated since 1890. All recovered well. Interestingly, Boldt reported, the most serious objection raised by his colleagues was that early ambulation increased the risk of thrombosis. This was clearly wrong, he said, from both a theoretic and an empirical point of view, because patients had a better circulation from exercising.

Early ambulation was discussed repeatedly in the succeeding decades, but it received far from universal acceptance. Even Howard Kelly, the country’s leading teacher of gynecology, noted in 1911 that great progress was made as a result of Boldt’s and Ries’s work, but that it was far from standard practice. Early ambulation really became a routine practice with the exigencies of World War II (which resulted in a shortage of hospital personnel) and with the work of Daniel J. Leithauser, a general surgeon from Detroit who rediscovered Boldt and Ries.

In the 1890s, when Thomas Cullen (1868–1953) was a medical student in Toronto, he recalled that “... there were antepartum complications, anteflexions, retroflexions, and retroversions and that some of the displacements might be relieved by appropriate measures.” Abdominal gynecologic operations, Cullen continued, “... were limited almost entirely to the removal of large ovarian cysts. An occasional myomatous uterus was removed, but the fatality in this class of cases was so high that the operation was rarely attempted.” Cullen also said that he did hear of cancers of the uterus in his student days, but only cautery or curettage was performed. Entire removal of the uterus was not yet being done.

By the turn of the 20th century, the leadership of gynecology in this country had clearly moved to the new Johns Hopkins Hospital, where Howard A. Kelly (1858–1943) (Fig. 1.6) began to train a series of young men who put gynecology on a strong academic footing in the next two generations. Kelly received both his bachelor’s and medical degrees from the University of Pennsylvania. After his medical graduation in 1882, Kelly spent some time in Germany learning the latest surgical techniques.
and pathologic techniques. Back in Philadelphia at Kensington Hospital, he soon acquired a reputation as a brilliant operator. When his fellow Philadelphian William Osler became chief of medicine at the opening of the Johns Hopkins Hospital in 1889, he urged the trustees to hire Kelly as chief of obstetrics and gynecology.

At age 31, the youthful-appearing Kelly, who many patients thought was still a student or resident, initiated a residency program in gynecology with a strong link to the pathology department. Even more than half a century later, the leading texts in the field—Eastman’s (Williams’) Obstetrics, Te Linde’s Operative Gynecology, and Novak’s Gynecologic and Obstetric Pathology—were written by professors in Baltimore who had received their training at Hopkins with Kelly and his assistants.

Kelly soon found that his interests and skills were in gynecologic surgery; therefore, he turned the obstetric service over to J. Whitridge Williams (1866–1931), who became a leader in that field and the author of the most widely used textbook of the time. Kelly had a great interest in the female urinary system, realizing that the symptomatology of urinary tract disease is often intertwined with that of the reproductive organs. He invented the air cystoscope and devised ureteral catheters. He was the first to plicate the vesical sphincter for stress incontinence of urine. Physicians from all over the world came to Baltimore to watch him operate (Figs. 1.7 and 1.8).

Kelly’s legendary operative skill was well described by Cullen, who later became one of Kelly’s outstanding residents and successors to the chair at Hopkins. Kelly and Hunter Robb,
his earlier resident, went to the Toronto General Hospital not long after Kelly became chief at Hopkins. Cullen was an intern in Toronto at the time and handled the instruments during an operation that Kelly and Robb had agreed to perform. Cullen’s description speaks for itself:

I turned around to thread a needle and when I turned back found to my amazement that the operator had the abdomen open. Operators in the General often took ten minutes to get that far. After cutting through the skin, fat and fascia they were apt to get lost in the muscles. Kelly and Robb working together used dissecting forceps as I had never seen them used. One man pulling each way, the cleavage between the muscles was seen at once and the opening in the abdomen could be completed without difficulty. I watched, fascinated, while Kelly went ahead and finished that operation and did the second, working with clock-like precision and at a speed I had not imagined possible. By the time he had finished, the course of my professional life was decided. Up to that afternoon I had intended to be a physician. From that afternoon I knew I had to be a surgeon.

Chance often determines the course of one’s life, so it was fortunate for Cullen that he had to wait 6 months for his residency with Kelly to start. He used this time to begin the study of pathology with William H. Welch at Hopkins, and it was the close alliance of gynecology and pathology, begun by Kelly and continued by Cullen, that shaped the careers of many future gynecologists at Hopkins and elsewhere and determined the course of the field itself.

In 1898, Kelly published a two-volume textbook called Operative Gynecology, certainly the direct ancestor of the volume you have in your hands. Kelly wrote in the preface, “My aim in writing this book has been to place in the hands of the many friends who have from time to time visited me and followed my work, a convenient summary of the various gynecological operations I have found best in my own practice.”

Although gynecology at the end of the last century was still a very young science, in Kelly’s words, change was at hand: “Although I have spent several years in the preparation of my book, so rapid have been the changes in the gynecological field that I have found it necessary to rewrite some of the chapters two and even three times.” A little more than a dozen years later, in the preface to his text entitled Medical Gynecology, Kelly reiterated the pace of the changes: “What a transformation two generations have witnessed in the field of gynecology! From modest beginnings, as a sort of minor specialty coupled with diseases of children and often professed by general practitioners with no special training, it has grown to the dignity of a major surgical specialty, so extensive that many gynecologists of today [1912] claim the entire field of abdominal surgery as their proper domain by right of discovery and conquest.” This was also a time when radical or complete removal of tumors and repair of hernias became increasingly common. Kelly and his residents were pioneers in radical hysterectomy when Hugh Young of Hopkins introduced radical prostatectomy.

What imparted even greater value to all of Kelly’s texts were the illustrations of Max Böttel, a German medical illustrator brought to Hopkins by Kelly (Fig. 1.9). Böttel’s contributions to operative gynecology, including Te Linde’s text 50 years after Kelly’s, were portraits of operative techniques, pelvic anatomy, and pathologic conditions. He set a standard for medical illustration never attained before or surpassed since.

As long ago as 1905, in his classic text, Cancer of the Uterus, Thomas Cullen, student of and successor to Kelly (Fig. 1.10), wrote that “The number of cases of cancer of the genital tract coming too late for operation is so appalling that the surgeon
General Topics Affecting Gynecologic Surgery Practice

Herbert Traut (1894–1963) published their seminal monograph entitled Diagnosis of Uterine Cancer by the Vaginal Smear. Papanicolaou had worked on this technique since the 1920s, but, like many other innovations in medicine, it took years to find widespread acceptance. Further publications by Papanicolaou and others, notably Ruth Graham, demonstrated beyond a doubt that cytologic studies could almost unfailingly detect cervical cancer.

Cancer in situ was recognized early in the century by Cullen and in 1912 by J. Schottlander and F. Kermanner, but its relation to invasive cancer was not well understood. This relation was more clearly described in 1944 by G. A. Galvin and Te Linde. Since then, the relation has been amply confirmed, and early cervical cancer has become a detectable and curable disease. Since its inception by Hans Hinselmann in Germany in the 1920s, colposcopy has given a new dimension to the assessment of cervical carcinoma, making blind, random cervical biopsies unnecessary and providing more accuracy in finding and treating localized lesions.

By the early 1970s, the editor of a new journal, Gynecologic Oncology, pointed out that "...the scientific importance of gynecologic oncology may be gained from the observation that the tumors that we study and treat are prototypes for cancer in other areas of the body, for the histogenesis of the two principal uterine cancers is probably understood better than that of any other tumor in the body."

The immediate post–World War II years were a period of truly astounding medical developments and saw the explosive growth of medical research funding and new hospital construction. After 1945, penicillin became available for civilian use, and this was soon followed by other antibiotics. Hormone replacement became increasingly possible, and in 1946, the year that Richard Te Linde published the first edition of this textbook, Congress passed the Hill-Burton Act, making federal money available for new hospital construction.

Although the emphasis of this historical chapter is on developments before the introduction of laparoscopy, the ability to visualize and subsequently to intervene by the less invasive laparoscopic technique surely represents an important milestone in the history of operative gynecology. The details of the history of the various endoscopic possibilities are discussed in the chapters devoted to these techniques, but a few general historical reflections may be in order at this point.

Laparoscopy seems to have been developed more or less independently in the United States and in various countries in Europe. In 1911, Bertram Bernheim, a general surgeon at Johns Hopkins, reported two cases in which, through a small abdominal incision, he introduced a proctoscope to examine the upper abdomen in a procedure he called organoscopy. The source of the illumination was an incandescent light on a band around his head. The experience must not have been satisfactory, as there were no follow-up reports.

In the mid-1930s at the same Johns Hopkins, in a trial of a small series of patients that was never published, Richard Te Linde introduced a Kelly air cystoscope into the abdomen through a small subumbilical incision with the patient in a deep Trendelenburg position. The Kelly air cystoscope was simply a 10-cm-long tube, which came in various diameters up to 2 cm, with a flange at the distal end and a suitable handle. It was routinely used at Hopkins to examine the bladder. The patient was in the knee-chest position for the cystoscopic examination. The bladder distended with air and when the instrument, which normally was also a part of the instrument, was removed. The light source was an incandescent bulb placed just above the patient's buttocks and a conical head mirror with a central hole to direct the light along the line of sight. The illumination was very good with this technique. Although the pelvic organs could be seen with the introduction of the cystoscope into the abdomen, the area of inspection was so small that the concept was abandoned.

It is curious indeed that Te Linde apparently did not think of introducing the cystoscope through the posterior fornix with the patient in the knee-chest position, especially as this was the exact position used to cystoscope the bladder with the Kelly cystoscope and was a technique commonly and frequently used at Johns Hopkins during this era. At that time, female urology was part of the division of gynecology.

It remained for Albert Decker with T. H. Cherry to use the knee-chest position to introduce a lens cystoscope with a miniaturized incandescent bulb at the tip through the posterior fornix to visualize the pelvic organs. Thus, culdoscopy was born and was widely used in the United States during the era of 1950 to 1970, especially after the adoption of the fiberoptic cold light system, which gave far better illumination than the miniaturized incandescent bulb. During this era, it was not unusual at Johns Hopkins to have five or six patients per day listed in the operating room for a culdoscopic examination.

After about 1970, laparoscopy, with its fiberoptic cold light system, superseded the culdoscopic approach. About this time, operative laparoscopy blossomed, and one of the first widely used procedures was the ligation of the fallopian tubes by various techniques.

In Europe, in contrast to the United States, there was no great use of the culdoscope. The development of observational and operative laparoscopy continued uninterruptedly from about 1912, when, according to Cohen, the Swedish Hans Christian Jacobaeus described 109 laparoscopies in 69 patients using an electric cystoscope. As previously mentioned, the historical details of procedures are included in the appropriate chapters. However, two general observations may be made.

First, developmental progress in endoscopy of the abdominal cavity has been a function of development of the physical sciences: optics, mechanics, electronics, etc. Thus, the current popular robotic laparoscopic procedures resulted not only from medical ingenuity but from participation of the capitalistic industrial complex. The consequence of this is that the use of the laparoscopic instrumentation is greatly encouraged by commercial interests. The danger is—if there is a danger—that physicians may be unduly influenced by commercial as opposed to scientific priorities.

Second, the laparoscopic operative procedures have been widely adopted, often without randomized clinical trials to scientifically define and evaluate their role in operative gynecology.

These two points are made as an observation and not necessarily as a criticism, as the advantages of a shortened hospital stay and less patient discomfort are obvious. However, the fact is that there are few data on the short- and long-term results that are designed to evaluate results from laparoscopy with alternate procedures. The adoption of laparoscopic operative procedures progressed in spite of the recent emphasis on the importance of evidence-based medicine. Rock and Warshaw have elaborated on this aspect of operative laparoscopy.

THE BEGINNING OF THE ERA OF LAPAROSCOPY

Although the emphasis of this historical chapter is on developments before the introduction of laparoscopy, the ability to visualize and subsequently to intervene by the less invasive laparoscopic technique surely represents an important milestone in the history of operative gynecology. The details of the history of the various endoscopic possibilities are discussed in the chapters devoted to these techniques, but a few general historical reflections may be in order at this point.

Laparoscopy seems to have been developed more or less independently in the United States and in various countries in Europe. In 1911, Bertram Bernheim, a general surgeon at Johns Hopkins, reported two cases in which, through a small abdominal incision, he introduced a proctoscope to examine the upper abdomen in a procedure he called organoscopy. The source of the illumination was an incandescent light on a band around his head. The experience must not have been satisfactory, as there were no follow-up reports.

In the mid-1930s at the same Johns Hopkins, in a trial of a small series of patients that was never published, Richard Te Linde introduced a Kelly air cystoscope into the abdomen through a small subumbilical incision with the patient in a deep Trendelenburg position. The Kelly air cystoscope was simply a 10-cm-long tube, which came in various diameters up to 2 cm, with a flange at the distal end and a suitable handle. It was routinely used at Hopkins to examine the bladder. The patient was in the knee-chest position for the cystoscopic examination. The bladder distended with air and when the instrument, which normally was also a part of the instrument, was removed. The light source was an incandescent bulb placed just above the patient's buttocks and a conical head mirror with a central hole to direct the light along the line of sight. The illumination was very good with this technique. Although the pelvic organs could be seen with the introduction of the cystoscope into the abdomen, the area of inspection was so small that the concept was abandoned.

It is curious indeed that Te Linde apparently did not think of introducing the cystoscope through the posterior fornix with the patient in the knee-chest position, especially as this was the exact position used to cystoscope the bladder with the Kelly cystoscope and was a technique commonly and frequently used at Johns Hopkins during this era. At that time, female urology was part of the division of gynecology.

It remained for Albert Decker with T. H. Cherry to use the knee-chest position to introduce a lens cystoscope with a miniaturized incandescent bulb at the tip through the posterior fornix to visualize the pelvic organs. Thus, culdoscopy was born and was widely used in the United States during the era of 1950 to 1970, especially after the adoption of the fiberoptic cold light system, which gave far better illumination than the miniaturized incandescent bulb. During this era, it was not unusual at Johns Hopkins to have five or six patients per day listed in the operating room for a culdoscopic examination.

Aafter about 1970, laparoscopy, with its fiberoptic cold light system, superseded the culdoscopic approach. About this time, operative laparoscopy blossomed, and one of the first widely used procedures was the ligation of the fallopian tubes by various techniques.

In Europe, in contrast to the United States, there was no great use of the culdoscope. The development of observational and operative laparoscopy continued uninterruptedly from about 1912, when, according to Cohen, the Swedish Hans Christian Jacobaeus described 109 laparoscopies in 69 patients using an electric cystoscope. As previously mentioned, the historical details of procedures are included in the appropriate chapters. However, two general observations may be made.

First, developmental progress in endoscopy of the abdominal cavity has been a function of development of the physical sciences: optics, mechanics, electronics, etc. Thus, the current popular robotic laparoscopic procedures resulted not only from medical ingenuity but from participation of the capitalistic industrial complex. The consequence of this is that the use of the laparoscopic instrumentation is greatly encouraged by commercial interests. The danger is—if there is a danger—that physicians may be unduly influenced by commercial as opposed to scientific priorities.

Second, the laparoscopic operative procedures have been widely adopted, often without randomized clinical trials to scientifically define and evaluate their role in operative gynecology.

These two points are made as an observation and not necessarily as a criticism, as the advantages of a shortened hospital stay and less patient discomfort are obvious. However, the fact is that there are few data on the short- and long-term results that are designed to evaluate results from laparoscopy with alternate procedures. The adoption of laparoscopic operative procedures progressed in spite of the recent emphasis on the importance of evidence-based medicine. Rock and Warshaw have elaborated on this aspect of operative laparoscopy.
Knowledge of the history of operative gynecology is not only of intrinsic interest but also allows us to appreciate our innovative predecessors and may stimulate some of us to be the subject of future historians.

OPERATIVE GYNECOLOGY, FIRST EDITION, 1946

Richard Wesley Te Linde was born in Wisconsin in 1894 and, except for the years that he attended a small liberal arts college in Holland, Michigan, he spent all his formative years in Wisconsin. When he was ready to go to medical school, he went to Madison, but in 1916, the University of Wisconsin had only a 2-year school. Te Linde completed the 2 preclinical years and then transferred to Johns Hopkins for the final 2 years. He graduated with the class of 1920 and spent the rest of his professional career associated with Hopkins, where he became chief of the gynecology division of the department of surgery and then chair of the separate department of gynecology in 1939. He held that post until his retirement in 1960, when the newly reunified department of obstetrics and gynecology was reestablished.

Just as his teacher Howard Kelly had felt the need to compile a textbook of operative gynecology half a century earlier, Te Linde believed that the many-sided specialty that gynecology had become by World War II required a new text. With Kelly’s earlier text as a model, Te Linde wished to incorporate the vast changes that had occurred in the period separating the two books. During this 50-year span, there were changes in our knowledge of hormones, new surgical techniques, and the ability to visualize the abdominal and pelvic organs.

Te Linde chose the same simple title for his own text. Although Kelly’s had been published by Appleton in New York, Te Linde chose Lippincott in Philadelphia. Gynecology, Te Linde wrote in the preface in 1946, was no longer to be considered simply a branch of general surgery. The gynecologist, he stressed, must still be a good surgeon but must also master the pathology of gynecologic disorders and the newly burgeoning field of endocrinology. New books were appearing in all these fields except gynecologic surgery, and it was the void that Te Linde wished to fill.

Te Linde wrote his text with the “… primary purpose of describing the technique of the usual and some of the rarer operative procedures. It also includes indications for and against operations as well as pre- and postoperative care of patients.” Gynecologic pathology, Te Linde stressed in the Hopkins tradition, is the bedrock of good gynecologic surgery. “Without an understanding of it, surgery becomes merely a mechanical job, and errors in surgical judgment are inevitable.” In the organization of his text and in the subsequent editions over the succeeding half century to the present edition, one can readily see important landmarks in the history of operative gynecology. Some of these were discussed in a previous section.

The 751-page first edition of 1946, all of it written by Te Linde, had a first printing of 5,000 copies, which quickly sold out. A second printing was equally successful. The reviews have always been laudatory. Of the sixth edition of 1985, edited by Richard Martingly and John Thompson, the Journal of the American Medical Association reviewer ended by saying, “I cannot imagine any gynecologist who performs surgery doing without it, first as a primer and then as a reminder.” By 1962, when the third edition appeared and Te Linde had retired from the chairmanship of his department, he decided that, like all the other major medical textbooks of the time, his book needed a group of authors to bring out new revisions. In the preface to that edition, he states that his book has never been simply a manual of surgical technique—that surgical philosophy is equally important. “What does it profit a woman if the operation is technically perfect and the procedure unnecessary or even harmful?” One reason unnecessary procedures still prevailed, Te Linde noted, was the lack of knowledge of gynecologic pathology, still the “bedrock upon which good surgery is done.” Therefore, Te Linde justified including a considerable amount of pathology in his text. Pathology is what has differentiated gynecologic surgery from general surgery since Howard Kelly’s years at the turn of the 20th century. Surgeon and gynecologic texts, and by implication their surgical readers, have generally not devoted nearly as much attention to pathology as have gynecologists, some of whose leaders have actually been very well versed in pathology.

The fact that Te Linde could produce three editions, each larger than the first, is a testament to his broad knowledge of his field, his ability as a writer, and his stamina for hard work. He died in Baltimore in 1989 at the age of 95.

In the decades since the third edition of 1962, the world of medicine and the society in which it is practiced has seen much change. By the mid-1960s, when significant advances in the treatment of infections, malignancies, and hormonal disorders had become evident, these successes had an impact on gynecology just as they did in other areas of medicine. The reduction in mastoid infections, for instance, has changed the practice of the otolaryngologist considerably. In gynecology, the reduction in major pelvic inflammatory disease forced gynecologists to focus more of their attention on other disorders. Also affecting gynecologic surgery by the middle of this century were significant improvements in obstetric practices, which sharply reduced injuries to the bladder and rectum. Hysterectomy and suspensory operations were not performed for vague symptoms of illness as often as they had been.

We have also lived through social revolutions that have changed the way our society carries on its business and dispenses its social prerogatives. Especially prominent in the 1960s, a civil rights movement, greater concern for our environment, a resurgence of consumer rights, and a revitalized women’s movement profoundly affected our social institutions, including medicine. Within medicine, no specialty has been more touched by these trends than obstetrics and gynecology.

The new feminism viewed abortion, childbirth, contraception, and gynecologic surgery as a means of social control of female patients by doctors, most of whom were men. The feminist movement challenged not only the domination of doctors but also the supposed benevolence of their knowledge and practice.

As the world has changed, so have our expectations. In the decades after the first edition of Te Linde’s book appeared, when wonder drugs were touted as curing previously untreatable illnesses, the public began to expect much from its doctors, and we were not shy in claiming that ever-greater investments in medical research would lead to more cures. It is hardly surprising, then, that in those last few decades, as we began to spend increasing amounts of our gross national product for health, those who paid the bill became increasingly interested in seeing just what their money was actually buying. Like most other social institutions, medicine lost much of the autonomy it had for so long taken for granted. Although as a profession we did not want the public to know exactly how much money we were making, we were now willing to tolerate efforts for decades amazingly adept at preventing those things we did not want. Now that, too, has changed, as has the practice of medicine.
The division of labor in all areas of medicine grew as the 20th century progressed. In the last decades of the century, what used to be called general practice became the specialty of family practice. In the Anglo-American world of the late 20th century, both gynecology and obstetrics were caught in the middle of the battles between specialists and generalists. Likewise, they became involved in the tensions among primary, secondary, and tertiary medical care. Similar strife occurred in earlier centuries among those vying for a place and for status among physicians caring for women in childbirth and in disease. If one looks at the table of contents of this edition and compares it with a similar sample of period of half a century ago, one will see what great breadth the field of operative gynecology continues to enjoy.

CHAPTER 2 ■ THE ETHICS OF PELVIC SURGERY
RUTH M. FARRELL, ELI A. RYBAK, AND EDWARD WALLACH

DEFINITIONS

Autonomy—The concept describing an individual’s self-determination and the right to direct his or her own life through his or her own decisions, actions, and beliefs.

Informed consent—A process of communication between a physician and a patient that addresses the risks, benefits, and alternatives of a proposed medical intervention while meeting the core criteria of competence, exchange of information, understanding of exchanged information, and voluntary authorization.

Nonmaleficence—Literally translated as “do no harm,” this concept describes the need to both prevent harm and refrain from harmful acts.

Beneficence—The duty to do good on the behalf of others through an active promotion of the good of the patient and shelter from harm.

THEORY AND PRACTICE OF ETHICS IN MEDICINE

The practice of medicine is governed by a system of beliefs that guide the actions of physicians and other health care professionals to act and make decisions that are regarded as ethically acceptable. Throughout the practice of medicine, different sets of standards and concepts of ethically acceptable behavior have existed as the predominant code for health care professionals. Codes such as those set by the Hippocratic oath served as the mainstay of professional behavior for centuries until a different system took its place in the first half of the 20th century. This transition is a reflection of changing societal values of health and well-being that evolved over time as a result of political, cultural, scientific, and technological advancement. The field of bioethics emerged in the 1950s. Before that time, ethical principles of the Hippocratic oath were regarded as the ethical standards for medicine. The guiding principle of physician action was primum non nocere—first do no harm. In the Hippocratic tradition, the model of paternalism structured the therapeutic relationship. The physician was designated as the most qualified person to make decisions about treatment options for a patient. As such, it was the physician’s judgment that determined what was to be considered as harm or benefit resulting from a medical procedure, not that of the patient or the patient’s family. This was based on the belief that only an expert in science and medicine was qualified enough to make the best choice among treatment options for patients. During a time when medical therapies were limited and choices were few, this was not viewed as a problematic approach to patient care. However, as changes in society, science, and medicine unfolded, patients and the general public began to question these traditional views of the physician-patient relationship.

With the introduction of significant scientific and cultural revolutions that characterized the post–World War II period in the United States, these standards set by the Hippocratic oath were considered to be ineffectual to meet the growing demands of medicine and ethics. Movements advancing civil rights, women’s issues, and the growing recognition of individual rights and autonomy dominated the social climate. Carried over into medicine and science, a new set of health care innovations introduced new moral debates to society and the medical profession about the purpose of medical care, the definition of health, and the ability of mankind to regulate the physiology of the human body. The birth control pill, organ transplant, and dialysis are just a few examples of the significant life-altering innovations of the time. The ethical questions raised in response to the cultural and scientific climate challenged the previous notions of ethical behavior of physicians. In particular, the notion that physicians were the most appropriate members in the therapeutic relationship to make choices for the patient was rejected. Decisions about the vast array of available medical therapies and choices seemed inherently incongruent with the concept of paternalism. With the rise in the importance of autonomy and individual rights, society campaigned to replace the paternalistic structure of medicine with a model that established the patient as the primary decision maker.

This movement resulted in the establishment of a system of principle-based ethics as the driving force behind modern medicine. In 1977, the Belmont Report outlined what these standards, also known as principles, should be. This massive effort to reshape modern bioethics resulted in the establishment of the following principles as the cornerstone of contemporary medical ethics: autonomy, beneficence, nonmaleficence, and justice.

Autonomy—The concept of autonomy embodies the ideal of self-determination—that a person shapes his or her own life through his or her own decisions, actions, and beliefs. As such, individuals have the right to make decisions about their lives that reflect their own beliefs of well-being and values. Inherent in the principle of autonomy is the requirement that others (i.e., physicians) must respect a patient’s right of self-determination.

Nonmaleficence—Nonmaleficence, defined as “do no harm,” has its origins in the original tenets of the Hippocratic oath. This principle encompasses both the need to prevent harm and to refrain from harmful acts.

Beneficence—The definition of the principle of beneficence is to do good on the behalf of others. In the case of the principle of beneficence, physicians are expected to actively promote the good of the patient, not just shelter him or her from harm. Though this may seem to be a subtle
distinction from the principle of nonmaleficence, it is criti-
cal to the principle-based theory of ethics, as it requires the
performance of positive acts to advance the well-being of
others.

Justice—The principle of justice addresses the need to
treat all persons fairly. In the case of health care, this per-
tains to both the physician–patient relationship and also the
public health obligation of physicians in the allocation of
scarce medical resources.

In this principle-based ethics model, all four core elements hold,
in theory, equal importance. In many of the clinical situations
that physicians currently address, the solution to complex eth-
cical dilemmas requires the balancing of these principles and,
only times, a prioritization of one over the others. An example
of this is in an emergent medical situation when the principle
of beneficence may temporarily override autonomy. However
these principles are weighted, they must, ultimately, must be
used in a way that results in medical choices serving the good
of the patient by reflecting his or her values and beliefs.

Though the system of principle-based ethics as established
by the Belmont Report is the forerunner of ethical standards
of behavior in modern medicine, other legitimate models of
bioethical theory exist. They are broad in nature and are guid-
ing principles, but all come from the view that the system of
principle-based ethics does not offer enough to guide behavior
in the complex setting of health care. Two examples of this are
feminist ethics and casuistry. Feminist ethics is based on the
notion that decisions are made in the context of relationships
and personal virtues, such as compassion, friendship, and love.
Principle-based ethics does not take these factors into consider-
ation, neglecting the problems raised in a society in which men
and women are not viewed as equals and, as a result, does not
serve the interests of the patient. A second example is casu-
istry, or case-based ethics. This theory is founded on the prin-
ciple that moral lessons gained from the resolution of actual
cases in medicine have more value than a set of theoretic and
unchanging principles. Using this model, ethical reasoning re-
sults from weighing the outcomes of real cases as examples and
forming a set of modifiable principles from those conclusions.

These are just two examples of the diversity of ethical theories
that guide medicine and serve as solutions to ethical puzzles
that cannot be solved using the standard principle-based ethics
commonly in place today.

The very nature of the field of obstetrics and gynecology sets
the stage for a variety of ethical dilemmas. Issues surrounding
the beginnings of human life and reproductive function natu-
really facilitate profound and often controversial questions and
debate. In addition, the women’s rights movement has raised
other issues specific to the care of women, such as subjugation
and control of women’s bodies through society and medicine.

Despite this broad range of issues, ethical discussions in ob-
stetrics and gynecology are often perceived in terms of a sin-
gle controversial issue: abortion. Yet the field of bioethics in
women’s health has a rich and broad set of important impli-
cations for the practice of medicine and the health of women.

Recent advances in medicine and science have introduced novel
therapeutic options to many of the conditions that gynecolo-
gists face on a daily basis, such as cervical cancer, fibroids, and
infertility. Genetic and pharmaceutical therapies, new diagno-
sic modalities, and noninvasive surgical options set the stage
for a multitude of multifaceted ethical questions and debates.

This chapter will present some of the foundational concepts in
bioethics and women’s health that serve as a launching point
for addressing the more complex and novel ethical issues as they
arise in the present setting of medicine and the future.

THE PATIENT’S AUTONOMY AND
INFORMED CONSENT

Autonomy is one of the four cornerstones of the physician-
patient relationship. Informed consent is a mechanism whereby
the autonomy of a patient is recognized, respected, and pre-
served in health care decisions. It is the result of a process
whereby a patient makes a voluntary decision to proceed with
a medical intervention with a good understanding of the nature
and risks of the procedure, in addition to alternative therapies
if the procedure is declined. The respect of informed consent
has two purposes. On the one hand, the process of achieving
informed consent respects and recognizes the patient’s auton-
omy as a good in and of itself. On the other hand, patients
benefit when they make decisions on their own behalf because
they themselves are the most familiar with their own values, be-
liefs, and ideas of well-being and health. When patients make
informed and voluntary decisions about their health care, they
can make choices that meet their concept of good and benefi-
cial.

The term informed consent has legal and ethical dimensions.
Legally, informed consent can be viewed as an end point. The
legal requirements of informed consent are met when the con-
versation between the physician and the patient is documented,
either on an informed consent form or in the medical record.

Often, getting a signature on a form is synonymous with achiev-
ing informed consent, but informed decision making goes well
beyond the legal form. Ethically, informed decision making
involves a process of communication between the physician
and the patient, through which the patient is able to make an
autonomous decision either to authorize the intervention (in-
formed consent) or reject the intervention (informed refusal).

The legal and ethical dimensions of informed consent are of-
ten used interchangeably but can have very different meanings
and implications. Unfortunately, the function and meaning of
informed consent is often misinterpreted, and it is viewed pri-
marily as a legal document with a patient’s signature denoting
full understanding and authorization. It is important to keep in
mind that both the legal and ethical requirements of informed
consent are essential in health care. However important legal
documentation is, it should always be placed before the ethical
duties to the patient. Legal documentation in a chart or on a
form is not a substitute for the process of communication and
autonomous decision making. It is important to keep in
mind that not all legal documents with a patient’s signature
reflect that an adequate informed consent process has taken
place.

A valid informed consent is both informed and au-
tonomously authorized. To achieve this, the physician must en-
sure that five core components are met in the decision-making
process: (i) competence, (ii) voluntariness, (iii) disclosure, (iv)
understanding, and (v) authorization or refusal. These core
components serve as a guide for physicians when discussing
medical interventions with patients to ensure that a patient
makes the most appropriate decision possible. Without satis-
fying all five of these core components, an adequate informed
consent process has not been achieved.

Competency

In the usual clinical setting, other than situations involving
formal psychiatric evaluation, the determination of compe-
tence tends to be more of a working judgment than a formal
assessment. Often the terms competence and decision-making
Informed refusal can be defined as the decision of the patient to decline the proposed medical intervention, even when the decision is made against the recommendation of the physician. Informed refusal is the decision by a patient to refuse treatment, even when the decision is made against the recommendation of the physician. It is not sufficient merely to meet the criteria of decision-making capacity, disclosure, and understanding. The patient must make a decision based on an understanding of the information provided. It is not sufficient to mention or list the possible risks, including the possible risks to an intervention. The patient must comprehend the ramifications of these risks when considering whether he or she believes it to be harmful or incongruous with his or her personal beliefs.

A balance must be met between respect for the autonomy of the patient and the physician’s duty to beneficence. It is the job of the physician to be as certain as possible that this decision is informed and consistent with the values and beliefs of the patient. In situations when the refusal may result in significant impairment, pain, or death, the physician should make every attempt to ensure that these decisions are consistent with the patient’s beliefs and have been so over time. Physicians may still be considering their patient’s best interest by giving preference to his or her spiritual or personal convictions over the medical good. Another important aspect of informed refusal is that it can occur either at the initiation of a treatment or later during the course of the treatment. This becomes apparent when a patient refuses to continue a treatment or undergo a similar or identical intervention. The willingness of the patient to undergo a therapy in the past does not mean that consent is implied in the future.

There are circumstances when a physician must proceed with a medical intervention without the informed consent of the patient. Generally, these circumstances involve emergent situations. For example, the patient may be suddenly incapacitated or unconscious and therefore incapable of providing any sort of autonomous authorization. Alternatively, the patient may be conscious and otherwise able to make decisions but, because of the emergent and critical nature of her condition, it is medically necessary to initiate an immediate intervention, and there is no time to engage in a discussion with the patient. In the first situation, there may be time to obtain authorization from an appropriate family member or designated medical decision maker. In the second situation (and sometimes in the first), there is no time, and the physician must make a decision on behalf of the patient. This decision should be made based on what is judged to be in the medical best interest of the patient and usually assumes most people would opt on the side of instituting lifesaving measures.

Informed consent plays a vital role in the practice of obstetrics and gynecology because this field of medicine pertains to the anatomy and function of the women’s reproductive system and sexuality. Issues specific to women’s health have been brought to the forefront because of concerns of historical control and subjugation of women and their bodies through society and medicine. In addition, there is a growing trend to recognize the vital role of relationships in a patient’s medical decision making about reproductive issues. Patients rarely make decisions about their sexuality and reproduction in a vacuum but instead do so within the context of relationships with others, whether friends, partners, or families. It is critical to recognize these qualities inherent in obstetrics and gynecology when obtaining informed consent for a medical therapy or procedure to maximize the autonomous expression of the patient’s personal preferences.

**ETHICAL ISSUES IN SURGICAL TRAINING**

Competence of the surgeon is a moral commitment to the patient, especially before undertaking a novel surgical procedure.
Adequate preparation in the basic and clinical sciences and training in surgical techniques must have been accomplished before any new surgical procedure is introduced into clinical medicine. An illustrative example of an overenthusiastic rush into a procedure was the sudden popularity of cardiac transplantation in the 1960s. The preparatory laboratory work in cardiac transplantation started in 1953, but the first successful experiment by Dr. Christian Barnard took place in 1960. Immune suppression, which is crucial to the procedure, was introduced in 1918, and long-term survival of grafts occurred by 1965. T. H. H. H. heart transplantsations had been performed by 64 surgical groups in 22 countries. Most patients improved briefly and then died of rejection of the transplant or infections. In 2 years, the procedure was largely discredited, and it took more than 10 additional years to reestablish wide acceptance of the operation. This experience illustrates the need to limit difficult and complex procedures to specialized centers that have the resources and adequately trained surgeons to perform them.

This is equally true for complex pelvic surgery. The advent of subspecialty boards by the American Board of Obstetrics and Gynecology, each with requirements for postresidency fellowship training and evaluation standards for certification, have helped to emphasize the need for specialized training in surgical techniques for pelvic surgeons. The rapid expansion of the use of laparoscopic surgery training procedures means the responsibility of providing future obstetricians and gynecologists who are technically skilled to serve society effectively and safely. In addition to underlying knowledge, clinical experience, training, and practice, the competent surgeon operates with the attentiveness and focus commensurate with the surgical task. In surgical settings, legitimate concerns regarding the potential impairment of overfattigued house staff managing and operating on patients have facilitated changes in house staff work hours and training. Training programs are now charged with the simultaneous challenge of vigilantly protecting the welfare of the patients from potentially suboptimal care while ensuring that those surgeons, after completion of training, operate competently under emergent and suboptimal conditions.

Many surgeons trained before World War II participated in residency programs affiliated with large inner-city hospitals where patients without adequate resources or health insurance received care. It was accepted that these patients would receive treatment or even surgery by physicians-in-training (including senior medical students, interns, and residents), preferably under the supervision of skilled volunteers or paid clinical faculty and only when the trainee had reached the necessary level of competence. When health care became an entitlement under Medicare and Medicaid government-funded health insurance became more prevalent, many patients sought the services of private physicians. The so-called free care or resident services were often unable to recruit sufficient patients to provide adequate training for new surgeons. This was peculiarly true in pelvic surgery; given the choice, these patients sought treatment from the clinic, where privacy and dignity were hard to maintain, and fled in large numbers to private doctors’ offices. Surgical teaching thereafter often involved the private patient, with the resident now performing complete procedures.

The problem with this arrangement was that patients were either poorly informed or uninformed about the participation of physicians-in-training, and thus often became apparent only when complications arose or the medical records were reviewed during litigation. Although patients are typically better informed now, it remains ethically necessary to inform them about teaching or training in each case so that objections can be dealt with before the planned procedure or other arrangements made. Most surgeons involved in teaching programs inform their patients that surgery demands a team effort and that residents may be involved in assisting or operating with them, but that, as the private surgeons of record, they not only will be present but also will be in charge and responsible for everything that takes place during the procedure. Teaching should not take place in the operating room without such a disclosure and the patient’s informed consent. The resident’s role, status, and experience should be clear to the patient. We are long past introducing medical students to patients as doctors rather than revealing their actual status.

Because of the limitation on the number of hours a doctor in training may work, producing competent surgeons today has become even more challenging than in the past. This situation has necessitated approaches to supplement and amplify the residency program specifically as it affects surgical training. Novel training methods designed to accelerate the learning curve have been devised. These are directed at familiarizing the trainee with instrument handling and the handling of surgical instruments, improving manual dexterity, sharpening hand-eye coordination, and heightening awareness of pelvic anatomy. In addition, decision-making skills and essentials of emergency management need to be developed during the course of residency training. One of the valuable approaches that has recently been resurrected is the animal surgical laboratory. Obviously, the size of structures in laboratory animals does not precisely simulate that in humans, and anatomic relationships do not reflect those of a human patient. Simulators for endoscopic surgical procedures use mannequins or human models. Fabricated pelvic models are used to teach and practice skills for simulating maneuvers for normal and operative delivery. These innovative exercises assist in preparing the student for experiences encountered in the operating room and may even succeed in refreshing the already practicing surgeon in performance of specific techniques. The final arbiter for gaining surgical skills is the surgical procedure itself, carried out in actual patients under the guidance and supervision of an accomplished surgeon who has the ability to communicate effectively about both the procedure and techniques. The only way to learn to manage surgical complexities adversity is through personally encountering such complications while under the direct tutelage of a preceptor who has himself experienced these very complications. Simulated programs have also been developed that incorporate computerized lessons for improving history-taking skills and for simulating emergency management in the form of skill stations.

In addition to foundational medical and surgical knowledge, clinical experience, training, and practice, the competent physician must act in a responsible and professional manner, whether in the clinical or surgical setting. Impairment of a physician’s skills must be fully evaluated so that he may be given assistance to improve and injury to his patients is avoided. Health care institutions must have peer accessible mechanisms in place to facilitate this process.
medical students were performing preoperative pelvic examinations on anesthetized patients without having obtained specific prior consent, and, because of public concern, both the American College of Obstetricians and Gynecologists (ACOG) and the Association of American Medical Colleges released statements emphasizing the predominance of patient autonomy and appropriate informed consent over the exigencies of medical education.

In actual practice, examination under anesthesia (EUA) is routinely performed only by members of the surgical team to enable better appreciation of the patient's pelvic anatomy. The surgical team typically numbers between one to four members; at its largest, it includes an attending surgeon, senior resident, junior resident/intern, and medical student. Although the major portions of the surgery are performed by the senior experienced surgeons, the junior assistants, such as the medical student, perform the essential and ancillary tasks of retraction, exposure, and minor suturing.

The ACOG statement issued in 2003 noted: ‘If a pelvic examination that is planned for an anesthetized woman undergoing surgery offers her no personal benefit and is performed solely for teaching purposes, it should be performed only with her specific informed consent, obtained when she has full decision-making capacity.’ One can legitimately argue that all surgeons and surgical assistants, including the medical student, require maximum appreciation of the surgical field to optimize their performances during the procedure. Accordingly, the pelvic examinations should not be construed as offering “no personal benefit” to the patient. Furthermore, the EUA should not be considered as separate from the rest of the procedure but as a necessary adjunct. This ability of the members of the house staff that provide intraoperative and postoperative assistance should not be curtailed by exclusion from an essential component of the gynecologic procedure.

At least three steps can be taken to ensure that the rights of the patient are respected while ensuring appropriate surgical care: (i) explicitly incorporating the EUA on the operative consent form, (ii) openly discussing with the patient the importance and participation of all team-members in the EUA, and (iii) ensuring an atmosphere of patient respect and dignity by agreeing in advance to a specific number of pelvic examinations.

MEDICAL LEGAL ASPECTS OF GYNECOLOGIC CARE

In addressing the issue of professional liability among obstetricians and gynecologists, the ACOG survey in 2003 indicated the mean number of claims among practicing obstetricians/gynecologists during their professional careers to date was 2.6. Of the respondents to the survey, 76% had experienced one or more claims. Obstetricians and gynecologists pay among the highest premiums for professional liability insurance of all medical specialties. In many states, this factor has led to early retirement, elimination of obstetric and/or surgical procedures from practice, or relocation to another state. Being named in a malpractice suit leads to endless hours of effort unrelated to medical practice, undesired anxiety, and, in some instances, withdrawal from practice. A number of factors contribute to the cost of insurance premiums. Obstetricians and gynecologists can exercise control over some of these factors to minimize the chances of being cited in a claim. Two simple principles are helpful in preventing a legal claim or in providing a defense should a claim be filed. These two concepts form the basis of all risk-management and loss-prevention strategies. Plaintiffs and defense attorneys have reached consensus that two factors, documentation and communication, improve the odds that a lawsuit will not be filed or that a lawsuit, once filed, can be successfully defended.

By way of documentation, the following basic and simple initiatives should be a component of each physician’s protocol for charting and record keeping.

1. Recording of date and time of each entry in the chart
2. Legible handwriting
3. Contemporary entry of all notes in the chart
4. Appropriate correction of inaccurate entries
5. Avoidance of conflict among physicians and nurses in the charting of patient information

The altruism with which a physician responds to a patient’s symptom or concern can be established with certainty if notes are complete, properly dated, and timed. This chronology is instrumental in establishing a timeline for a patient’s care and will be more credible in a courtroom or in a hearing than a plaintiff’s client’s recollection weeks or months after the fact. Because an adverse surgical outcome is not synonymous with negligence, expression of reasons for clinical judgment in choice of a diagnostic or treatment plan demonstrates that alternatives have been considered by the physician. The physician should document these alternatives in the chart and indicate that they were each discussed with the patient before treatment.

Entries in the chart should clearly demonstrate the course of care rendered and rationale underlying the choice of a specific treatment plan. These notes should be legible and interpretable by anyone who reviews the chart. An inability to read one’s own handwriting can only negatively affect the physician’s credibility. The time frame of management is crucial, and proper recording of events will prevent doubt when events occurring before a complication are documented only after the complication has occurred. Notations regarding telephone conversations with consulting physicians or family members should also be entered in the chart with the date and time of contact. An incorrect entry in the chart should be corrected properly by striking out the erroneous entry and initialing and dating the changes. If a supplemental note is written, it should be listed as an addendum. A patient’s chart should not be used as a vehicle for expressing opinions on the intelligence of or decision rendered by another health care provider or for the purpose of criticism.

When an unanticipated adverse event occurs, the insurance company or risk-management representative should be notified promptly. The communication of a physician with legal and/or insurance representatives and health care providers is important in anticipating legal problems. However, a cornerstone of medical care is the physician’s sensitivity in communicating with the patient with understanding and compassion. She should be given ample time to ask questions, and these inquiries should be answered truthfully. Breakdown of communications in the physician-patient relationship is a recurring theme in the pathway leading to litigation.

A physician may appear in court to testify in three possible scenarios: as a defendant, as a material witness, or as an expert witness on behalf of either the plaintiff or the defendant. Although each instance has its unique aspects, in all cases the physician will have an opportunity to prepare the testimony with the attorney who is trying the case. As a defendant at either a sworn deposition or in a courtroom, the physician will have received general and specific instructions from the attorney representing him/her with regard to how
to respond to questions. Each response should be concise, to the point, and directed only at the specific question raised by the plaintiff’s attorney. Most of all, the answers must be honest and forthright, as well as accurate with respect to the patient’s clinical course and management as described in the medical records. The defendant should request the opportunity to view the medical record at any time should there be need to recall specific details such as dates, times, and sequences of events.

A physician may be called as a material witness because of his/her association with the specific case as a participant or observer, but not as a defendant. The same principles of demeanor apply as for an appearance as a participant. Second, the expert witness is called on to do so because of his/her personal experience and training with the particular clinical situation under consideration. The role of an expert witness carries with it significant responsibilities. First and foremost is the possession of knowledge, skills, and experience to fulfill this role. Second, the expert witness should be objective and unbiased, and able to discuss standards of care on a broad scale rather than be constrained by his/her personal approach. It is clearly unethical for an expert witness to lack the appropriate credentials and/or to misrepresent the standard of care reflected in the case for which he/she is testifying. Fundamentally, standard of care refers to a level of care that is generally thought to represent the norm. Standard of care rendered in specific conditions may differ from one locale or group of physicians to another, simply because standards are arbitrarily developed and not universally held. If an adverse event occurs, a distinction must be made between a bad outcome that is independent of the quality of rendered care and a bad outcome that is clearly due to negligence or substandard care.

A number of safeguards exist to protect patients from faulty or unethical clinical practice. At the local level, hospital credentials committees, as required by the Joint Commission on Accreditation of Hospitals and Health Care Organizations, are given the responsibility for reviewing the credentials of applicants for initial and continuing staff privileges. This responsibility mandates attention to the volume of cases attended and the quality of care rendered. Privileges can be curtailed for performance of specific procedures or may be suspended for practice in general in cases in which the physician provides inappropriate care or exhibits ethical infractions. The American Board of Obstetrics and Gynecology credentials specialists and subspecialists on the basis of training, experience, and performance on examinations. Over the past three decades, a periodic reexamination is required for maintenance of specialty certification. This maintenance-of-certification process involves evaluation of performance on didactic examinations and assessment of cognitive skills. Recently, the Accreditation Council for Graduate Medical Education (ACGME) and the American Board of Medical Specialties (ABMS) have stressed the importance of education and achievement of core competencies (patient care, medical knowledge, communication, decision-making, practice-based learning and improvement, and systems-based practice). In addition, certifying boards require proof of licensure in good standing for certification and recertification. State medical societies are empowered to review patients’ complaints and charges of unethical behavior of physicians. The National Practitioners Data Bank receives and makes available data regarding infractions of practice standards. This device was established by Congress to prevent physicians with past disciplinary action and malpractice awards from relocating from one state to another without detection.

Unfortunately, there are too few safeguards aside from legal observation that can monitor surgical technique and/or interaction with patients. The physician’s ability to practice safely and effectively is implicitly implicit in day-to-day behavior and self-assessment. A recent publication that addressed the issue of discipline action against physicians with unprofessional behavior in medical school emphasized the importance of professionalism as a core competency. The conclusion in the report was that disciplinary action among practicing physicians by state medical licensing boards correlated strongly with a history of unprofessional behavior in medical school. The strongest association was in those who had demonstrated irresponsible behavior or diminished ability to improve their behavior as students earlier on.

PRIVACY AND THE HEALTH PORTABILITY AND ACCOUNTABILITY ACT

In 1996, Congress passed the Health Insurance Portability and Accountability Act (HIPAA), establishing minimal national standards to ensure confidentiality of protected health information (also referred to as individually identifiable health information). This move was due, in part, to the mainstream use of electronic technology in health care, which promoted concern over patient confidentiality. The subsequent additions to the original HIPAA provisions included the Privacy Rules, extending jurisdiction to health plans, billing services, hospitals, and individual health care providers. At the time of compliance deadlines, all of these covered entities were required to implement the established standards to protect patients’ individually identifiable health information. The caveat to the Privacy Rules was that the protection of patients’ privacy could not negatively interfere with the quality of care or create unnecessary burdens to patient care.

Quoting from the guidelines published by the Centers for Disease Control and Prevention and the U.S. Department of Health and Human Services (DHHS), the HIPPA Privacy Rule:

- Gives patients control over their health information;
- Sets boundaries on the use and release of health records;
- Establishes appropriate safeguards that the majority of health care providers and others must achieve to protect the privacy of health information;
- Holds violators accountable with civil and criminal penalties that can be imposed if they violate patients’ privacy rights;
- Strikes a balance when public health responsibilities support disclosure of certain forms of data;
- Enables patients to make informed choices based on how individual health information may be used;
- Enables patients to find out how their information may be used and what disclosures of their information have been made;
- Generally limits release of information to the minimum reasonably needed for the purpose of the disclosure.
Generally gives patients the right to obtain a copy of their own health records and request corrections; and
Empowers individuals to control certain uses and disclosures of their health information.

The complexity of the HIPAA regulations has made their implementation challenging and controversial. Specific confusion regarding disclosures to family members about, particularly in cases when the patient has authorized his or her family to be an active participant in health care. This also arises among health care providers when seeking information about their patients to provide continuity of care. Ultimately, HIPAA does afford latitude to professional judgment as to the “best interests” of the particular patient, so long as the disclosures conform to the “minimum necessary standards.” In addition, the Privacy Rule does not replace federal or state laws and makes an allowance for individual institutions to adopt more stringent policies to protect patients’ privacy.

CONFIDENTIALITY

The foundation of the physician-patient relationship is trust. This is based on the premises that a patient has the right to privacy and respect of privacy allows for patients to disclose the necessary information to be assisted by their physician. This is particularly relevant in gynecology, in which patients share sensitive information with their physicians about intimacy and sexuality. For this reason, confidentiality is one of the most essential aspects to the successful therapeutic relationship.

It is the exception, more than the rule, for patient confidentiality to be violated. Tension and ambiguity, however, have long surrounded the parameters wherein breaches of patient confidentiality are justified. The Code of Ethics of the American Medical Association (AMA), revised in 1957, stated:

“A physician may not reveal the confidences entrusted to him in the course of medical attendance, or the confidences he may observe in the character of patients, unless he is required to do so by law or unless it becomes necessary to protect the welfare of the individual or of the community.” Exceptions to the breach of confidentiality include times when the withholding of information may harm a third party or threaten public health. Mandatory exceptions include cases of violence and voluntary crime and the neglect and abuse of individuals, including women, children, and the elderly. Some states also require mandatory reporting of infectious diseases that may pose a serious public health risk, such as certain sexually transmitted diseases and tuberculosis. A notable case of the need to violate patient confidentiality is Tarasoff v. Regents of the University of California. In this case, a court found the University of California negligent for failing to forewarn murder victim Tatiana Tarasoff and her family after Prosenjit Poddar confided in one of his therapists that he intended to kill her. Two months after the temporary detainment of Poddar for this initial threat, he acted on it by murdering Tarasoff. As the majority opinion in the 1976 Tarasoff case emphasized: “The protective privilege ends where the public peril begins.”

Gynecologists are confronted with a variety of complex and difficult scenarios in the clinical and surgical arenas when it comes to maintaining or breaking patient confidentiality. In this setting, physicians must balance their legal obligations with their professional duties, a hospital ethics committee may be required to intervene. Ultimately, however, in the absence of a counter-balancing public health or legal mandate, the obligation of patient confidentiality predominates.

ETHICAL ISSUES IN RESEARCH ON HUMAN SUBJECTS

Although the Nuremberg medical war crimes trials of Nazi doctors and the ensuing Nuremberg Code in 1949 represent a landmark in research ethics involving human subjects, they made little impact on research practices in the United States. Biomedical research expanded exponentially after World War II without significant regulation or oversight. The Nuremberg Code established the need for the “voluntary consent of the human subject.” It covered such other matters as the need to justify a study in terms of expected beneficial results and risks, avoiding harm and injury to subjects, freedom for the subject to withdraw, and obligation of the investigator to stop a study if continuation would likely cause injury, disability, or death.

In 1966, the U.S. Public Health Service introduced the requirement that all human subject research funded by the government must be peer reviewed by a local institutional review board. The objective was to protect the rights of the individuals involved and review the quality of the informed consent and the risks and benefits of research. This regulation was the result of a growing awareness that these kinds of safeguards often were not followed even in the best academic institutions in the United States.

Indeed, in 1966, Dr. Henry K. Beecher, professor of anesthesiology at Harvard University, published an article in the New England Journal of Medicine describing ethically troubling studies from prestigious institutions published in reputable journals. One disturbing publication described transplantation of a malignant melanoma from a terminally ill daughter to her consenting mother to look for tumor antibodies. The mother died of diffuse melanoma just more than a year later.

Several unethical studies reached the attention of the public during the 1960s and 1970s. In the Willowbrook study, for example, new residents on admission to an institution for the retarded were infected with hepatitis virus to study the course of the disease and search for a vaccine. Of highest notoriety was the Tuskegee study, which was organized by the U.S. Public Health Service to follow the natural history of syphilis in a cohort of 400 rural African American men. The lack of meaningful informed consent in 1932, when the study began, and the subsequent withholding of penicillin treatment until the study was exposed and halted in 1972 shocked the public and spurred Congress into action. The end result, as described above, was the issuance of the Belmont Report and its articulation of the prevailing principles of bioethics: autonomy, justice, and beneficence.

Federal regulations mandate the creation of ongoing institutional review boards (IRBs) with appropriate oversight of human subject research. Pursuant to the doctrine of autonomy, informed consent procurement is now a formalized process. In randomized controlled trials, potential participants must be notified of the risks, benefits, and alternatives to the care provided
Extensive, confidential preoperative counseling to ascertain
preoperative consultation with the anesthesiologist.
Consultation, as needed, with the hospital ethics committee.

INFORMED REFUSAL AND THE
JEHOVAH’S WITNESS PATIENT

Founded in the late nineteenth century, the Jehovah’s Witness
community is governed by the Watchtower Society, which is-
sues doctrinal positions via its official journal, the Watchtower.
On July 1, 1943, an article in that journal established the famil-
iar Jehovah’s Witness prohibition against blood transfusions.
The biblical sources cited—Genesis 9:4, Leviticus 17:13–14,
and Acts 15:19–21—are understood by conventional Juda-
Christian theology as proscriptions against consuming the
blood of animals. Nevertheless, Jehovah’s Witnesses forbid
transfusion of whole blood or of any of its components:
packed red blood cells, platelets, and white blood cells. The penalty
for transgression is severe: eternal damnation and, more im-
mEDIATELY, social ostracism and “disfellowshipping” by other
Witnesses. In the June 15, 2004, edition of the Watchtower,
however, explicit clarifications were issued revealing that trans-
fusion of fractionated components of plasma, packed red blood
cells, platelets, and white blood cells were permissible and sub-
ject to the individual’s discretion.

The wrenching ethical quandary arises when a Jehovah’s
Witness patient asserts her autonomy to refuse transfusion,
thereby risking exsanguination during surgery or from med-
ical conditions such as dysfunctional uterine bleeding. Could
or should physician beneficence override a competent patient’s
refusal of treatment? When locked in conflict, which bioethical
principle prevails: autonomy or beneficence? In these instances,
it is also important for physicians to consider the concept of
good and well-being from the perspective of the patient. Physi-
cians often are in situations in which they cannot provide med-
cal beneficence, but that does not prevent them from assisting
in spiritual or emotional beneficence. In the case of a Jehovah’s
Witness, a physician may appeal to the principle of beneficence
while withholding treatment at the request of a competent
patient.

American courts have not reached consensus concerning the
withholding of blood products for Jehovah’s Witnesses, but
several dominant trends appear. Surgeons who choose to re-
spect the wishes of a competent Jehovah’s Witness patient to
refuse blood products in the face of imminent exsanguination are
not considered negligent, provided that the patient is not at risk of
dying from a wrongful death lawsuit. Likewise, courts generally endorse a patient’s right to refuse treat-
ment. However, when the patient has dependents who would
be otherwise abandoned, or in obstetric situations in which the
fetal well-being will be placed in jeopardy, courts have inter-
vened to order transfusions.

From an ethical perspective, a gynecologist contemplating a
surgical procedure for a Jehovah’s Witness should take the
following steps to ensure that the patient and surgical team
are prepared for the potential decision to withhold blood products:

■ Extensive, confidential preoperative counseling to ascertain
informed consent. Specifically, the surgeon should verify the
patient’s understanding and acceptance of Watchtower soci-
ety doctrine, understanding of the potential repercussions of
refusing transfusion, and the patient’s views of discordant
views of Jehovah’s Witnesses. This should be thoroughly documented
in the chart. In cases in which the patient’s decision-making
capacity may be in question, the physicians should request
additional professional input from a psychiatrist.

■ Consultation, as needed, with the hospital ethics committee.

■ Preoperative consultation with the anesthesiologist.

There are several prophylactic steps that can be taken to
avoid the likelihood of a transfusion. These include pre-
operative iron and/or recombinant erythropoietin therapy
and intraoperative use of vasopressor, volume expanders,
hypotensive anesthesia, hypothermia, and ligation of major
vessels.

ADVANCED PLANNING AND END-OF-LIFE DECISION MAKING

Policies and regulations regarding death and dying have been
set largely by the courts on a case-by-case basis when in-
tractable controversies have arisen with doctors, patients, pa-
tients’ families, or hospital administrators that must be re-
solved before a judge. The introduction of life-sustaining
technology—such as the respirator that can keep the human
body functioning biologically even in cases when the prospect
of a return to normalcy is unlikely—has introduced a host of
dilemmas and questions about medical decisions at the end
of life. When terminally ill patients, their families, and their
health care teams all agree on the use and withholding of treat-
ment at the end of life, there is usually no overt dilemma, except
the question of the prudent use of scarce resources. When there
is agreement among all parties, there is seldom a need to go to
court, and courts discourage bringing these cases before them.

When there is disagreement among the patient, the patient’s
family, the physician or team of physicians, and/or the hospi-
tal, the stage is set for conflict that often must be decided by
an arbitrator. The courts have traditionally provided guidance
in these types of cases. However, these rulings often are not
universal and are influenced by contemporary public attitudes.

Although not every case and its outcome are comparable, the
general consensus is that the patient’s autonomous choices are
binding and that the ultimate goal of medicine is not to preserve
life at any cost, but to relieve pain and suffering in keeping with
the patient’s wishes.

Since the development of these life-sustaining interventions,
there have been several landmark cases: Karen Ann Quinlan,
Nancy Cruzan, and Terri Schiavo. Each of these cases rep-
resents a different scenario in which physicians and family
members struggle to make difficult decisions in surrogate for
their loved one. The situation of Karen Ann Quinlan was an
example of the type of disagreement that can occur between
a patient’s family and the providing health care institution.
Karen Ann Quinlan was a 21-year-old woman who had been
be...
in a prolonged coma and sustained on a respirator. When the
likelihood of recovery disappeared, her family’s request to re-
move the respirator was challenged by the hospital. The courts
ultimately ordered the removal of the respirator, and she died
10 years later.

In the case of Nancy Cruzan, a difficult decision had to be
made when the wishes of the patient were unknown. Nancy
Cruzan suffered a myocardial infarction resulting in se-
vere cerebral cortex injury leaving only minimal brain stem
function intact. At the time of this initial event, Schiavo did
not have a living will or written documentation of her medical
care wishes. Her husband and parents worked together to care
for her with the hope that she would recover all or part of her
cognitive functions, having a feeding tube inserted and placing
her in a skilled nursing facility. Eight years later, Terri’s husband
came to the conclusion that her status had not and would not
improve. Stating that his wife had previously expressed her
wishes to not live under such circumstances, he appealed to
the court to take on the role of the ward’s surrogate to re-
move the feeding tube and allow her to die. A court order to
remove the feeding tube in April 2001 was immediately fol-
towed by an appeal by her parents claiming that they had evi-
dence that Schiavo would want to live. Furthermore, they be-
lieved that novel medical therapies would be able to improve
Schiavo’s condition and restore some of her ability to function.
They based this on the belief that Schiavo was conscious and
responsive and, given the ability to speak for herself, would
express her desire to live.

In response to this new information, the court reversed its
inguad clinic. In 1990, Terri Schiavo suffered a myocardial infarction resulting in se-
vere cerebral cortex injury leaving only minimal brain stem
function intact. At the time of this initial event, Schiavo did
not have a living will or written documentation of her medical
care wishes. Her husband and parents worked together to care
for her with the hope that she would recover all or part of her
cognitive functions, having a feeding tube inserted and placing
her in a skilled nursing facility. Eight years later, Terri’s husband
came to the conclusion that her status had not and would not
improve. Stating that his wife had previously expressed her
wishes to not live under such circumstances, he appealed to
the court to take on the role of the ward’s surrogate to re-
move the feeding tube and allow her to die. A court order to
remove the feeding tube in April 2001 was immediately fol-
towed by an appeal by her parents claiming that they had evi-
dence that Schiavo would want to live. Furthermore, they be-
lieved that novel medical therapies would be able to improve
Schiavo’s condition and restore some of her ability to function.

ETHELICAL CHALLENGES SPECIFIC TO GYNECOLOGIC CARE

Several issues specific to the care of women and their re-
productive health are ethical dilemmas unique to gynecology.
These include abortion, examination under anesthesia before
surgery, and assisted reproductive technologies. In each case,
the nuances of addressing the health care issues of women
require additional consideration to ethical topics mentioned
above.

Abortion

The termination of pregnancy is encountered in a variety of
settings in obstetrics and gynecology. A patient may seek an
abortion for a broad spectrum of circumstances, ranging from
an unintended and undesired pregnancy (failure or nonuse of
birth control, sexual assault, failure of emergency contracep-
tion), severe fetal anomalies (aneuploidy, congenital abnormal-
ites incompatible with life), or threatened maternal health (pre-
eclampsia, severe hyperemesis gravidarum, cardiomyopathy).
Because of the many diverse clinical scenarios for the termina-
tion of a pregnancy, it benefits physicians to be aware of the
issues surrounding abortion, whether or not they have personal
objections to the procedure.

The core ethical and legal issues surrounding abortion in-
clude the right of the woman to control her own body and
reproduction, the moral and legal status of the fetus, the rights
and interests of the fetus to be protected from harm, and the
degree to which outside parties such as national and state
governments have authority in the protection or restriction of
these rights. These issues tend to divide the general public and

who are terminally ill and suddenly incapacitated. These are
referred to as advanced directives, and they include a vari-
ety of different mechanisms whereby a patient can direct his
medical care in the case of his sudden or gradual decline in
decisional capacity. The different forms of advanced directives
include:

- Durable power of attorney for health care—This is a
  legal document in which a patient designates a specific in-
dividual to make health care decisions in the setting of loss
of decisional capacity.

- Living will—This is a legal document in which the pa-
tient describes his/her treatment preferences in the setting
of decisional capacity, such as the continuation of nutrition, hydration, or ventilator support.

- Health care proxy (attorney-in-fact for health care)—
This is the individual designated by the patient to make
surrogate decisions in the case of loss of decision-making
capacity.

- Do not resuscitate (DNR)—This is one type of advanced
directive that specifically directs the withholding of lifesav-
ing procedures in the case of cardiopulmonary arrest, such
as cardiopulmonary resuscitation and dehilation.

Gynecologists should familiarize themselves with different
forms of advance directives and the applicable laws. They
should also discuss these issues with their patients and their
families to ensure that the best arrangement can be made. The
ideal time to do this is preferably before such decisions are
actually needed for implementation, such as before significant
illness or surgery.
government into two polarized camps: prolife or prochoice. Because of the two extremes of positions that exist in the debate about abortion, very little headway has been made to find a common ground since the beginning of abortion law in the United States.

The two major legal cases that have shaped most abortion law in the United States in the past century are Roe v. Wade and Planned Parenthood v. Casey. Although these deicides do not encompass all laws pertaining to abortion, they are the two most well known and influential. In 1973, Roe v. Wade recognized the following rights: the fundamental right of privacy, protection of an individual’s bodily integrity, and protection of an individual’s decisional autonomy. The rights outlined in Roe v. Wade were weighed against the interests of the state in terms of the protection of a potential human life and the health of the mother. However, Roe v. Wade did not address questions such as the moral or legal status of the fetus. Under these three rights, the Supreme Court interpreted the Constitution as granting significant protections to an individual’s right not to have a child. As such, a woman’s choice to terminate a pregnancy was given to her and not to the government. At the same time, the Supreme Court recognized the states’ interests in protecting both women’s health and the potential life of the fetus, giving the individual states the authority to enact laws imposing strict safeguards and even restricting procedures.

Roe v. Wade also accomplished several other legal milestones. It set out to limit states’ restrictions on a woman’s right to terminate a pregnancy by instituting a “strict scrutiny standard.” By this standard, individual states that proposed laws such as mandatory husband consent requirements and mandatory waiting periods were determined to be unconstitutional. In addition, Roe v. Wade established a trimester framework for evaluating the extent of the state’s interests in abortion law. During the first trimester, the woman’s interests had precedence above the interests of the state to protect the potential life. During the second trimester, a woman’s privacy interests and the state’s interest in the protection of the woman’s life and the potential life of the fetus were balanced. After the time of viability, the state’s interest in protecting the potential life had priority unless the life of the woman is at stake. Minors were also addressed under the Roe framework. Under Roe v. Wade, minors were required to inform or involve their parent or guardian in the decision to terminate the pregnancy. In cases when this was not possible, either because of fear of the consequences of disclosure or an unavailable guardian, minors were required to obtain a waiver of parental involvement mandate from the court, also known as a judicial bypass. Finally, Roe v. Wade placed federal and state limitations on the use of public funding of abortions for Medicaid patients.

Planned Parenthood v. Casey (1992) reaffirmed the central tenets of Roe v. Wade but changed the law significantly by removing the trimester framework based on the notion that it did not adequately recognize the state’s interest in the potential life before viability. Under Casey, the state’s interests take priority from the outset of pregnancy, not just during later gestations, and, as such, states were permitted to make laws to restrict abortion in the process of protecting their interests. These individual state-by-state laws were constitutional only if they met the “undue burden” standard. Under this, the state’s restrictions could not place an undue burden on the woman to make a decision to terminate a pregnancy, such as a restriction that has the purpose or effect of placing a substantial obstacle in the path of a woman seeking an abortion of a nonviable fetus. Many states have interpreted “undue burden” in different ways, creating restrictions—such as increased parental involvement, mandatory waiting periods, and counseling biased toward continuing the pregnancy—that are deemed constitutional.

Abortion is one of the few medical procedures from which physicians may opt out in nonemergent situations because of ethical or religious objections. Under this situation, legislatures have recognized that physicians may legally refuse to provide abortion services. “Conscience” or “refusal” clauses make abortion services one of the few areas in which a physician legally may opt out of performing a medically indicated procedure because of personal objections; however, the scope of such rights to opt out differs from state to state. Legally, under the protections of conscientious objection, no physician is required to do a procedure if it is in conflict with his or her ethical, moral, or religious beliefs. This applies only in situations in which the patient’s life is not at stake. In cases when the life of the woman is threatened by the ongoing pregnancy and no other providers are immediately available, a physician cannot refuse to treat the woman.

The statutes of conscientious objection do not exempt physicians from making a responsible, truthful, and timely referral to another practitioner or health care facility that provides the service or from rendering care in a life-threatening emergency when an alternate health care provider is not available. Failure to provide an appropriate referral can constitute malpractice (i.e., fall below the legal standard of care) and also may violate ethical standards of care. Many states have patient abandonment laws that put specific burdens on physicians to refer or transfer care of patients before terminating a relationship. At minimum, the physician is expected to guide the patient to valid resources to find an abortion provider.

The most recent debates about abortion pertain to the issues of partial birth abortion and RU-486. Partial birth abortion is a nonmedical term sometimes referring to a particular abortion procedure known as intact dilation and extraction (intact D&E) or D&E—which is a variant of the more common procedure known as dilation and evacuation (D&E)—and including procedures that would be used for terminations in the early second trimester, beginning at 13 weeks of gestation. Many professional organizations for women’s health have rebuked the validity of the partial birth bans. Legislation addressing partial birth abortion has been described by ACOG as “inappropriate, ill advised, and dangerous” because “intact D&E may be the best or most appropriate procedure in a particular circumstance to save the life or preserve the health of a woman, and only the doctor, in consultation with the patient, based upon the woman’s particular circumstances, can make this decision.” Arguments against partial birth abortion have been criticized for being simply a rhetorical strategy to place greater restrictions on the present abortion statutes. To date, all proposed bans on partial birth abortion have been deemed unconstitutional because it does not make exceptions for the health of the woman. The issue is still in question as an appeal to these rulings is expected.

A second area of controversy addresses new agents that facilitate access to abortion. In 2000, the Food and Drug Administration (FDA) approved mifepristone, also known as RU-486, for pregnancy termination. RU-486 had been established as a safe method of pregnancy termination in Europe for several years before it was marketed in the United States. However, the controversy that surrounded the introduction of this country by several years. Concerns about increased access and ease to abortion services fueled much of the debate. Despite this, RU-486 has been accepted as a safe
and effective option to women considering termination of a pregnancy.

CONCLUSION

This chapter has presented a sample of the issues pertinent to the practice of gynecology. As a field that combines the challenges of medicine, surgery, and the complex issues specific to the care of women and their reproductive health, there are several other important ethical aspects that have not been addressed here. In addition, innovative technologies and therapeutic procedures present new dilemmas to the practicing physician on a regular basis. Physicians have many resources with which to approach some of the difficult questions that may arise in their own practices. Institution or individual practice ethics committees, oversight committees, and ethics consult services are available for multidisciplinary and peer review of challenging ethical cases. Physicians at all levels of practice should feel confident to turn to these mechanisms for guidance in the case of difficult ethical situations.

BEST SURGICAL PRACTICES

- Informed consent is a mechanism whereby the patient’s autonomy is respected.
- Physicians are responsible for maintaining medical and surgical competence.
- The confidentiality of the patient should be protected. Only in special circumstances can it be overridden.
- Physicians should be familiar with the different forms of advance directives and discuss end-of-life decision making with their patients.
- Gynecologists should be aware that several issues specific to the care of women and their reproductive health present ethical dilemmas that are often unique to gynecology.

CHAPTER 3 ■ PSYCHOLOGICAL ASPECTS OF PELVIC SURGERY

BETTY RUTH SPEIR

DEFINITIONS

Anxiety—A feeling of apprehension, uncertainty, and fear without apparent stimulus and associated with physiological changes (tachycardia, sweating, tremor, etc.).

Grief—The normal emotional response to an external and consciously recognized loss; it is self-limited, gradually subsiding within a reasonable time.

Insanity—Mental derangement or disorder. The term is a social and legal rather than medical one, and indicates a condition that renders the affected person unfit to enjoy liberty of action because of the unreliability of his behavior with concomitant danger to himself and others.

Regression—A return to a former or earlier state; a subsidence of symptoms or of a disease process; the turning backward of the libido to an early fixation at infantile levels because of inability to function in terms of reality.

PSYCHOLOGICAL ASPECTS OF PELVIC SURGERY

Neuroscientific research over the past decade continues to validate the oneness of the psyche and soma. Gynecological surgery does not simply alter the soma, but temporarily and sometimes permanently alters the psyche of the patient.

The modern gynecologist needs to be more than a skilled technician and must be willing and able to identify the potential psychological effects of the surgery performed and be prepared with the knowledge and skills to address these effects with the patient.

The technological revolution has presented today's surgeon with a vast array of sophisticated equipment. In capable hands, miraculous surgical feats can be performed on a woman's body, but at what cost to her psychological self? The removal or reconstruction of diseased or dysfunctional anatomy may set off a chain reaction of parallel events in a woman's psyche.

For a surgeon, the gynecologic operation may be an ordinary event of usually simple dimension. For the patient, each procedure is a unique experience. Her sense of well-being and health may be threatened. She may lose control over her body for some indefinite period of time. She may perceive the planned procedure as temporarily or even permanently affecting her sexual identity.

As complicated procedures become routine, the surgeon risks losing perspective about the impact of surgery on the life of the individual woman. The patient who experiences ablative genital (or breast) surgery is strongly influenced by her emotions. These vary in degree but are usually cumulative. As the patient passes through the presurgical, surgical, and postsurgical experiences, she may be stressed beyond her capacity to compensate. If help is not available to facilitate emotional healing and rehabilitation, permanent psychological damage may result.

The majority of women do heal and take up their lives, raise their children, work at their jobs, and relate well to their husbands or lovers. For them, the healing interval is relatively quick, and the stress is modest. Do not underestimate what can be learned from this segment of psychologically healthy women patients. In the 1940s, Abraham Maslow studied people with exceptional mental health to develop his hierarchy of needs theory. He discovered that these people's potential had never been weakened by negative thinking, destructive outlook, or destructive self-image. "The rest of us," he declared, "exist at a lower level because someone or thing has implanted notions of limitations."

Once you become cognizant of the success statistics in your own patient population, you may discover why most women recover after gynecologic surgery to zestfully reembrace life, whereas others begin to slowly turn away from its possibilities.

It will never be enough for a surgeon to be a trained mechanic, able only to diagnose and repair. He or she must also be prepared to predict, recognize, and begin treatment of the psychological consequences of gynecologic disorders. This chapter is designed to help surgeons and other physicians better understand the female perspective and to use that knowledge to facilitate multidimensional healing.

ANKH

The ankh cross, Egyptian emblem of generation, symbol for life and soul and eternity, is a mark universally designated to depict feminality (Fig. 3.2). By using this hieroglyph, modern scientists continue an ancient tradition of respect and reverence for women. Within the inner sanctum of every woman's mind lie symbols that are powerful and personal. These feminine identity markers are guarded and guided by her instincts, and no surgeon can successfully maneuver in this labyrinth of psychological and psychosexual emotion and cause no harm unless the female patient acts as a guide.

Egyptian writings from 2,000 years ago in the Kahan Papyrus depict the uterus as having an important and powerful effect on mental life, and current research tends to agree with the ancient scribes. The uterus has great symbolic value for many modern women, too. Beginning with the rite of passage called menstruation, a strong invisible bond is formed between a woman and her body. Her biological clock has been set. For the next 40 years or so, she will be reminded each month that...
she is a woman, and menstruation is regarded by many as palpable proof of their femininity.

Others believe that menstruation is part of a natural cleansing cycle that purges the body of poisons that accumulate during the month. They know from experience that the premenstrual symptoms of edema, bloating, headaches, and emotional tension will be washed away in the tide of their monthly flow.

For some, the rhythm of the menstrual cycle is used as a way to time and order their lives. Like the phases of the moon, this cycle bestows a sense of routine, regularity, and predictability that has emotional significance. With the onset of menstruation, a woman is forever changed. Surgical removal of any of the reproductive organs will change her again, but how?

The effect of a woman’s menstrual cycle on many medical conditions is well documented. Medical suppression of ovulation is commonly used as a way to evaluate and treat such chronic conditions as migraine headache, epilepsy, asthma, rheumatoid arthritis, irritable bowel syndrome, and diabetes. Research at the National Institutes of Health and other leading institutions has shown “how nerves, molecules and hormones connect the brain and immune system, how the immune system signals the brain and affects our emotions, and documents how our brain can signal the immune system, making us more vulnerable to illnesses.” What we have known intuitively is now understood scientifically. Hormones secreted during a woman’s menstrual cycle affect her mood. Could the decline of these hormones during the natural aging process contribute to dementia? The future is alive with fascinating neuroscientific and neuroimmunomodulation elucidation, but today’s woman is backlit by the skepticism of some scientists. Her concerns about her body and the way it will work after surgery are immediate and quite often heartrending.

A woman about to undergo a hysterectomy might wonder if her lover will be able to detect the absence of her uterus. After the surgery, will she be thought of as less of a woman? Will her partner abandon her for someone who is still complete, either in the sense of being able to offer the possibility of a child or complete in the sense of having experienced no unnatural surgical transformations?

Will orgasm be as pleasurable for her after the surgery? For many women, the uterus has symbolic significance as a sexual organ. The uterus contracts during orgasm. Some women perceive this as most pleasurable. If the patient believes the uterus is essential to sexual response, then, in fact, it often becomes so, and women with this mind-set may become sexually dysfunctional when it is removed.

Once the procedure is accomplished, will she still look and sound like a woman, or will she become noticeably more masculine? For others, the uterus is closely tied to feelings of attractiveness and sexual desirability. To a few women, removal of the uterus or ovaries or both constitutes a desexualizing, a permanent destruction of female identity and function. Sadly, certain members of the medical community as well as the feminist community perpetuate this notion and increase the attendant fear when they refer to women who must have their ovaries removed as castrates.

Some women become distressed when they learn they must deal with the certainty of absolute sterility. For those who choose motherhood, the uterus, ovaries, breasts, and vagina work in harmony with other factors to attract a necessary mate and get down to the business of creating new life. These organs become vital coconspirators in the sexual and reproductive aspects of a woman’s life. Impending loss of these physical structures because of disease or dysfunction sometimes creates deep anger that must be resolved before surgery is attempted. Many women who have all the children they want and who do not wish to get pregnant again are still sometimes disturbed by the finality of the decision. The gynecologist should assure these
maternal women that, although they will no longer be able to conceive a child, the powerful urge to create will never leave them. In time, they will learn to direct this primal energy to other areas of their lives and be immensely satisfied with the results. Studies such as the ENDOW Study: Ethnicity, Needs and Decisions of Women—a 5-year, three-phase, multicenter collaboration—are focusing on many of these issues and will help the gynecologists better understand their patients.

Today’s modern woman, for the most part, is an avid information seeker. She surfs the Internet, buys the latest books, reads magazine articles, and conducts in-depth interviews with peers who have experienced similar gynecologic problems. A certain proportion of the harvested material is useful to her and perhaps even illuminating for the physician, but unfortunately, some of the sources are inherently flawed, prejudicial, illogical, or without scientific basis. It is the physician’s responsibility to separate the grains of truth from the chaff. All the information she has gathered represents her attempt to prepare herself psychologically for the ordeal ahead, and she must never be condemned or made to feel small for trying to protect herself. For the gynecologist, it is not necessary to change a patient’s basic attitude or feelings. It is, however, vital to acknowledge them. The right information, reassurance, and support usually quickly modify many negative factors and lead to a healthier attitude and understanding of the surgical process. It is crucial that the patient be allowed to vent her anxiety and speak of her fears.

COMMUNICATION

Patients in General

Diplomats the world over understand the significance of effective communication. Indeed, the prospect for world peace depends on their ability to interact efficiently. A female patient’s psychological hearing before, during, and after the gynecologic procedure can depend on the communication techniques used by her physician. You must establish rapport, speak of the real and present danger to her health, and then elaborate on your plans to protect her.

Whenever possible, provide pleasant surroundings where you and your patient can comfortably hold a private conversation. Push all other thoughts out of your mind. These few minutes belong exclusively to her, and the quality of the time you spend actively communicating will pay healthy dividends for you both.

Whether explaining the simplicity of a needle-directed breast biopsy or the intricacies of hysterectomy, you must be able to highlight the technical details of the procedure and its postsurgical realities in a nonthreatening but utterly truthful manner. Begin the presentation using simple but thorough explanations and examples of the procedures. Your patient will let you know how much information she can or wishes to process by the questions she asks.

Your patient needs confidence in your technical ability, and to know that her problem is being taken seriously and that you are qualified to competently help her cope with all of the ramifications of this new experience.

Dealing with the patient’s feelings usually is not difficult if the surgeon accepts the viewpoint that many of the patient’s emotions are part of her new experience. To the physician, the presurgical tension is predictable, familiar, transient, and simply comes with the territory, but to each new patient, the presurgical tension is predictable, familiar, transient, and perhaps even illuminating for the physician, but unfortunately, some of the sources are inherently flawed, prejudicial, illogical, or without scientific basis. It is the physician’s responsibility to separate the grains of truth from the chaff. All the information she has gathered represents her attempt to prepare herself psychologically for the ordeal ahead, and she must never be condemned or made to feel small for trying to protect herself. For the gynecologist, it is not necessary to change a patient’s basic attitude or feelings. It is, however, vital to acknowledge them. The right information, reassurance, and support usually quickly modify many negative factors and lead to a healthier attitude and understanding of the surgical process. It is crucial that the patient be allowed to vent her anxiety and speak of her fears.

To interpret the patient’s true feelings, simply listen to her. Listening well is both an art and a skill, and the surgeon who cares about the patient’s complete health as well as her quick recovery works diligently to hone a sharp edge on this valuable tool. Listen, and you will hear the woman give a name to her most profound doubts and fears. Repeat her words so that you are absolutely certain you understand what she said and is absolutely assured that you are listening to her.

Begin the communication process by finding out what the patient perceives will be done to her body and why the procedure is necessary. Find out what she believes the consequences of the surgery will be. How does she think the surgery will affect her life? As she discusses the implications of her decision, her knowledge, fears, and biases emerge. At this point, you should be able to supplement the patient’s perspective with appropriate explanations about anatomy, physiology, and pathology. After this, it is time to describe in detail the usual preoperative, operative, and postoperative routines. Address the patient’s questions and fears in as many ways as it takes for her to become confident that she understands what is about to happen to her.

Carefully explain what you are going to do to help her. If she wants to know, or needs to know, describe the common physical sensations, bandages, incisions, catheters, tubing, and medications that are associated with her particular procedure. Define the patient’s role in her own convalescence and recovery. Give her a general timetable for how long she will feel discomfort, how long she will have to use pain medication, when she will be ambulatory, and finally, when she will be discharged from the hospital or outpatient center.

Relate the most common complications that might occur as the result of her surgery. Injuries that might affect the quality of her life, even temporarily, should never come as a postsurgical surprise, nor should they be glossed over during the signing of the consent forms. Iatrogenic injury remains the most common cause of lower urinary tract trauma. An understanding of the prevention, recognition, and treatment of urologic complications is important for every surgeon performing major pelvic surgery. Injury to a woman’s genitourinary system may take 10 to 20 years to develop full-blown sequelae, about the same timeline as from multiple childbirths, but it remains a possibility. Physicians, however, disagree on whether to tell the patient that urinary incontinence after hysterectomy because of slippage to the pelvic nerves or pelvic supportive structures could be a long-term adverse effect. Only 4% of the hysterectomies performed are for relief from symptoms of incontinence.

Complications such as the formation of adhesions may occur in as many as 53% of patients after gynecologic surgery. These adhesions can become a critical issue from a standpoint of reproductive potential. Their presence is also strongly associated with pelvic pain, abnormal bowel function, and small bowel obstruction.

The mentally competent patient has a moral, legal, and ethical right to make an intelligent informed decision and can only do it if she is privy to all of the available facts concerning her situation. It is essential that you involve her in the decision-making processes, because the more committed she is to the proposed treatment, the more involved she will become in her own preparation and rehabilitation. This point is supported by the findings of the ENDOW Study.

The art of touching, the therapeutic laying on of the hands, is important. Being lonely, frightened, and sick is a reason for the patient to be touched by her physician, especially if she seems particularly overwhelmed by her situation. To hold the patient’s hand while talking to her or touch her shoul-

der is therapeutic. Even a comforting hug is appropriate if it exes the circumstances and the patient reaches out to you.
Before fetal monitoring, quality of labor was evaluated by setting at the patient’s bedside with the physician’s hand on her abdomen to feel uterine contractions. Often, the presence of the physician and a warm hand on her abdomen made the patient relax, rest, and become calmer during active labor. Cancer patients, especially, on hearing bad news, need immediate human-to-human contact to stay grounded enough to face that terrible moment. The professional boundaries of roles, time, place and space, gifts and services, chaperoned examinations, physical contact, money and formal language were never intended to be an impermeable membrane separating a doctor’s ability to administer human kindness. A healer’s touch can often comfort a distressed patient when words are inadequate.

A patient’s family is a vital part of her support system and can be a potent ally, or not, to the health care team. If your patient requests that family members be present during her consultation, allow it, but speak directly to her whenever possible.

Once the initial presurgical discussions are complete, your patient may need some time to digest all the new information she has received. After assimilation, allow her to contact you for clarification or to ask more questions. You should be available to her. You should instruct your personnel to facilitate her access to you. Too often, office personnel believe their role is to shield the physician from patients rather than to facilitate meaningful contact.

Patients from Other Cultures

Patients from other cultures abound in the United States and their numbers are increasing dramatically. These patients in many cases are often situated in dense clusters. Physicians in these areas have either multilingual assistants or have assistants who are able to act as interpreters. However, no matter where your practice is located, chances are that at some point during your career as a physician, an individual from another culture will need your help.

Mull makes the following suggestions for communicating effectively with a person whose language you do not speak and whose culture is foreign to you. Make sure that your office staff are courteous and respectful. Show the genuine concern you feel. Be friendly and helpful to build rapport and develop a repertoire of knowledge. Familiarize yourself with the general principles of their traditional medicine. Whenever possible, have an interpreter present. Learn a few key phrases from their language, and use these for initial greeting and during examinations. Electronic linguistic assistants, such as the Franklin language, and use these for initial greeting and during examinations. Electronic linguistic assistants, such as the Franklin

■ Fear of blood loss

■ Intolerance of side effects from medication
■ Expectation of expeditious wellness
■ Reluctance to discuss emotions with people who are not family members

Matters of Life and Death, Daniel Bruns writes, “Even the strongest person can be shaken by the horrors of some medical cues. Beyond this, life anxiety is even more common in persons with pre-existing emotional difficulties or characterological disorders. These persons may go through life like eggshells, intact and functioning, but with psychological fragility. When faced with an extreme life stressor, such a person may simply shatter.” How will you, as the physician, recognize the vulnerable?

Rosko researched 13 factors related to poor prognosis for excellent mental health after hysterectomy. The following factors begin to define the patient who might react negatively to genital surgical stress:

1. Gender identity
2. Previous adverse reactions to stress

Psychological Aspects of Pelvic Surgery

Masler and Devanssa said there is an emotional response to any physical assault on the body. The magnitude of the response is expected to be proportional to the degree of emotional investment one has in the part of the body under siege. Among women, anatomic entities most vulnerable to this emotional reaction are the face, hair, breasts, genitalia, and abdominal wall.

Second only to cesarian birth, hysterectomy is the most frequently performed major surgical procedure done on reproductive-aged women. More than 600,000 women a year have a hysterectomy in the United States. Newer minimally invasive procedures have shortened hospital stays and have lessened visible disfigurement of the body. The majority recovery quickly from the procedure and enjoy the new freedom that comes to an individual when a chronic health problem has been solved. Your patients, however, are not always older, wiser women, and they do not always recover quickly. If you know the signs to look for, you will be able to help that patient who is having a harder time adjusting to pelvic surgery, especially if it was a radical, life-threatening, or unexpected event.

In his book, Matters of Life and Death, Daniel Bruns writes, “Even the strongest person can be shaken by the horrors of some medical cues. Beyond this, life anxiety is even more common in persons with pre-existing emotional difficulties or characterological disorders. These persons may go through life like eggshells, intact and functioning, but with psychological fragility. When faced with an extreme life stressor, such a person may simply shatter.” How will you, as the physician, recognize the vulnerable?

Rosko researched 13 factors related to poor prognosis for excellent mental health after hysterectomy. The following factors begin to define the patient who might react negatively to genital surgical stress:

1. Gender identity
2. Previous adverse reactions to stress
3. Previous depressive episodes
4. Family history of mental illness
5. History of multiple physical symptoms, especially lower back pain
6. Numerous hospitalizations or surgeries
7. Age less than 35 years at time of hysterectomy
8. Desire for a child or more children
9. Fear of loss of libido
10. Significant other's negative attitude toward procedure
11. Marital dissatisfaction or instability
12. Cultural or religious disapproval
13. Lack of vocation or hobbies

Barnes and Tinkham's research also indicates that patients tend to react to current stress in much the same way as they reacted to past crises and personal losses. Well-established patterns of behavior repeat themselves. By taking a patient's history, the surgeon can be forewarned about which patients are likely to have the most difficult time handling the emotional aspects of gynecologic surgery. Equipped with this information, the surgeon can prepare to offer extra support in the form of reassurance, educational information, and, if indicated or requested, the names of psychotherapists who are trained to deal with women's health issues.

### COMMON EMOTIONAL RESPONSES TO SURGERY

#### Insecurity

Giving up control of one's body, even temporarily, is uncomfortable for all of us, but it is terrifying for people who feel generally insecure. One of the most common defense mechanisms against feelings of insecurity is to institute rigid controls over all aspects of life. These patients may have no control over getting sick. They will have little if any control during the surgical procedures. The posturgical setting will be a hospital room where the staff tells the patient when to awake, take medicine, eat, bathe, walk, have visitors, and get blood drawn. The health care workers will probe such personal matters as urination, defecation, and passage of flatus. Anxiety, anger, and feelings of being assaulted combine with insecurity can produce an unhappy, fearful, and sometimes raging patient.

These feelings are greatly diminished when the patient believes the surgery will improve the quality of her life. There will eventually be relief of pain, removal of cancers, an end to heavy bleeding, restoration of fertility, or some other positive result. She will be better than she was before the surgery. The transition to becoming this healthier person is made easier when she trusts and believes in her physician.

#### Anxiety or Fear

Anxiety or fear associated with surgery is essentially universal. Most common is fear of the unknown or of what the patient imagines she will be forced to endure during hospitalization. Factual information about the surgical and recovery process and competent care by a compassionate hospital staff help to diminish this fear. Surgeons should assume responsibility for the behavior of the hospital staff toward their patients. When a patient reports ill treatment by any of the health care providers, the physician should deal with the situation personally to decrease the probability of a future recurrence of the offensive or thoughtless behavior.

Patients may fear the loss of economic competence. A woman who has worked for many years may lose her sense of usefulness when disabled for some variable length of time. Whether she plays a major or minor role, the contribution she makes to her family’s economic stability will be important to her. Her identity and self-esteem derived from her job may also be threatened by the outcome of her surgery.

Fear of anesthesia is often a thinly disguised fear of dying as well as a fear of loss of control. It may be appropriate to confront the fear of dying directly so that the patient has the opportunity to express why she is afraid. Is the fear general or specific? Did a close relative suffer from the same affliction and die during or shortly after surgery? Does the patient have a strong intuitive feeling that something will go wrong? If so, ask her what you can do to modify the surgical situation. Determine whether the scheduled date of surgery or the particular hospital is significant. The fact that you consider her feelings an important issue and a normal part of the gynecologic disease process may be enough to calm her fears.

#### Regression and Dependency

In most people who are ill or who undergo surgery, regression to a more dependent state is fairly common. Dealing with a woman who is no longer self-sufficient or emotionally stable is difficult for the patient's family and friends. These members of her supporting cast are accustomed to her presurgical roles as wage earner, wife, mother, friend, cook, advisor, shopper, housekeeper, taxi driver, entertainer, and more. When she becomes ill and can no longer function to make their lives easier, family members and friends often become frustrated and angry. They may apply overt or subtle pressure to try to force the woman to exert herself and fulfill her usual roles. A change in roles is difficult, but often the illness teaches family and friends why this particular woman is valuable to them. Those who temporarily assume her normal duties or help her cope with the surgical experience, in many cases, discover strengths of hers of which they were previously unaware.

When the disease and prospect of surgery are new to the patient, all these factors, as well as a feeling of ill health, contribute to an emotional fragility that yields extremely labile emotions, including feelings of sadness, despondency, tearfulness, and irritability. The usual defense mechanisms are often temporarily weakened or destroyed. The woman is vulnerable to attack on all personal and professional fronts. She needs time with people she cares about, and she needs time alone to sort out her thoughts and emotions.

#### Grief

Grief is a normal, natural reaction to illness or loss of any kind and is essential to emotional healing. Recognizing the normal stages of grief allows the surgeon to help the female patient understand what is happening to her.

Denial is the first and most primitive emotional response to loss and can take many forms. The patient may demonstrate denial by not going to the doctor when she feels a lump in her breast or when she notices abnormal bleeding. She may pretend the symptoms do not exist or are a temporary nuisance. Not remembering instructions the physician gave her could...
Playing in her life.

particular surgical experience, look for the role grief might be of the realm of what would usually be anticipated during her If a female patient's behavior seems bizarre, excessive, or out patiend may feel fragments of several of them at the same time.

is the second stage of grief. Depression comes in varying degrees to most people ex-

ing grief and is characterized by feelings of helplessness,

middlete-of-the-night insomnia, nightmares, loss of appetite or excessive eating, lethargy, difficulty making decisions, psychosomatic symptoms, and fatigue unexplained by activity.

Ask the patient if she has any of these symptoms. Post-
surgical depression is common. Depressed patients usually ad-
mit that the sad feelings are routine and occur daily. When prolonged, they indicate the patient has been unable to work through the grief process. Something emotional has yet to be resolved.

Rage turned inward often manifests as depression. When the patient is able to identify what she is angry about, to vent-

tilate the rage, the depression usually begins to lift. When she takes charge of her life again and makes decisions, even small ones, she begins to feel better, and feelings of helplessness, hopelessness, and worthlessness abate. However, when the de-
pressed patient becomes suicidal, stringent intervention must occur. The suicidal patient presents serious challenges and so is discussed in specific detail later in this chapter.

The stage at which the patient ventilates her anger can be difficult for those providing care, but it should be accepted as healthy. The patient may go to extremes, writing letters to

somatic symptoms, and fatigue unexplained by activity.

who might use their position of authority to hurt, not help, them.

The Ultimate Rape: What Every Woman Should Know about Hysterectomies and Ovarian Removal was inspired after the author underwent a hysterectomy. She suffered extreme physical and emotional trauma following the surgery, but when she reported this to her physicians, they advised her to go see a psychiatrist, because the symptoms were in her head. The book’s title is evidence of the rage she felt at their pronounce- ment. Now her voice is joined by others who believe that every woman has the right to be thoroughly informed about procedures and consequences before consenting to gynecologic mod-
odifications. And certain truths are the same.

In No More Hysterectomies, touted as the first living text-
book on the Web, the reader learns how the male-dominated medical profession and the insurance industry have sanctioned millions of unwarranted hysterectomies. One testimonial to the ideas presented in the book describes the current medical envi-
ronment as a “woman’s hormonal holocaust.”

The enlightening news is that interest generated by these sources and their legions of followers has had a positive and direct effect on women’s health research. Global studies are numerous and are concentrating on traditional as well as al-
ternative methods of treatment for menopause, hysterectomy, hormone replacement therapy, cancer, endometriosis, fibroids, and dementia. For the first time in the history of medical sci-
ence, ethnic research is being conducted on a large scale to de-
termine how women in various cultures and with variances in their physiology react to menopause, gynecologic surgery, hor-

eone therapy, and sexual function. The ENDO Study has found ethnic/racial differences in women’s perceptions of hys-
terectomy and their determinants in decision making regarding elective surgery. Negative connotations were found to be more prevalent among African American women, thus indicating a need for added support and information preoperatively. Future generations of women will reap the benefits from this research, but the overwhelming aura that prevails in today’s gynecologic patient is one of confusion.

After reading just a sampling of the lay literature, some women feel that surgical removal of their female organs and commencement of hormonal therapy constitutes an unnatural, chemotherapy-like assault on their physical bodies. It is the task of the physician to admit into evidence the medical facts necessary to correct any gross misconceptions that could affect patient care. Sometimes it may seem as if the patient, armed with advice about natural remedies for her severe pelvic pain, heavy bleeding, or hot flashes, wants to drag you with her back into the Dark Ages. Be patient and also prepared, if necessary, to explain the medically sound benefits of life lived outside the cave.

Be compassionate. No matter how routine the job becomes, compassion is a vital requisite to becoming an exceptional com-
municator and healer. Empathy often follows experience, and those times when you are able to make a noticeably positive difference in your patient’s life are inestimational. To try the one new thing that might help many patients in the future, it is necessary to earn the trust of a single patient in the present. A few days are gone when a doctor was considered omnipo-
tent, when he, and rarely, she, received a hock of ham for the birth of a child, or had to tell a woman that she would have to live with the eventual hump on her back because it was a natural process of aging. Patients know about osteoporosis and its consequences before they even become aware of their physiologic needs. Even those that point to a devastating diagnosis, but never lie. In 1981, 90% of physicians surveyed in a single large urban hospital stated that they withheld the diagnosis of cancer from their patients. Today, the position had been totally reversed, with 97% reporting that they reveal the true diagnosis of cancer.

Doctors, however, are not the only members of the team with ethical considerations. Patients also have the responsibil-
ity to tell the physician the truth relative to their symptoms, medications, allergies, past medical histories, and to relate any significant traumas or family history that could bear on their current situations. Question your patient specifically about stressful life events. Did she respond to these in a positive or negative way? Of all inquiries, this is the most important indicator of how the patient will respond to any current stress. Once the physician knows the answer, psychological preparation for diagnosis or surgery can begin in earnest.

Researchers in the United Kingdom have compiled data from multiple trial studies confirming that psychological prepa-
ration for surgery is effective. The general hypothesis was that communication and counseling are important determinants of numerous factors, including the following:

• Accuracy of the diagnosis
• Effectiveness of disease management
• Disease or problem prevention
• Patient satisfaction
• Adherence to treatment
• Psychological well-being
• Patient understanding of procedures
• Professional satisfaction and levels of stress

Information about each of these parameters was compiled, and considerable evidence existed to support all the hypotheses. In review, Davis and Johnston reported that psychological prepa-
ration is effective in reducing negative effect, pain, medication, length of hospital stay, and in improving behavioral recovery and physiologic functioning.

Surgical Whispers

The surgeon should make it a point to be with the patient while anesthesia is administered. Knowing that you are there with her from the beginning will help her feel safe. At the end of each surgical procedure, whisper into your patient’s ear, “You’re going to be well very soon.” You may be surprised to find she needs less pain medication and recovers quicker than patients without the benefit of this positive prophecy, because the mind itself is a powerful force, as evidenced by neuroscientific re-
search. Dr. Esther M. Sternberg, director of integrative neural immune program and chief of the section on neuroendocrine immunology and behavior at the National Institute of Mental Health and National Institutes of Health, concludes that stress reduction endogenous opiates are produced that decrease pain. These come from the same cells in the hypothalamus that make the stress hormone CRH. “Understanding these brain-immune
connections will help the surgeon understand how his support and encouragement can decrease the patient’s pain. Youngs and colleagues believe the surgeon or a familiar associate also should be present immediately after surgery to reassure the pa-
tient, orient her to her surroundings, and make certain she has adequate pain relief. Even if the patient appears unresponsive during the immediate postoperative phase, a familiar voice and reassuring word can be immensely beneficial.

Immediate Postoperative Care

Hospital stays are much shorter. Some outpatient hysterectomies are being performed. These factors are having a pos-
tive psychological effect on patients. A patient knows that she is getting well when she no longer requires needles and is able to ambulate and urinate without assistance. It has long been known that early ambulation significantly reduces morbidity as well as the incidence of phlebitis and pneumonia. As long as intravenous therapy and urethral catheterization are maintained, the patient remains immobile and consequently at higher risk for venous stasis, ileus, and pulmonary complications. The inci-
dence of pulmonary embolus in the postoperative hysterectomy patient has decreased in the past decades with shortened stay and early ambulation.

Crisis Intervention

It is important to recognize a patient who is overwhelmed by stress. A stress crisis can occur during any phase between di-
agnosis and recuperation. A crisis has been described as an obstacle to important life goals that becomes insurmountable when the individual employs customary methods of problem solving. Kaplan highlighted the following four phases of crisis:

1. Arousal occurs, and attempts are made at problem solving.
2. Increased tension leads to distress and disorganization be-
because arousal hinders rather than promotes coping behavior.
3. Internal and external emergency resources are mobilized.
4. A state of progressive deterioration, exhaustion, and decom-
pensation ensues as the problems drag on and on without resolution.

Dennerstein and van Hall report that the types of problems dealt with in crisis therapy include loss, change in status or role, interpersonal problems, and problems of choice between two or more alternatives. As an advocate, encourage your patient to communicate her feelings, to understand the problem enough to identify and define it, and then help her rehearse alternative ways of coping.

One of the best concepts to apply during any stressful situa-
tion is to give the assurance that this particular moment, no matter how painful, is temporary. The surgical procedure and all the stages of mending that follow will have a beginning, middle, and an end.

PSYCHOSEXUAL REHABILITATION

The goal of psychosexual rehabilitation after gynecologic or breast surgery is to restore sexual function, sexual identity, body image, and self-esteem. Most of the work must be done by the patient herself, but she may need assistance from her doctor and other health care providers because the experience is new to her. She has no gauge to measure what is normal for her particular situation and what is aberrant. You do.

She may expect too much too soon from herself, or she may head off in the opposite direction and begin to assume the role of invalid, but in most cases, she will be caught somewhere between these two extremes. Once she begins to see her normal patterns of relating to others, you will know she has officially begun the process of genuine healing.

You will be able to tell when she enters the healing phase because she will become less dependent on you, the nurses, and even her family members. As her strength increases, she will want to resume her usual activities. The inevitable, nor-
mal, uncomfortable grief process will commence. Encourage the patient to talk about her feelings rather than repress them and begin to brood, because worry and rumination are forms of repetitive thought that are concommitant and predictive of depressed mood. Dreary thoughts fuel a depressed mood, turn it into something ugly and dangerous, and have the potential to cause long-term or permanent psychological damage.

The patient has the power within to effect change in herself. Family members and friends should be cautioned, at this point, to allow verbal ventilation. It’s a form of healthy discontent that frequently provides the impetus to hurry and lose the sick image and begin to see herself well and strong again.

Cosmetics, dress, and grooming are important parts of the rehabilitation process. When a postoperative patient combs her hair, puts on lipstick, and demands her own nightgown instead of hospital garb, she has begun to heal. When a patient feels that the surgery was disfiguring, she needs to compensate by learning new ways to dress or groom. She needs to feel whole and complete and responsible again as quickly as possible.

The surgical patient begins to see herself as a sexual per-
son when her sexual identity is validated by her sexual partner, friends, family, and even admiring strangers she passes on the street. The woman who has had a mastectomy or other body-altering surgery needs to know her partner still finds her at-
tractive and desirable. Without this affirmation, she may have a great deal of trouble seeing herself as a sexual being. Some sexual partners cannot accept an incomplete person. This is another potential problem.

Some surgical procedures result in loss of vulva, cititoris, or vagina. Radical pelvic surgery can leave a woman with a colostomy or urinary diversion. A severely altered body image concurrent with loss of health and vigor poses a serious threat to a woman’s self-esteem. The woman who has lost her sexual identity feels damaged beyond repair. Some report continuing pelvic pain without obvious structural cause. Interest in sex vanishes, and the patient may actually leave her sexual partner or force the partner to abandon her. As she terminates her sexual identity, she feels out of time and begins to draw in the edges of her life. These women need intense psychosexual therapy if they are ever to heal emotionally. Table 3.1 outlines the major factors that occur with psychosexual dysfunction.

Most of the time, the mate or lover of the woman is caring and considerate of her. There is genuine concern for her health, hope for a quick recovery, and willingness to assume many aspects of her role until she is well. Often there is a deepening of affection between the couple as gifts of love and concern are given and received. That special someone is in the waiting room during the surgical ordeal and by the patient’s bedside when she awakes. There are flowers and gifts and promises made and kept. There is an abundance of reciprocal love. Adjustment to new roles is relatively smooth, causing new bonds to form and old ones to strengthen.
In other cases, the woman’s partner becomes a bigger problem than her physical disability. It is possible her significant other constructed a fragile emotional bond with body parts rather than with the actual woman. If she had or has cancer, the partner may irrationally feel that the cancer is contagious. If she is receiving radiation treatment, he may feel that if he resumes sexual relations with her, he, too, might absorb radiation from her body and be burned. The couple may be accustomed to frequent sex, and any change in the woman’s availability stresses the relationship. The fear of causing pain also has an inhibiting effect. Emotional isolation and loss of nurturing occur in both circumstances, who sometimes fear they are not qualified to help, are reluctant to discuss sexual dysfunction. Many women and their physicians, who are so embarrassed. Whether from obstetric injuries, injury to the actual woman and labia, one third of the women lacked sexual interest, and one fourth were unable to experience orgasm in the general population. One third of the patients lack sex-ual interest, one fourth were unable to experience orgasm in the majority, one fifth reported lubrication difficulties, and another one fifth said they did not find sex pleasurable. These figures come from members of the population willing to discuss sexual dysfunction. Many women and their physicians, who are so embarrassed. Emotional isolation and loss of nurturing occur in both circumstances, who sometimes fear they are not qualified to help, are reluctant to speak of personal problems such as libido, arousal, coital pain, or past traumatic sexual events. Much of this reluctance can be overcome if the gynecologist knows what questions to ask when taking a sexual history, preferably during an initial or annual examination before any body-altering surgery.

Sexual Cycle Primer
Davis suggests that the physician ask the following open-ended questions to obtain a sexual history: Are you sexually active? Are you or your partner having any sexual difficulties at this time? Has there been any change in your sexual activity? Have you or your partner having any sexual difficulties at this time? Has there been any change in your sexual activity? Have you ever experienced any unwanted or harmful sexual activity? Are you or your partner having any sexual difficulties at this time? Has there been any change in your sexual activity? Have you ever experienced any unwanted or harmful sexual activity? Another good question is: What sort of sexual problems do you have? Even if the patient is initially reluctant to discuss such personal issues, she will have learned that you are willing to discuss them should the need arise. Davis also believes that a physi}-cian’s confidence in dealing with sexual issues increase when the cycles of sexual response (desire, arousal, plateau, orgasm, and resolution) are learned and factors that affect them (psy- chological, environmental, and physiologic) understood.

Davis, in a sexual and sexual dysfunction tutorial, describes the following stages: desire, arousal, plateau phase, orgasm, and resolution phase. Desire is the motivation and inclination to be sexual. It is dependent on internal (fantasies) and external sexual cues and also on adequate neuroendocrine functioning. Arousal is characterized by erotic feelings and vaginal lubrication as blood flow increases to the vagina. In addition to feelings of sexual tension, the sexually excited woman may also experience tachycardia, rapid breathing, elevated blood pressure, breast engorgement, muscle tension, nipple erection, and other physical signs of arousal such as a flush. This is the stage where the vagina lengthens, distends, and dilates, and the uterus elevates partially out of the pelvis. During the plateau phase, sexual tension, erotic feelings, and vasoscongestion reach maximum intensity. The labia become more swollen and turn dark red, and the lower third of the vagina swells and thickens to form the orgasmic platform. The clitoris becomes more swollen and elevated, and the uterus elevates fully out of the pelvis. Eventually, women reach the threshold point of orgasmic inevitability. Orgasm is a my- otonic response mediated by the sympathetic nervous system and is experienced as a sudden release of the tension built up during previous phases. Women, unlike men, experience no refractory period but can experience multiple orgasms during a single cycle. They can also experience orgasms before, dur- ing, and after intercourse provided they receive enough clitoral stimulation.

The last phase is called the resolution phase. Women experi- ence a feeling of relaxation and well-being. The body returns to a resting state. Complete uterine descent, detumescence of the clitoris and orgasmic platform, and decongestion of the vagina and labia take about 5 to 10 minutes. Sexual adjustment is often significantly improved in women after pelvic exenteration and gracilis myocutaneous vaginal reconstruction. Eighty-four percent of the patients in one of the few studies that exist, resumed sexual activity within the first year after surgery. A modified version of the Sexual Adjust- ment Questionnaire was used and the responses outlined the most common problems patients face after the surgery: self-consciousness about a urostomy or colostomy, being seen nude by their partner, vaginal dryness, and vaginal discharge. It is hoped that future modifications in surgical technique, more realistic patient counseling, and aggressive postopera- tive support will minimize these problems in the future. Less serious matters can cause self-esteem and body image prob- lems, too, if their aftermath includes or leads to bowel in-continence, urinary incontinence, vaginal vault prolapse, and scarring. Bowel incontinence is rarely discussed even with a woman’s physician because it is so embarrassing. Whether from obstet- ric injuries, injury to the anal muscles, infections, or dimin- ished muscle strength from aging, once the cause and sever- ity are determined, treatments can begin that include dietary changes, constipating medications, muscle strengthening exer- cises, biofeedback techniques, and sometimes, surgical repair of the muscle. Some or all of these remedies help the woman control the discharge of embarrassing gas or stool. It is most important to discuss possible remedies because many patients feel there is nothing that can be done for them but the fright- ening colostomy, when in actual fact, colostomy is a procedure that is rarely required.

Davis and sexual dysfunction, describes the following stages: desire, arousal, plateau phase, orgasm, and resolution phase. Desire is the motivation and inclination to be sexual. It is dependent on internal (fantasies) and external sexual cues and also on adequate neuroendocrine functioning. Arousal is characterized by erotic feelings and vaginal lubrication as blood flow increases to the vagina. In addition to feelings of sexual tension, the sexually excited woman may also experience tachycardia, rapid breathing, elevated blood pressure, breast engorgement, muscle tension, nipple erection, and other physical signs of arousal such as a flush. This is the stage where the vagina lengthens, distends, and dilates, and the uterus elevates partially out of the pelvis. During the plateau phase, sexual tension, erotic feelings, and vasoscongestion reach maximum intensity. The labia become more swollen and turn dark red, and the lower third of the vagina swells and thickens to form the orgasmic platform. The clitoris becomes more swollen and elevated, and the uterus elevates fully out of the pelvis. Eventually, women reach the threshold point of orgasmic inevitability. Orgasm is a myotonic response mediated by the sympathetic nervous system and is experienced as a sudden release of the tension built up during previous phases. Women, unlike men, experience no refractory period but can experience multiple orgasms during a single cycle. They can also experience orgasms before, during, and after intercourse provided they receive enough clitoral stimulation.

The last phase is called the resolution phase. Women experience a feeling of relaxation and well-being. The body returns to a resting state. Complete uterine descent, detumescence of the clitoris and orgasmic platform, and decongestion of the vagina and labia take about 5 to 10 minutes. Sexual adjustment is often significantly improved in women after pelvic exenteration and gracilis myocutaneous vaginal reconstruction. Eighty-four percent of the patients in one of the few studies that exist, resumed sexual activity within the first year after surgery. A modified version of the Sexual Adjustment Questionnaire was used and the responses outlined the most common problems patients face after the surgery: self-consciousness about a urostomy or colostomy, being seen nude by their partner, vaginal dryness, and vaginal discharge. It is hoped that future modifications in surgical technique, more realistic patient counseling, and aggressive postoperative support will minimize these problems in the future. Less serious matters can cause self-esteem and body image problems, too, if their aftermath includes or leads to bowel incontinence, urinary incontinence, vaginal vault prolapse, and scarring. Bowel incontinence is rarely discussed even with a woman’s physician because it is so embarrassing. Whether from obstetric injuries, injury to the anal muscles, infections, or diminished muscle strength from aging, once the cause and severity are determined, treatments can begin that include dietary changes, constipating medications, muscle strengthening exercises, biofeedback techniques, and sometimes, surgical repair of the muscle. Some or all of these remedies help the woman control the discharge of embarrassing gas or stool. It is most important to discuss possible remedies because many patients feel there is nothing that can be done for them but the frightening colostomy, when in actual fact, colostomy is a procedure that is rarely required.
As many as 50% of all women experience occasional urinary incontinence. In an attempt to lessen the blow to a woman's ego and make the event more socially acceptable, manufacturers hire movie stars to make commercials about the effectiveness of diapers for grown women. Diapers do treat the symptoms and allow for more freedom of movement, but not in an intimate setting. For many years, gynecologists have instructed patients about Kegel exercises to tighten the muscles of the pelvic floor, but this may not be enough to stop the embarrassing leakage of urine. The patient needs to know that there are tests that can determine the exact cause of the problem, and treatment using bladder retaining therapy, medica- tions, and surgery. Urinary incontinence may be more socially acceptable today, but it is never normal, no matter what the woman's age.

Both bowel and urinary incontinence can be caused by vaginal vault prolapse, and this condition must be ruled out because it drastically affects sexual functioning. The presence of a mass can cause painful intercourse, difficulty accepting penetration, and a great deal of psychological anxiety when the tissue can be seen in the vaginal opening. This condition, if left untreated, only worsens with time, but techniques that correct female organ-supporting defects in the pelvis can restore sexual functioning and with it, a woman's sense of vitality and feminine allure.

Patients who talk about their sex lives frequently describe four pleasures associated with sexuality. These universal elements are touching, genital caressing, orgasm, and gratifying a partner. When a patient is recovering from surgery or has experienced surgical loss of coital function, genital caressing as a receiver or giver can be satisfying. Once a woman learns early in life how to be orgasmic, and gratifying a partner. When a patient is recovering from surgery or has experienced surgical loss of coital function, genital caressing as a receiver or giver can be satisfying. Once a woman learns early in life how to be orgasmic, she can often learn to be so again despite major genital loss, including her clitoris. When the ability to produce an adequate response is destroyed by disease, the patient can be encouraged to experiment with alternative methods that do not conflict with her value system. Women who will never experience vaginal intercourse again can discover they are able, with education and imagination, to fulfill their feminine role as givers of pleasure if they choose to do so.

When a patient's psychosexual rehabilitation after surgery seems to be impeded and she fails to make steady progress toward resumption of her usual role, with appropriate self-esteem, energy, identity, and ability to handle stress, she should be offered help. Help should be offered as soon as she mentions the problem. Early intervention is often easy and brief. The surgeon should be the first person to help the patient, with counseling and, if necessary, suitable medications.

Hormonal Therapy

Hormone replacement therapy (HRT) remains a controversial issue. It is imperative that HRT be discussed preoperatively with the patient facing surgery and the loss of her ovaries. Initial misinterpretation of the results of the Women's Health Initiative Study (WHI) has created much fear and angst for women facing surgery and the loss of her ovaries. The harmful effects were overestimated, and the media created undue alarm regarding both the gynecologist and the patient. The WHI study recruited 68,135 women of age. It must be remembered that the WHI study recruited about 0.1% for every year of use. Six years has been observed for women younger than 60 years of age. It must be remembered that the WHI study recruited women in their late 60s.

A 16-year study that involved 60,000 postmenopausal female nurses found that those who took hormone replacement therapy for 10 years reduced their risk of dying from all causes by 37%, with the most dramatic reduction being death from breast cancer. After 10 years, the reduced risk for all causes was 16%; because of the increased risk of dying from breast cancer. That risk rose to 43%, but the women who contracted breast cancer during the first 10 years had a lower risk of dying from breast cancer than women who had never taken hormones, probably because of early detection. Chances of early detection of breast cancer are probably better for hormone users because they receive regular check-ups.

In an extensive review of current literature on the subject, dubbed “the New Science of Estrogen,” Hammond provides an overview of the risks and benefits of hormone replacement therapy and also includes information on therapeutic alternatives. Cardiovascular benefits of estrogen outweigh the risks. With combined estrogen-progestin therapy, studies have shown some increase in stroke and venous thrombembolism. Hammond feels that steroid hormonal therapy should be considered an integral part of the appropriate and necessary care of American women after menopause, and the anticipated reduction of cardiovascular disease and osteoporotic fractures by nearly 50% should be laudable goals for any health care system.

Statistics show overwhelmingly that cardiovascular disease (CVD)—not cancer—is the leading cause of mortality for postmenopausal women. In fact, one in two women will eventually die of heart disease or stroke, whereas only one in 25 women die of breast cancer. Although the incidence of heart disease, including coronary artery disease and stroke, is low in premenopausal women, heart disease is the most frequent cause of death in women older than the age of 50. Since 1984, the death rate from CVD in men has decreased, whereas the death rate for women has remained the same. Nevertheless, epidemiologic studies support the long-term benefit of estrogen in preventing CVD. Observational studies, such as the Postmenopausal Estrogen/Progestin Intervention Study sponsored by the National Institutes of Health, revealed that HRT can increase high-density lipoprotein cholesterol and decrease low-density lipoprotein cholesterol. The Nurses' Health Study demonstrated a reduction in the risk of CVD of as much as 50% among current HRT users. Women on estrogen have significantly less coronary artery stenosis than women who do not use it. Takahashi found that long-term HRT—for more than 2 years—may delay carotid intima-media thickness in healthy postmenopausal women. Moreover, patients with the most advanced coronary artery disease experience the most benefit from HRT. Only 35% of women surveyed were aware of the connection between heart disease and menopause.

Current theories indicate that estrogen has extraordinarily complex biological effects that translate into a variety of actions in diverse tissues. There is growing scientific evidence that estrogen exerts its beneficial actions on tissues of the skeletal, urogenital, digestive, cardiovascular, ocular, and nervous systems.

Estrogen replacement therapy (ERT)/HRT is also first-line therapy for osteoporosis for most women, and treatment should begin as soon as possible after the menopause. Enough time has elapsed since the WHI media scare and cessation of estrogen therapy by users that a marked and rapid loss of bone density is being noted in those who stopped their replacement therapy. Yates and Barrett-Jones studied the association between hormone therapy (HT) cessation and hip fracture rate. Concurrent with WHI, women in National Osteoporosis Risk Assessment currently on HT had a 40% lower incidence of hip fractures.
fracture compared with those who had never used HT. Women who stopped using HT more than 5 years earlier had similar hip fracture use to never users. Preliminary data suggest that even the elderly respond to estrogen replacement. However, there are therapeutic alternatives and lifestyle modifications (diet and routine exercise) that perimenopausal women must be counseled about to create a comprehensive preventive pro-

gram. It is an effort that has a significant impact on long-term morbidity and mortality associated with osteoporosis.

Women have phenomenal memories because one of their jobs is to find every needle that gets lost in the proverbial haystacks of their homes. When they become less adept at remembering where they and other people put their things, they fear the worst—that they are losing their minds, and this fear is not illogical. Women compose 72% of the population older than the age of 85 years, and roughly half of this group has Alzheimer disease (AD). Not only do women constitute a greater proportion of this older population, but AD is expressed earlier in women than men. This may be related to the estrogen loss that occurs with menopause. Hammond cites a study that found women who took estrogen for more than 1 year experienced a dramatic delay in AD onset. But even the group of women who averaged only 4 months of estrogen therapy and most likely took the medication to control symptoms such as hot flashes experienced a delay in AD onset. It has been speculated that a brief exposure to estrogen influ-

enced AD expression 20 to 30 years later by preventing an ir-

reversible loss of neurons associated with the occurrence of hot flashes. Research is ongoing, but one study found that estrogen replacement therapy in postmenopausal women is associated with a 50% reduction in the risk of developing AD because it slows the decline of visual memory. The study by Lebrun and colleagues in clinical endocrinology supports findings that endogenous estrogens protect against cognitive decline with aging.

Colon cancer occurs more often in women than men and is a leading cause of cancer incidence and deaths in women. Even though mortality rates for colon cancer have decreased 25% among women in the last 20 years, it remains the third-leading cause of cancer deaths in this group. The concept that post-

menopausal ERT may decrease the risk of colorectal cancer has received considerable attention, even though the hormone is delayed.

With ovarian preservation, the need for exogenous hormones at least age 65 because of its benefit to long-term survival.

Routinely, ERT/HRT counseling should go beyond simple symptom control to include both short- and long-term benefits, contraindications, common patient concerns, and misconcep-

Counseling women about replacement therapy must be combined with discussions about the importance of lifestyle changes, including:

- Normalization of weight
- Dietary intervention
- Smoking cessation
- Regular exercise
- Control of hypertension
- Control of diabetes
- Control of alcohol consumption
- Control of lipid elevations

Routine use of ERT/HRT counseling should be included as a measure to prevent colon cancer should be part of the Counseling should include the American Cancer Society rec-

ommendations for annual digital rectal examination and fecal occult blood testing as well as a flexible sigmoidoscopy every 5 years or colonoscopy every 10 years.

Age-related macular degeneration (AMD) may be reduced by estrogen administration. This disease is the leading cause of legal blindness in the United States, accounting for as many as 60% of all new cases. There is no medical treatment, and surgical management in the form of photocoagulation is effec-

tive in only a small percentage of patients with the wet type surgical management in the form of photocoagulation is effec-
tive in only a small percentage of patients with the wet type of disease. In the Rotterdam study, women who experi-

enced menopause at a later age. These data suggest that HRT reduces the risk of developing AMD.

The natural conjugated estrogens do not cause hypercoagulability and are safe during the immediate convalescent period.

The natural conjugated estrogens do not cause hypercoagulability and are safe during the immediate convalescent period.

Parker and colleagues, in a recent lead study in Obstet-

rics and Gynecology, recommend ovarian conservation until at least age 65 because of its benefit to long-term survival. With ovarian preservation, the need for exogenous hormones is delayed.

The long-term benefits of estrogen replacement therapy in preventing osteoporosis, cardiovascular disease, and colon can-

cer are well established. The health of the vagina and lower uri-

nary tract is maintained. The Journal of the British Menopause Society says that various studies have demonstrated the efficacy of estrogen replacement in improving urinary and stress incontin-

ence. The vagina lubricates more easily with sexual arousal, and intercourse is more comfortable with an estrogenic vaginal mucosa. Many women report an increased interest in and enjoyment of sex.

For women who do experience a loss of libido, even while taking estrogenic hormones, the new androgen therapies look promising as a way to improve sexual function and psychologi-

cal well-being. Testosterone delivered via transdermal patches or gel bypasses the liver and has no negative effect on choles-
terol. The skin serves as a constant reservoir; therefore, blood levels show fewer fluctuations.

However, there are physicians who believe that hormonal balances induced by prescription medications should only be offered for relief of extreme menopausal symptoms and only for a short while. The author of Dr. Susan Love's Hormone Book and Dr. Susan Love's Breast Book is one such physi-

ician. She is a staunch supporter of eating soybean products and...
or humiliate the senior patient by assuming her sexuality is a private business and be loath to discuss it. Do not antagonize assume she is asexual. She may simply view her sex life as her of the natural urges, even temporarily, is discomforting.

It is easy to imagine a grandmother baking cookies or rocking an energetic romp in the sack with her favorite beau. Sex after age 60 is a reality for many women and men. These people can recall the passion and sensitivity. Women in tumultuous life situations at the time of surgery present the greatest challenge.

Every patient is special and deserves to be treated with compassion and sensitivity. Women in tumultuous life situations at the time of surgery present the greatest challenge.

The Teenager
Bluestein and Starling report that 1 million teenagers per year conceive. Of these million pregnancies, 400,000 end in abortion and 100,000 in miscarriage. Childbearing teenagers face a 60% excess in maternal mortality compared with adults and are most likely to suffer toxemia, anemia, hemorrhage, cervical trauma, cephalopelvic disproportion, excessive weight gain, and premature labor. These complications are due more to social and behavioral correlates than inherent adolescent aspects. Correlates include inadequate prenatal care, poor nutrition, substance abuse, and emotional distress.

One to two teenagers per 1,000 who have first-trimester abortions experience fever, hemorrhage, and emergency abdominal surgical procedures. These numbers are lower than for older women, but the rate for cervical injury, which could affect future childbearing, is 5.5 per 1,000 teenagers, notably higher than the 1.7 to 3.1 per 1,000 for adults. Bluestein and Starling recommend recontacting the communization techniques for the teenage patient: Guarantee confidentiality to build trust. Conduct the initial interview alone. Teenage girls may want to relay private information to the physician but not in the presence of a parent. Be patient. Gear communication to the patient's emotional and intellectual development. Be nonjudgmental. Gently explore the teenager's family and social environments. Will family members and friends support or harm your patient? Discuss the teenager's long-term plans. Be aware of ethnic differences in health-related matters.

Female patients who belong to local or national gangs come to the health care system with a unique set of problems and values. It is imperative that the surgeon not add to the patient's mental trauma, cephalopelvic disproportion, excessive weight gain, and microbiologically unnecessary if competent sterilization procedures are followed. As men age, they sometimes lose hair on the head. As women age, the pubic hair sometimes thins and once shaved, may never grow back.

Many older women have managed to curtail their sexual appetites to compensate for physiologic changes that have occurred in a mate. Removal of excessive vaginal mucosa during pelvic surgery compromises the vagina, which is already losing elasticity. This inhibits penetration during coitus and can cause painful intercourse. Be understanding and helpful if solutions are possible. If the dysfunction resulting from the surgery will be permanent, encourage the couple to experiment with various ways to please each other or seek the advice of a sex therapist who is knowledgeable about creative sexual play.

Butler and colleagues instruct physicians to educate themselves about the effects of medications on sexuality. More than 200 medications have sexual dysfunction as a side effect. Many are effective in lower doses that do not harm the libido or the patient's physical ability.

The positive benefits of a healthy sex life are multiple. Emotional intimacy and the ability to connect physically with another human being brings great joy and satisfaction. This need to connect intensifies rather than diminishes with age.

The Senior Woman
It is easy to imagine a grandmother baking cookies or rocking a new baby in the family. Our culture makes it a little more difficult to imagine this same woman flushed and happy from an energetic romp in the sack with her favorite beau. Sex after age 60 is a reality for many women and men. Those people enjoyed sex when they were young, they perfected it as the years flowed by, and the thought of doing without expression of the natural urges, even temporarily, is disconcerting.

When an older woman faces gynecologic surgery, do not assume she is asexual. She may simply view her sex life as her private business and be loath to discuss it. Do not antagonize or humiliate the senior patient by assuming her sexuality is a thing of the past.

If the surgical procedure will affect her sexually, explain the consequences. Assure her that the surgery will leave her as whole and as functional as possible. Give this woman the opportunity to express her anxieties and to ask questions. If her mate or lover is present, include this person in the discussion. In the senior woman who has a large cystocele, rectocele, or uterine or vault prolapse, every effort should be made to avoid colpocleisis. Hysterectomy is not a justifiable step for a woman who wants to maintain her fertility. Colpocleisis is a novel and humbling experience.

The positive benefits of a healthy sex life are multiple. Emotional intimacy and the ability to connect physically with another human being brings great joy and satisfaction. This need to connect intensifies rather than diminishes with age.

The Sexually Assaulted Patient
According to Federal Bureau of Investigation (FBI) statistics, reported rapes and sexual assaults in the United States are up nearly 5% since 2000. It is estimated that only about 16% of the rapes that occur are ever reported. One in three sexually assaulted victims is younger than the age of 12. Convicted rape and sexual assault offenders testify that two thirds of their victims are younger than 18. Two thirds of the victims older than 18 knew their attacker before the rape. A sad fact is that almost one fifth of the women who are raped before the age of 18 are raped again after the age of 18. Many require medical
Attention, as many as 22% suffer genital trauma, as many as 40% incur sexually transmitted disease, and 1% to 5% become pregnant as a result of the rape. Rape survivors are 13 times more likely than the general population to attempt suicide.

Most hospital emergency rooms have strict protocols to follow when treating sexually assaulted patients. The proper collection of evidence and initial treatment of injuries is a priority. The surgeon who repairs the gynecologic damage done to these female patients should be aware of the general characteristics of psychological trauma associated with rape.

The symptoms of rape trauma syndrome compiled by Blair and Warner can be found in Table 3.2. Many of these symptoms are the same as seen in posttraumatic stress disorder. These symptoms of rape trauma syndrome compiled by Blair and Warner can be found in Table 3.2. Many of these symptoms are the same as seen in posttraumatic stress disorder. These symptoms such as anorexia, insomnia, tachycardia, fear, and panic. Acute depression is not uncommon and can lead to suicidal tendencies.

The patient is afraid of becoming unable to take care of her family members. Will she be sick for long? Will who will raise her children if she dies? Will who care for her pets? Will her loved ones be supportive, or will they begin to back away from her? If the woman is alone, without mate or family, she fears becoming unable to care for herself.

The treating surgeon can ease some of the cancer patient’s fear by free and open communication. Educate the patient about exactly what to expect, and offer reassurance if possible. Explain the procedure she is about to undergo, and offer reassurance if possible. The psychological effect of cancer on a woman is largely determined by whether the malignancy is primary, recurrent, or terminal. The surgeon must wrestle with personal ethical and moral conflicts when the surgery for the cancer patient is palliative. Should procedures be performed that extend death and not life? If she is able, the patient herself must make the choice. If the cancer patient elects to have the procedure, her care postoperatively may be shared by radiologists, chemotherapists, and others who specialize in cancer treatment. However, you as her gynecologist should maintain contact and assist in trying to get the patient well or at least enhance the quality of the remainder of her life. Meaningful psychosocial support should be based on established concepts of crisis intervention because cancer is a major life crisis. Counseling should be aimed to support adaptive behaviors and feelings that reduce the psychological stress, restore and consolidate the patient’s self-image, and normalize sexual functioning as quickly as possible.

The Cancer Patient

Bloch cautions physicians that the manner in which the diagnosis of cancer is disclosed to the patient can determine whether the patient lives or dies. It is imperative to instill hope and the desire to fight the disease. A diagnosis of cancer by telephone can be devastating and is viewed by many physicians and patients as a form of cruelty. In her book The Balance Within: The Science Connecting Health and Emotions, Dr. Esther M. Sternberg presents evidence that the relief of stress can make you less vulnerable to illness. The cancer patient shares the same fears common to all surgical patients. She may be psychologically attached to the body part that must be removed. She may fear disfigurement, the unknown, the hospital experience and staff, debility, loss of economic competency, and sexual function. In addition to the normal realm of anxiety associated with surgery, a diagnosis of cancer brings special stresses to a woman’s life. Schain describes universal concerns experienced by people diagnosed with cancer no matter where in the body the cancer is located. These people fear death, postoperative adjuvant treatment, and recurrence.

The cancer patient is concerned about dying or being injured during the operation. Preoperative anxiety can manifest as anorexia, insomnia, tachycardia, fear, and panic. Acute depression is not uncommon and can lead to suicidal tendencies. The patient is afraid of becoming unable to take care of her family members. Will she be sick for long? Will who raise her children if she dies? Will who care for her pets? Will her loved ones be supportive, or will they begin to back away from her? If the woman is alone, without mate or family, she fears becoming unable to care for herself.

The treating surgeon can ease some of the cancer patient’s fear by free and open communication. Educate the patient about exactly what to expect, and offer reassurance if possible. Explain the procedure she is about to undergo and the positive benefits that you both hope will result.

Surgery and cancer in the urogenital region can be consciously or unconsciously interpreted as mutilation. The possibility of some degree of postoperative sexual dysfunction can create a fear of abandonment by the sexual partner. If possible, assure both the patient and her partner that they will continue to be able to bring joy, pleasure, and comfort to each other.

The psychological effect of cancer on a woman is largely determined by whether the malignancy is primary, recurrent, or terminal. The surgeon must wrestle with personal ethical and moral conflicts when the surgery for the cancer patient is palliative. Should procedures be performed that extend death and not life? If she is able, the patient herself must make the choice. If the cancer patient elects to have the procedure, her care postoperatively may be shared by radiologists, chemotherapists, and others who specialize in cancer treatment. However, you as her gynecologist should maintain contact and assist in trying to get the patient well or at least enhance the quality of the remainder of her life. Meaningful psychosocial support should be based on established concepts of crisis intervention because cancer is a major life crisis. Counseling should be aimed to support adaptive behaviors and feelings that reduce the psychological stress, restore and consolidate the patient’s self-image, and normalize sexual functioning as quickly as possible.
The Suicidal Patient

The World Health Organization (WHO) reports that suicide rates have increased 60% worldwide in the last 43 years, with 870,000 annual deaths. Approximately 30,000 people commit suicide each year in the United States. Cooper and colleagues studied more than 6,000 individuals and found that hopelessness ranked the highest of all symptoms associated with suicidal ideation in psychiatric patients and adolescents.

A surgeon probably will not know if a patient is contemplating suicide unless the patient admits to thinking about ending her life or unless a family member voices concern. Subtle warning signs include a chronic state of depression, lethargy, an inability to relate to others, weight loss or gain, lack of interest in life in general or the surgical procedure in question, a change in personal appearance, abnormal sleep patterns, or any strange behavior uncharacteristic of the particular patient. Many of these symptoms are normal for the presurgical and postsurgical patient, so it is easy to see how suicidal tendencies could hide within the maze.

To determine a patient’s suicide potential, ask: Have you been troubled with thoughts of hurting yourself? Barber advises physicians to ask directly: Have you ever thought of taking your own life? Do you feel like taking your life now? If the patient answers yes, the physician should find out if the patient has a simple, straightforward suicide plan that is likely to succeed.

A patient with low to moderate suicide potential is noticeably depressed but can identify some support system. There may be suicidal thoughts but no specific plan. A patient with a high suicide potential feels profoundly helpless. Little or no support system seems to exist. Thoughts of suicide are frequent, and a plan exists that is likely to succeed. The surgeon may be the first person to realize the patient is in emotional trouble and could be the only support system available if the patient has significantly withdrawn from others. Crisis therapy for the suicidal patient begins when the patient requests help or when the surgeon recognizes her potential for self-destruction. By showing interest in her feelings and concern for her welfare, the surgeon initiates crisis intervention.

DEALING WITH DEATH

Death is a taboo subject for most physicians. Many doctors go to great lengths to avoid discussing the eventuality, and most are uncomfortable dealing with the emotional consequences of the death of a patient. To many physicians, death is viewed as a personal failure. Regardless of any internal attitudes, the surgeon is responsible for communicating the facts of the death to the family and for being the first person to help them cope with the loss of their loved one.

When a patient dies, explain to the family, to the best of your ability, exactly what happened. Assure them that everything medically possible was done. Ufema suggests the following guidelines to make the death experience as bearable as possible for all concerned:

- Ask about donations for transplantation.
- Provide an area where the family members can say goodbye.
- If it is true, tell the family members how the patient affected you personally.
- Transfer your protective feelings for the patient to the family members.
- Begin the grief process by saying, “Jane’s body is ready for the morgue now. Would you like to say a final goodbye?”
- If family members want a lock of hair, allow them to take it.
- Give family members the patient’s belongings.
- Provide an escort for any family member who is alone.
- Help the hospital staff cope with the loss.

Remember that it is permissible for the physician to show emotion with the family if the emotion is genuine. Someone is gone and will never see tomorrow.

FUTURE TRENDS

The new millennium was heralded with great joy and celebration. Its predominant theme was one of hope, and nowhere is this more evident than in the field of medicine, specifically for women’s health issues. The hand that rocks the cradle now rules important aspects of the research world. During the next 20 years, 45 million women will enter menopause and live one third to one half of their lives postmenopausally. Research into improving the quality of their lives—and subsequently, all those they touch—has never been more important or timely.

As a multitude of women move through the life stages of maiden, mother, and crone, the health care they receive during one stage will be reflected in all those that follow. Boomer women, born between 1946 and 1964, will continue their legacy of reform by participating in medical clinical studies concerning endocrinology, gynecology, neurology, oncology, genetics, and finally, geriatrics. The daughters and sons they presented to the world will advance reproductive technology in all its genetic and social ramifications.

Robotic gynecological surgery, a recent gift of the technological world, is being performed. It is envisaged that most surgery in the future can and will be performed robotically. The systems currently in use are not intended to act independently from surgeons nor to replace them. They provide a means for the skilled surgeon to complete complex and advanced procedures with increased precision and without a minimally invasive approach. Medical students will soon be able to perfect their surgical techniques using cyberscalps, simulated lifelike patient bodies, three-dimensional models, and long-distance mentors. The space industry has also yielded a smart surgical probe that will be used for breast biopsies. The small disposable needle with multiple sensors will be able to distinguish normal tissue from tumor tissue and greatly reduce the 18,000 breast biopsies per week now performed on women with suspicious lesions. Originally conceived as a robotic tool to aid astronaut/physicians during long-duration space flights, it has already found a medical application on Earth in neurosurgery.

Voice-activated language programs are making it possible to effectively communicate with multicultural patients and international colleagues. Advances in documentation techniques have made keeping and transferring accurate records less of a burden. More ethics classes will emerge to better prepare the medical student for the real-world challenges such as end-of-life issues, fiduciary responsibilities, confidentiality, informed consent, and religious or philosophical conflicts. As surgeons, it will be your duty and privilege to witness, record, and practice the new knowledge and incorporate it with what is already known so that you can make a positive difference in the lives of women now living as well as those yet to be born.
CONCLUSION

Technology will never change the fact that women are emotional creatures by nature, even now that they have the choice whether to menstruate. Few experiences give women more satisfaction than sexuality and conception. Surgery on or near her reproductive tract is potentially fraught with emotional sequelae. The gynecologic surgeon’s responsibility transcends a stunning performance in the surgical arena. Making appropriate decisions about the surgical procedure and consequently managing the patient’s return to physical and psychological health are the hallmarks of an accomplished surgeon.

BEST SURGICAL PRACTICES

■ The gynecologist shall treat the patient’s psyche as well as her soma.
■ Neuroscientific investigation has proven that stress contributes to unfavorable outcomes postoperatively.
■ Preoperatively, the surgeon must make every effort to answer a patient’s questions, allay her fears, and reduce her stress.

■ Unanswered questions regarding the diagnosis, the intended procedure, possible complications, and postoperative sexuality are sources of stress.
■ Cancer patients, young patients, patients living alone without family support, and patients with a language barrier should be considered special-needs patients. Extra time should be devoted to them.
■ Personal communication on a one-to-one basis between the surgeon and patient should take place. Counseling by ancillary personnel and informative booklets should only be used additively.
■ A surgeon should try to be with the patient immediately before her surgery and during the induction of anesthesia.
■ Be familiar with symptoms of depression and look for them during preoperative evaluation. Address potential problems before surgery, and make referrals when indicated.
■ When oophorectomy is anticipated in a premenopausal patient, estrogen replacement therapy should be discussed and encouraged before surgery if there are no contraindications.
■ Extra time spent listening, informing, and reassuring an anxious patient before surgery is often rewarded by a fast and uneventful recovery.

CHAPTER 4  PROFESSIONAL LIABILITY AND RISK MANAGEMENT FOR THE GYNECOLOGIC SURGEON

Charles J. Ward

DEFINITIONS

Ethical principles are the principles utilized to guide the medical profession in resolving conflicting obligations in health care. The five major ethical principles that are utilized are:

1. Autonomy—The moral right to bodily integrity and self-determination.
2. Beneficence—The duty to do good and be concerned for the medical well-being of the patient.
3. Nonmaleficence—The duty to refrain from harming the patient.
4. Justice—The right of the patient to be treated fairly and to a fair allocation of limited medical resources in the community.
5. Freedom—The ability to choose as well as to refuse treatment. Freedom also implies a lack of coercion, manipulation, or infringement on the patient's decision-making process.

Informed consent—A legal doctrine that requires physicians to obtain consent for treatment, whether it is diagnostic or therapeutic, medical or surgical, invasive or noninvasive.

Judgmental decision—A decision supported by either literature or common use that is generally defensible and not malpractice.

Medical malpractice—Occurs when the treatment rendered is constituted to be below the degree of care exercised by physicians generally under the same or similar set of circumstances. A direct cause-and-effect relationship must exist between the breach in the standard of care and the outcome to constitute malpractice.

Malocurrence—A poor clinical outcome that did not arise from a breach in the standard of care.

Standard of care—The degree of care exercised by physicians generally under the same or similar set of circumstances.

Risk management—Refers to those medical practices, protocols, and procedures that are designed to reduce patient injury and improve clinical outcomes.

In the new millennium, the gynecologic surgeon both in the United States and in Europe is not only faced with the constant threat of malpractice litigation but also with rapid advances in technology. These pressures require the need for continued education and training so that the surgeon practices within the current and evolving standard of care. This chapter outlines practical steps that should reduce the exposure to malpractice claims. It also discusses the litigation process and its emotional impact on the physician. This chapter is neither to be considered a substitute for legal counsel nor a source of legal advice. A bibliography is furnished for those who wish to explore this subject further.

The history of liability suits extends back to the 14th century. The first recorded malpractice suit in English law occurred in 1374. This case involved an action brought before the King's Bench against a surgeon, J. Mort. The plaintiff sustained an injury to the hand, and treatment of this injury left the hand maimed. The defendant surgeon was found not liable because of a legal technicality in the writ of complaint. But the rule was clearly laid down that if negligence were proven, the law would provide a remedy. The court further held that, "if the surgeon does well as he can and employs all his diligence to the care, it is not right that he should be held culpable."

The civil liability of surgeons arises out of the rule laid down in 1534 by the English jurist Sir Anthony Fitzherbert, which stated, "it is the duty of every artificer to exercise his art right and truly as he ought."

The first recorded malpractice suit in the United States occurred in Connecticut in 1794 and was also against a surgeon. In this case, Cross v. Guthrey, the patient's husband sued the surgeon, Dr. Guthrey, after the patient died from postoperative mastectomy complications. The suit alleged that the doctor was guilty of negligence in operating on the plaintiff's wife in the most unskilful, ignorant, and cruel manner, contrary to all the well-known rules and principles of practice in such cases, that the patient survived by but three hours, and that the defendant had wholly broken and violated his undertaking and promise to the plaintiff to perform and operation skillfully and with safety to his wife.

The jury found the surgeon liable and awarded damages of £40.

The 1970s and 1980s found the United States engulfed in a malpractice crisis. The malpractice trend has continued into the 21st century, both in the United States and Europe. The millennium continues to bring additional pressures to bear on the gynecologic surgeon. These pressures arise from areas such as the transformation of the practice from a fee-for-service (FFS) reimbursement to various managed care programs, third-party payer interventions, declining incomes yet increasing overhead costs, longer work hours, and sizable malpractice premiums. The 2003 survey of the American College of Obstetricians and Gynecologists (ACOG) membership revealed that nationally a 53% increase in malpractice premiums had occurred in the United States since the 1999 survey. Because the obstetrician/gynecologist performs six of the 10 most common surgical procedures, it is not surprising to find
this specialty to be the most frequently sued. The 2003 ACOG survey found that 76.3% of all fellows have been sued at least one time. The obstetrician/gynecologists surveyed had an average of 2.64 claims filed against them during their career. Even resident physicians in training reported that 28.6% had at least one professional liability claim filed against them during their training. Gynecologic care involved 38.3% of all claims filed. Of the gynecologic claims, delay in or failure to diagnose was the most common allegation and accounted for 29% of gynecologic claims. Of these, failure to diagnose cancer accounted for 62.8% of the claims. Failure to diagnose breast cancer was the most frequent type of cancer involved and accounted for 19% of the claims. The second most frequent claim involved failure to diagnose cervical cancer, which accounted for 7.4% of the claims. Failure to diagnose ovarian cancer accounted for 7.3% and was third in the failure to or delay in diagnosis of cancer cases. Major patient injury accounted for 25.4% of these claims. On average, four years elapsed from the onset of the claim to its closing. Of all the claims, 49.5% were dropped or settled without any payment on behalf of the Physicians. Obstetricians/gynecologists won 73.1% of those claims that were resolved by jury or court verdict, arbitration, or other alternative dispute resolution mechanism.

Contrary to popular impressions that “bad doctors” are the cause of most malpractice actions, studies have shown that physicians who possessed higher qualifications, were board certified, and had more experience were more likely to be sued. This is in part because of the fact that such physicians manage higher-risk patients; therefore, they are more likely to encounter adverse outcomes that can be a source of litigation. Medical malpractice occurs when the treatment rendered is constituting to be below the degree of care exercised by physicians generally under the same or similar set of circumstances. Today most communities are held to a national standard of care that is defined as a duty to exercise the degree of care and skill expected of a reasonably competent practitioner in the same specialty acting under similar circumstances. Malpractice, or a poor outcome, is not malpractice unless the outcome arises from a direct effect of a breach of the standard of care. Substandard care per se does not always imply malpractice. There must exist a direct cause-and-effect relationship between the breach of the standard of care and the outcome to constitute malpractice.

RISK MANAGEMENT

Risk management refers to those medical practices and procedures that are designed to reduce patient injury and improve clinical outcomes. Risk management is an approach to the practice of medicine that minimizes the risk of lawsuits by practicing in a manner that reduces the possibility of human error, increasing the likelihood of obtaining desired results and providing a medical record that clearly outlines the treatment rendered, which in turn makes such a record very defensible. Risk management, whether in an office or hospital setting, must be a team effort. Each member of the health care team must understand that his or her actions can lead to liability for the others. This means that each member of the health care team must not only understand his or her responsibilities and duties, but also be capable of carrying out those responsibilities and duties.

Many hospitals now employ risk managers. Among their duties is the investigation of incident reports and adverse outcomes. The use of incident reports should be encouraged. An appropriate reply should be made to the author of such reports so that the author feels that they are not only contributing to the improvement of patient care but also that the hospital appreciates and considers their contributions. The risk manager should be able to establish appropriate targeted audits that help the institution identify its risks. With this knowledge, the staff and appropriate departments then can develop procedures and policies to correct the identified problems. Risk management should never be considered a punitive exercise, but rather an approach that will improve the quality of care rendered by all health care professionals.

Risk management cannot always prevent a lawsuit; however, frequently it can protect against a nonmeritorious claim or at least improve the outcome of a malpractice claim. Risk management also has been shown to decrease malpractice premiums in states where it was actively employed. The four cornerstones to solid risk management for the gynecologic surgeon are good surgical technique, appropriate knowledge of current developments and therapies, adequate documentation, and good patient communication. The former two are discussed throughout this book; the latter two are discussed in this chapter.

DOCUMENTATION

Documentation, or its absence, is a major problem in malpractice claims. The finest care given under the best of circumstances, if not documented, may be difficult if not impossible to defend in a court of law. Documentation should be made contemporaneously so that significant facts or incidents are not forgotten. Records should contain adequate documentation to provide sufficient reasons why a procedure was indicated or undertaken. Typed reports are preferred to handwritten reports because they are more legible and open to less question of interpretation. Physician notes should be factual, complete, and relevant. They should neither embellish nor appear grandiose. Only appropriate and widely accepted abbreviations are to be used. It is prudent to document both important negative findings and positive findings, especially in complicated cases. In court, those findings, positive or negative, not documented are often presumed to never have been established. Determination of statements about the patient should be avoided, but it is prudent to document inappropriate patient behavior. This includes noncompliant behavior, such as failure to get requested tests or follow given advice. Broken or missed appointments also should be recorded. Medical records, especially operative notes, should avoid the words unintentionally, inadvertently, accidentally, unfortunately, and unexplainable because they imply negligent behavior. For example, in the case of ureteral injury, the surgeon can state that the ureter was cut, and the injury recognized and repaired. However, it is important to detail difficult dissections, the presence of extensive adhesions, or any event that makes a surgical case more difficult. It is always wise to outline a plan of therapy. The surgeon should be aware that judgmental decisions, supported by either literature or common use, are defensible and are not malpractice, even if they result in a less than desirable outcome.

There is a proper way to correct a record. Draw a single line through the error, but never obliterate the error. Write the correction either in the margin or on a separate page. Then date and initial the correction. Never change a record after a suit has been filed, because such behavior can lead to loss of credibility and generally makes a case indefensible.

OFFICE SETTING

The office frequently can be the catalyst of a malpractice claim. It can begin with the telephone, which some consider to be the...
most dangerous of liability risks. Misunderstanding and miscommunication easily can occur over the telephone. Improper telephone etiquette may change a disgruntled patient into an angry one who contemplates the instigation of a malpractice claim. Make sure that messages that require a reply by the physician are delivered in a timely manner and that the advice given is documented. Telephone calls of an urgent or emergency nature must be handled appropriately, but also documented in the office chart with the date, time of call, time of response, and advice given. Prescription refills as well as patient instructions given over the telephone should be contemporaneously entered in the chart. Only standard abbreviations should be used in the medical chart. A protocol should be established to make sure that after-hour phone calls, problems, advice rendered, and prescriptions are documented in the patient’s record.

Employees of the surgeon’s office should be encouraged to provide a warm, courteous, and caring environment for patients who, for the most part, will be under considerable stress as they anticipate surgery or encounter the postoperative limitations that the surgery places on them.

New patients should be told of office policies regarding type of examination, laboratory work, and expected charges. This may be accomplished through written material. Owing to the time constraints that are often placed on the physician by managed care plans, the initial intake information is often obtained by forms filled out by the patient or a member of the office staff. The information should include not only the patient’s symptom and pertinent history, but also past medical, surgical, social, and family history. Drug allergies, identified risk factors, and current medications should be noted. The physician should review this information with the patient to clarify any questionable areas and be sure that the information is adequate for the appropriate management of the patient. Because the gynecologist is now taking care of an aging population, it is extremely important that the gynecologist be aware of all medications the patient is taking. This knowledge can decrease the risk of drug interactions and adverse reactions as new medications are added to the patient’s regimen. In this regard, physicians should be encouraged to have the names of the patient’s current practitioners, so that the gynecologist can consult with them as needed. It also is prudent for the gynecologist to have access to a pharmacist, who may be more qualified to check for drug interactions, so that he or she can discuss any questions in this area when new medications are prescribed.

Appointments should be scheduled so that long delays are avoided, and overbooking should be discouraged. Remember that the patient’s time is as valuable to her as yours is to you. Records should be kept of broken or missed appointments. This type of information is extremely helpful in establishing a noncompliant behavioral pattern. A protocol should be established for the follow-up on patients who fail to keep appointments. The patient’s confidentiality can be broken not only by employee gossip, but also by inadequate soundproofing in examination and consultation rooms. A simple test can be conducted by the surgeon by going into an examination room during working hours to see if he or she can hear conversation by the staff in the halls or other areas of the office. If such a problem exists, the staff should be made aware of it. Some simple solutions—such as background music and keeping up-to-date reading materials in the examination room to absorb the attention of patients awaiting the physician—may help to alleviate this potential breach of the patient’s confidentiality.

A protocol should be in place so that reports, such as laboratory and x-ray studies, are seen and initialed by the physician before filing. Patients should be encouraged to call for the results of their tests (especially mammograms, because such results can be lost in the mail), but the physician may be held responsible for such reports. The patient can be made aware of this responsibility through verbal reminders as well as written notices posted conspicuously in the office.

Because the failure to diagnose breast cancer is a leading cause of malpractice claims, it is prudent for the gynecologist to have a clear and sound approach to patients presenting with a breast mass or symptom. Chapter 41 outlines the risk factors, diagnosis, and treatment of breast diseases. From a risk management approach, documentation is critical. It is prudent that the patient’s medical record document the date the patient first noticed the change, the symptoms noted, and a detailed description of the physician’s findings. Drawings of the mass showing the location and exact measurements of the change are most helpful. In some malpractice claims involving breast cancer, the patient has alleged that she told the gynecologist about breast symptoms on prior visits. Thus, it would be prudent for the gynecologist to document whether the patient had any breast symptoms or symptoms or complaints on every visit. Recommended referrals, as well as follow-up and return visits, should be recorded. A system of in-office chart follow-up for these high-risk patients is prudent. Reports of mammograms or other studies should exhibit evidence of review by the physician. If the patient fails to follow advice, the office records should note this, along with all attempts to contact the patient.

Billing and financial records have no place in the medical records. They must be kept separate. A confidential area should be made available for the patient to discuss the fees, insurance matters, or the bill. It is strongly advisable that the physician review every bill before it is turned over to a collection agency. The act of turning a bill over to a collection agency has been the start of many malpractice claims. When records are requested, make sure to send only copies and only after the appropriate patient authorization has been obtained. Most states have laws that prohibit the transfer of records that deal with drug and alcohol abuse or mental illness without the express authorization of the patient. If the physician sends such information without proper authorization, a separate cause of action can be brought against the physician. Therefore, it is important to be aware of the individual state’s laws. Always retain the original copy for as long as your state requires or the statute of limitation exists. Information of this nature usually can be obtained from the state medical board or medical society.

HOSPITAL SETTING

The hospital setting is the source of most events that lead to malpractice claims involving the surgeon. Patients entering the hospital are under considerable stress and may not comprehend the full scope of their therapy. Patients should be made aware that perfect outcomes cannot be guaranteed. They should be made to understand that the chance of an unfavorable outcome is not necessarily related to the quality of care but can occur virtually in any medical encounter. Results should never be guaranteed, but realistic expectations should be given, especially when performing corrective surgery, such as procedures for the treatment of urinary incontinence.

The hospital chart is an important vehicle for communicating significant information needed by the entire health team. Because what is not written cannot be presumed to not have occurred, it is critical that the chart is complete, thorough, and that documentation be recorded contemporaneously. The chart should reflect the outline for...
the plan of management, both current and future, using only approved abbreviations. By clearly writing out the plan of management, especially in complicated cases, the entire health team is able to understand the approach to the treatment and respond in a positive and appropriate manner. Electronic medical records that contain the history, physical exam, physician progress notes, nursing notes, and lab and radiology reports, and that are readily accessible to the entire health care team have been shown to improve patient care.

Daily progress notes are generally advisable; however, more frequent notes are appropriate in complicated cases. Progress notes should not be dated, but also timed. The timing of notes can be most beneficial from a risk management point of view. When a change in the patient’s condition develops and the surgeon is notified of the patient’s status, the response time may be critical in establishing the standard of care. The surgeon should develop the habit of timing all notes so that the habit becomes well established. Thus, the surgeon is less likely to forget to time a note in a critical situation.

Consultation should be encouraged, especially in complicated cases. Most patients appreciate this concern and understand that it is impossible with today’s rapidly expanding advances in technology for one physician to have complete and superior knowledge in all situations. When consultation is obtained, to avoid confusion and lack of direction in the patient’s therapy, one physician should be appointed to coordinate therapies and supervise critical orders.

The surgeon should carefully review all nursing notes on a daily basis. When there is a discrepancy between the observations of the physician and the nurse, the differences should be discussed. Then both parties should write clarifying notes that make sure that the physician and the nurse, because mistakes can be made when what is heard was not what was intended. For example, the nurse may misinterpret an order for 16 units of insulin as 60 units of insulin, thus it is prudent to say “one-six” instead of 16 when giving a verbal numerical order. Never prescribe by ampules, vials, or volume, but rather by milligrams. Avoid the symbols < for less than and > for greater than, but rather write out the words for the symbols, as the symbols have been misinterpreted, leading to significant errors.

Abbreviations used in physician orders have led to many errors in interpretation. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has issued a minimum list of dangerous abbreviations that must be on every hospital’s do not use list to be in compliance with accreditation requirements (Table 4.1). These abbreviations should not be used in any of their forms, including upper- or lowercase or with or without periods. Other abbreviations that should be considered for prohibition are:

- mg (for microgram); use mcg
- D/C (for discharge); write out discharge
- H.S. (for half-strength); write out half-strength
- c.c. (for cubic centimeter); use mL
- T.I.W. (for three times a week); write out three or 3 times a week
- Q.I.D. (for four times a day); write out four or 4 times a day

JCAHO, Joint Commission on Accreditation of Healthcare Organizations.

It is imperative that derogatory remarks not be made in a patient’s record. Physicians should never criticize the care rendered by another physician in front of the patient, nurse, or professional liability and risk management for the gynecologic surgeon. 45
in an area where others may hear the discussion. There are proper avenues to take if one is dealing with an incompetent physician. To avoid breaching patient’s confidentiality, idle discussions with other health care providers on elevators, in halls, or in the operating theater are to be avoided.

Follow-up and discharge care should be explained thoroughly to the patient. In an outpatient surgical center, at the time of discharge, many patients may still be under the influence of anesthesia or drugs that cloud their memories. Therefore, it is prudent not only to give verbal but also written discharge instructions. These instructions should cover medication, activity, diet, wound care, and follow-up appointments. The dose of any medication as well as the duration of its use should be noted clearly. Abbreviations that may not be understood by the patient are to be avoided. The physician’s answering service and emergency phone numbers should be provided. A copy of the discharge instructions should be given to the patient, and one should be retained in the chart.

When a complication or less than desirable outcome occurs, the surgeon should promptly have a frank discussion concerning the matter with the patient and other significant family members. Spending the time and providing quality information in an honest and thorough manner is appreciated by the patient and the family and often diffuses a potential malpractice claim. Saying that you are sorry is not an admission of guilt. Most patients, when given a reasonable explanation of a less than desirable outcome, accept our human limitations, but disgruntled patients sue. It is important to convey the fact that medicine remains an art and is not an exact science.

Hospital rules and protocols are established to insure uniform quality of care. The physician or nurse’s failure to comply with these rules and protocols can be interpreted as a violation of the standard of care. Therefore, it behooves all members of the health team to know and understand the appropriate rules and protocols. If the surgeon feels that he or she needs to alter a rule or protocol for a patient’s benefit, he or she should document the reason contemporaneously in the hospital chart.

Surgeons must stay abreast of current technological advances; however, before using these advances, they must be adequately trained. A borderline skilled surgeon who is learning new procedures on private patients without the patient’s knowledge or approval is not only risking a malpractice suit, but also may be accused of practicing under questionable ethical standards.

The resident or house officer adds another potential risk to the patient’s safety. All residents or house officers practice as trainees under the supervision of the training institution and the clinical faculty, or full-time faculty, are usually held accountable for their own actions. Thus, it is important for the surgeon in a supervisory role to not only review the chart, but also assess the patient. If the supervising physician disagrees with a resident’s evaluation, a discrete discussion of the matter should be held with the resident. Then the surgeon and resident should document the appropriate findings and note the rationale behind his or her change in observations or therapy.

On initial contact with the patient, residents or house officers should convey the fact that they are trainees or residents, especially when training in a private hospital or facility. The patient has the right to refuse treatment by a resident, but most accept the advantage of such supervised training. It is prudent to document the acceptance or refusal of medical care from the resident or house officer, especially in an institution that is not directly connected with a medical school. When the patient is admitted to the hospital under the care of a resident, the resident should go over the reason for hospitalization. They should discuss the recommended therapy, appropriate alternatives, potential benefits, risks, and complications of the proposed therapy. The resident should only perform those procedures, without supervision, for which he or she has been fully trained. If a patient’s condition requires expertise beyond the resident’s capabilities, the resident must inform the supervisory physician of the nature of the patient’s condition and the need for procedures beyond the resident’s expertise. If a complication arises, the resident, preferably in the presence of the attending physician, or a nurse, or other member of the medical team should take time to thoroughly and openly discuss the complication and its impact on the patient’s subsequent treatment and hospital stay. This conversation should then be documented in the chart.

**MANAGED CARE AND SOCIALIZED MEDICINE**

Managed care was created in an effort to control the rapidly rising U.S. health care costs. The ideal goals of managed care were to reduce cost, improve clinical outcomes, and control the utilization of resources; however, these goals have not always been achieved. Managed care has become the dominant form of health care delivery in the United States and has had a tremendous impact on physicians as various types of managed care programs have rapidly replaced FFS. Managed care continues to evolve in an effort to meet the demands of the health care industry. At present, the major types of plans include: (a) health maintenance organization (HMO), which also includes independent practice associations (IPA) and preferred provider organizations (PPO); and (b) point-of-service (POS) plans. HMO plans provide or arrange coverage of specific health care services for a fixed prepaid fee. In-network providers required by the members then provide the service. In the IPA-type HMO, the plan contracts with individual physicians who maintain their own independent practice, offices, medical records, and staff but see HMO members. POS plans contract with independent providers who provide services at a discounted rate. Members in this plan generally use in-network providers but are permitted to use out-of-network providers as long as the member is willing to pay a higher out-of-pocket fee.

POS plans generally offer the cost control of an HMO plan with the choice of the FFS plans. This is accomplished by allowing members in the plan to choose from an HMO, PPO, or indemnity plan at the time the service is rendered. At present, POS plans have become the fastest growing managed care type plan.

In any managed care plan, financial conflicts can give rise to risks and liabilities for the physician not seen in an FFS form of medicine. Problems can potentially arise when a physician is paid through a capitation scheme or receives year-end bonuses or other monetary rewards for utilization of services. In capitation, the physician receives a fixed dollar amount to cover the cost of health care services for enrolled members of the plan. This per capita rate is paid on a periodic basis whether the physician does or does not provide service to all members of the plan. This is intended to reduce overuse of services. Although this system of payment is a powerful incentive for the physician to manage patients as efficiently as possible, conflicts can arise when services provided by the physician exceed the financial reimbursement from the plan. Such conflicts of
interest can impair the physician’s moral judgment, threaten the patient’s health and well-being, and threaten the physician’s professional credibility. The physician cannot jeopardize the patient’s care because of financial constraint placed on him or her by the managed care plan. Physicians must make patient-care decisions based on what is best for the patient even if such decisions adversely affect the physician’s financial status. The patient’s care should not be compromised because of financial constraints or treatment that are available, even if the plan does not cover the cost of the preferred method of treatment, drug, test, or device. In such cases, the physician must become the patient’s advocate and provide the care required to meet the patient’s needs, even if the physician is not compensated for the care rendered. Legal precedents have established that the physician should act as a patient advocate in disputes over the financial cost of appropriate treatment and should attempt to convince the managed care plan administrators that the care is not only warranted, but that the care is the most appropriate for the patient’s condition. Failure to practice within the standard of care because of the financial constraints of a managed care plan is never a defense should a malpractice suit arise from such an incident.

Under managed care plans in the United States and socialized medical plans in Europe, certain fundamental ethical values have become endangered owing to the financial constraints placed on the access to certain treatments, tests, or drugs, and the limitation to the availability of these treatments in a timely manner. These include fiduciary beneficence (the physician’s obligation to act for the benefit of the patient), patient autonomy (the patient’s right to make informed judgments regarding her care), and justice (the right to an adequate level of health care that is both available and accessible to all individuals). The physician must remain a strong advocate for the patient. The physician must have input into the decision-making process to be sure that resources are allocated in a proper and just way so that cost containment and economic efficiency are morally legitimate goals that enhance rather than undermine the quality of health care. Physicians must continue to inform the patient of the best treatment options available, whether or not these options are covered by the managed care plan or socialized medicine. They must remain a strong advocate for their patient’s rights and should refuse to participate in medical plans or schemes that have policies that are deemed unethical.

COMMUNICATION

Good communication is a major key to preventing malpractice claims. It has often been stated that satisfied patients are less likely to sue, but disgruntled patients will sue. It has been shown that even physicians with borderline skills but excellent bedside manners are less likely to be sued than well-trained board-certified specialists who lack communication skills. Initial impressions are usually long lasting. Therefore, it is important on the first visit to convey the physician’s philosophy and the nature of his or her practice. It is prudent to explain what the physician expects from the patient in this relationship because expectations and responsibilities exist for both the patient and physician. Patients are generally looking for a physician who is easy to talk to and will answer questions, be accessible, be fair, show respect, and provide good care for a reasonable cost. Inattention, indignation, and injury can be not only the cause for a suit, but in combination also dramatically increase the probability of a suit.

Surgeons should be aware that the majority of what a patient perceives is obtained through nonverbal communication. Patients generally retain only 30% of verbal communication. Body language, posture, and facial expressions all convey strong messages. For example, the surgeon who stands with his or her hand on the door and asks, do you have any questions, sends a strong message that he or she really does not have the time to answer questions; that his or her time is more important than the concerns of the patient. Simple things such as sitting in a relaxed position when the physician discusses a patient’s condition or treatment generally convey a feeling of caring and concern. If notes or prescriptions are written in the examination room, the surgeon should make every attempt to face the patient while performing this task. The surgeon’s back does not convey a sense of caring or concern.

In the hospital, the physician has to write daily progress notes and orders. The patient’s bedside is an excellent place to write them. The surgeon can explain the orders and therapy as they are written. Patients who are medicated have a slower reaction time and tend to easily forget things that are important to them. The silence that may ensue as the surgeon writes a note or thinks about the management gives the patient time to recall those important questions. This type of interaction builds trust and gives the patient the feeling that she is actively participating in her care and therapy.

Surgeons often do not realize the significant degree of stress a patient undergoes while she lies on the operating table before being anesthetized. The simple act of holding the patient’s hand at this time can not only have a calming effect, but also demonstrate the physician’s concern and care for the patient’s well-being. In the operating room, little things such as warming speculum on a heating pad in the examination table drawer, providing adequate areas to dress and undress, and having mirrors in the examination room all help to convey a sense of caring for the patient’s needs. During the preoperative visits, patients will often mention that their physicians are praying for them. The surgeon may request that prayers are also offered to guide the surgeon’s hands and judgment to bring about a cure from the malady requiring surgery. Some surgeons are known to offer a prayer at the start of an operation. Patients generally appreciate this expression of faith and sensitivity. These gestures also tend to strengthen the patient-surgeon bond.

Good communication encourages questions and involvement of family members, especially partners. Therefore, it is important that the physician, preferably, or a designated nurse or physician assistant take the necessary time to answer the patient’s questions and address concerns in a setting where respect and confidentiality can be maintained easily. Beware of the patient with the “great expectation syndrome.” Physicians have greatly oversold their abilities and have created false expectations that have led to unjustified expectations. If the surgeon feels that the patient expects more than he or she can reasonably provide, it is prudent to refer this patient to another physician.

When it becomes necessary to terminate the doctor-patient relationship, the surgeon must remember that this relationship is a contract, be it informal or implied, and certain steps are required to break the contract. The patient should be sent a letter by certified mail, return receipt requested. The letter should state a specific date for the termination to occur, usually 30 days from the date of mailing. The letter should contain a release for the patient’s records. The patient should be instructed to sign and return the release before forwarding any of the patient’s records. Always send a copy of the records, and never the original records, to the physician of her choice. The physician may include a list of other gynecologists in the patient’s area or refer her to the local medical society for appropriate referral. These letters of termination need not go into great detail as to
why the contract is being terminated. It is perfectly acceptable to say that, owing to a personality conflict, the surgeon does not feel that he or she can provide the quality of care the patient should receive. Thus, the physician is requesting that the patient seek care elsewhere. The physician is required to treat any emergency that might arise before the specified termination date.

Proper communication can result in physicians getting other physicians sued. Negative comments made about other physicians continue to be a major source of problems. As Walt Kelly's cartoon character Pogo once stated, “We have met the enemy and he is us.” Nonprofessional opinions written in the medical record can open the treating surgeon, hospital, or other health care members to malpractice actions. Careless talk, second-guessing colleagues, and open debate, carried out in public areas, regarding the patient's treatment or status can all lead to unwarranted malpractice claims.

In situations involving multiple physicians, such as a group practice, communication between those physicians is extremely important. The medical records must be a complete and thorough source of this information. The records should reflect clear and factual accounts so that confusion does not arise regarding the patient's treatment or status. Lack of such communication can increase the risk of liability claims. In group practices, it is prudent to have set aside a specific time to discuss patients, especially those with complicated courses.

A physician should know his or her limitations and not let an inflated or unrealistic ego prevent appropriate consultations when the patient's condition may exceed his or her expertise. Continuous and appropriate communication with the consulting physicians ensures that the patient receives the highest quality of care, the goal all physicians strive to achieve.

**INFORMED CONSENT**

Informed consent is a legal doctrine that requires physicians to obtain consent for treatment, whether it is diagnostic or therapeutic, medical or surgical, invasive or noninvasive. Without informed consent, the physician can be held liable for violating the patient's rights regardless of whether the treatment was appropriate and rendered within the standard of care. Failure to obtain informed consent may result in the physician being accused of battery under common law.

Failure to provide informed consent was the primary charge in 2% of malpractice claims in the 2003 ACOG survey. This was a decrease from 5% recorded in the 1999 ACOG survey. The failure to provide adequate informed consent was found to be a secondary issue in almost one third of malpractice claims. Informed consent is an ongoing process that includes the exchange of information and the development of choices. Informed consent is a process of ongoing shared information. Physicians must disclose varying amounts of information based on the individual's personal needs and peculiar circumstances for reasonable communication. A physician's biases, the patient's rights, and confidentiality may also create problems while making ethical decisions. Conflicts of interest may arise. These conflicts may occur when the patient's well-being conflicts with managed care, physician's financial interests, treatment protocols, care plans, or practice guidelines. The American College of Obstetricians and Gynecologists has published excellent texts to address these concerns in detail.

Courts have recognized and states have adopted three different degrees of disclosure in informed consent. The first, the professional or reasonable physician standard, was prevalent before the 1970s. This degree of disclosure was based on the type and amount of information that a reasonable physician would tell the patient about the risks and benefits of a particular treatment. This paternalistic approach began to give way in the 1970s to the second type of disclosure, the materiality or reasonable patient viewpoint standard. This gave patients more input into the decision-making process. Under this standard, the physician had to disclose what a “reasonable person” would want to know under similar circumstances concerning the risks and benefits of a particular treatment. This concept is based on the patient's need rather than the professional perception of what the patient should know. The third, but not widely held, disclosure is the subjective patient viewpoint. Under this disclosure, physicians must disclose varying amounts of information based on the individual's personal needs and peculiar requirements. This form renders a standard extremely difficult for physicians to understand and apply. The need for informed consent can be suspended in an emergency situation, but specific criteria must be met for a situation to be declared an emergency. The patient must be unconscious or incapacitated and suffering from a life-threatening or serious health-threatening condition requiring immediate medical treatment. It is important in these situations for the physician to document the following: a description of the patient's condition at the time of the emergency, the reason the emergency existed, and an explanation for the need for immediate attention.

Patients have the right to refuse treatment after receiving informed consent. Under these circumstances, for legal protection, the physician should document the reason the patient gave for refusal of the proposed treatment. The reason the physician felt that the proposed treatment was indicated, and the possible jeopardy to the future health and well-being of the patient that might occur from the refusal of the treatment.
It would be prudent to have the patient sign a statement acknowledging the refusal for treatment and listing the potential adverse consequences that might occur. Another possible solution to informed refusal is to have the patient write a note in their own hand, in the clinical record, that not only states that the patient understands the consequence of refusal of treatment but goes on to list the potential adverse complications of her refusal, even during death if that is appropriate. The patient should then sign her statement, and the physician and preferably a third party—such as a nurse, or preferably a family member—should witness the note.

The office setting provides the best environment for providing informed consent for several reasons. In this setting, the time for adequate consideration and adequate discussion is provided. Family members who have a definitive influence on the patient's decision can attend or be encouraged to attend. If the physician lacks the ability or time to provide the necessary adequate informed consent, the physician can delegate this responsibility to a nurse practitioner or physician assistant who has been previously trained to provide informed consent and is able to answer the patient's questions. Pamphlets, audiovisual, and even interactive visuals can greatly assist in this process. Because people rarely retain more than 30% of verbal communications, the average patient leaves the physician's office having forgotten or not understanding most of what was shown and explained. Thus, the more the patient receives in writing or by audiovisual instruction, the better is her understanding.

Once the process of informed consent is complete, the physician can document the record to reflect when it took place, what was disclosed, that the patient had time to ask questions and have her questions answered to her satisfaction, and that the patient then requested the proposed treatment. Well-informed patients are more likely to have unrealistic expectations and sue when these expectations are not met. Therefore, the best protection to a malpractice claim may come from taking full advantage of the legal doctrine of informed consent.

The degree of disclosure in informed consent varies from state to state. Some states require elaborate consent, others much less. When a complication develops that was disclosed, that the patient had time to ask questions and have her questions answered to her satisfaction, and that the patient then requested the proposed treatment. Well-informed patients are more likely to have unrealistic expectations and sue when these expectations are not met. Therefore, the best protection to a malpractice claim may come from taking full advantage of the legal doctrine of informed consent.

There is almost universal agreement that informed consent should encompass the following six areas:

1. Diagnosis
2. Nature and purpose of the procedure
3. Risks of the procedure
4. Likelihood of success
5. Reasonable alternatives
6. Prognosis if the treatment is refused

Figure 4.1 is a general surgical informed consent form meeting these requirements. There are several particular points to note. Firstly, throughout the form, the words “I request” or “request for surgery” are included. These words are used to place greater emphasis on the patient's responsibility for her choice in selecting the proposed procedure. Next, a list of the “general risks of surgery” is provided. This list not only covers those risks that can arise from any surgical procedure but also the risks associated with anesthesia. In describing the risks and complications of the procedures, the words “may include but are not limited to such complications as” have been added and are used to indicate that the physician did not attempt to list every potential complication but rather those that a reasonable patient would expect to know before making a decision. In the section on alternative forms of treatment, the words “such as” indicate that only those alternatives considered to be appropriate need to be listed. Finally, space is provided to list any additional materials that the patient was given or might have reviewed in making her decision. If a claim is made by the patient that the decision was made in a jury the situation surrounding the alleged act of negligence and use the same material in his or her defense to show that a reasonable person was properly informed.

Figures 4.2 through 4.7 are informed consent forms covering the six most common gynecologic operative procedures. These forms describe each procedure in words that a patient can comprehend easily. A reading specialist has reviewed these informed consent forms and placed them in a language level of an individual with a sixth-grade education, which is generally that used by daily newspapers. Each of these forms covers the risks and complications as well as alternatives that apply to the specific procedure along with the “general risks of surgery.”

Figure 4.2, the informed consent and request for dilation and curettage, hysteroscopy, and cervical biopsy, lists the most common complication seen—namely, perforation of the uterus. It also notes that the procedure can have an adverse impact on subsequent pregnancies.

Figure 4.3, the informed consent and request for hysterectomy, covers complications seen, including injuries to the gastrointestinal tract, the most frequently seen complication. It also discusses the risk associated with blood transfusion.

Figure 4.4, the informed consent for laparoscopy-assisted vaginal hysterectomy or LAVH, goes over the complications of hysterectomy and the complications that laparoscopy may add to the procedure.

Figure 4.5, the informed consent and request for sterilization, clearly states that the procedure is not designed to be reversible. Many patients have a sterilization procedure performed in their twenties and, in this age of divorce and remarriage, later request that the sterilization be reversed. When the procedure cannot be reversed, patients may sue with a claim of “lost opportunities.” This statement in the informed consent is designed to cover that particular area. Ectopic pregnancy, one of the known and accepted risks of any sterilization procedure, is clearly spelled out.

Figure 4.6, the informed consent and request for diagnostic and therapeutic laparoscopy, reviews the more commonly seen complications of injury to the gastrointestinal or genitourinary tracts and vascular injury. The form also notes the risk of exploratory laparotomy. This provides an opportunity for the physician to discuss this potential extension of a laparoscopy procedure so that the physician is not hesitant to proceed with laparotomy when the findings require that procedure.

Figure 4.7, the informed consent for repair of relaxation of pelvic organs and/or the correction of urinary incontinence problems, notes that recurrence of urinary incontinence is a potential complication. This is designed so that false expectations from the surgical procedure are not created.

These procedure-specific informed consent forms are detailed but have been found to be acceptable to patients. They also have made the defense of surgical complications much easier, especially when there is no negligence.

The legal requirements of informed consent vary from state to state and jurisdiction to jurisdiction. The surgeon should be aware of the degree of specificity required in specific laws on informed consent that exist in his or her state. County or state medical societies are usually able to assist in providing this necessary information.
INFORMED CONSENT AND REQUEST FOR SURGERY

I, ___________________________________, request Dr.____________________________________________
and his/her associates / assistants to perform upon me (name of procedure):

____________________________________________________________________________

Diagnosis and Procedure: The following has been explained to me in general terms and I understand that:

My condition has been diagnosed as: _____________________________________________________________
The nature of the procedure is: __________________________________________________________________
The purpose of this procedure is to: ______________________________________________________________

General Risks of Surgery: As a result of the performance of this procedure there may be general risks involved
such as: INFECTION, ALLERGIC REACTION, DISFIGURING SCAR, SEVERE LOSS OF BLOOD, LOSS OF
FUNCTION OF ANY LIMB OR ORGAN, PARALYSIS, PARAPLEGIA OR QUADRIPLEGIA, BRAIN
DAMAGE, CARDIAC ARREST, OR DEATH. In addition to these general risks, there may be other possible risks
involved in this procedure. These risks and/or complications may include but are not limited to such complications
as: _________________________________________________________________________________________
___________________________________________________________________________________________

Likelihood of Success: The likelihood of success of the above procedure is: () Good () Fair () Poor

Prospects: If I choose not to have the above procedure, my prognosis (future medical condition) is:

Alternative Forms of Treatment, such as: __________________________________________
have been explained to me and I have chosen this surgical procedure as my method of treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may
make it necessary to do an extension of the original procedure or another procedure that is not named above. I
request Dr. _____________________________ and his/her associates or assistants of his/her choice to perform
those procedures that they judge to be necessary.

BY SIGNING THIS FORM, I ACKNOWLEDGE THAT I HAVE READ OR HAD THIS FORM READ AND
EXPLAINED TO ME AND THAT I FULLY UNDERSTAND ITS CONTENTS.

I HAVE BEEN GIVEN AMPLE OPPORTUNITY TO ASK QUESTIONS AND ANY QUESTIONS I HAVE
ASKED HAVE BEEN ANSWERED OR EXPLAINED IN A SATISFACTORY MANNER. ALL BLANKS OR
STATEMENTS REQUIRING COMPLETION WERE FILLED IN AND ALL STATEMENTS WITH WHICH I
DISAGREE WERE MARKED OUT BEFORE I SIGNED THIS FORM.

I accept that medicine is not an exact science and understand that no guarantees can be given as to the results.

Witness ____________________________
Person giving consent

Relationship to patient if not the patient

Patient unable to sign because of:

Additional materials used, if any, during the informed consent process for this procedure include:

____________________________________________________________________________________________

Figure 4.1. Informed consent and request for surgery.
These alternative treatments have been explained to me, and I have elected this surgical procedure as my method of treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may make it necessary to do an extension of the original procedure or another procedure that is not named above. I request that Dr. ___________________ and associates or assistants of his/her choice to perform those procedures that they judge to be necessary.

BY SIGNING THIS FORM, I ACKNOWLEDGE THAT I HAVE READ OR HAD THIS FORM READ AND EXPLAINED TO ME AND THAT I FULLY UNDERSTAND ITS CONTENTS.

I HAVE BEEN GIVEN AMple OPPORTUNITY TO ASK QUESTIONS AND ANY QUESTIONS I HAVE ASKED HAVE BEEN ANSWERED OR EXPLAINED IN A SATISFACTORY MANNER. ALL BLANKS OR STATEMENTS REQUIRING COMPLETION WERE FILLED IN AND ALL STATEMENTS WITH WHICH I DISAGREE WERE MARKED OUT BEFORE I SIGNED THIS FORM.

I accept that medicine is not an exact science and understand that no guarantees can be given as to the results. Understanding these limitations, I request that Dr. ___________________ and his/her associates/assistants to proceed with surgery.

Alternative forms of treatment such as:
1. Office biopsy of the lining of my uterus (endometrial biopsy) or cervix (cervical biopsy)
2. Hormone therapy
3. Do-nothing and accept the consequences of my present condition

These alternative treatments have been explained to me, and I have elected this surgical procedure as my method of treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may make it necessary to do an extension of the original procedure or another procedure that is not named above. I request that Dr. ___________________ and associates or assistants of his/her choice to perform those procedures that they judge to be necessary.

I, ______________________________________, request Dr. ___________________________________________ and his/her associates/assistants to perform upon me (Circle procedure to be performed):
1. Dilation & Curettage--stretch open the canal of my uterus and scrape the lining of my uterus to obtain tissue for study.
2. Hysteroscopy--look inside my uterus with a small telescope and possibly remove any abnormal tissue, such as fibroid tumors, polyps, or scar tissue.
3. Cervical Biopsy--remove tissue from tip of my uterus for tissue study.

Diagnosis and Procedure: The following has been explained to me in general terms and I understand that:

My condition has been diagnosed as: ________________________________________________________________

The purpose of this procedure is to: ________________________________________________________________

General Risks of Surgery: As a result of the performance of this procedure there may be general risks involved such as InfectIon, alleRgic reAction, disfiguring sARc, seveRе loss of blood, loss of function of any limb or organ, Paralysis, Paraplegia or Quadriplegia, Brain damage, Cardiac Arrest, or Death. In addition to these general risks, there may be other possible risks involved in this procedure. These risks and/or complications may include but are not limited to such complications as:

1. Perforation of my uterus (womb)—that is, one of the instruments might go through the wall of the uterus and make it necessary to do an immediate or future operation that could include the removal of my uterus and/or tubes and ovaries.
2. Biopsy of my cervix—which may make it difficult for me to get pregnant or carry a pregnancy to term or 9 months.
3. Injury to my cervix, uterus, tubes, and bowel—which could make necessary immediate and/or future surgical procedures

Likelihood of Success: The likelihood of success of the above procedure is: ( ) Good ( ) Fair ( ) Poor

Prognosis: If I choose not to have the above procedure, my prognosis (future medical condition) is:

Additional materials used, if any, during the informed consent process for this procedure include:

General Topics Affecting Gynecologic Surgery Practice

INFORMED CONSENT And REQUEST FOR HYSTERECTOMY

I, _________________________________, request Dr. ________________________________ and his/her associates / assistants to perform upon me: (Circle procedure of choice)

1. Removal of uterus (womb)
2. Possible removal of tubes and/or ovaries
3. Possible removal of appendix

Diagnosis and Procedure: The following has been explained to me in general terms and I understand that:

My condition has been diagnosed as: _______________________________________________________________

The nature of the procedure is: __________________________________________________________________

The purpose of this procedure is: _________________________________________________________________

General Risks of Surgery: As a result of the performance of this procedure there may be general risks involved such as: INFECTION, ALLERGIC REACTION, DISFIGURING SCAR, SEVERE LOSS OF BLOOD, LOSS OF FUNCTION OF ANY LIMB OR ORGAN, PARALYSIS, PARAPLEGIA or QUADRIPLEGIA, BRAIN DAMAGE, CARDIAC ARREST, or DEATH. In addition to these general risks, there may be other possible risks involved in this procedure. These risks and/or complications may include but are not limited to such complications as:

1. Injury to bowel, bladder, or ureter, which could result in a fistula formation, an opening between bowel, bladder, ureter, and the vagina and/or skin
2. Need for a colostomy or a second operation to repair any of the above injuries
3. Possible need for hormones
4. Blood loss necessitating transfusion, which carries the risk of exposure to AIDS or the hepatitis virus
5. Pelvic pain due to adhesions, scar tissue, or residual ovary

Likelihood of Success: The likelihood of success of the above procedure is: () Good () Fair () Poor

Prognosis: If I choose not to have the hysterectomy, my prognosis (future medical condition) is: __________________________________________________________

Alternative Forms of Treatment such as:
1. Do nothing and accept the consequences of my present condition
2. Dilatation & Curettage procedure, laser treatment, or removal of fibroid tumors
3. Uterine artery embolization
4. Hormone therapy

These alternative treatments have been explained to me, and I have elected this surgical procedure as my method of treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may make it necessary to do an extension of the original procedure or another procedure that is not named above. I request that Dr. ________________________________ and associates or assistants of his/her choice perform those procedures that they judge to be necessary.

BY SIGNING THIS FORM, I ACKNOWLEDGE THAT I HAVE READ OR HAD THIS FORM READ AND EXPLAINED TO ME AND THAT I FULLY UNDERSTAND ITS CONTENTS.

INFORMED CONSENT AND REQUEST FOR STERILIZATION

I request Dr. ____________________________ and his/her associates/assistants________________________ to perform upon me: (Circle procedure of choice)

1. Removal of a portion of the tubes through an incision in my lower abdomen
2. Laparoscopy (“band-aid” incision or incisions)
   a. Coagulation technique: ( ) Bipolar ( ) Unipolar
   b. Bands
   c. Clips
3. Hysteroscopy: insert a telescope-like instrument into my uterus (womb) and place _______________ into the opening of my tubes, inside the uterus, so that the openings will be blocked.

Diagnosis and Procedure: The following has been explained to me in general terms and I understand that:

This procedure is NOT designed to be reversible, and that I am intentionally giving up my ability to become pregnant.

The nature of the procedure is: __________________________________________________________________________

General Risks of Surgery: As a result of the performance of this procedure there may be general risks involved such as: INFECTION, ALLERGIC REACTION, DISFIGURING SCAR, SEVERE LOSS OF BLOOD, LOSS OF FUNCTION OF ANY LIMB OR ORGAN, PARALYSIS, PARAPLEGIA, or QUADRIPLEGIA, BRAIN DAMAGE, CARDIAC ARREST, or DEATH. In addition to these general risks, there may be other possible risks involved in this procedure. These risks and/or complications may include but are not limited to such complications as:

1. Failure to become sterile—that is, I could become pregnant either in my uterus (womb) or have an ectopic pregnancy in my tube or other sites
2. Injury to bowel, bladder, ureter or blood vessel by way of burn and/or perforation, fistula formation (which is an opening that develops between the bowel, bladder, ureter and the vagina and/or or skin), requiring a second operation to repair the fistula
3. Major surgery—requiring colostomy or possible removal of uterus, tubes and/or ovaries
4. Necessity for an exploratory laparotomy (opening the abdomen) to either complete the laparoscopy procedure or repair any injury
5. Blood loss necessitating transfusion, which carries the risk of exposure to AIDS or the hepatitis virus

Likelihood of Success: The likelihood of success of the above procedure is: ( ) Good ( ) Fair ( ) Poor

Prognosis: If I choose not to have the above procedure, my prognosis (future medical condition) is: __________________________________________________________

Alternative Forms of Treatment such as:
1. Diaphragm
2. Birth control pills
3. Intrauterine devices (IUD)
4. Barrier methods, (use of foams, condoms, etc.)
5. Rhythm method
6. Abstinence
7. Vasectomy (male sterilization)

These alternative treatments have been explained to me, and I have elected this surgical procedure as my method of treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may make it necessary to do an extension of the original procedure or another procedure that is not named above. I request that Dr. ____________________________ and his/her associates or assistants of his/her choice perform those procedures that they judge to be necessary.

BY SIGNING THIS FORM, I ACKNOWLEDGE THAT I HAVE READ OR HAD THIS FORM READ AND EXPLAINED TO ME AND THAT I FULLY UNDERSTAND ITS CONTENTS.

I HAVE BEEN GIVEN AMPLE OPPORTUNITY TO ASK QUESTIONS AND ANY QUESTIONS I HAVE ASKED HAVE BEEN ANSWERED OR EXPLAINED IN A SATISFACTORY MANNER. ALL BLANKS OR STATEMENTS REQUIRING COMPLETION WERE FILLED IN AND ALL STATEMENTS WITH WHICH I DISAGREE WERE MARKED OUT BEFORE I SIGNED THIS FORM.

I accept that medicine is not an exact science and understand that no guarantees can be given as to the results. Understanding these limitations, I request that Dr. ____________________________ and his/her associates/assistants to proceed with surgery.

FIGURE 4.5. Informed consent and request for sterilization.
INFORMED CONSENT And REQUEST FOR LAPAROSCOPY

I, ________________________________, request Dr. ______________________________________________ 
and his/her associates/assistants to perform upon me:

Laparoscopy—which involves inserting a telescopic-like instrument into my abdomen through one or more small 
("band-aid") size incisions to diagnose and/or repair any problems

Diagnosis and Procedure: The following has been explained to me in general terms and I understand that:

My condition has been diagnosed as: ______________________________________________________________ 
The nature of the procedure is: __________________________________________________________________ 
The purpose of this procedure is to: _______________________________________________________________

I understand that treatment may require the use of laser and/or electrocautery during the performance of this surgery.

General Risks of Surgery: As a result of the performance of this procedure there may be general risks involved 
such as: INFECTION, ALLERGIC REACTION, DISFIGURING SCAR, SEVERE LOSS OF BLOOD, 
LOSS OF FUNCTION OF ANY LIMB OR ORGAN, PARALYSIS, PARAPLEGIA or QUADRIPLEGIA, BRAIN 
DAMAGE, CARDIAC ARREST, or DEATH. In addition to these general risks, there may be other possible risks 
involved in this procedure. These risks and/or complications may include but are not limited to such complications as:

1. Injury to blood vessels, bowel, bladder, uterus (tube that connects kidney to bladder) by way of puncture 
and/or burn
2. Fistula formation, which is an opening between the bowel, bladder, or urethra and the vagina and/or skin, 
that requires a second operation to repair
3. Colostomy
4. Embolism, which is the spreading of a gas or other fluid into other parts or organs of the body
5. Hernia in the incision site
6. Injury to the cervix, uterus, or tubes that might require additional surgery or might affect my ability to get 
pregnant or carry a pregnancy to full term (9 months)
7. Necessity for an exploratory laparotomy, which is the making of a larger incision through which the 
necessary surgery can be performed
8. Blood loss necessitating transfusion, which carries the risk of exposure to AIDS or the hepatitis virus

Likelihood of Success: The likelihood of success of the above procedure is: () Good () Fair () Poor

Prognosis: If I choose not to have the above procedure, my prognosis (future medical condition) is:

____________________________________________________________________________________________

Alternative Forms of Treatment 
such as:
1. Do nothing and accept the consequences of my present condition
2. Performance of surgery through a larger incision in my abdomen
4. Drug therapy

These alternative treatments have been explained to me, and I have elected this surgical procedure as my method of 
treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may make it necessary to 
do an extension of the original procedure or another procedure that is not named above. I request that Dr. 
________________________ and associates or assistants of his/her choice to perform those 
procedures that they judge to be necessary.

BY SIGNING THIS FORM, I ACKNOWLEDGE THAT I HAVE READ OR HAD THIS FORM READ AND

INFORMED CONSENT
And
REQUEST FOR REPAIR OF RELAXATION OF PELVIC ORGANS
And/or
CORRECTION OF URINARY INCONTINENCE

I, _________________________________, request Dr. _________________________________ and his/her associates/assistants to perform upon me: (Circle procedure to be performed)

1. Anterior and/or posterior repair, that is, "tack up" the bladder and/or rectum
2. Enterocele repair, a repair to a hernia at the top of the vagina
3. Surgical correction of urinary incontinence problem by the following procedure(s) _____________________________________________________________________

Diagnosis and Procedure: The following has been explained to me in general terms and I understand that:

My condition has been diagnosed as: ________________________________________________________
The nature of the procedure is: _____________________________________________________________
The purpose of this procedure is to: _________________________________________________________

General Risks of Surgery: As a result of the performance of this procedure there may be general risks involved such as: INFECTION, ALLERGIC REACTION, DISFIGURING SCAR, SEVERE LOSS OF BLOOD, LOSS OF FUNCTION OF ANY LIMB OR ORGAN, PARALYSIS, PARAPLEGIA, or QUADRIPLEGIA, BRAIN DAMAGE, CARDIAC ARREST, or DEATH. In addition to these general risks, there may be other possible risks involved in this procedure. These risks and/or complications may include but are not limited to such complications as:

1. Injury to bowel, bladder, ureter (the tube from the kidney to the bladder) and urethra (tube from bladder to outside of body)
2. Fistula formation, an opening between the bowel, bladder, ureter and the vagina and/or skin, which would require a second operation to repair
3. Colostomy
4. Recurrence of my loss of control of urine
5. No improvement in my control of urine
6. Prolonged need of a catheter to drain my bladder
7. Discomfort with intercourse

Likelihood of Success: The likelihood of success of the above procedure is: () Good () Fair () Poor

Prognosis: If I choose not to have the above procedure, my prognosis (future medical condition) is: ______________________________________________________________________________________________

Alternative Forms of Treatment such as:
1. Exercise
2. Use of artificial supports (pessary)
3. Do nothing and accept my present condition and its potential risks

These alternative treatments have been explained to me, and I have elected this surgical procedure as my method of treatment.

I understand and accept that during the procedure unexpected or unforeseen circumstances may make it necessary to do an extension of the original procedure or another procedure that is not named above. I request that Dr. _________________________________ and associates or assistants of his/her choice perform those procedures that they judge to be necessary.

FIGURE 4.7. Informed consent and request for repair of relaxation of pelvic organs and/or correction of urinary incontinence.
Several occurrences can forewarn a physician that a legal action may be impending. These include a complication or poor outcome, a disgruntled patient or dissatisfied family member, a request for medical records, or direct contact by the plaintiff’s attorney. The physician should consult his or her insurance carrier for advice and/ or insurance carrier claim investigator. Some plaintiff attorneys have been known to call a physician and ask for the physician’s opinion about an alleged incident. The attorney may tape this conversation or later in a courtroom allege that on the date of such a contact the physician said something different from what the physician is now alleging occurred. This situation could possibly lead to the jury questioning a physician’s credibility. Thus, it is best for the physician never to respond to a plaintiff’s attorney except through his or her own defense team.

A lawsuit actually begins when a plaintiff’s attorney files a formal Complaint or Declaration. This is a legal document that lists the allegations to support a claim of medical malpractice. Some states require that an affidavit from an expert witness supporting the contention of malpractice be filed with the Complaint or Declaration. Once the filing occurs, the court serves the defendant physician with a summons. The summons is attached to the complaint and may contain questions to be answered by the physician. Responses to the complaint must be filed within a specified period of time, usually within 20 to 30 days. The defendant physician must respond within that period of time or he or she can be found guilty by default. Thus, it is critical that the physician immediately contact his or her insurance carrier and/or attorney on receiving the summons. The physician should send the original summons by certified mail or hand deliver these documents to the insurance carrier. Keep a copy of the summons in a separate file. Most insurance carriers require that the physician notify them of any incidence that might result in a claim. Failure to do so could negate the physician’s policy. It is prudent to know what the requirements of the insurance carrier are in this regard.

Once a suit has been filed, do not communicate with the plaintiff, her family, or her attorney. When records are requested, be sure that a proper authorization from the patient has been received, and then send a complete copy of the chart. Never change or alter a record once the suit has been filed, because there are many methods by which a plaintiff’s attorney can prove that records have been tampered with or altered.

Prepare a thorough chronological account of all events surrounding the incident. Include any oral communications that the physician had with the patient or her family. Gather all records, radiographs, laboratory tests, and consultant’s reports, and maintain these documents along with the complaint in a separate file.

The physician’s defense attorney will know all aspects of the law and will not be knowledgeable about the specific medical condition. Thus, it is imperative that the physician take an active role in mediating the attorney in all medical aspects of the case, discussing not only the positive aspects of the therapy, but also any questionable areas. The defense attorney should thoroughly educate the defendant physician and the physician’s reasoning behind the particular treatment chosen. The physician should research literature for articles by authors who completely support the treatment rendered. The physician should help select expert witnesses who can support his or her views on the treatment that was rendered in the case.

During the discovery process, both parties submit questions called interrogatories that are to be answered under oath within a specific period of time. The defendant physician should help prepare answers to these interrogatories.

If a physician has only peripheral involvement in a case and receives a summons requesting records, he or she may be advised by his or her attorney or the insurance claims representative to not notify the insurance carrier as well as his or her attorney before any response is given. There are times when poorly worded answers result in the physician who has only a peripheral involvement being named in the actual suit. The physician should not take unnecessary risks by either notifying his or her attorney or the insurance claims representative. Idle conversation in a surgical dressing room may be overheard by a physician who could become the plaintiff’s expert. The only people with whom it is safe to discuss a case are the defense attorney and the insurance claims representative.

**The Deposition**

The deposition is a standard legal process that takes place as part of the discovery process. A deposition is taken under oath in the presence of a court reporter and is generally admissible during the trial phase of the lawsuit. The deposition is serious in that what a defendant physician states is cast in stone and if not properly articulated can end up as a millstone about the physician’s neck. Thus, adequate preparation cannot be overemphasized. The physician should be familiar with all of the records, both office and hospital, including office and hospital protocols, rules, and regulations. The physician should insist on considerable preparation and education from the attorney about this important legal process before the deposition.

The deposition has many purposes, including to (a) discover facts, (b) lock in testimony, (c) narrow and clarify issues, (d) discover additional witnesses, and (e) provide an opportunity for settlement if appropriate. The deposition is primarily taken so that each side can learn opinions, theories, and strategies of the physician, the opposing experts, and the other parties involved in the case. The opposing attorneys can thus prepare their cases for trial with the knowledge gained.

The demeanor of the physician is important. He or she should be professional, honest, and confident. Boredom, frustration, and hostility should not be shown. Anger can disrupt a physician’s ability to concentrate, and under those circumstances, the physician may divulge things that should not be discussed. The physician should neither attempt to teach nor lecture during a deposition, remembering that the plaintiff already has an expert who stated that the physician committed malpractice. Therefore, any attempt to educate the lawyer is a frivolous and potentially dangerous act. During the deposition phase, the defendant physician is not acting as his or her own expert and thus should confine answers to short factual statements with no elaboration unless it is prompted by further questioning. Answers should be specific and simple. Do not bring into a deposition any personal notes or records that include the physician’s predeposition preparation. Such records are discoverable by the plaintiff’s attorney if they are in the room. However, the physician should have a complete set of records to refer to. Never guess about an answer. If the physician does not understand the question, then simply state, “I do not understand the question,” or “I do not know,” or “I cannot
recall.” Avoid complex questions. Make the attorney break the questions down into simple ones by stating, “I do not under-stand the question. Would you please rephrase it?” Avoid repetitive questions by noting, “I have already answered that.” When a question is asked, listen attentively, think, and organize your thoughts before responding. Then respond slowly, clearly, and as concisely as possible.

In deposition, the physician should be sure the facts are consistent with his or her case and reply only as it applies to the case. If the hypothetical situation is not applicable to the physician’s case, the physician should qualify the response and so state that the given facts are not applicable to the case. Again, remember that you are defending yourself and not acting as your own expert witness.

If the defense attorney objects to a question or the phrasing, do not answer the question until instructed to do so by the defense attorney. The physician should listen carefully to the objection raised by the defense attorney so that he or she can appropriately word the response. The physician should know the various alternative methods of therapy that might have been employed. The physician should have reasons why he or she selected the chosen therapy and be prepared to explain them in the courtroom. The deposition, however, is generally not the time to divulge any literature research that took place.

Avoid the word authoritative. Legally, it implies that every single statement in a book or journal is absolute fact. Because medicine is an art rather than an exact science, experts may have different opinions on the same subject. The physician can admit that a book is scholarly or written by intelligent, re-spected people, but should never concede that every statement in the text is absolutely correct, which would make such a text authoritative by legal definition.

Do not engage in bantering or make comments that could be used against you. Avoid saying, “I don’t recall.” The physician feels that the plaintiff’s pain is of a mental or emotional nature and not physical, never belittle the patient’s testimony. The plaintiff wants to present himself or herself to the jury as a kind, considerate, compassionate person who projects warmth and sincerity, as well as being a voice of authority. The defen-dant physician should go to the court before the trial to become familiar with the surroundings. He or she may even want to sit in on a trial to get a feel for this new and foreign environment. The physician should discuss in great detail any questions that he or she has regarding the trial, its proceedings, or the defense. Listen to your attorney’s advice! The more familiar a physician is with the court and its proceedings, the more confident and less frightened he or she will be as the trial proceeds.

Preparation for the trial is critical and should cover even demeanor and dress. Dress should be plain, conservative, and neat. Flashy or casual clothes project the wrong image. The physician wants to present himself or herself to the jury in a non-confrontational manner. Always state your case and let the jury decide. Do not make the assumption that the jury will know the facts of the case or the area of the testimony, he or she can elaborate further on a subject. Therefore, it is critically important that the physician employ all of his or her talents to be sure that the jury understands the testimony. Be polite and humble. Important words in the courtroom are Sir and Madam. When a physician uses these words they generate an air of humility that is pleasing to a jury. When a question is asked, be sure to take time to think before a response is given. Respond in non-technical language that a 12-year-old child could understand. Listen carefully, and then speak clearly and audibly. Jurors like a physician who really tries to explain what he or she did step by step. Unlike during the deposition, in the courtroom the physician should be a teacher, using a black-board or other audiovisual aids to explain complex issues. If the plaintiff’s attorney tries to be overbearing and abrasive, re-act by being humble yet dignified. Repeat significant facts often so that the jury will remember them. Remember, people generally retain only 30% of verbal communication, so repetition is essential. The physician’s body language, posture, and facial expressions also convey strong messages to the jury.

There are several things a defendant physician should do when called to the stand to testify. The physician should make and keep eye contact with the jury throughout the testimony. Physicians generally tend to focus their attention on the plaintiff’s attorney as he or she asks questions; however, this is not helpful to the physician. Physicians are trained to read people’s facial expres-sions. By maintaining eye contact with the jury, the physician can closely observe whether the jurors comprehend the testi-mony. If the physician feels that the jury does not understand an area of the testimony, he or she can elaborate further on a subject. Always state your case and let the jury decide. Do not be arrogant, pompous, or over-bearing. Never try to outsmart or manipulate the plaintiff’s attorney; this is the way attorneys make their living. Never in-stigate a fight or argue with an attorney because it will cause you to lose dignity and respect in front of the jury. Even if the physician feels that the plaintiff’s pain is of a mental or emotional nature and not physical, never belittle the patient’s injury or pain. Remember that in the patient’s mind, she is hurting, so show compassion and understanding. Never guess at an answer. If you do not know, then state, “I do not know,” or “I do not recall.” The physician should not worry if he or she missespeak. The defense attorney, with further appropriate
questions, generally is able to correct the mistake. Never get angry or show anger because anger breaks your concentration and often leads you to say things that should not be said.

The trial begins with opening statements. The plaintiff's attorney proceeds first because he or she has the burden to prove the existence of malpractice and causation of injury. Then the trial testimony phase begins. Again, the plaintiff's attorney begins with testifying to the client's history to try to establish that the defendant is negligent and the negligence caused the plaintiff's injury. During this initial presentation, the plaintiff's attorney has the right to and frequently does call the defendant physician to the stand. At this stage of the trial, the defendant's attorney can object to the physician to the stand and give a complete response so that the jury can understand the physician's position on the matter in question. Do not leave any question-able areas unexplained, because at this stage, the plaintiff's attorney is trying to establish points that are beneficial to their case. If the plaintiff's attorney asks a series of short questions that only require a yes-or-no answer and do not seem to give the physician time to explain his or her position completely, it is very important that the physician break such a sequence and take as much time as needed to clarify the answer. The physician can simply say to the plaintiff's attorney, "Sir or Madam, I did not finish my response to the last question."

During the testimony phase, the plaintiff's attorney usually employs one of four basic forms of attack on the defendant's reputation. The plaintiff's attorney may challenge the physician's competence, accuse the physician of being careless, or allege that the physician is not compassionate but rather an indifferent, uncaring, wealthy person. Finally, the attorney may challenge the physician's credibility, especially if records were altered or if the physician contradicted testimony given under oath during the deposition. This is why it is so important for a physician to know exactly what he or she said in the deposition. The physician should outline the deposition, noting significant facts from the notes or records, and provide all the evidence a plaintiff's attorney needs to raise a question of the physician's competence. If at the end of the presentation the plaintiff has not pro-duced sufficient evidence to establish the cause-and-effect re-lationship, the defense may request and be granted a directed verdict, and the suit is over.

Next, through testimony, expert witnesses, and medical documents, the defense tries to prove that the allegation of negli-gence is false and that the injuries were not a direct result of the defendant's actions. The defense attorney, on direct examina-tion, will generally have the physician elaborate in detail those issues that are important to the defense, as such repetition is still very important that the physician break such a sequence and take as much time as needed to clarify the answer. The physi-cian can simply say to the plaintiff's attorney, "Sir or Madam, I did not finish my response to the last question."

The physician's marriage also is put under considerable stress. The spouse carries a great part of the emotional burden of one's professional integrity and stirs strong feelings of anger. This anger may be so intense that it spills out in all directions, frequently in an inappropriate manner that may strain many personal and professional relationships.

An emotional impact study conducted by psychiatrist Dr. Sarah Charles of physicians who had been sued, 96% of physicians reported not only emotional reactions, but also physical problems related to the stress and emotional reaction one undergoes during the loss of a loved one. Unlike other professionals, a physician is unable to accept that a malpractice suit is part of the risk of doing business owing to the very nature of the doctor-patient relationship.

Part of the intense anger the physician experiences at the onset of a suit arises because of the shock that he or she experiences when a bond built on trust has been broken. The physician feels betrayed. The accusation of being incompetent or at least practicing one's job badly challenges the very core of one's professional integrity and stirs strong feelings of anger. This anger may be so intense that it spills out in all directions, frequently in an inappropriate manner that may strain many personal and professional relationships.

In a study conducted by psychiatrist Dr. Sarah Charles of physicians who had been sued, 96% of physicians reported that a malpractice suit is part of the risk of doing business owing to the very nature of the doctor-patient relationship.

The practice of medicine in general, and of obstetrics and gynecology in particular, is filled with daily stresses uncommon to other professions. Physicians must deal with pain and suffering, problem patients, intense interpersonal relationships, and often unrealistic expectations. A relatively new—but unfortunately rather frequent—stress is the threat of malpractice litigation. The stress of a malpractice suit has been equated to the stress and emotional reaction one undergoes during the loss of a loved one. Unlike other professionals, a physician is unable to accept that a malpractice suit is part of the risk of doing business owing to the very nature of the doctor-patient relationship.

The 2003 ACOG survey revealed that obstetrician-gynecologists win 73.1% of the claims resolved by jury, court verdict, arbitration, or other alternative dispute resolution mechanism.

Emotional Impact

The practice of medicine in general, and of obstetrics and gynecology in particular, is filled with daily stresses uncommon to other professions. Physicians must deal with pain and suffering, problem patients, intense interpersonal relationships, and often unrealistic expectations. A relatively new—but unfortunately rather frequent—stress is the threat of malpractice litigation. The stress of a malpractice suit has been equated to the stress and emotional reaction one undergoes during the loss of a loved one. Unlike other professionals, a physician is unable to accept that a malpractice suit is part of the risk of doing business owing to the very nature of the doctor-patient relationship.

Part of the intense anger the physician experiences at the onset of a suit arises because of the shock that he or she experiences when a bond built on trust has been broken. The physician feels betrayed. The accusation of being incompetent or at least practicing one's job badly challenges the very core of one's professional integrity and stirs strong feelings of anger. This anger may be so intense that it spills out in all directions, frequently in an inappropriate manner that may strain many personal and professional relationships.

In a study conducted by psychiatrist Dr. Sarah Charles of physicians who had been sued, 96% of physicians reported not only emotional reactions, but also physical problems related to the suit. Eight percent had the onset of physical ailments, of which one fourth were life-threatening, such as coronary diseases, strokes, ulcers, and hypertension. Forty percent showed symptoms suggestive of major depressive disorders. Commonly experienced reactions were anger, mood changes, depression, tension, frustration, insomnia, fatigue, and alcohol and drug abuse. Fifteen percent of physicians lost confidence in themselves. Nineteen percent lost confidence in certain clinical situations. Fear is another common emotion experienced by sued physicians. They fear the loss of their patient's respect and confidence. They fear the loss of their own self-confidence, and, in this day of excess awards, they fear the loss of financial security. The physician's reputation, ego, and self-worth are challenged. Professional training demands that the physician hold his or her reactions in check. This training becomes counterproductive at the time of a malpractice suit.

The physician's marriage also is put under considerable stress. The spouse carries a great part of the emotional burden of litigation. There are many sleepless nights and interrupted plans as depositions and trials are scheduled, postponed, and rescheduled by a seemingly uncaring legal system. Mood
changes and periods of irritability have to be handled by the spouse. These stressful situations can be the downfall of a weak or borderline marriage. Children are often disturbed by the knowledge that a parent is legally accused of malpractice. They may indeed feel that their parent has deceived or shamed them. Younger children especially may misunderstand the nature of the accusation and believe the allegations as fact, especially if the allegations are broadcast on radio, television, or in the newspaper. Physicians must take action to protect their mental health during this major period of stress, realizing that we live in a litigious environment and that the stress surrounding malpractice suits not only affects physicians, but also adversely affects all professionals and occupations. Physicians need to discuss their feelings with their spouse, loved ones, mentors, or counselor.

Physicians and their spouses should become active in support groups. These groups have received the support of both the American College of Obstetricians and Gynecologists and American Academy of Pediatrics as outlined in their joint publication titled “Coping with Malpractice Litigations Stress.” Such forums are not intended to provide psychiatric therapy, but rather are safe and informal groups where participants can share their common stresses and experiences in a sympathetic environment. The physician should not hesitate to seek counseling if the stress becomes so great that daily functions become impaired.

An open discussion with your children that shares their feelings and concerns, as well as yours, often relieves their anxiety. This type of communication often strengthens the family relationship and ultimately results in a positive effect from the terrifying ordeal of a malpractice suit.

BEST SURGICAL PRACTICES

- Risk management can lead to an improvement in clinical outcomes, reduce patient injury, reduce human errors, and provide better medical records, which not only assists the entire health care team in providing better care but can also assist the legal team in providing a better defense of an alleged medical malpractice claim.
- The cornerstones of risk management for the surgeon are good surgical technique, current knowledge and training in surgical advancements, good communication, and adequate documentation.
- Because patients rarely retain more than 30% of verbal communication, printed material can greatly assist the surgeon in providing adequate information about a surgical procedure or recommended treatment. Communication also is conveyed by body language; thus, it is prudent to sit in a relaxed posture when communicating with a patient, her significant other, or her family members.
- In the office, appropriate procedure and protocol manuals should exist that outline the duties of each employee and the proper procedure to handle phone messages, especially those of an urgent nature, so that not only a timely response occurs, but also instructions and medications are documented. The surgeon should periodically review his or her office procedures to insure that the patient’s confidentiality is respected and that proper phone etiquette is maintained.
- Documentation that is contemporaneous, factual, complete, relevant, and preferably dictated and that uses approved abbreviations is essential in providing an appropriate medical record.
- Medical errors pose a serious threat to the patient’s well-being. Using computerized orders, improving physician handwriting, using only standard approved abbreviations, and having all verbal orders read back to the surgeon by the nurse taking the orders have all been shown to reduce these errors.
- When multiple consultants are required to provide appropriate care, it is imperative that one of the consultants is designated to write critical orders, covering such things as fluids, medications, and important laboratory studies.
- Informed consent must respect the ethical principles of autonomy, beneficence, nonmaleficence, justice, and freedom. Informed consent must contain the diagnosis, nature, and purpose of the procedure; the risks; likelihood of success; and alternatives and prognosis if treatment is refused. Procedure-specific informed consent forms outline not only the risks that are specific to the procedure, but also the alternatives so that the patient is better informed. Informed consent is suspended in an emergency situation when the patient is unconscious or incapacitated. The surgeon should document the status of the patient and the fact that the situation is life-threatening and represents a serious threat to the patient’s health. When a patient refuses appropriate treatment, the surgeon should document the potential risks; the consequence of her refusal and preferably have the patient sign this documentation.
- In a managed care setting, the surgeon must be an advocate for the patient to insure that the patient does receive appropriate treatment even when the managed care plan may refuse to provide the best treatment for the condition being treated.
- Preparation for both a deposition and trial should consist of a review of the surgeon’s office records, the hospital records, and the policies and procedure manuals for both the office and hospital. The surgeon should educate the defense team and be sure that the attorney has adequately prepared the surgeon for these legally challenging events. The surgeon should also review the literature, select articles that support his and/or her treatment, and help select expert witnesses that can be used by the defense.
- The litigation process can both be extremely stressful and have an impact on the surgeon’s mental and physical health. Appropriate medical and emotional consultations may be required to get the surgeon through this adversarial process.

CHAPTER 5 ■ THE CHANGING ENVIRONMENT IN WHICH WE PRACTICE GYNECOLOGIC SURGERY

ERIC J. BIEBER AND EDIE L. DERIAN

DEFINITIONS

Institute for Healthcare Improvement (IHI)—A not-for-profit organization founded in 1991 dedicated to improving health care throughout the globe. Initiated the 100,000 lives campaign (www.ihi.com).

Institute of Medicine (IOM)—Not-for-profit organization chartered in 1970 as part of the National Academy of Sciences to provide unbiased, evidenced-based guidance to improve health in the United States (www.iom.com).

Pay for performance (P4P)—A broad construct that attempts to pay providers or health care organizations for achieving predetermined quality thresholds.

Hospitalist—Physician/providers who dedicate all or part of their practices to providing care specifically to patients within the hospital.

Computerized physician order entry (CPOE)—Use of a computer (especially within an electronic record interface) to perform electronic entry of medical orders for patients. Can occur in an inpatient or ambulatory setting.

100,000 lives campaign (100K)—An initiative from the IHI begun in 2005 to save 100,000 patients through dissemination of six quality initiatives in hospitals throughout the United States (www.ihi.com).

As gynecologic surgeons and care providers of women, we have witnessed major changes in our practices over the years. When we think back to our days as medical students and residents, even the youngest of us is able to appreciate the palpable differences that exist today: from how we manage our offices to how we approach diagnostic testing and treatment. Few of us appreciated how profound a role the computer would play in our daily practice or how this tool might empower us to provide the best possible care in each encounter. In this chapter, we will review the changes that are occurring in medical education from residency to postgraduate training. Issues regarding credentialing, especially as it relates to novel procedures, will be discussed. The importance of connectivity between services and the relevance of this in a time of multidisciplinary diagnosis and treatment will be reviewed. The electronic health record (EHR), its implementation and daily use, and its significant benefits and pitfalls will be reviewed in part. The cornerstone of the modern practice of medicine continues to be the resounding theme of evidence-based medicine. Quality initiatives, including the Institute for Healthcare Improvement (IHI) recommendations, as well as many other proposals, have made attempts to promote the safest, most effective care of our patients. Additionally, pay-for-performance evaluations continue to be discussed; in some cases, they are actually included in pilot projects for surgical procedures. We are also being challenged to move from a time when surgical and other treatments were the mainstay of our practice to a new time of screening, prevention, and the promise of genomics.

One of the most significant changes in medical education has been the limitation of resident duty hours. Such regulation of work hours has been common in industries such as aviation, in which pilots and other crew are limited both in the number of hours worked as well as requirements for time off between work episodes. Although many gynecologists were trained in a time of every second or third night call, this is no longer acceptable or allowable. In July 2003, the Accreditation Council for Graduate Medical Education (ACGME) put into effect new requirements and regulations (www.acgme.org). These new regulations limit total duty hours to 80 hours per week when averaged over 4 weeks, limit in-house call to no more than every third night with 1 day off in 7, and limit continuous patient care hours to 30, with the last 6 hours to patient handoffs and educational activities, such as grand rounds. In addition, there must be 10 hours between shifts worked. New York led the way in creating legal mandates, but the ACGME and the various specialty resident review committees have quickly followed. This paradigm shift is a dramatic departure from times past, but recent data has suggested that decision making as well as technical skills may suffer with sleep deprivation. What is less clear is how this has affected actual patient care as well as resident experience.

Hutter and colleagues evaluated the impact of changing to the 80-hour workweek on surgical residents in Boston. They noted that after implementation of the 80-hour workweek, residents had lower burnout scores and less emotional exhaustion, whereas sleep and motivation to work were improved (Table 5.1). Objective quantitative measurement demonstrated no differences in the quality of patient care. In contrast, another prospective, postduty-hour implementation study from the surgery department of University of California Irvine did not show changes in measures of burnout. They did note a decrease in yearly work hours from 100.7 to 82.6. After implementation and found a significant decrease in formal educational time (Fig. 5.1). Of interest, time in the operating room, on clinical rounds, and in the clinic were not significantly different.
In contrast to previous publications, a recent report from University of California San Francisco internal medicine residency did not demonstrate improvement in educational satisfaction with the onset of the new duty-hour regulations. Similarly, another obstetric and gynecologic survey pre- and postimplementation of duty hours at the University of Colorado demonstrated no differences in overall satisfaction with the residency. However, some key elements were found to be statistically elevated after implementation, including reading, reviewing literature, doing research, and some clinical aspects of training.

It is of interest that in the 2006 residency match, both general surgical as well as obstetric and gynecology slots were filled at a much higher percentage than previous years. Whether this is consistent with senior medical students sensing a change after the decrease in duty hours, thus creating a new perception is consistent with senior medical students sensing a change after the decrease in duty hours, thus creating a new perception of these “difficult” specialties, remains to be seen. Less investigation has been performed on the impact of the duty-hour changes to medical students and how this might affect their learning. Brasher and colleagues used completed duty-hour changes to medical students and how this might affect their learning. Brasher and colleagues used completed

POSTGRADUATE TRAINING

Questions continue regarding how best to train clinicians in the postgraduate environment. Most find learning easy while in residency, with time often dedicated to didactic lectures. Few practicing physicians are afforded similar luxury, and yet significant technological and medical advances continue throughout our careers. Given the limitations that state-by-state licensure imposes, as well as malpractice constraints, it is also difficult for physicians to cross state boundaries to learn new surgical procedures and be tutored. Fortunately, there have also been advances in our ability to utilize with Web-based or computer technology. The classic forum of the in-person lecture remains the gold standard for education. However, some institutions such as our own, have moved to Web-based programs to allow transmission of grand rounds or other educational forums in real time. This allows attendees to log on and participate regardless of their location, be it at home, in the office, or in the hospital. It also allows for lecturers to limit their time away from work as they may deliver their lecture from afar with remote transmission to multiple sites. In a time of shrinking grand-round budgets and limited external support for lectures, this may be one methodology for continuing to deliver state-of-the-art education to a diverse, ever-changing audience.

As we continue our transition from open surgery to minimal invasive surgery and now to robotic surgery, there continue to be questions regarding how to best credential surgeons on new technologies. As we have discussed previously regarding limitations in postgraduate opportunities to mentor and train are the origin of some of these problems. How many preceptor cases are adequate for an individual surgeon to be able to demonstrate mastery? Unfortunately, most of us as educators realize there are profound differences between cases and surgeons. What one surgeon is able to master in 20 cases another may be able to conquer in five or fewer. At the writing of this chapter, most residents will garner adequate experience with minimal invasive techniques during their training, but few will master robotics during this time.

Previously, many gynecologic services existed in a silo, consulting other services only when specific situations existed. In the new practice of medicine, we are being faced with many multidisciplinary procedures requiring seamless transition between multiple providers and specialties to assure the best outcome. Uterine artery embolization would be one such example. Generally, gynecologists see the patient with symptomatic myomata, but on occasion, patients will self-refer to an interventional radiologist. In most cases, the interventionalist performs the procedure, but often this individual does not have admitting privileges. If the patient requires admission for pain management, the gynecologic service may be asked to admit and manage the patient. In addition, appropriate preoperative evaluation will need to be performed to decrease the risk of a failed or inappropriate procedure. Generally, all of the above are best accomplished in a setting where excellent communication exists between the services, and the patient seamlessly transitions through the treatment and is not held hostage to political or other bureaucratic issues that often exist in the complicated systems we work within. This requires physicians and surgeons from multiple specialties to decide in advance how such programs should work and what each individual team member is responsible for providing. This often requires identification of specific team leaders (physician and nursing) from each discipline, as well as a specific leader who will have proximate authority to resolve issues that will predictably arise in such complex interactions. When services work in this manner, functioning at a high level, patient care is optimized. Because of the need to act across disciplines and in a teamlike manner, resident and even medical student curriculums have begun to address the need to work as teams—a concept adopted long ago in the business world but adopted much more slowly in the world of independent thinking and functioning within medicine. In fact, team-building retreats are becoming departmental norms in many training programs around the country.

ELECTRONIC HEALTH RECORD

The advent of the electronic health record (EHR) has changed forever how medicine will be practiced. Most of us were trained in a time where orders and notes were written and charts were sent to a large repository (i.e., medical records). Many notes written by our colleagues were difficult to read or were unable to be located. Certainly, these were not often available in real time, across specialties or from home. Authentication of results was performed by hand and had to be reassociated with the correct chart, wasting significant time and resources that might be better directed. Prescriptions were written and handed to patients who then delivered them to a pharmacy. In a best-case scenario, writing was legible, charts were placed in their appropriate position within the repository, and the pharmacist could read the prescription. Unfortunately, often this was not the case.

In modern times, much of this has changed. Numerous opportunities exist with the EHR to go beyond many of the technical issues associated with handwriting, but the opportunities go well beyond legibility. In addition, groups like the American Medical Informatics Association’s College of Medical Informatics has called for integration of the EHR and personal health records (PHR) to provide the greatest value for our patients. Recent data have suggested other potential positive consequences of an EHR implementation. The Kaiser group reported that with an implementation of an EHR in the northwest United States, age-adjusted outpatient visits dropped by 9%, with only a slight increase in phone calls from patients but no change or a slight improvement in quality metrics. Embi and colleagues found that by using EHR data to define patient eligibility into a clinical trial and then causing an electronic prompt to let the provider know of patient eligibility, they were able to double study enrollment as well as improving physician referrals to their study.

There are multiple factors, which have made the adoption of the EHR difficult for some providers and groups. Likely highest amongst these is the cost to implement as well as maintain the EHR. Multiple third-party vendors exist that have various EHR platforms. These range from simple documentation and chart programs to software and hardware that integrates patient care across both inpatient and ambulatory platforms. There are currently efforts to standardize EHR language, but many of these efforts are in their infancy. It will become critical as we evolve to an all-digital-based health record that these systems are able to communicate with one another, allowing patients to have their records available anywhere and anytime. Ford and colleagues evaluated EHR adoption rates in small physician groups of 10 or fewer partners. Using models, they projected the potential for broad adoption of EHR into the future. They suggest that it may take until 2024 for small
groups to fully implement EHRs, which is much longer than is currently being called for by agencies interested in quality initiatives and cost containment (Fig. 5.2). Unfortunately, the health digital information superhighway appears to have a long way to go to be completed.

Baron and partners detail their personal experience as a small group of internists (four members) with implementing an EHR. They described alterations in workflow and the initial deterioration in their office environment for staff, patients, and physicians alike. However, they also state that in spite of the various limitations, “... none of us would go back to paper health records.” They identified five key issues that are likely relevant for both small and large groups involved with implementing an EHR:

1. Financing of the EHR
2. Interoperability, standardization, and connectivity
3. Work-flow redesign issues
4. Technical support
5. Issues of change management

More recently, there have been questions regarding whether the EHR is really the panacea for moving medicine to Six-Sigma quality. Computerized physician order entry (CPOE) has been suggested as a key element in decreasing errors and improving quality. Several papers have recently addressed this issue with different conclusions. Upperman and colleagues evaluated the rates of adverse drug events (ADE) pre- and post-CPOE implementation. They noted an improvement in verbal order regulation, as well as an elimination of transcription errors after implementation. They also noted a statistical decrease in harmful ADEs and suggested that this improvement would result in one less harmful ADE for every 64 patient days. Han and colleagues noted a different experience when implementing a CPOE system in an academic tertiary-care children’s hospital. Surprisingly, they noted that the mortality rate increased from 2.3% before CPOE implementation to 6.57% after, an increase that remained significant even after multivariate analysis. It is noteworthy that in this paper, the authors document that the CPOE training was given 3 months before implementation. They also note that the implementation itself occurred over a period of only 6 days for the entire pediatric hospital. This may be too long an interval from training and too short a period for implementation. It is interesting that two papers, both published from the same institution, could have such different conclusions.

Ash and colleagues have suggested that the mere implementation of an EHR is not in and of itself enough to insure that unexpected errors won’t occur. They suggest that these errors fall into two broad categories: “those in the process of entering and retrieving information and those in the communication and coordination process that the patient care information system is supposed to support.” The key for powering the CPOE and the EHR is likely through well-thought-out algorithms that allow us to take advantage of the computer’s ability to maintain data while attempting to best understand what a particular patient needs, and while limiting changes in underlying clinical functionality, unless that change actually improves functionality.

There has also been a push to allow patients to have access to their records. This may allow patients to participate in their own care in a way not previously thought possible. Patients might be able to view data within the EHR for accuracy, reviewing such things as current or prior medications, allergies, etc. They could also be made aware of when lab tests or studies are due or overdue, helping to improve compliance and screening. An even more novel concept that has been introduced by several groups is the ability of the patient to communicate with her care providers through Web-based messaging. Initially, providers were concerned regarding the potential for overuse or abuse, but Geisinger Health Systems now has almost 60,000 active users, and little evidence demonstrates this type of abuse. Indeed, in a time when it may be quite difficult to locate your patient during the course of a business day, asynchronous communication may be a preferable manner to communicate nonemergent information with patients. In addition, these data may be appropriately security encrypted at 128 bits and easily made part of the health record.

**QUALITY INITIATIVES**

Few clinicians would argue that quality is the most important parameter in health care today. Yet, it is becoming ever more...
evident that many patients do not receive state-of-the-art health care. In a landmark article published in 2006, Asch and colleagues demonstrated efficacy in well-performed clinical trials. These initiatives from a broad base of organizations. In December 1999, the Institute of Medicine released a report suggesting that 99,000 patients per year die secondary to inadequate care being rendered. Many subsequent debates ensued regarding the methodologies used to attain these numbers. However, this report created a call to arms, challenging those individuals and organizations who provide care to improve the quality of care delivered to all patients. It has caused a number of initiatives to join in implementing six broad initiatives that have caused a number of hospitals and large organizations to create chief quality officer (CQO) positions and implement the IHI recommendations as well as multiple other元素 to bring the various constituencies together and set goals for Healthcare Research and Quality (AHRQ) to act as the key entity to bring the various constituencies together and set goals.

Consistent with the IHI initiatives, other initiatives have come from CMS, including recommendations for optimization of diabetic patients. These include bundles of care much like the IHI central line bundle, in which appropriate care consists of all elements being appropriately performed or delivered within the correct time frame. Unfortunately, as the bundles become more complicated, it becomes more and more difficult for the provider to remember what has or has not been done. This may be yet another opportunity for the EHR to allow both the clinician and the patient to know what tests or interventions need to be performed, thus optimizing the encounter. Pilot trials are currently under way to evaluate what level of compliance can be accomplished within this new paradigm. JCAHO has also released its latest recommendations for 2007 (Table 5.2).

How to best implement quality-improvement programs in a given setting is also continuing to be investigated. A recent evaluation of hospital quality-improvement implementation and subsequent impact on discrete patient safety metrics suggested that involvement by multiple units within a hospital might have a negative impact on results. Alternatively, having a higher percentage of hospital staff or senior management involved had no impact on any of the indicators.

Most clinicians have not been trained in how to develop and implement quality-improvement programs. Curtis and colleagues have published a how-to paper that came out of an outcomes task force of the Society of Critical Care Medicine but has wide applicability to many areas of medicine (Table 5.3). The generalized lack of education and training in quality may explain some of the lethargy that Leape and Berwick allude to in their article “Five Years after To Err Is Human: What Have We Learned?” Table 3.4, which is presented in this same paper, suggests significant quality improvements that have been achieved by implementing discrete strategies in specific environments. If each of our organizations could fractionalize achievements, the impact on patient care might be quite remarkable. Leape and Berwick additionally call for the Agency for Healthcare Research and Quality (AHRQ) to act as the key entry to bring the various constituents together and set goals that should be reached by 2010—a lofty proposal by anyone’s standards, but well worth striving toward.

**PAY FOR PERFORMANCE**

The additional lingering question remains as to whether these measures will be subjected to pay for performance, with groups achieving higher levels of patient compliance being awarded higher levels of reimbursement. This is a marked change from...

2007 AMBULATORY CARE/OFFICE-BASED SURGERY NATIONAL PATIENT SAFETY GOALS

<table>
<thead>
<tr>
<th>Goal</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Improve the accuracy of patient identification.</td>
</tr>
<tr>
<td>1A</td>
<td>Use at least two patient identifiers when providing care, treatment, or services.</td>
</tr>
<tr>
<td>2</td>
<td>Improve the effectiveness of communication among caregivers.</td>
</tr>
<tr>
<td>2A</td>
<td>For verbal or telephone orders or for telephonic reporting of critical test results, verify the complete order or test result by having the person receiving the information record and read back the complete order or test result.</td>
</tr>
<tr>
<td>2B</td>
<td>Standardize a list of abbreviations, acronyms, symbols, and dose designations that are not to be used throughout the organization.</td>
</tr>
<tr>
<td>2C</td>
<td>Measure, assess, and, if appropriate, take action to improve the timeliness of reporting—and the timeliness of receipt by the responsible licensed caregiver—of critical test results and values.</td>
</tr>
<tr>
<td>2E</td>
<td>Implement a standardized approach to hand off communications, including an opportunity to ask and respond to questions.</td>
</tr>
<tr>
<td>3</td>
<td>Improve the safety of using medications.</td>
</tr>
<tr>
<td>3B</td>
<td>Standardize and limit the number of drug concentrations used by the organization.</td>
</tr>
<tr>
<td>3C</td>
<td>Identify and, at a minimum, annually review a list of look-alike/sound-alike drugs used by the organization, and take action to prevent errors involving the interchange of these drugs.</td>
</tr>
<tr>
<td>3D</td>
<td>Label all medications, medication containers (for example, syringes, medicine cups, basins), or other solutions on and off the sterile field.</td>
</tr>
<tr>
<td>7</td>
<td>Reduce the risk of health care-associated infections.</td>
</tr>
<tr>
<td>7A</td>
<td>Comply with current Centers for Disease Control and Prevention (CDC) hand hygiene guidelines.</td>
</tr>
<tr>
<td>7B</td>
<td>Manage as sentinel events all identified cases of unanticipated death or major permanent loss of function associated with a health care–associated infection.</td>
</tr>
<tr>
<td>8</td>
<td>Improve the accuracy and completely reconcile medications across the continuum of care.</td>
</tr>
<tr>
<td>8A</td>
<td>There is a process for comparing the patient’s current medications with those ordered for the patient while under the care of the organization.</td>
</tr>
<tr>
<td>8B</td>
<td>A complete list of the patient’s medications is communicated to the next provider of service when a patient is referred or transferred to another setting, service, practitioner, or level of care within or outside the organization. The complete list of medications is also provided to the patient on discharge from the facility.</td>
</tr>
<tr>
<td>11</td>
<td>Reduce the risk of surgical fires.</td>
</tr>
<tr>
<td>11A</td>
<td>Educate staff, including operating licensed independent practitioners and anesthesia providers, on how to control heat sources and manage fuels with enough time for patient preparation, and establish guidelines to minimize oxygen concentration under drapes.</td>
</tr>
<tr>
<td>13</td>
<td>Encourage patients’ active involvement in their own care as a patient safety strategy.</td>
</tr>
<tr>
<td>13A</td>
<td>Define and communicate the means for patients and their families to report concerns about safety and encourage them to do so.</td>
</tr>

being paid for delivery of units of health care or procedures in which disease states are being managed. As of 2004, almost 100 pay-for-performance initiatives had been started by a wide variety of sponsors, ranging from employers to the federal government. Epstein and colleagues, in an early article on the subject of paying for high quality care, called for several significant changes to facilitate adoption of pay-for-performance initiatives. These recommendations included an expansion in the scope of the efforts, as well as the amount of incentive available to the clinician or group; the importance of large groups such as CMS becoming involved; an expansion from the current small cadre of clinical indicators; an improvement in our ability to establish reliable metrics for evaluation of quality; and, finally, a call for investment in electronic infrastructure to facilitate all of the above.

A Cochrane systematic review of the subject of targeted payments to affect outcomes in primary care was unable to reach a conclusion because of limitations in prior study quality and power. Kouides and colleagues evaluated the use of financial incentives to increase rates of influenza vaccine administration and found that modest incentive increased an already high baseline administration rate. In another study on
### TABLE 5.3

**KEY STEPS FOR INITIATING, IMPROVING, EVALUATING, AND SUSTAINING A QUALITY IMPROVEMENT PROGRAM**

**Initiating or improving a quality improvement program**
1. Do background work: Identify motivation, support team work and develop strong leadership.
2. Prioritize potential projects and choose the projects to begin.
3. Prepare for the project by operationalizing the measures, building support for the project, and developing a business plan.
4. Do an environmental scan to understand the current situation (structure, process, or outcome), the potential barriers, opportunities, and resources for the project.
5. Create a data collection system to provide accurate baseline data and document improvement.
6. Create a data reporting system that will allow clinicians and other stakeholders to see and understand the problem and the improvement.
7. Introduce strategies to change clinician behavior and create the change that will produce improvement.

**Evaluating and sustaining a quality improvement program**
1. Determine whether the target is changing with ongoing observation, periodic data collection, and interpretation.
2. Modify behavior change strategies to improve, regain, or sustain improvements.
3. Focus on sustaining interdisciplinary leadership and collaboration for the quality improvement program.
4. Develop and sustain support from the hospital leadership.

From: Leape LL, Berwick DM. *Five years after To Err Is Human: what have we learned?* *JAMA* 2005;293:2384, with permission.
immunizations, Fairbrother and colleagues evaluated use of cash bonus, enhanced fee for service, and feedback for improving baseline vaccination rates. They found only the bonus group statistically improved (increased by 25.3%), although they believed much of this effect was due to better documentation versus actual increased administration of vaccine. Rodki and colleagues noted that in incentivized groups, documentation of tobacco use was markedly increased, as was ascertainment to counseling programs; unfortunately, other important clinical end points were not different.

A more recent investigation evaluated a pay-for-performance initiative by PacifiCare Health Systems. Three quality measures were evaluated: cervical cancer screening, mammography, and HgbA1c. Unfortunately, only in the cervical cancer screening group was there an improvement after the intervention, and in spite of $3.4 million paid in pay-for-performance incentives, only nominal gains were made. Also, physicians with the highest initial baseline performance had the least improvement but were the recipients of the greatest portion of the paid bonus. This trial demonstrates the potential limitation of identifying discrete end points to reward heterogeneous groups of providers, all of whom start from different baseline levels of efficacy. Dudley has suggested that how an incentive is offered (i.e., reward or penalty) and factors such as what percentage of patients in a provider's panel incentives are applicable to may affect the success of these programs (Table 5.5). Rosenthal and colleagues, in evaluating multiple trials and multiple industries in which pay for performance has applicability, found little evidence that paying for quality is effective. They noted that even in other industries, results are inconsistent. They raise the concern that incentives may be too low, with limited penetrance within a given provider's or group's practice panel. An additional concern is making the target for incentive so much higher than baseline that the providers feel it is unachievable and therefore do not try. This is consistent with data from Beckman and colleagues, who interviewed providers in a pay-for-performance program. Interestingly, providers reviewed their personal profiles but did not always change their functional behaviors in response to the data.

A variation on pay-for-performance is where a provider being paid only if a certain outcome of a surgical procedure has been achieved and the entire care relative to the procedure is covered under one payment. These types of programs may have the greatest initial application in the area of cardiovascular surgery, for which outcome metrics of individual surgeons and hospitals have been reported for several years. In addition, there are well-defined clinical algorithms regarding “best practice.” This may have driven the American Heart Association’s Reimbursement Coverage and Access Policy Development Workgroup to publish a statement on pay-for-performance.

In addition to the previously noted problems with pay-for-performance programs, another limitation is that most programs to date have focused on single disease states or outcomes (such as immunization, or Pap test or mammogram compliance). In reality, many patients aged 65 or older have multiple medical problems, and treating single disease states in isolation may not lead to overall improved outcomes and enhanced quality. It is not surprising that 89% of Medicare’s annual budget is consumed by patients with three or more chronic conditions. Boyd and colleagues evaluated current clinical practice guidelines (CPGs), which are often used in pay-for-performance programs, but which also focus on single disease states. In a hypothetical 79-year-old female patient with the common comorbidities of chronic obstructive pulmonary disease, diabetes, osteoporosis, hypertension, and osteoarthritis, they found that following each CPG would lead to 12 prescribed medications and a potential outlay of $406 per month. There were also significant issues with the potential for drug-drug interactions if this “optimal” regimen was followed. They concluded that pay for performance based on CPGs for single disease states may create “perverse incentives” and actually decrease quality of care, and that significant effort should be placed on effectively treating the multiple chronic conditions that many of our patients have.

While these initiatives are in their infancy, there will likely be future pressures both at the state and federal level to achieve an ever-higher level of quality. In addition, pay-for-performance needs to evolve to incorporate these early findings into rationales for physicians, which align the needs of payers, providers, and our patients. It may also become quite difficult for groups and practices that do not have access to electronic data to be able to participate in such projects. Further incentives or underwriting installation of appropriate infrastructure will be critical.

### HOSPITALISTS

In the last decade, there has been a move toward some practitioners working solely within the hospital setting to care for inpatients, a practice common outside the United States for decades. This started when data suggested that in some cases, patient care might be optimized and length of stay reduced by having a single individual responsible for overseeing a patient’s stay in the hospital. Emergency department physicians have performed shift work for decades, but the change was most dramatic for hospitals who are generally interested in reducing costs. In addition, pay-for-performance needs to evolve to incorporate these early findings into rationales for physicians, which align the needs of payers, providers, and our patients. It may also become quite difficult for groups and practices that do not have access to electronic data to be able to participate in such projects. Further incentives or underwriting installation of appropriate infrastructure will be critical.
Within the general topic of gynecologic surgery practice, the range of LOS reductions was 7% to 27%, which even on the lower end often translate into significant savings to health care organizations. Several variations on the hospitalist model exist, including use of combinations of private staff, academic staff, and house staff. One study evaluated differences between community physicians, a private hospitalist service, and an academic hospitalist group within the same tertiary care hospital and found a 20% LOS and 10% cost reduction on the academic service versus 8% and 6% reductions for the private hospitalists and the community physicians, respectively. They did not note differences in mortality rates (either inpatient or 30-day) or readmission rates between the three groups. Another variation is to use the hospitalist to cover patients typically covered by surgical services. One trial evaluated use of a hospitalist in managing elderly hip fracture patients along with orthopedic surgeons. They noted decreased time to get patients to surgery, decreased length of hospitalization after surgery, and overall decreased LOS with no adverse impact on mortality or readmission. Another area of question has been how a hospitalist service might affect teaching and education for students and residents. Hauer and colleagues analyzed 1,387 house staff and student evaluations on internal medicine rotations during a 2-year period. They scored the hospitalist group (versus traditional attending physicians) higher in teaching effectiveness, knowledge, and feedback. More recently, the hospitalist trend in internal medicine and family practice has carried over to pediatric hospitals that have now created pediatric hospitalist services. Dwight and colleagues describe that with manpower reductions and limitations in house staff, among other issues, some Canadian hospitals have begun to successfully use a non-house-staff-based model effectively. Landrigan and colleagues performed a systematic review of the pediatric hospitalist literature, and consistent with nonpediatric hospitalist studies, these programs had an average LOS and cost decrease of 10%. They do note that many of the programs themselves do not generate adequate revenue to not lose money. An interesting article on keys to success for creating a pediatric hospitalist program suggests six key principles that may have broad applicability to establishment of similar programs in obstetrics and gynecology (Table 5.6).

Only recently has this trend carried over into obstetrics and gynecology. At this time, there are only a handful of hospitals in the country where “laborists” manage patients sent in from their colleagues, who are then only responsible for managing patients in the ambulatory setting. In a time when clinicians have become highly interested in balancing lifestyle and work, these programs had an average LOS and cost decrease of 10%. They do note that many of the programs themselves do not generate adequate revenue to not lose money. An interesting article on keys to success for creating a pediatric hospitalist program suggests six key principles that may have broad applicability to establishment of similar programs in obstetrics and gynecology (Table 5.6).

It has become increasingly important for physicians to evaluate the adequacy of data to which we are constantly exposed. There has been a transition in articles published in the peer-reviewed literature over the last 10 years to a significant effort toward asking and answering questions in the most rigorous manner possible. Numerous methodologies exist for evaluating these trials, which place differing values on the quality, quantity, and consistency domains expressed within each report. Given the subtleties of these differing methodologies, a paper may be deemed to be stronger or weaker. AHRQ has reported on an evaluation of these various systems and describes the differences relative to the type of trial being evaluated (e.g., randomized controlled trial versus observational). One of the most commonly used systems is seen in Table 5.7 and is described by the U.S. Preventive Services Task Force. This method describes the type of trial and gives a recommendation.
regarding the strength of the conclusion. It is relevant for us as practicing surgeons to be able to differentiate between data and reports that are merely interesting and those that should cause us to reevaluate our practice patterns. It is also important to understand not only what the grading system means but how the conclusions are reached for each of these unique systems. Because there are presently a number of systems and no one is universally used in journals or textbooks, this is an even greater challenge.

In a recent review of 53 American College of Obstetricians and Gynecologists practice bulletins, Chauhan and colleagues found that only 25% of 438 recommendations were level A (good and consistent evidence), whereas 33% of recommendations were level B (limited or inconsistent evidence) and 38% were level C (consensus and expert opinion). This is the quandary in medicine today: Evidence-based medicine is how all of us would like to practice, but unfortunately, all questions have not been answered to the extent needed. Because of this, panels of experts may by necessity have to revert to the best available data, which may be less than optimal. However, even in the field of medical ethics, there is an effort toward moving to formal tools for evaluating the validity of discussions and data. If the last 10 years is any indication to what will happen in the future, there will be a increasing number of randomized controlled trials that are well thought out and executed to aid us in determining how to best counsel our patients.

CONCLUSION

The examples illustrated in this chapter are but a small sampling of the numerous ongoing changes occurring daily. Many of these changes will likely affect our lives and practices—some more than others—but all are a radical departure from times not too distant. It will be interesting to evaluate how these changes evolve over editions of this textbook. Changes underscore the importance of lifelong education, not only in the functional practice of medicine but also in the art of the practice of medicine. It certainly makes our profession an exciting place to be—stay tuned!

BEST SURGICAL PRACTICES

■ Resident education has been transformed to being less service oriented and more competency based. The 80-hour workweek has had revolutionary changes in the mind-sets of today’s trainees and the people who train them.

■ Quality has always been important to physicians in theory, but new initiatives, such as the 100,000 lives IHI program, are making evidence-based practice a reality.

■ The EHR is only in its infancy. This modality will alter every aspect of care delivered by physicians and effect communication between providers and their patients.

■ By being dedicated providers for inpatients, hospitalists will render more efficient and timely care and therefore more effectively manage patients, with an eye to improving quality and decreasing error.

■ Pay-for-performance is being investigated as a means to reward providers and health care organizations for optimizing predefined outcomes and quality metrics.

CHAPTER 6 ■ TRAINING THE GYNECOLOGIC SURGEON

ROBERT M. ROGERS, JR.

DEFINITIONS

The competent surgeon—Definition yet to be determined.

Apprenticeship model—A teacher-oriented teaching model, usually without structure, purpose, or defined goals.

Learner-oriented model—A learner-oriented teaching model with structure as well as specific and directed objectives, using observational activities and developmental hands-on surgical skills, including sound clinical judgment. The program emphasizes competency-based training in primary care and basic surgical education.

Aims for health system improvement—Safety, effectiveness, patient-oriented care, timeliness, efficiency, and equity, according to the Institute of Medicine.

Accreditation Council for Graduate Medical Education competencies for optimal patient care—ACGME has issued six competencies for resident physicians:

1. Patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health.
2. Medical knowledge about established and evolving biomedical, clinical, and cognitive sciences and the application of this knowledge to patient care.
3. Practice-based learning and improvement that involves investigation and evaluation of their own patient care.
4. Interpersonal and communication skills that result in effective information exchange and teaming with patients, their families, and other health professionals.
5. Professionalism as manifested through a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population.
6. Systems-based practice as manifested by actions that demonstrate an awareness of and responsiveness to the larger context and system of health care and the ability to effectively call on system resources to provide optimal care that is of optimal value.

The goal of a surgical residency is to prepare the resident surgeon for the independent practice of surgery. Societal and governmental pressures in the United States are now requiring the practitioner of surgery to be “competent” and accountable. However, the term competent surgeon has yet to be defined. Furthermore, the curricula and strategies to train the competent surgeon are not yet developed. The Residency Review Committee for Obstetrics and Gynecology structures and certifies “adequate” training for the gynecologic surgeon. Presently, the federal and state governments in the United States, as well as in other countries, are now questioning the quality of surgical education and the competency of practicing surgeons. This is true in all surgical specialties, including the training and practice of gynecologic surgery. Medicare and Medicaid patients are now demanding monitoring of quality indicators of surgical procedures and subsequent outcomes. Soon, these data on hospitals and individual surgeons will be translated into a pay-for-performance program. These data will also become available for public scrutiny. Unfortunately, the governmental laws, rules, and regulations concerning the practice of medicine and surgery are coming much faster than medical educators have time to study, develop, and validate the coming “competency-based” surgical training programs.

This chapter briefly discusses the present state of surgical training, the present-day problems that need to be addressed, and the pressures that are moving the development of training programs that will produce the “competent” gynecologic surgeons in the near future. Where have we been and where are we now? Where must we go and why? What are we to do? The interested reader will find more depth, other views, and further specifics on this topic in the references at the end of this chapter. In particular, the reader is referred to “Teaching and Evaluating Surgical Skills,” edited by Rebecca G. Rogers, in Obstetrics and Gynecology Clinics of North America, June 2006.

WHERE HAVE WE BEEN AND WHERE ARE WE NOW?

For more than one hundred years, the apprenticeship model has been how gynecologic surgeons are transformed from medical students to resident gynecologic surgeons to independent practitioners. This system continues to be a “see one, do one, teach one” teaching model under the supervision of a surgical mentor. The surgical mentor predominantly teaches surgery based on his or her own personal experiences and modes on evidenced-based studies. The mentors in many surgical training programs today, as over the past century, have widely variable training, the present-day problems that need to be addressed, and the pressures that are moving the development of training programs that will produce the “competent” gynecologic surgeons in the near future. Where have we been and where are we now? Where must we go and why? What are we to do? The interested reader will find more depth, other views, and further specifics on this topic in the references at the end of this chapter. In particular, the reader is referred to “Teaching and Evaluating Surgical Skills,” edited by Rebecca G. Rogers, in Obstetrics and Gynecology Clinics of North America, June 2006.

For more than one hundred years, the apprenticeship model has been how gynecologic surgeons are transformed from medical students to resident gynecologic surgeons to independent practitioners. This system continues to be a “see one, do one, teach one” teaching model under the supervision of a surgical mentor. The surgical mentor predominantly teaches surgery based on his or her own personal experiences and modes on evidenced-based studies. The mentors in many surgical training programs today, as over the past century, have widely variable surgical skills and teaching styles. Thus, surgical instruction continues to be a “trial by exhaustion and humiliation, as well as a journey of harassment and abuse (Dunnington).” Surgical instructors have not been schooled in how to be effective mentors, how to teach surgery, and how to evaluate surgical skills. This is as true today as it has always been. Some instructors don’t even allow the resident any hands-on surgical experience. They allow the resident to learn by assisting at the surgery. The apprenticeship model does not offer uniform case loads with seasoned mentors to assure adequate experience in performing gynecologic surgery. The teaching of ethics, professionalism, patient care, medical knowledge, and leadership were and are rarely taught, except by the happenstance examples of the mentors.

73
Teaching in the apprenticeship model is teacher oriented rather than student oriented. Teacher-oriented teaching has been shown to be random, without structure and purpose or defined goals. The Residency Review Committee (RRC) for Obstetrics and Gynecology eventually established structure- and-process guidelines for surgical training in gynecology by defining the types of surgery with which the resident should be involved. This is, of course, a clinic-based practice and the judgment of the resident is subjectively determined by the individual residency program director.

The newly graduated gynecologic resident has simply fulfilled a requirement of time served with no defined minimum requirements of acquired surgical skills and experience.

The educators and practitioners of clinical gynecology today have seen the significant inconsistencies and weaknesses of training gynecologic surgeons by the traditional apprenticeship model. In the past 15 to 20 years in the United States, various factors have arisen to further deteriorate the quality of surgical training. Observations within the obstetric residency programs themselves show several unfortunate trends. The two most crucial are the decreasing number and variety of gynecologic procedures and the exodus of many dedicated surgical instructors from academic centers to private practice or retirement.

A third trend, being evaluated now, is the impact of the Accreditation Council for Graduate Medical Education (ACGME) restriction on resident duty hours in clinical training and on-call experience. However, Nuthalapaty and colleagues, in studying the new restriction on residents’ working hours, report that “A reduction in resident participation in surgical care/procedures had a minimum prevalence of 38% across all clinical service types.”

Surgical cases are moving out of the teaching centers to private surgical specialty centers. This is especially significant with gynecologic procedures such as laparoscopy for hysterectomy, midurethral slings for stress urinary incontinence, and operative hysteroscopy. More and more subspecialty gynecologic surgeons have opened private centers for operative laparoscopy and operative hysteroscopy to evaluate and treat many gynecologic problems, including the need for hysterectomies, infertility, pelvic pain, and urinary incontinence. This marketing by private gynecologic surgeons is in direct competition with the teaching centers for patient population. These private practitioners are not interested in teaching because the resident will “slow me down and increase my medical-legal liability.” Historically, operative laparoscopy and laparoscopic hysterectomies among gynecologists primarily evolved in the private sector, not in the academic or teaching centers.

In addition, some traditional surgical diseases, often requiring hysterectomy and/or oophorectomy, are now increasingly managed medically without surgery or with minimally invasive procedures. Examples of such traditional surgical diseases are chronic pelvic pain, endometriosis, urinary incontinence, infertility, abnormal uterine bleeding, uterine fibroids, and ectopic pregnancy. Third-party payers have grasped hold of these medical and less invasive surgical therapies. They are more and more denying payments for the more invasive surgical procedures. These nonsurgical therapies significantly reduce financial costs but also the many departmental activities and financial obligations. These pressures urge the attending surgeon to operate himself/herself as much as possible in order to speed the case along to get done and get the next case under way as soon as possible. The goal is to do as many surgical cases as possible in a day to generate more income. Obviously, the resident becomes a technical assistant with little opportunity for verbal and hands-on instruction. In addition, the attending surgeon perceives that he/she can perform the case faster and better with less medical-legal risk. However, this perception may not be true.

Also observed has been a shift in the learning environment of many residents. In the past, the older gynecologic surgeons spoke of a sense of community, a sense of purpose, a sense of pride in their individual residency training programs. That sense of uniqueness in a residency program has disappeared with the departmental budget restraints and faculty turnover. Today, more residents appear to be overwhelmed by their patient responsibilities and lack real surgical training. There are presently no measurable standards by which to determine how well a gynecologic resident has been trained in various gynecologic surgical procedures. The surgical training method of apprenticeship with an individual mentor is no longer producing surgically qualified gynecologic surgeons. The role of “see one, do one, teach one” is wholly inadequate in this new era of laparoscopic surgery, operative hysteroscopy, and the expansion of surgical and medical knowledge needed to treat previous surgical gynecologic problems. The operating room cases available for resident training vary widely in complexity. They cannot be standardized for resident training. They may or may not be of sufficient difficulty and complexity for training, and they too often involve instructors who are not educated or experienced enough to do effective training in the operating room. In addition, the same patient may be treated and stressed, and the surgical mentor may be uninterested in teaching and more interested in getting the case done quickly without undue teaching. Surgical training has become a game of chance, a hit-or-miss lucky draw of getting good training from a good mentor during good surgical cases.

In general within our specialty, the reality exists that the present resident in gynecologic surgery is now learning surgery with less surgical experience in the operating room with less experienced surgical instructors. Therefore, in general, the present-day gynecologic surgeon leaving residency is deficient in surgical experience, knowledge, and skill. As a result, some graduated residents continue their surgical training in postgraduate surgical fellowships or subspecialty fellowships, or join practices with experienced gynecologic surgeons who are willing to mentor them. This perception is now met head-on with continued reports of medical and surgical mistakes in U.S. hospitals and the ever-increasing costs for the delivery of health care. A true crisis in the quality and quantity of gynecologic surgical training is now fully upon us. As a specialty, our own observations of surgical teaching deficiencies have now been memorialized by governmental regulation and the recent efforts to standardize the collection of surgical case data on complications and outcomes, and subsequent financial reimbursements.

General Topics Affecting Gynecologic Surgery Practice
WHERE MUST WE GO, AND WHY?

As a result of the societal and governmental outcry for top-quality medical and surgical care, the ACGME and the American Board of Medical Specialties (ABMS) have firmly moved to establish guidelines for the competency-based training for all physicians and surgeons. The former structure-and-process educational mandates are now being converted to competency-based educational programs. Unfortunately, the process toward competency-based training is neither well defined nor clear at this time. The steps in designing the new programs and curricula include (i) defining a competencies, development of a competent educational process, reliable and valid tests of knowledge and performance, and continuing assessment and evaluation of the whole process from beginning resident to “competent” practicing surgeon. In 1999, the ACGME identified in principle six general competencies upon which all graduate medical education must be based: (i) patient care, (ii) medical knowledge, (iii) practice-based learning and improvement, (iv) interpersonal and communication skills, (v) professionalism, and (vi) systems-based practice. Few guidelines and definitions have been issued since. The RRC is struggling to define and implement these six core elements of a competent residency education. The timeline for implementation is ambitious and being pressured by the federal government payers and legislature. However, there is little to implement at this time. Current professional literature is beginning to generate some articles on developing and evaluating the outcomes of competency-based educational models. However, much remains to be accomplished.

Just as clinical and surgical care should be guided by evidence-based clinical studies, gynecologic surgical education should be guided by evidence-based educational studies. The studies will directly assist the RRC in establishing requirements for how best to teach a particular clinical or surgical skill or professional attribute, including techniques, decision making, and leadership qualities. Surgical teaching methods and outcomes need to be standardized in a standardized manner. Surgical curricula need to be established and standardized to know what to teach and how to best teach the mandatory core knowledge. An important aspect of teaching operative skill is a realization that skill is a process. This final maturation process, called automization, involves the development of memory, skill, and certain intellectual skills. This framework enables the resident to perform a procedure step by step. However, fluency of these skills, along with operative judgment, demands further refined practice and experience under close critical supervision. This final maturation process, called automation, not only involves psychomotor skill development, clinical judgment, excellence, and knowledge of the literature, but also involves the development of interpersonal skills with emphasis on managing the operating room team.

WHAT ARE WE TO DO?

As Roger C. Crafts said, “You will remember a little of what you hear, considerably more of what you see, but almost all of what you understand.” This statement applies not only to the learning of scientific knowledge and principles, but also to the learning of technical skills and medical/surgical judgments. As emphasized, the training of the skilled and talented gynecologic surgeon must involve a skilled, caring, and interested mentor. The teaching quality of the surgical faculty does have an impact on positive student performance. This must also include a positive environment for immediate evaluation from a trained observer. As has been said, “Practice does not make perfect, perfect practice makes perfect.” The repetitive performance of specific skills has been shown to be much more effective in surgical training than general training involving multitask procedures.

Third, the highest-performing successful individuals have clarity, purpose, and imagination in their chosen field. “The ability to improvise, to cope skillfully with novel situations, requires vision, which takes years to develop.” As emphasized, the training of the skilled and talented gynecologic surgeon must involve a skilled, caring, and interested mentor. The teaching quality of the surgical faculty does have an impact on positive student performance. This must also include a positive environment for immediate evaluation from both self and mentor. This environment many times is delicate and balances between confidence-building positive and self-defeating negative. Reznick writes:

Surgical preceptors serve as extremely potent and influential role models. We do so in all the aspects of an operation, from our approach to tissue handling to our interpersonal relationships in the operating room. The second aspect is coaching. This role as a coach reminds us of a need to provide encouragement and discipline to the resident. In this way, we help create a scaffold upon which the resident can build.

Levels of resident surgical training include the use of the individual senses: hearing, seeing, and tactile feeling. In addition, individual surgical skills need to be practiced and then integrated into an operative framework. This framework enables the resident to perform a procedure step by step. However, fluency of these skills, along with operative judgment, demands further refined practice and experience under close critical supervision. This final maturation process, called automation, not only involves psychomotor skill development, clinical judgment, excellence, and knowledge of the literature, but also involves the development of interpersonal skills with emphasis on managing the operating room team.
RESIDENTS AND SURGICAL EDUCATION

Learning through hearing involves carefully crafted, presented, and coordinated lectures, case presentations, and discussions. Observational activities include seeing videos, watching various surgical exercises on inanimate trainers, watching cadaveric dissections, and, of course, observing live surgical procedures. The development of hand-eye coordination and hands-on surgical skills involves the use of inanimate trainers, computer simulators, animal models, human cadaveric dissections, and, of course, surgically intact patients under the careful tutelage of a surgical instructor and mentor. Obviously, the teaching and evaluation of surgical skills and clinical judgment before entering the live operating room presents several distinct ethical, medical-legal, and financial advantages. Lectures and case discussions must include patient presentations; appropriate history taking; focused physical examinations; discussion of findings; medical or surgical options, including possible benefits; and possible risks and complications. An interactive teaching environment among teacher and students with feedback and explanations is more beneficial for learning. The modern gynecologic surgeon must not have the mindset that “if you can cut it, you can cure it.” Above all, the gynecologic surgeon must become an expert in the understanding, evaluation, and treatment options of gynecologic diseases and disorders. Auditory learning must include appropriate objectives, enthusiastic lecture presentations by the teacher, and appropriate postpresentation objective testing. Individual progress is best achieved when made accountable and measurable to the individual learner.

Likewise, observational learning when observing videos or surgery on animals, human cadavers, or live patients needs to be focused and broken down into individual surgical skills and decision components. The observations by the residents again must involve individual accountability and appropriate testing and measurement. Hands-on training must focus on specific and individual tasks within each complex surgical procedure.

Beginning exercises involve minimal equipment to practice knot-tying and the ergonomic use of surgical instruments. Knot-tying boards and simple plastic trainers are available from various surgical instrument companies. In addition, video laparoscopic trainers are also available for practicing more involved laparoscopic skills. Anastakis and colleagues showed “that both bench and cadaver training were superior to text learning and that bench and cadaver training were equivalent.”

A formal surgical training program within a residency does objectively improve the resident’s surgical skills. Animal models, particularly anesthetized pigs, allow the emerging gynecologic surgeon to get the actual feel of tissue dissections, see physiologic response, and experience a physical realism of operating on a live patient, especially with the immediate feedback of hemorrhage. However, the drawback of animal models is that the anatomy is often much different and the dimensions within the pelvis are much smaller than those in the human patient. However, the cost is much more affordable than present human cadaver courses and computer simulations. Despite this, the animal model has a role: physiologic hands-on operative experience. Other animal models may include various body parts of various animals to recreate the feel and texture of various human parts. However, to work on a live animal model, the technical support aspects can be complex, just as in the human model. The animal must be properly anesthetized in a properly prepared room with appropriate lighting, equipment, instrumentation, and technical and surgical support.

Advanced Surgical Training on Unembalmed Human Cadavers

A more advanced model for surgical training is the performance of dissection techniques and procedures on unembalmed human cadavers. This excellent model has been successfully used in teaching vaginal surgery, open laparotomy, hysteroscopy, and, of course, operative laparoscopy. We are fortunate in the United States to have the opportunity to have resident and postgraduate education courses using unembalmed cadavers. The use of human cadavers for postgraduate surgical education is not allowed or feasible in most countries of the world today.

The human cadaver model is an excellent model on which to learn human pelvic anatomy, including the dimensions and relations of the various structures and tissues within the human body, proper dissection techniques, and the performance of various surgical procedures. Even though the overhead financial cost of these courses is high, the intense and concentrated nature of the learning is well worth the expense in the minds of many individuals who have taken such training. The overhead expenses include the cost of administering the willed body programs in the various states; the immediate testing of the bodies for human immunodeficiency virus, hepatitis B and C, and syphilis; the proper handling of the bodies for cold preservation; the appropriate shipping, preparation of the body at the course site, and cost of technical support personnel in setting up the body at each workstation; and setting up the appropriate audiovisual equipment, instrumentation, and appropriate universal safety precautions. Teaching institutions interested in organizing such human cadaver teaching opportunities must inquire and coordinate their programs with their local medical school and state board of anatomic gifts. They must conform to the prevailing rules, regulations, and laws that control the use of these voluntarily willed bodies. Students and their instructors must be respectful, courteous, and appreciative of these individuals who allow their bodies to be used for their learning.

The participants in such a learning exercise must realize the purpose of this teaching is not only to appreciate and understand structural and pelvic support anatomy, but more importantly, to learn and practice proper tissue dissection techniques on human tissues. The practicing surgeon must be a master of the various tissue dissection skills and techniques to safely develop the surgical fields involved with the procedure. Further hands-on exercises in the cadaver allow each student to perform various gynecologic procedures. The purpose of cadaver learning is not to learn surgical instrumentation and basic skills, such as how to handle laparoscopic instruments and knot tying; these can be mastered with inanimate trainers. The purpose of cadaver learning is to learn dissectional surgical anatomy and to integrate surgical skills, already mastered, into an entire operative procedure. The goal of cadaver training is to significantly improve the operative experience of each participating surgeon. Ideally, operative procedures on human own patients will become safer (fewer operative complications), become more efficient (smoother dissections with less wasted motion and hesitation), have less blood loss (to obscure the field), and become more effective (better long-term results).

Teaching on human cadavers must have specific and directed objectives. Most gynecologic surgeons, when left to dissect a
cadaver alone, do not have a clear understanding of the relevant anatomy and dissection techniques that need to be mastered. Dissection techniques must be taught in a specific and directed manner, likewise. The participant should already have the appropriate surgical skills to take full advantage of his or her learning on the cadaveric model. These skills can certainly be learned, as noted earlier, via training on the various simulators, animal models, and, eventually, the computer-simulated trainers.

All aspects of gynecologic surgery may be understood and practiced on the human cadaver. This includes dissection of the anterior abdominal wall, correlation with surgical incisions and laparoscopic trocar placement; and practicing of dissectional techniques, layer by layer within the pelvis itself, particularly in the retroperitoneal areas. The retroperitoneal areas include the presacral space; the pelvic brim area; the pelvic sidewall; the base of the broad ligament, where the ureter passes underneath the uterine artery; the paravesical space anteriorly; the pararectal space posteriorly; the vesicocervical and vesicouterine spaces; the rectovaginal space, including the rectovaginal septum, and, of course, a thorough dissection and understanding of the anatomy of the retroperitoneal space of Retzius. These dissections must be carried out carefully in a directed manner to find the structures contained within the dissection plane and to understand their relationships to other vital structures within the same and surrounding anatomic areas. Further dissections, whether open laparotomy or through the laparoscope, can also include appreciation of the various somatic nerves, such as the obturator nerve and even the femoral nerve in the iliohypogastric groove. Other dissections can reveal the sacrospinous ligament; the sacral plexus of nerves, including the pudendal nerve and the sciatic nerve; the vesical nerve; the internal iliac artery and vein; and the hypogastric plexus and its many branches; the cardinal ligament and uterosacral ligament complex; and the various support tissues, such as the pubocervical fascia and rectovaginal septum.

Unembalmed cadavers also allow the opportunity to understand and practice on a live patient. This enables the student to dissect and to understand the structural and relational anatomy, and to perform procedures through the vagina for understanding of anterior vaginal wall prolapse or cystocele repair, apical prolapse or enterocele repair, and posterior wall prolapse or rectocoele repair. Within the pelvic cavity, the various tissue layers—such as the peritoneum, visceral fascia, and anatomic structures—have the feel of the live patient, but neither bleeds much nor cause undue anxiety during the learning of dissectional techniques. The operating gynecologist has the opportunity to practice surgical skills in a specific, focused manner, step by step, integrating all the steps to perform an entire procedure without the pressures of medical-legal considerations.

A less effective but still viable method of learning anatomy is on the embalmed cadaver, such as is found in medical schools. However, the opportunity to have the feel of live patient tissue is lost with the embalming process.

After these human cadaver specimens have been used for learning, these individual specimens are respectfully taken to a funeral home, where they are cremated. Their remains are returned to their home states and then to their families by the respective anatomic gifts registries. Again, we are appreciative for these individuals and their families who have voluntarily allowed their bodies to be used for anatomic and surgical training.

The program involving human cadavers must also have specific goals to allow the gynecologic resident and interested attending physician to develop a base of clinical and anatomic knowledge upon which to grow and develop as more experience is obtained in surgery. This core of knowledge and understanding in anatomy and surgical procedures is important so that the independent gynecologic surgeon can understand new techniques and surgical developments as the field of gynecology progresses in the future.

### Computer-generated Simulators

Several computer companies are well on their way to developing effective computer-based simulators, or in vitro gynecologic trainers, particularly involving open surgery, laparoscopic surgery, and hysteroscopic surgery. These computer-based simulators not only give the perception of operating on a “normal” patient but also allow for anatomic and pathologic variations within the practice patient. The computer provides a virtual attending mentor that offers immediate objective and nonjudgmental feedback. These computers are being programmed to allow for realistic haptics and the true feel of instrument motion and tissue pressure. The simulators provide skills maintenance, even with the decreasing caseload of major surgical procedures found in gynecologic residencies today. They are accessible for on-demand training 24 hours a day, every day of the week, 365 days of the year. The objective, unbiased, and nonjudgmental quantitative skills assessment motivates the individual because each resident is directly accountable for his or her own measured progress. Computer-based simulators allow for objective assessment of performance and outcome before the individual resident operates on a living patient.

The development of computer-based simulators by various research computer engineers is rapidly overcoming the challenges of computer costs, virtual anatomic realism, physical realism, haptic realism, and physiologic realism. Computer costs have decreased dramatically, thereby making this teaching modality much more affordable. Visual realism compares the look of the tissues on the computer screen with the real patient. Anatomic realism deals with the structural and relational anatomy within the field of operation. Physical realism deals with the size and feel of the instruments and tissues encountered. Haptic realism pertains to how things feel, like the feel of live surgery. The feel of mass, elasticity, gravity, and moving instruments is important in peristomotor development. Physiologic realism deals with possible hemorrhage at the surgical site; various movements of the patient, such as during respiration; and even pain perception by the poorly anesthetized patient. Visual realism and haptic realism allow the individual to practice hand-eye coordination. Issues of ethics, medical-legal concerns, and patient safety in teaching gynecologic surgery will be better solved as computer-based education becomes more affordable and more available.

### Training in Laparoscopy

As a result of the need to train surgeons in complex laparoscopic procedures, various training formats have evolved in recent years in various countries around the world. Many of these training models are based on individual laparoscopic procedures (see Bibliography). However, in August 1998, Brill and Rogers published “A Comprehensive Program for Resident Training in Operative Laparoscopy.” The thesis of this outline is that the basic laparoscopic anatomy, pathology, and fundamental technical and ergonomic skills—even for the most advanced laparoscopic procedures—can be
General Topics Affecting Gynecologic Surgery Practice

Millions of dollars are spent each year by commercial airlines and by the U.S. military in training aviation pilots using computer-modulated flight simulators, as well as actual training flights. Why has gynecologic surgical training lagged so far behind in the use of these modern modalities? Is a well-trained and seasoned surgeon not worth the expense to individuals in this society?

Julian and Rogers have again proposed a 5-year program for training competent obstetricians and gynecologic surgeons. The first year, PGY-1, consists of competency-based training in primary care medicine and basic surgical education. PGY-2, PGY-3, and PGY-4 consist of core education in obstetrics, gynecology, and their contained subspecialties. Importantly, for the first time in this era of limits on residents' work hours, the time to repetitively deliver hundreds of normal, spontaneous vertex vaginal deliveries needs to be rethought and revised. The PGY-5 year is a transition period from residency to independent practice. The fifth-year resident is a minimally supervised junior faculty member and assists in teaching, supervising, and evaluating the junior residents. The best way to learn and understand a clinical subject is to practice and teach. Concurrently, the resident will generate case lists and other experiences directly leading to board certification.

Julian and Rogers also propose the designation of several academic centers for developing excellence in surgical mentors who are well trained and dedicated will become enthusiastic, competency-based mentors. Seasoned surgical training will also teach motivated surgeons how to develop the most effective use of educational time in this era of limits on residents' work hours, the time to repetitively deliver hundreds of normal, spontaneous vertex vaginal deliveries needs to be rethought and revised. The PGY-5 year is a transition period from residency to independent practice. The fifth-year resident is a minimally supervised junior faculty member and assists in teaching, supervising, and evaluating the junior residents. The best way to learn and understand a clinical subject is to practice and teach. Concurrently, the resident will generate case lists and other experiences directly leading to board certification.

Julian and Rogers also propose the designation of several centers in the United States to develop and study the best methods to teach competency-based gynecologic surgery. Academic and practical input, as well as funding, from public and private payers of health care, from national foundations, and from specialty societies should be included in the process. The goal of these centers is the development of the best teaching methods for surgical training, as well as reliable competency criteria for learning evaluation. In turn, these centers will supply the RRC with an objective tested program to guide surgical training and establish criteria for program certification. It is in the financial and patient safety interests of the federal and state governments, as well as the private insurance payers, to fund this work in training competent surgeons, who will best use the limited funds available to care for the surgical needs of future society.

Also, with the loss of many skilled and seasoned educators from academic and teaching centers, the problem of dedicated and available educators must be immediately and directly addressed. The teachers themselves need to be mentored and trained, and must have financial incentives to be the best possible teachers. This is a proven business method of developing quality. The problem of dedicated and available surgical teachers must be addressed directly, not only by teaching institutions and the specialty, but most importantly, by the health care payers and the government policy makers. Postgraduate programs must be developed to increase the numbers of quality surgical instructors. These physicians should be getting PhDs in how to teach, not MBAs.

Testing of technical skills must be clearly addressed. The residents must be accountable for their own progress. Tests must be crafted so that they can measure their progress, both quantitatively and qualitatively. These tests must be feasible, reliable, and valid. Assessment and measurement leads to personal accountability, motivation to learn, and true measurable progress.

In addition, training of the individual gynecologic surgeon must not only emphasize individual skill development but should also include training in creating effective and harmonious surgical teams, particularly involving their administration and interpersonal relationships. Teamwork in the operating room is important to realize optimal performance. Until recently, there have been no tools to measure teamwork in the surgical setting. MaKary and coauthors have demonstrated that the Safety Attitudes Questionnaire can be used to measure teamwork, identify disconnects between or within disciplines, and evaluate interventions aimed at improving patient safety. Clearly, residents will participate as team members in the operating room. Using operating room briefings and debriefings as a means of improving teamwork communication will also optimize the student learning experience.

We need to train more effective and sensitive mentors. Mentors must provide ongoing feedback in a positive and constructive manner. Without this continual feedback, deficiencies in an individual's training will not be corrected. The caring and effective mentor will have a professional yet personal relationship with the learner. The effective mentor in surgical education must be skilled in questioning, must ensure a comfortable environment for learning, and must be willing to question present surgical practices. “Without effective mentoring, students feel alone, perplexed, overwhelmed” with a decreased enthusiasm for learning (Dunnington).

Last, Resnick concludes:

What makes an excellent operative teacher is adherence to basic, almost simple principals: treat residents as adult learners; set specific objectives; realize that operative skills are multidimensional; and be there, observe, be patient, provide feed-back, be positive, take the job seriously and structure the assessment process.

The proposed academic centers for developing excellence in surgical training will also teach motivated surgeons how to become enthusiastic, competency-based mentors. Seasoned surgical mentors who are well trained and dedicated will be the engines that power the longevity and practicality in modern surgical training and practice in the United States.
BEST SURGICAL PRACTICES

Although the regulatory agencies have set the parameters for education in the surgical specialties, there is considerable latitude for optimization of the learning experience. Training of the individual gynecologic surgeon must not only emphasize individual skill development, but should also include training in creating effective and harmonious surgical teams, particularly involving their administration and interpersonal skills.

The seasoned, well-trained, dedicated surgical mentor remains an important element that powers the overall progress to competency in modern surgical training and practice.
SECTION II  ■  PRINCIPLES OF ANATOMY AND PERIOPERATIVE CONSIDERATIONS
CHAPTER 7  SURGICAL ANATOMY OF THE FEMALE PELVIS

JOHN O. L. DELANCEY

DEFINITIONS

Urinary trigone—The urinary trigone is a triangular visible area in the bladder, the apexes of which are the ureteral orifices and the internal urinary meatus. This is a layer of smooth muscle connecting the ureters and the urethra, the edges of which are visible cystoscopically and when the bladder is open.

Urethra and vesicle neck—The urethra is that portion of the lower urinary tract outside of the bladder that the urethral lumen traverses. That portion of the urethra lumen that is surrounded by the bladder vasculature is referred to as the vesicle neck.

Endopelvic fascia—The endopelvic fascias are those tissues outside of the muscularis of the pelvic organs that attach these organs to the pelvic sidewall. There is also some extension of loose areolar tissue over the surfaces of the organs. The surgical fascia used by gynecologists during pelvic reconstructive surgery, however, is primarily composed of the muscularis of the vaginal wall.

Pelvic spaces—The space between the bladder and the anterior portion of the pelvic walls is the perivesical space or space of Retzius. The space between the lower urinary tract and the genital tract is the vesicovaginal or vesicocervical space. This is bounded laterally by the “bladder pillars,” which is the region in which the tissues that go to the vagina separate from those that go to the bladder base. The recto-vaginal space lies between the posterior vaginal wall and the anterior surface of the rectum, and lies primarily above the top of the perineal body.

Pelvic diaphragm—The term pelvic diaphragm refers to the levator ani muscle and its covering fasciae, both the superior fascia and the inferior fascia. The term pelvic floor refers to all of the supportive structures that are involved with pelvic organ support. Sometimes the term pelvic floor and pelvic diaphragm can be used interchangeably, especially in the British literature.

VULVA AND ERECTILE STRUCTURES

The bony pelvic outlet is bordered by the ischiopubic rami anteriorly and the coccyx and sacrotuberous ligaments posteriorly. It can be divided into anterior and posterior triangles, which share a common base along a line between the ischial tuberosities. The tissues filling the anterior triangle have a layered structure similar to that of the abdominal wall (Table 7-1). There is a skin and adipose layer (vulva) overlying a fascial layer (perineal membrane) that lies superficial to a muscular layer (levator ani muscles).

Subcutaneous Tissues of the Vulva

The structures of the vulva lie on the pubic bones and extend caudally under its arch (Fig. 7.1). They consist of the mons, labia, clitoris, vestibule, and associated erectile structures and their muscles. The mons consists of hair-bearing skin over a cushion of adipose tissue that lies on the pubic bones. Extending posteriorly from the mons, the labia majora are composed of similar hair-bearing skin and adipose tissue, which contain the termination of the round ligaments of the uterus and the obliterated processus vaginalis (canal of Nuck). The round ligament can give rise to leiomomas in this region, and the obliterated processus vaginalis can be a diluted embryonic remnant in the adult.

The labia minora, vestibule, and glans clitoris can be seen between the two labia majora. The labia minora are hairless skin folds, each of which splits anteriorly to run over, and under, the glans of the clitoris. The more anterior folds unite to form the hood-shaped prepuce of the clitoris, whereas the posterior folds insert into the underside of the glans as the frenulum.

Unlike the skin of the labia majora, the cutaneous structures of the labia minora and vestibule do not lie on an adipose layer but on a connective-tissue stratum that is loosely organized and permits mobility of the skin during intercourse. This loose attachment of the skin to underlying tissues allows the skin to be easily dissected off the underlying fascia during skinning vulvectomy in the area of the labia minora and vestibule.

In the posterior lateral aspect of the vestibule, the duct of the major vestibular gland can be seen 3 to 4 mm outside the hymenal ring. The minor vestibular gland openings are found along a line extending anteriorly from this point, parallel to the hymenal ring and extending toward the urethral orifice. The urethra bulges slightly around the surrounding vestibular skin anterior to the vagina and posterior to the clitoris. Its orifice is flanked on either side by two small labia. Skene ducts open into the inner aspect of these labia and can be seen as small, punctate openings when the urethral labia are separated.

Within the skin of the vulva are specialized glands that can become enlarged and thereby require surgical removal. The holocrine sebaceous glands in the labia majora are associated with hair shafts, and in the labia minora they are freestanding. They lie close to the surface, which explains their easy recognition with minimal enlargement. In addition, lateral to the introitus and anus, there are numerous apocrine sweat glands, along with the normal eccrine sweat glands. The former structures undergo change with the menstrual cycle, having increased secretory activity in the premenstrual period. They can become chronically infected, as in hidradenitis suppurativa, or neoplastically enlarged, as in hidradenomas, both of which may require surgical therapy. The eccrine sweat glands present in the vulvar skin rarely present abnormalities, but on occasion they can form palpable masses as syringomas.

The subcutaneous tissue of the labia majora is similar in composition to that of the abdominal wall. It consists of lobules of fat interlaced with connective tissue septa. Although there are no well-defined layers in the subcutaneous tissue, regional variations in the relative quantity of fat and fibrous tissue exist. The superficial region of this tissue, where fat predominates, has been called Camper’s fascia, as it is on the abdomen. In this region, there is a continuation of fat from the anterior abdominal wall, called the digital process of fat.

In the deeper layers of the vulva, there is less fat, and the interlacing fibrous connective tissue septa are much more evident than those in Camper’s fascia. This more fibrous layer is called Colles fascia and is similar to Scarpa’s fascia on the abdomen. Its interlacing fibrous septa of the subcutaneous tissue attach laterally to the ischiopubic rami and fuse posteriorly with the posterior edge of the perineal membrane (i.e., urogenital diaphragm). Anteriorly, however, there is no connection to the pubic rami, and this permits communication between the area deep to this layer and the abdominal wall. These fibrous attachments to the ischiopubic rami and the posterior aspect of the perineal membrane limit the spread of hematomas or infection in this compartment posterolaterally but allow spread into the abdomen. This clinical observation has led to the consideration of Colles fascia as a separate entity from the superficial Camper fascia, which lacks these connections.

**Superficial Compartment**

The space between the subcutaneous tissues and perineal membrane, which contains the clitoris, crura, vestibular bulbs, and ischiocavernous and bulbocavernous muscles, is called the superficial compartment of the perineum (Fig. 7.2). The deep compartment is the region just above the perineal membrane; it is discussed later.

The erectile bodies and their associated muscles within the superficial compartment lie on the caudal surface of the perineal membrane. The clitoris is composed of a midline shaft (body) capped with the glans. This shaft lies on, and is suspended from, the pubic bones by a subcutaneous suspensory ligament. The paired crura of the clitoris bend downward from the shaft and are firmly attached to the pubic bones, continuing dorsally to lie on the inferior aspects of the pubic rami. The ischiocavernous muscles originate at the ischial tuberosities and the free surfaces of the crura to insert on the upper crura and body of the clitoris. A few muscle fibers, called the superficial transverse perineal muscles, originate in common with the ischiocavernous muscle from the ischial tuberosity and lie medial to the perineal body.

The paired vestibular bulbs lie immediately under the vestibular skin and are composed of erectile tissue. They are covered by the bulbocavernous muscles, which originate in the perineal body and lie over their lateral surfaces. These muscles, along with the ischiocavernous muscles, insert into the body of the clitoris and act to pull it downward.

The Bartholin greater vestibular gland is found at the tail end of the bulb of the vestibule and is connected to the vestibular mucosa by a duct lined with squamous epithelium. The gland lies on the perineal membrane and beneath the bulbocavernous muscle. The intimate relation between the enormously vascular erectile tissue of the vestibular bulb and the Bartholin gland is responsible for the hemorrhage associated with removal of this latter structure.

The perineal membrane and perineal body are important to the support of the pelvic organs. They are discussed in the section on the pelvic floor.

**Pudendal Nerve and Vessels**

The pudendal nerve is the sensory and motor nerve of the perineum. Its course and distribution in the perineum parallel the pudendal artery and veins that connect with the internal iliac vessels (Fig. 7.3). The course and division of the nerve are described with the understanding that the vascular channels parallel them.
84 Principles of Anatomy and Perioperative Considerations

**FIGURE 7.2.** Superficial compartment and perineal membrane.

**FIGURE 7.3.** Pudendal nerve and vessels, with the position of the ischiorectal fossa (asterisk) and the perineal body (cross) indicated. (From: Anson BJ. *An atlas of human anatomy.* Philadelphia: WB Saunders, 1950, with permission.)
The pudendal nerve arises from the sacral plexus (S2–S4), and the vessels originate from the anterior division of the internal iliac artery. They leave the pelvis through the greater sciatic foramen by hooking around the ischial spine and sacrospinous ligament to enter the pudendal (Alcock’s) canal through the lesser sciatic foramen.

The nerve and vessels have three branches: the clitoral, perineal, and inferior hemorrhoidal. The clitoral branch lies on the perineal membrane along its path to supply the clitoris. The perineal branch (the largest of the three branches) enters the subcutaneous tissues of the vulva behind the perineal membrane. Here it supplies the bulbocavernous, ischiocavernous, and transverse perineal muscles. It also supplies the skin of the inner portions of the labia majora, labia minora, and vestibule. The inferior hemorrhoidal branch goes to the external anal sphincter and perianal skin.

The inferior hemorrhoidal branch goes to the external anal sphincter and perianal skin. The large saphenous vein joins the femoral vein through the saphenous opening. Within 2 cm of the inguinal ligament, several superficial blood vessels branch from the saphenous vein and femoral artery. They include the superficial epigastric vessels that supply the subcutaneous tissues of the lower abdomen; the superficial circumflex iliac vessels that course laterally to the region of the iliac crest; and the superficial external pudendal vessels that supply the mons, labia majora, and clitoral hood.

Lymphatics from the superficial nodes enter the fossa ovalis and drain into one to three deep inguinal nodes, which lie in the femoral canal of the femoral triangle. They pass through the fossa ovalis (saphenous opening) in the fascia lata, which lies approximately 1 cm below the inguinal ligament, lateral to the pubic tubercle, along with the saphenous vein on its way to the femoral vein. The membranous layer of the subcutaneous tissues spans this opening as a trabeculae layer called a fascia cribrosa, pierced by lymphatics. The deep nodes are found under this fascia in the femoral triangle.

The femoral triangle is the subfascial space of the upper one third of the thigh. It is bounded by the inguinal ligament, sartorius muscle, and adductor longus muscle. Its floor is formed by the pectineal, adductor longus, and iliopectineus muscles. The femoral artery bisects it vertically between the anterosuperior iliac spine and pubic tubercle. The femoral vein lies medial to the artery; the femoral nerve is lateral to it.

As these vessels pass under the inguinal ligament, they carry with them an extension of the transversalis fascia, which is the extraperitoneal connective tissue deep to the rectus abdominis muscle called the femoral sheath. These sheaths extend about 2 to 3 cm below the inguinal ligament before fusing with the vascular adventitia. Besides the two parts of the femoral sheath that accompany these vessels, a third portion—the femoral canal—can be found in the space medial to the vein. The abdominal opening of this is the femoral ring. The femoral canal contains the deep inguinal lymph nodes. Lymph channels from these nodes pierce the membrane filling the femoral ring to 1 cm below the inguinal ligament, with the stem extending down along the saphenous vein. The nodes are often divided into four quadrants, with the center of the division at the saphenous opening. The vulvar drainage goes primarily to the medial nodes of the upper quadrant. These nodes lie deep in the adipose layer of the subcutaneous tissues, in the membranous layer, just superficial to the fascia lata.
Principles of Anatomy and Perioperative Considerations

communicate with the external iliac nodes. Also within this region, the femoral vessels give rise to the deep external pudendal vessels. The external pudendal vessels run deep to the femoral vein over the pectineal muscle to pierce the fascia lata. Here they become subcutaneous and form anastomoses with branches of the internal pudendal vessels as well as the deep femoral and lateral circumflex femoral arteries.

THE PELVIC FLOOR

When humans assumed the upright posture, the opening in the bony pelvis came to lie at the bottom of the abdominopelvic cavity. This required the evolution of a supportive system to prevent the pelvic organs from being pushed downward through this opening. In the woman, this system must withstand these downward forces but allow for the passage of the large and cranially dominant human fetus. The supportive system that has evolved to meet these needs consists of a fibromuscular floor that forms a shelf spanning the pelvic outlet and that contains a cleft for the birth canal and excretory drainage. A series of visceral ligaments and fasciae tethers the organs and maintains their position over the closed portions of the floor. The floor consists of the levator ani muscles and perineal membrane. The openings in these structures for parturition and elimination have required the development of ancillary fibrous elements that are concentrated over open areas in the muscular floor to support the viscera in these weak areas. This section discusses the structures of the pelvic floor; the fibrous supportive system is described in the section on the pelvic viscera and cleavage planes and fascia.

Perineal Membrane (Urogenital Diaphragm)

The perineal membrane forms the inferior portion of the anterior pelvic floor. It is a triangular sheet of dense, fibromuscular tissue that spans the anterior half of the pelvic outlet (Fig. 7.2). It was previously called the urogenital diaphragm, and this change in name reflects the appreciation that it is not a two-layered structure with muscle in between, as was previously thought. It lies just caudal to the skeletal muscle of the striated urogenital sphincter (formerly the deep transverse perineal muscle). Because of the presence of the vagina, the perineal membrane cannot form a continuous sheet to close off the anterior pelvis in the woman, as it does in the man. It does provide support for the posterior vaginal wall by attaching the perineal body and vagina to the ischiopubic rami, thereby limiting their downward descent. This layer of the floor arises from the inner aspect of the inferior ischiopubic rami above the ischiovaginal muscles and the crura of the clitoris. The medial attachments of the perineal membrane are to the urethra, walls of the vagina, and perineal body. Just cephalad to the perineal membrane lie two arch-shaped muscles that begin posteriorly to arch over the urethra (Fig. 7.5). These are the compressor urethral and the urethrovaginal sphincter. They are a part of the striated urogenital sphincter muscle in the woman and are continuous with the sphincter urethrae muscle. They act to compress the distal urethra. Posteriorly, intermingled within the membrane are skeletal muscle fibers of the transverse vaginal muscle and some smooth muscle fibers. The dorsal and deep nerve and vessels of the clitoris are also found within this membrane and are described later.

The primary function of the perineal membrane is related to its attachment to the vagina and perineal body. By attaching these structures to the bony pelvic outlet, the perineal membrane supports the pelvic floor against the effects of increases in intraabdominal pressure and against the effects of gravity. The amount of downward descent that is permitted by this mechanism can be assessed by placing a finger in the rectum, hooking it forward, and pulling the perineal body downward. If the perineal membrane has been torn during parturition, then an abnormal amount of descent is detectable, and the pelvic floor sags and the introitus gapes.

Perineal Body

Within the area bounded by the lower vagina, perineal skin, and anus is a mass of connective tissue called the perineal body (Fig. 7.3). The term central tendon of the perineum has also

---

**FIGURE 7.5.** Structures visible after removal of the perineal membrane and superficial perineal muscles. (From: DeLancey, copyright 1995, with permission.)
been applied to this structure and is descriptive, suggesting its role as a central point into which many muscles insert.

The perineal body is attached to the inferior pubic rami and ischial tuberosities through the perineal membrane and superficial transverse perineal muscles. Anterolaterally, it receives the insertion of the bulbocavernous muscles. On its lateral margins, the upper portions of the perineal body are connected with some fibers of the pelvic diaphragm. Posteriorly, the perineal body is indirectly attached to the coccyx by the external anal sphincter that is embedded in the perineal body, and it is attached at its other end to the coccyx. These connections anchor the perineal body and its surrounding structures to the bony pelvis and help to keep it in place.

Posterior Triangle: Ischiorectal Fossa

In the posterior triangle of the pelvis, the ischiorectal fossa lies between the pelvic walls and the levator ani muscles (Fig. 7.5). It has an anterior recess that lies above the perineal membrane. It is bounded medially by the levator ani muscles and anterolaterally by the obturator internus muscle. The main portion of the fossa is lateral to the levator ani and external anal sphincter, and it has a posterior portion that extends above the gluteus maximus. Traversing this region is the pudendal neurovascular trunk.

Anal Sphincters

The external sphincter lies in the posterior triangle of the perineum (Fig. 7.6). It is a single mass of muscle, which has traditionally been divided into superficial and deep portions. The subcutaneous portion lies attached to the perianal skin and forms an encircling ring around the anal canal. It is responsible for the characteristic radially oriented folds in the perianal skin. The superficial part attaches to the coccyx posteriorly and sends a few fibers into the perineal body anteriorly and forms the bulk of the anal sphincter seen separated in third-degree midline obstetric tears. The fibers of the deep part generally encircle the rectum and blend indistinguishably with the puborectalis, which forms a loop under the dorsal surface of the anorectum and which is attached anteriorly to the pubic bone (Fig. 7.6).

The internal anal sphincter is a thickening in the circular smooth muscle of the anal wall. It lies just inside the external anal sphincter and is separated from it by a visible intersphincteric groove. It extends downward inside the external anal sphincter to within a few millimeters of the external sphincter’s caudal extent. The internal sphincter can be identified just beneath the anal submucosa in repair of a chronic fourth-degree laceration of the perineum as a rubbery white layer that is often erroneously been referred to as fascia during obstetrical repair of 4th degree laceration. The longitudinal smooth muscle layer of the bowel, along with some fibers of the levator ani, separates the external and internal sphincters as they descend in the intersphincteric groove.

Levator Ani and Pelvic Wall

Unfortunately, the extreme abdominal pressures generated during embalming greatly distort the levator ani muscles by forcing them downward. Most anatomy atlases therefore fail to give a true picture of the horizontal nature of this strong supportive shelf of muscle. Examination of the normal standing patient is the best way to appreciate the nature of this closure mechanism, because the lithotomy position causes some relaxation of the musculature. During routine pelvic examination of the nullipara, the effectiveness of this closure can be appreciated, because it is often difficult to insert a speculum if the muscles are contracted and not relaxed.

The opening between the bones and muscles of the pelvic wall is spanned by the muscles of the pelvic diaphragm: the pubococcygeal, iliococcygeal, puborectal, and coccygeal muscles (Fig. 7.7). The most medial of these muscles is the puborectal–pubococcygeal complex. The pubococcygeal portion of these muscles has an insertion into the anococcygeal raphe and the superior surface of the coccyx, whereas the puborectal portion represents those inferior fibers that pass behind and insert...
into the rectum. Both portions arise from the inner surface of
the pubic bones and pass the urethra without attaching to it.
Some fibers attach to the lateral vaginal wall and external anal
sphincter and form a sling around the rectum before return-
ing to a similar course on the other side. The pubococcygeal
portion passes posteriorly from its origin ventral to the ilio-
coccygeal muscle, where its fibers insert between the internal
and external anal sphincter muscles in the intersphincteric
groove, and form a sling behind the rectum. A few fibers also run on the
cephalic surface of the iliococcygeal muscle to reach the inner
surface of the sacrum and the coccyx.

The iliococcygeal muscle arises from a fibrous band overly-
ing the obturator internus called the arcus tendineus levatoris
ani. From these broad origins, the fibers of the iliococcygeal
muscle pass behind the rectum and insert into the midline
anococcygeal raphe and the coccyx. The coccygeal muscle
arises from the ischial spine and sacrospinous ligament to in-
sert into the borders of the coccyx and the lowest segment of
the sacrum.

These muscles are covered on their superior and inferior
surfaces by superior and inferior fasciae. When the levator
ansi muscles and their fasciae are considered together, they are
called the pelvic diaphragm, not to be confused with the uro-
genital diaphragm (perineal membrane).

The muscle fibers of the pelvic diaphragm form a broad
U-shaped layer of muscle with the open end of the U directed
anteriorly. The open area within the U through which the ure-
trah, vagina, and rectum pass is called the urogenital hiatus.

The normal tone of the muscles of the pelvic diaphragm keep
the base of the U pressed against the backs of the pubic bones,
keeping the vagina and rectum closed. The region of the levator
ani between the anus and coccyx formed by the anococcygeal
raphé (see previous discussion) is clinically called the levator
plate. It forms a supportive shelf on which the rectum, upper
vagina, and uterus can rest. The relatively horizontal position
of this shelf is determined by the anterior traction on the fibrous
levator plate by the pubococcygeal and pubococcygeal muscles
and is important to vaginal and uterine support.

The iliococcygeal and coccygeal muscles receive their innerv-
ation from an anterior branch of the ventral ramus of the third
and fourth sacral nerves, whereas the medial portions of the pu-
borot and pubococcygeal muscles are probably supplied by the
pudendal nerve.

THE PELVIC VISCERA

This section on the pelvic viscera discusses the structure of
the individual pelvic organs and considers specific aspects of
their interrelations (Fig. 7.8). Those aspects of blood supply,
nervation, and lymphatic drainage that are idiosyncratic to
the specific pelvic viscera are covered here. However, the section
on the retroperitoneum, where the overall description of these
systems is given, provides the general consideration of these
latter three topics.

Genital Structures

Vagina

The vagina is a pliable hollow viscus with a shape that is deter-
mined by the structures surrounding it and by its attachments
to the pelvic wall. These attachments are to the lateral margins
of the vagina, so that its lumen is a transverse slit, with the
anterior and posterior walls in contact with one another. The lower portion of the vagina is constructed as it passes through the urogenital hiatus in the levator ani. The upper part is much more capacious. The vagina is bent at an angle of 120 degrees by the anterior traction of the levator ani muscles at the junction of the lower one third and upper two thirds of the vagina (Fig. 7.9). The cervix typically lies within the anterior vaginal wall, making it shorter than the posterior wall by about 3 cm. The former is about 7 to 9 cm in length, although there is great variability in this dimension.

When the lumen of the vagina is inspected through the introitus, many landmarks can be seen. The anterior and posterior walls have a midline ridge, called the anterior and posterior columns, respectively. These are caused by the impression of the urethra and bladder and the rectum on the vaginal lumen. The caudal portion of the anterior column is distinct and is called the urethral carina. The recesses in front of and behind the cervix are commonly called the anterior and posterior fornices of the vagina, and the creases along the side of the vagina, where the anterior and posterior walls meet, are called the lateral vaginal sulci.

The vagina’s relations to other parts of the body can be understood by dividing it into thirds. In the lower third, the vagina is fused anteriorly with the urethra, posteriorly with the perineal body, and laterally to each levator ani by the “fibers of Luschka.” In the middle third are the vesical neck and trigone anteriorly, the rectum posteriorly, and the levators laterally. In the upper third, the anterior vagina is adjacent to the bladder and ureters (which allow these latter structures to be palpated on pelvic examination), posterior to the cul-de-sac, and lateral to the cardinal ligaments of the vagina.

The vaginal wall contains the same layers as all hollow visera (i.e., mucosa, submucosa, muscularis, and adventitia). Except for the area covered by the cul-de-sac, it has no serosal covering. The mucosa is of the nonkeratinized stratified squamous type and lies on a dense, dermislk submucosa. The similarity...
of these layers to dermis and epidermis has resulted in their being called the “vaginal skin.”

The vaginal muscularis is fused with the submucosa, and the pattern of the muscularis is a helical arrangement. Outside the muscularis there is an adventitia that has varying degrees of development in different areas of the vagina. This layer is a portion of the connective tissue in the pelvis called the endopelvic fascia and has been given a separate name because of its unusual development. When it is dissected in the operating room, the muscularis is usually adherent to it, and this combination of specialized adventitia and muscularis is the surgeon’s “fascia,” which might better be called the fibromuscular layer of the vagina, as Nichols and Randall suggested in Vaginal Surgery.

Uterus

The uterus is a fibromuscular organ with shape, weight, and dimensions that vary considerably, depending on both estrogenic stimulation and previous parturition. It has two portions: an upper muscular corpus and a lower fibrous cervix. In a woman of reproductive age, the corpus is considerably larger than the cervix, but before menarche, and after the menopause, their sizes are similar. Within the corpus, there is a triangular-shaped endometrial cavity surrounded by a thick muscular wall. That portion of the corpus that extends above the top of the endometrial cavity (i.e., above the insertions of the fallopian tubes) is called the fundus.

The muscle fibers that make up most of the uterine corpus are not arranged in a simple layered manner, as is true in the gastrointestinal tract, but are arranged in a more complex pattern. This pattern reflects the origin of the uterus from paired paramesonephric primordia, with the fibers from each half crisscrossing diagonally with those of the opposite side. The uterus is lined by a unique mucosa, the endometrium. It has both a columnar epithelium that forms glands and a specialized stroma. The superficial portion of this layer undergoes cyclic change with the menstrual cycle. Spongy or hormonally sensitive spiral arterioles that lie within the endometrium cause shedding of this layer after each cycle, but a deeper basal layer of the endometrium remains to regenerate a new lining. Separate arteries supply the basal endometrium, explaining its preservation at the time of menses.

The cervix is divided into two portions: the portio vaginalis, which is that part protruding into the vagina; and the portio supravaginalis, which lies above the vagina and below the corpus.

The substance of the cervical wall is made up of dense fibrous connective tissue with only a small (about 10%) amount of smooth muscle. What smooth muscle there is lies on the periphery of the cervix, connecting the myometrium with the muscle of the vaginal wall. This smooth muscle and accompanying fibrous tissue are easily dissected off the fibrous cervix and form the layer reflected during infastructural hysterectomy. It is circularly arranged around the fibrous cervix and is the tissue into which the cardinal and uterosacral ligaments and subcervical fascia insert.

The portio vaginalis is covered by nonkeratinizing squamous epithelium. Its canal is lined by a columnar mucous-secreting epithelium that is thrown into a series of V-shaped folds that appear like the leaves of a palm and are therefore called plicae palmatae. These form compound clefts in the endocervical canal, not tubular racemose glands, as formerly thought.

There is little adventitia in the uterus, with the peritoneal serosa being directly attached to most of the corpus. The anterior portion of the uterine cervix is covered by the bladder; therefore, it has no serosa. Similarly, as discussed in the following, the broad ligament envelops the lateral aspects of the cervix and corpus; therefore, it has no serosal covering there. The posterior cervix does have a serosal covering.

Adnexal Structures and Broad Ligament

The fallopian tubes are paired tubular structures 7 to 12 cm in length (Fig. 7.10). Each has four recognizable portions. At the uterus, the tube passes through the cornu as an interstitial portion. On emerging from the corpus, a narrow isthmic portion begins with a narrow lumen and thick muscular wall. Proceeding toward the abdominal end, next is the ampulla, which has an expanding lumen and more convoluted mucosa. The infundibulated end of the tube has many frondlike projections to provide a wide surface for ovum pickup. The distal end of the fallopian tube is attached to the ovary by the fimbria ovarica, which is a smooth muscle band responsible for bringing the fimbria and ovary close to one another at the time of ovulation. The outer layer of the tube's muscularis is composed of longitudinal fibers; the inner layer has a circular orientation.

The lateral pole of the ovary is attached to the pelvic wall by the infundibulopelvic ligament and the ovarian artery and vein contained therein. Medially, it is connected to the uterus through the uteroovarian ligament. During reproductive life, it measures about 2.3 to 3 cm long, 1.5 to 3 cm thick, and 0.7 to 1.5 cm wide, varying with its state of activity or suppression, as with oral contraceptive medications. Its surface is mostly

FIGURE 7.9. Bead chain cystourethrogram with barium in the vagina showing normal vaginal axis in a patient in the standing position.
FIGURE 7.10. Uterine adnexa and collateral circulation of uterine and ovarian arteries. The uterine artery crosses over the ureter in the cardinal ligament and gives off cervical and vaginal branches before ascending adjacent to the wall of the uterus and anastomosing with the medial end of the ovarian artery. Note the small branch of the uterine or ovarian artery that nourishes the round ligament (Sampson artery).

The ovary has a cuboidal to columnar covering and consists of a cortex and medulla. The medullary portion is primarily fibromuscular, with many blood vessels and much connective tissue. The cortex is composed of a more specialized stroma, punctuated with follicles, corpora lutea, and corpora albicantia.

The round ligaments are extensions of the uterine musculature and represent the homolog of the gubernaculum testis. They begin as broad bands that arise on each lateral aspect of the anterior corpus. They assume a more rounded shape before they enter the retroperitoneal tissue, where they pass lateral to the deep inferior epigastric vessels and enter each internal inguinal ring. After traversing the inguinal canal, they exit the external ring and enter the subcutaneous tissue of the labia majora. They have little to do with uterine support.

The ovaries and tubes constitute the uterine adnexa. They are covered by a specialized series of peritoneal folds called the broad ligament. During embryonic development, the paired mullerian ducts and ovaries arise from the lateral abdominopelvic walls. As they migrate toward the midline, a mesentery of peritoneum is pulled out from the pelvic wall from the cervix on up. This leaves the midline uterus connected on either side to the pelvic wall by a double layer of peritoneum. Within the upper layers of these two folds, called the broad ligaments, lie the fallopian tubes, round ligaments, and ovaries (Fig. 7.11). The cardinal and uterosacral ligaments are at the lower margin of the broad ligament. These structures are visceral ligaments; therefore, they are composed of varying amounts of smooth muscle, vessels, connective tissue, and other structures. They are not the pure ligaments associated with joints in the skeleton.

The ovary, tube, and round ligament each have their own separate mesentery, called the mesovarium, mesosalpinx, and mesorectum, respectively. These are arranged in a constant pattern, with the round ligament placed ventrally, where it exits the pelvis through the inguinal ligament, and the ovary placed dorsally. The tube is in the middle and is the most cephalic of the three structures. At the lateral end of the fallopian tube and ovary, the broad ligament ends where the infundibulopelvic ligament blends with the pelvic wall. The cardinal ligaments lie at the base of the broad ligament and are described under the section on supportive tissues and cleavage planes.

**Surgical Anatomy of the Female Pelvis**

**Blood Supply and Lymphatics of the Genital Tract**

The blood supply to the genital organs comes from the ovarian arteries and uterine and vaginal branches of the internal iliac arteries. A continuous arterial arcade connects these vessels on the lateral border of the adnexa, uterus, and vagina (Fig. 7.10).

The blood supply of the upper adnexal structures comes from the ovarian arteries that arise from the anterior surface of the aorta just below the level of the renal arteries. The accompanying plexus of veins drains into the vena cava on the right and the renal vein on the left. The arteries and veins follow a long, retroperitoneal course before reaching the cephalic end of the ovary. They pass along the mesenteric surface of the ovary to connect with the upper end of the marginal artery of the uterus. Because the ovarian artery runs along the hilum of the ovary, it not only supplies the gonad but also sends many small vessels through the mesosalpinx to supply the fallopian tube, including a prominent fimbrial branch at the lateral end of the tube.

The uterine artery originates from the internal iliac artery. It usually arises independently from this source but can have a common origin with either the internal pudendal or vaginal artery. It joins the uterus near the junction of the corpus and cervix, but this position varies considerably, both with the individual and the amount of upward or downward traction placed on the uterus. Accompanying each uterine artery are several large uterine veins that drain the corpus and cervix.

On arriving at the lateral border of the uterus (after passing over the ureter and giving off a small branch to this structure), the uterine artery flows into the side of the marginal artery that...
Composition of the broad ligament.

The uterus receives its nerve supply from the uterovaginal plexus (Frankenhäuser ganglion) that lies in the connective tissue of the cardinal ligament. Details of the organization of the pelvic innervation are contained in the section on retroperitoneal structures.

**Lower Urinary Tract**

**Ureter**

The ureter is a tubular viscus about 25 cm long, divided into abdominal and pelvic portions of equal length. Its small lumen is surrounded by an inner longitudinal and outer circular muscle layer. In the abdomen, it lies in the extraperitoneal connective tissue on the posterior abdominal wall, crossed anteriorly by the left and right colic vessels. Its course and blood supply are described in the section on the retroperitoneum.

**Bladder**

The bladder can be divided into two portions: the dome and base (Fig. 7.12). The musculature of the spherical bladder does not lie in simple layers, as do the muscular walls of tubular viscera, such as the gut and ureter. It is best described as a meshwork of intertwining muscle bundles. The musculature of the...
dome is relatively thin when the bladder is distended. The base of the bladder, which is thicker and varies less with distention of the dome, consists of the urinary trigone and a thickening of the detrusor, called the detrusor loop. This is a U-shaped band of musculature, open posteriorly, that forms the bladder base anterior to the intramural portion of the ureter. The trigone is made of smooth muscle that arises from the ureters that occupy two of its three corners. It continues as the muscle of the vesical neck and urethra. There it rests on the upper vagina. The shape of the bladder depends on its state of filling. When empty, it is a somewhat flattened disk, slightly concave upward. As it fills, the dome rises off the base, eventually assuming a more spherical shape.

The distinction between the base and dome has functional importance, because they have differing innervations. The bladder base has α-adrenergic receptors that contract when stimulated and thereby favor continence. The dome is responsive to β or cholinergic stimulation, with contraction that causes bladder emptying.

Anteriorly, the bladder lies against the lower abdominal wall. It lies against the pubic bones laterally and inferiorly and abuts the obturator internus and levator ani. Posteriorly, it rests against the vagina and cervix. These relations are discussed further in consideration of the pelvic planes and spaces.

The blood supply of the bladder comes from the superior vesical artery, which comes off the obliterated umbilical artery and inferior vesical artery, which is either an independent branch of the internal pudendal artery or arises from the vaginal artery.

The urethral lumen begins at the internal urinary meatus and has a series of regional differences in its structure. It passes through the bladder base in an intramural portion for a little less than a centimeter. This region of the bladder, where the urethral lumen traverses the bladder base, is called the vesical neck.

The urethra itself begins outside the bladder wall. In its distal two thirds it is fused with the vagina (Fig. 7.12), with which it shares a common embryologic derivation. From the vesical neck to the perineal membrane, which starts at the junction of

FIGURE 7.12. Lateral view of the pelvic organs showing the urethra and bladder. Inset B: Two portions of the striated urogenital sphincter muscle, namely, the urethrovaginal sphincter and the urethral sphincter. The compressor urethra is not seen. (From: The Brédel Collection, Department of Art as Applied to Medicine, Johns Hopkins Medical Institution, Baltimore, MD, with permission.)
the middle and distal thirds of the bladder, the urethra has sev-
eral layers. An outer, circularly oriented skeletal muscle layer (urogenital sphincter) mingles with some circularly oriented
smooth muscle fibers. Inside this layer is a longitudinal layer of
smooth muscle that surrounds a remarkably vascular submu-
cosa and nonkeratinized squamous epithelium that responds
to estrogenic stimulation.

Within the submucosa is a group of tubular glands that lie
on the vaginal surface of the urethra. These paraurethral (or
Skene’s) glands empty into the lumen at several points on the
dorsal surface of the urethra, but two prominent openings on the
inner aspects of the external urethral orifice can be seen
when the orifice is opened. Chronic infection of these glands
can lead to urethral diverticula, and obstruction of their ter-
mental duct can result in cyst formation. Their location on the
dorsal surface of the urethra reflects the distribution of the
structures from which they arise.

At the level of the perineal membrane, the distal portion
of the urogenital sphincter begins. Here the skeletal muscle of
the urethra leaves the urethral wall to form the urethrovaginal
sphincter (Fig. 7.13) and compressor urethrae (formerly called
the deep transverse perineal muscle). Distal to this portion, the
urethral wall is fibrous and forms a muscle for aiming the uri-
nary stream. The mechanical support of the vesical neck and
urethra, which are so important to urinary continence, is dis-
cussed in the section of this chapter devoted to the supportive
tissues of the urogenital system.

The urethra receives its blood supply both from an inferior
extension of the vesical vessels and from the pudendal vessels.

### Sigmoid Colon and Rectum

The sigmoid colon begins its S-shaped curve at the pelvic brim.
It has the characteristic structure of the colon, with three tenia
colii lying over a circular smooth muscle layer. Unlike much
of the colon, which is retroperitoneal, the sigmoid has a def-
inite mesentery in its midportion. The length of the mesen-
tery and the pattern of the sigmoid’s curvature vary consider-
ably. It receives its blood supply from the lowestmost portion of
the inferior mesenteric artery: the branches called the sigmoid
arteries.

As it enters the pelvis, the colon straightens its course and
becomes the rectum. This portion extends from the pelvic brim
until it loses its final anterior peritoneal investment below the
col-de-sac. It has two bands of smooth muscle (anterior and
posterior). Its lumen has three transverse rectal folds that con-
tain the mucosa, submucosa, and circular layers of the bowel
wall. The most prominent fold, the middle one, lies anteriorly
on the right about 8 cm above the anus, and it must be nego-
tiated during high rectal examination or sigmoidoscopy.

As the rectum passes posterior to the vagina, it expands into
the rectal ampulla. This portion of the bowel begins under the
col-de-sac peritoneum and fills the posterior pelvis from the
side. At the distal end of the rectum, the anorectal junction is
bent at an angle of 90 degrees where it is pulled ventrally by the
puborectalis fibers’ attachment to the pubes and posteriorly by
the external anal sphincter’s dorsal attachment to the coccyx.

Below this level, the gut is called the anus. It has many
distinguishing features. There is a thickening of the circular
involuntary muscle called the internal sphincter. The canal has
a series of ridges on its inner aspect. At the lower border the mu-
cosa of the colon gives way to a transitional layer of
non-hair-bearing squamous epithelium before becoming the
hair-bearing perineal skin.

The relations of the rectum and anus can be inferred from
their course. They lie against the sacrum and levator plate pos-
teriorly and against the vagina anteriorly. Inferiorly, each half of
the levator ani abuts its lateral wall and sends fibers to mingle
with the longitudinal involuntary fibers between the internal
and external sphincters. Its distal terminus is surrounded by
the external anal sphincter.

The anorectum receives its blood supply from a number of
sources (Fig. 7.13). From above, the superior rectal (hemor-
rhoidal) branch of the inferior mesenteric artery lies within the
layers of the sigmoid mesocolon. As it reaches the beginning
of the rectum, it divides into two branches and ends in the
wall of the gut. A direct branch from the internal iliac artery
arises from the pelvic wall on either side and supplies the rec-
tum and ampulla above the pelvic floor. The anus and external
sphincter receive their blood supply from the inferior rectal
(hemorrhoidal) branch of the internal pudendal artery, which
reaches the terminus of the gastrointestinal tract through the
ischiorectal fossa.

### PELVIC CONNECTIVE TISSUE AND
CLEAVAGE PLANES

The pelvic viscera are connected to the lateral pelvic wall
by their adventitial layers and thickenings of the connective tissue
that lie over the pelvic wall muscles (Fig. 7.14). These
attachments, as well as the attachments of one organ to an-
other, separate the different surgical cleavage planes from one
another. These condensations of the adventitial layers of the
pelvic organs have assumed supportive roles, connecting the
viscera to the pelvic walls, in addition to their role in trans-
mittting the organs’ neurovascular supply from the pelvic wall.
They are somewhat like a mesentery that connects the bowel,
for example, to the body wall. It has a supportive function as
well as a role in carrying vessels and nerves to the organ. An
understanding of their disposition is important to both vaginal
and abdominal surgery.

The tissue that connects the organs to the pelvic wall has
been given the special designation of endopelvic fascia. It is
not a layer similar to the layer encountered during abdominal
incisions (rectus abdominis “fascia”). It is composed of blood
vessels and nerves, interposed with a supportive meshwork of
irregular connective tissue containing collagen and elastin.
These structures connect the muscularis of the visceral organs
to pelvic wall muscles. In some areas, there is considerable
smooth muscle within this tissue, as is true in the area of the
uterosacral ligaments. Although surgical texts often speak of
this fascia as a specific structure separate from the fascia, this
is not strictly true. These layers can be separated from the vis-
cera, just as the superficial layers of the bowel wall can be ar-
tificially separated from the deeper layers, but they are not
distinctive separate structures.

### Pelvic Connective Tissue

The term ligament is most familiar when it describes a
dense connective tissue band that links two bones, but it
also describes ridges in the peritoneum or thickenings of
the endopelvic fascia. The ligaments are somewhat like
mesenteries, extending from the gut wall to the PE-
LVIC CONNECTIVE TISSUE AND
CLEAVAGE PLANES
FIGURE 7.13. Rectosigmoid colon and anal canal, showing collateral arterial circulation from superior hemorrhoidal (inferior mesenteric), middle hemorrhoidal (hypogastric or internal iliac), and inferior hemorrhoidal (internal pudendal) arteries.

Uterine Ligaments

The broad ligaments are peritoneal folds that extend laterally from the uterus and cover the adnexal structures. They have no supportive function and were discussed in the section on the pelvic viscera.

Within the broad ligament, beginning just caudal to the uterine arteries, there is a thickening in the endopelvic fascia that attaches the cervix and upper vagina to the pelvic side walls (Fig. 7.15), consisting of the cardinal and uterosacral ligaments (parametrium). The term uterosacral ligaments refers to that portion of this tissue that forms the medial margin of the parametrium and that borders the cul-de-sac of Douglas. The term cardinal ligament is used to refer to that portion that attaches the lateral margins of the cervix and vagina to the pelvic walls. The cardinal and uterosacral ligaments, therefore, are simply two parts of a single body of suspensory tissue. The term parametrium refers to all of the tissue that attaches to the uterus (both cardinal and uterosacral ligaments), and the term paracolpium refers to the portion that attaches to the vagina (cardinal ligament of the vagina). The uterosacral ligament portion of the parametrium is composed predominantly of smooth muscle, the autonomic nerves of the pelvic organs, and some...
FIGURE 7.15. A: Suspensory ligaments of the female genital tract seen with the bladder removed. B: Close-up of the lower portion of the middle vagina (level II) shows how the lateral attachments of the vagina result in an anterior layer under the bladder (pubocervical fascia) and a posterior layer in front of the rectum (rectovaginal fascia). The cephalic surfaces of the transected distal urethra and vagina (level III) are shown. (From: DeLancey JO. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission.)

intermixed connective tissue and blood vessels, whereas the cardinal ligament portion consists primarily of perivascular connective tissue and the pelvic vessels. Although they are often described as extending laterally from the cervix to the pelvic wall, in the standing position they are almost vertical as one would expect for a suspensory tissue. Near the cervix, they are discrete, but they fan out in the retroperitoneal layer to have a broad, if somewhat ill-defined, area of attachment over the second, third, and fourth segments of the sacrum. These ligaments hold the cervix posteriorly in the pelvis over the levator plate of the pelvic diaphragm.

The cardinal ligaments lie at the lower edge of the broad ligaments, between their peritoneal leaves, beginning just caudal to the uterine arteries. They attach to the cervix below the isthmus and fan out to attach to the pelvic walls over the periformis muscle in the area of the greater sciatic foramen. Although when placed under tension they feel like ligamentous bands, they are composed simply of perivascular connective tissue and nerves that surround the uterine artery and veins. Nevertheless, these structures have considerable strength, and the lack of a separate “ligamentous band” in this area does not detract from their supportive role. They provide support not only to the cervix and uterus but also to the upper portion of the vagina (paracolpium) to keep these structures positioned posteriorly over the levator plate of the pelvic diaphragm and away from the urogenital hiatus.

**Vaginal Fasciae and Attachments**

The attachments of the vagina to the pelvic walls are important in maintaining the pelvic organs in their normal positions. Failure of these attachments, along with damage to the levator ani muscles, result in the clinical conditions of uterine prolapse, cystocele, rectocele, and enterocele.

The cervix and upper one third of the vagina are suspended within the pelvis by the downward extension of the cardinal ligaments (Fig. 7.15). Anterior to the vagina in this area is the vesicovaginal space; posterior to it is the cul-de-sac and rectovaginal space. In its middle third, the vagina is attached laterally to the arcus tendineus fasciae pelvis. The arcus tendineus fasciae pelvis is a fibrous band that extends from its ventral attachment at the pubic bone to its dorsal attachment to the ischial spine. These lateral attachments suspend the anterior vaginal wall across the pelvis and prevent its downward descent with increases in abdominal pressure. The structural layer formed by the vaginal wall and its lateral attachments to the arcus tendineus is clinically referred to as the pubocervical fascia.
Support of the posterior vaginal wall prevents the rectum from bulging forward in the clinical condition known as rectocele. This support varies in different levels of the vagina. In the distal 2 or 3 cm of the posterior vaginal wall, attachments of the perineal body to the ischiopubic rami hold the perineal body in place and prevent protrusion of the distal rectum (Fig. 7.16). In the midvagina above this, the vagina is attached laterally to the fascia covering the inside of the levator ani muscles (Fig. 7.17). This connection prevents the middle of the posterior vaginal wall from moving forward and downward during increases in abdominal pressure. The combination of these attachments results in a structural layer that has been referred to by the term *fascia of Denonvilliers*. Detailed histologic studies of this area, however, have failed to reveal a separate layer in the midline between the muscularis of the vagina and the rectovaginal space except in the distal vagina, where the dense connective tissue of the perineal body separates these structures.

Urethral Supports

The support of the proximal urethra is important in the maintenance of urinary continence during times of increased abdominal pressure. The distal portion of the urethra is inseparable from the vagina because of their common embryologic derivation. These tissues are fixed firmly in position by connections of the periurethral tissues and vagina to the pubic bones through the perineal membrane (Fig. 7.18). A hammock-like layer composed of the endopelvic fascia and anterior vaginal wall provides the support of the proximal urethra. This layer is stabilized by its lateral attachments both to the arcus tendineus fasciae pelvis and the medial margin of the levator ani muscles. The arcus tendineus fasciae pelvis is a fibrous band stretched from a ventral attachment at the lower portion of the pubic bones about 1 cm above the lower margin of the pubic bones and 1 cm from the midline to the ischial spine. The muscular attachment of the endopelvic fascia allows contraction and
relaxation of the levator ani muscles to elevate the urethra and to let it descend. During increases in abdominal pressure, the downward force caused by increased abdominal pressure on the ventral surface of the urethra compresses the urethra closed against the hammock-like supportive layer, thereby closing the urethral lumen against the increases in intravesical pressure. The stability of the fascial layer determines the effectiveness of this closure mechanism. If the layer is unyielding, it forms a firm backstop against which the urethra can be compressed closed; however, if it is unstable, the effectiveness of this closure is compromised. Therefore, the integrity of the attachment to the arcus tendineus and the levator ani is critical to the stress continence mechanism.

The muscular attachment is responsible for the voluntary control of vesical neck position visible during vaginal examination or fluoroscopy when the pelvic muscles are contracted and relaxed. Relaxation of these muscles with descent of the vesical neck is associated with the initiation of urination and contraction with arrest of the urinary stream. The limit of downward vesical neck motion is determined by the connective tissue elasticity in the attachments to the arcus tendineus fasciae pelvis.

**Cul-de-sacs, Cleavage Planes, and Spaces**

Each of the pelvic viscera can expand somewhat independently of its neighboring organs. The ability to do this comes from their relatively loose attachment to one another, which permits the bladder, for example, to expand without equally elongating the adjacent cervix. This allows the vesica to be easily separated from one another along these lines of cleavage. These surgical cleavage planes are called spaces, although they are not empty but rather are filled with fatty or areolar connective tissue. The pelvic spaces are separated from one another by the connections of the viscera to one another and to the pelvic walls.

**Anterior and Posterior Cul-de-sacs**

Properly termed the vesicouterine and rectouterine pouches, the anterior and posterior cul-de-sac separate the uterus from the bladder and rectum. The anterior cul-de-sac is a recess between the dome of the bladder and the anterior surface of the uterus (Fig. 7.19). The peritoneum is loosely applied in the region of the anterior cul-de-sac, unlike its dense attachment to the upper portions of the uterine corpus. This allows the bladder to expand without stretching its overlying peritoneum. This loose peritoneum forms the vesicouterine fold, which can easily be lifted and incised to create a bladder flap during abdominal hysterectomy or cesarean section. It is the point at which the vesicocervical space is normally accessed during abdominal surgery.

The posterior cul-de-sac is bordered ventrally by the vagina anteriorly, the rectosigmoid posteriorly, and the uterosacral ligaments laterally. Its peritoneum extends for approximately 4 cm along the posterior vaginal wall below the posterior vaginal fornix where the vaginal wall attaches to the cervix. This allows direct entry into the peritoneum from the vagina when performing a vaginal hysterectomy, culdoscopy, or colpotomy. The anatomy here contrasts with the anterior cul-de-sac. Anteriorly, the peritoneum lies several centimeters above the vagina whereas posteriorly, the peritoneum covers the vagina. Keeping this anatomic difference in mind facilitates entering both the anterior and the posterior cul-de-sac during vaginal hysterectomy.

**Prescervical Space**

The prescervical space of Retzius (Fig. 7.14) is separated from the undersurface of the rectus abdominus muscles by the transversalis fascia and can be entered by perforating this layer. Ventrolaterally, it is bounded by the bony pelvis and the muscles of the pelvic wall; cranially, it is bounded by the abdominal wall. The proximal urethra and bladder lie in a dorsal position. The dorsolateral limit to this space is the attachment of the bladder to the cardinal ligament and the attachment of the pubocervical fascia to the arcus tendineus fasciae pelvis. These separate
FIGURE 7.19. Sagittal section from a 28-year-old cadaver showing the anterior cul-de-sac (aCDS) and the posterior cul-de-sac (pCDS). Note how the posterior cul-de-sac peritoneum lies on the vaginal wall, whereas the anterior cul-de-sac lies several centimeters from the depth of the peritoneum in this area. (Peritoneum digitally enhanced in photograph to aid visibility.) (From: DeLancey, copyright 2001, with permission.)

Surgical Anatomy of the Female Pelvis

this space from the vesicovaginocervical space. This lateral attachment is to the arcus tendineus fasciae pelvis, which lies on the inner surface of the obturator internus and pubococcygeal and puborectal muscles.

Important structures lying within this space include the dorsal clitoral vessels under the symphysis at its lower border and the obturator nerve and vessels as they enter the obturator canal. A branch to the obturator canal often comes off the external iliac artery and lies on the pubic bone; therefore, dissection in this area should be performed with care (Fig. 7.20). Lateral to the bladder and vesical neck is a dense plexus of vessels that lie at the border of the lower urinary tract. They are deep to the pubovesical muscle, and although they bleed when sutures are placed here, this venous oozing usually stops when the sutures are tied. Also within this tissue, lateral to the bladder and urethra, lie the nerves of the lower urinary tract. The upper border of the pubic bones that form the anterior surface of this region has a ridgelike fold of peritoneum called the ilipectineal line. This is sometimes used to anchor sutures during urethral suspension operations.

Vesicovaginal and Vesicocervical Space

The space between the lower urinary tract and the genital tract is separated into the vesicovaginal and vesicocervical spaces (Fig. 7.14). The lower extent of the space is the junction of the proximal one third and distal two thirds of the urethra, where it fuses with the vagina, and it extends to lie under the peritoneum at the vesicocervical peritoneal reflection. It extends laterally to the pelvic side walls, separating the vesical and genital aspects of the cardinal ligaments.
Rectovaginal Space

On the dorsal surface of the vagina lies the rectovaginal space (Fig. 7.14). It begins at the apex of the perineal body, about 2 to 3 cm above the hymenial ring. It extends upward to the cul-de-sac and laterally around the sides of the rectum to the attachment of the rectovaginal septum to the parietal endopelvic fascia. It contains loose areolar tissue and is easily opened with finger dissection.

At the level of the cervix, some fibers of the cardinal-uterosacral ligament complex extend downward behind the vagina, connecting it to the lateral walls of the rectum and then to the sacrum. These are called the rectal pillars. They separate the midline rectovaginal space in this region from the lateral perirectal spaces. These perirectal spaces allow access to the sacrospinous ligaments (mentioned afterward). They also form the lateral boundaries of the retrorectal space between the rectum and sacrum.

Region of the Sacrospinous Ligament

The area around the sacrospinous ligament is another region that has become more important to the gynecologist operating for problems of vaginal support. The sacrospinous ligament lies on the dorsal aspect of the coccygeal muscle (Fig. 7.20). The rectal pillar separates it from the retrovaginal space.

As its name implies, the sacrospinous ligament courses from the lateral aspect of the sacrum to the ischial spine. In its medial portion, it fuses with the sacrotuberous ligament and is a distinct structure only laterally. It can be reached from the retrovaginal space by perforation of the rectal pillar to enter the pararectal space or by dissection directly under the enterocele peritoneum. This area is covered in more detail in Chapter 35. Many structures are near the sacrospinous ligament, and their location must be remembered during surgery in this region. The sacral plexus lies immediately to the ligament on the inner surface of the piriformis muscle. Just before its exit through the greater sciatic foramen, the plexus gives off the pudendal nerve, which, with its accompanying vessels, passes lateral to the sacrospinous ligament at its attachment to the ischial spine. The nerve to the levator ani muscles lies on the dorsal aspect of the coccygeal muscle (Fig. 7.20). It supplies the rectum, as described in the section concerning that viscus.

The lateral boundaries of the retrorectal space between the rectum and sacrum.

Retroperitoneal Structures of the Lower Abdomen

The aorta lies on the lumbar spine slightly to the left of the vena cava, which it overlies. The portion of this vessel below the renal vessels is encountered during retroperitoneal dissection to identify the paraaortic lymph nodes (Fig. 7.21). The renal blood vessels arise at the second lumbar vertebra. The ovarian vessels also arise from the anterior surface of the aorta in this region. In general, the branches of the vena cava follow those of the aorta, except for the vessels of the intestine, which flow into the portal veins, and the left ovarian vein, which empties into the renal vein on that side.

Below the level of the renal vessels and just below the third portion of the duodenum, the inferior mesenteric artery arises from the anterior aorta. It gives off ascending branches of the left colic artery and continues caudally to supply the sigmoid through the three or four sigmoid arteries that lie in the sigmoid mesentery. These vessels follow the bowel as it is pulled from side to side, so that their position can vary, depending on retraction.

 Inferiorly, a continuation of the inferior mesenteric artery forms the superior rectal artery. This vessel crosses over the external iliac vessels to lie on the dorsum of the lower sigmoid. It supplies the rectum, as described in the section concerning that viscus.

The aorta and vena cava have segmental branches that arise at each lumbar level and are called the lumbar arteries and veins. They are situated somewhat posteriorly to the aorta and vena cava and are not visible from the front. When the vessels are mobilized, as is done in excising the lymphatic tissue in this area, they come into view.

At the level of the fourth lumbar vertebra (just below the umbilicus), the aorta bifurcates into the left and right common iliac arteries. After about 5 cm, the common iliac arteries (and the medially placed veins) give off the internal iliac vessels from their medial side and continue toward the inguinal ligament as the external iliac arteries. These internal iliac vessels lie within the pelvic retroperitoneal region and are discussed afterward.

The aorta and vena cava in this region are surrounded by lymph nodes on all sides. Surgeons usually refer to this lumbar chain of nodes as the paraaortic nodes, reflecting their position. They receive the drainage from the common iliac nodes and are the final drainage of the pelvic viscera. In addition, they collect the lymphatic drainage from the ovaries that follows the ovarian vessels and does not pass through the iliac nodes. The nodes of the lumbar chain extend from the right side of the vena cava to the left of the aorta and can be found both anterior and posterior to the vessels.

The ureters are attached loosely to the posterior abdominal wall in this region, and when the overlying colon is mobilized, they remain on the body wall. They are crossed anteriorly by the ovarian vessels, which contribute a branch to supply the ureter. Additional blood supply to the abdominal portion comes from the renal vessels at the kidney and the common iliac artery.

This region can be exposed either by a midline peritoneal incision to the left of the small bowel mesentery or, retroperitoneally, by reflection of the colon. During embryonic development, the colon and its mesentery fuse with the abdominal wall. A cleavage plane exists here that allows the colon and its vessels to be elevated to expose the structures of the posterior abdominal wall. Because the ureter and ovarian vessels originally arise in this area, they are not elevated with the colon.
Surgical Anatomy of the Female Pelvis

The presacral space begins below the bifurcation of the aorta and is bounded laterally by the internal iliac arteries (Figs. 7.22 and 7.23). Lying directly on the sacrum are the middle sacral artery and vein, which originate from the dorsal aspect of the aorta and vena cava (and not from the point of bifurcation, as sometimes shown). Caudal and lateral to this are the lateral sacral vessels. The venous plexus of these vessels can be extensive, and bleeding from it can be considerable.

Within this area lies the most familiar part of the pelvic autonomic nervous system, the presacral nerve (superior hypogastric plexus). The autonomic nerves of the pelvic viscera can be divided into a sympathetic (thoracolumbar) and parasympathetic (craniosacral) system. The former is also called the adrenergic system, and the latter is called the cholinergic system, according to their neurotransmitters.

α-adrenergic stimulation causes increased urethral and vesical neck tone, and cholinergic stimulation increases contractility of the detrusor muscle. Similarly, adrenergic stimulation in the colon and rectum favors storage, and cholinergic stimulation favors evacuation. β-adrenergic agonists, which are used for tocolysis, suggest that these influence contractility of the uterus. As is true in the man, damage to the autonomic nerves during pelvic lymphadenectomy can have a significant influence on orgasmic function in the woman.

How these autonomic nerves reach the organs that they innervate has surgical importance. The terminology of this area is somewhat confusing, because many authors use idiosyncratic terms. However, the structure is simple: It consists of a single ganglionic midline plexus overlying the lower aorta (superior hypogastric plexus) that splits into two trunks without ganglia (hypogastric nerves), each of which connects with a plexus of nerves and ganglia lateral to the pelvic viscera (inferior hypogastric plexus).

The superior hypogastric plexus lies in the retroperitoneal connective tissue on the ventral surface of the lower aorta and
receives input from the sympathetic chain ganglia through the thoracic and lumbar splanchnic nerves. It also contains important afferent pain fibers from the pelvic viscera, which makes its transaction effective in primary dysmenorrhea. It passes over the bifurcation of the aorta and extends over the proximal sacrum before splitting into two hypogastric nerves that descend into the pelvis in the region of the internal iliac vessels. The hypogastric nerves end in the inferior hypogastric plexus. The hypogastric plexuses are broad expansions of the hypogastric nerves. Their sympathetic fibers come from the downward extensions of the superior hypogastric plexus and pelvic splanchnic nerves from the continuation of the sympathetic chain into the pelvis. Parasympathetic fibers come from sacral segments 2 through 4 by way of the pelvic splanchnic nerves (nervi erigentes) to join these ganglia. They lie in the pelvic connective tissue of the lateral pelvic wall, lateral to the uterus and vagina.

The inferior hypogastric plexus (sometimes called the pelvic plexus) is divided into three portions: the vesical plexus anteriorly, uterovaginal plexus (Frankenhäuser ganglion), and the middle rectal plexus. The uterovaginal plexus contains fibers that derive from two sources. It receives sympathetic and sensory fibers from the tenth thoracic through the first lumbar spinal cord segments. The second input comes from the second, third, and fourth sacral segments and consists primarily of parasympathetic nerves that reach the inferior hypogastric plexus through the pelvic splanchnic nerves. The uterovaginal plexus lies in the dorsal (medial) surface of the uterine vessels, lateral to the sacrouterine ligaments insertion into the uterus. It has continuations cranially along the uterus and caudally along the vagina. This latter extension contains the fibers that innervate the vestibular bulbs and clitoris. These nerves lie in the tissue just lateral to the area where the uterine artery, cardinal ligament, and uterosacral ligament pedicles are made during a hysterectomy for benign disease, and within the tissue removed during a radical hysterectomy.

The location of the sensory fibers from the uterine corpus in the superior hypogastric nerve (the presacral nerve) allows the surgeon to alleviate visceral pain from the corpus by transecting this structure. It does not provide sensory innervation to the adnexal structures or to the peritoneum and is therefore not useful for alleviating pain in those sites. Another important way in which the autonomic nervous system is involved is through damage to the inferior hypogastric plexus during radical hysterectomy. The extension of the surgical field lateral to the viscera interrupts the connection of the bladder and sometimes the rectum to their central attachments.

The ovary and uterine tube receive their neural supply from the plexus of nerves that accompany the ovarian vessels and that originate in the renal plexus. These fibers originate from the tenth thoracic segment, and the parasympathetic fibers come from extensions of the vagus.

As the lumbar and sacral nerves exit from the intervertebral and sacral foramina, they form the lumbar and sacral plexuses. The lumbar nerves and plexus lie deep within the psoas muscle on either side of the spine. The sacral plexus lies on the piriformis muscle, and its major branch, the sciatic nerve, leaves the pelvis through the lower part of the greater sciatic foramen. The

sacral plexus supplies nerves to the muscles of the hip, pelvic diaphragm, and perineum, as well as to the lower leg (through the sciatic nerve). The femoral nerve from the lumbar plexus is primarily involved in supplying the muscles of the thigh.

Pelvic Retroperitoneal Space
Division of the internal and external iliac vessels occurs in the area of the sacroiliac joint. Just before passing under the inguinal ligament to become the femoral vessels, the external iliac vessels contribute the deep inferior epigastric and deep circumflex iliac arteries. There are no other major branches of the external iliac artery in this region.

Internal Iliac Vessels
Unlike the external iliac artery, which is constant and relatively simple in its morphology, the branching pattern of the internal iliac arteries and veins is extremely variable (Figs. 7.24 and 7.25). A description of a common variant is included here. The internal iliac artery supplies the viscera of the pelvis and many muscles of the pelvic wall and gluteal region. It usually divides into an anterior and posterior division about 3 to 4 cm after leaving the common iliac artery (Table 7.2). The vessels of the posterior division (the iliohypogastric, lateral sacral, and superior gluteal) leave the internal iliac artery from its lateral surface to provide some of the blood supply to the pelvic wall and gluteal muscles. Trauma to these hidden vessels should be avoided during internal iliac artery ligation as the suture is passed around behind vessels.

The anterior division has both parietal and visceral branches. The obturator, internal pudendal, and inferior gluteal vessels primarily supply muscles, whereas the uterine, superior vesical, vaginal (inferior vesical), and middle rectal vessels supply the pelvic organs. The internal iliac veins begin lateral and posterior to the arteries. These veins form a large and complex plexus within the pelvis, rather than having single branches, as do the arteries. They tend to be deeper in this area than the arteries, and their pattern is highly variable.

Ligation of the internal iliac artery has proved helpful in the management of postpartum hemorrhage. Burchell’s arteriographic studies showed that physiologically active anastomoses between the systemic and pelvic arterial supplies were immediately patent after ligation of the internal iliac artery (Fig. 7.25). These anastomoses, shown in Table 7.2, connected the arteries of the internal iliac system with systemic blood vessels either directly from the aorta, as is true for the lumbar and middle sacral artery, or indirectly through the inferior mesenteric artery, as with the superior hemorrhoidal vessels. These in vivo pathways were quite different from the anastomoses that had previously been hypothesized on purely anatomic grounds.
Pelvic Ureter

The course of the ureter within the pelvis is important to gynecologic surgeons and is fully considered in Chapter 37. A few of the important anatomic landmarks are considered here (Fig. 7.24). After passing over the bifurcation of the internal and external iliac arteries, just medial to the ovarian vessels, the ureter descends within the pelvis. Here it lies in a special connective tissue sheath that is attached to the peritoneum of the lateral pelvic wall and medial leaf of the broad ligament. This explains why the ureter still adheres to the peritoneum and does not remain laterally with the vessels when the peritoneal space is entered.

The ureter crosses under the uterine artery (“water flows under the bridge”) in its course through the cardinal ligament. There is a loose areolar plane around it to allow for its peristalsis here. At this point it lies along the anterolateral surface of the cervix, usually about 1 cm from it. From there it comes to lie on the anterior vaginal wall and then proceeds for a distance of about 1.5 cm through the wall of the bladder. During its pelvic course, the ureter receives blood from the vessels that it passes, specifically the common iliac, internal iliac, uterine, and vesical arteries. Within the wall of the ureter, these vessels are connected to one another by a convoluted vessel that can be seen running longitudinally along its outer surface.

Lymphatics

The lymph nodes and lymphatic vessels that drain the pelvic viscera vary in their number and distribution, but they can be organized into coherent groups. Because of the extensive interconnection of the lymph nodes, spread of lymph flow, and thus malignancy, is somewhat unpredictable. Therefore, some important generalizations about the distribution and drainage of these tissues are still helpful. Distribution of the pelvic lymph nodes is discussed further in Chapter 46 on invasive carcinoma of the cervix. Figures 46.22 through 46.25 show this anatomy.

The nodes of the pelvis can be divided into the external iliac, internal iliac, common iliac, medial sacral, and pararectal nodes. The medial sacral nodes are few and follow the middle sacral artery. The pararectal nodes drain the part of the rectosigmoid above the peritoneal reflection that is supplied by the superior hemorrhoidal artery. The medial and pararectal nodes are seldom involved in gynecologic disease.

The internal and external iliac nodes lie next to their respective blood vessels, and both end in the common iliac chain of nodes, which then drain into the nodes along the aorta. The external iliac nodes receive the drainage from the leg through the inguinal nodes. Nodes in the external iliac group can be found lateral to the artery, between the artery and vein, and on the medial aspect of the vein. These groups are called the anterosuperior, intermediate, and postero medial groups, respectively. They can be separated from the underlying muscular fascia and peristemum of the pelvic wall along with the vessels, thereby defining their lateral extent. Some nodes at the distal end of this chain lie in direct relation to the deep inferior epigastric vessels and are named according to these adjacent vessels. Similarly, nodes that lie at the point where the obturator nerve and vessels enter the obturator canal are called obturator nodes.

The internal iliac nodes drain the pelvic viscera and receive some drainage from the gluteal region along the posterior division of the internal iliac vessels as well. These nodes lie within the adipose tissue that is interspersed among the many branches of the vessels. The largest and most numerous nodes lie on the lateral pelvic wall, but many smaller nodes lie next to the

these nodes are named for the organ by which they are found (e.g., parauterine). Not only is it difficult in the operating room to make some of the fine distinctions mentioned in this anatomic discussion, but also there is little clinical importance in doing so. Surgeons generally refer to those nodes that are adjacent to the external iliac artery as the external iliac group of nodes and to those next to the internal iliac artery as the internal iliac nodes. This leaves those nodes that lie between the external iliac vein and internal artery, which are called interiliac nodes.

The direction of lymph flow from the uterus tends to follow its attachments, draining along the cardinal, uterosacral, and even round ligaments. This latter connection can lead to metastasis from the uterus to the superficial inguinal nodes, whereas the former connections are to the internal iliac nodes, with free communication to the external iliac nodes and sometimes to the lateral sacral nodes. The anastomotic connection of the uterine and ovarian vessels makes lymphatic connections between these two drainage systems likely and metastasis in this direction possible.

The vagina and lower urinary tract have a divided drainage. Superiorly (upper two thirds of the vagina and the bladder), drainage occurs along with the uterine lymphatics to the internal iliac nodes, whereas the lower one third of the vagina and distal urethra drain to the inguinal nodes. However, this demarcation is far from precise. The common iliac nodes can be found from the medial to the lateral border of the vessels of the same name. They continue above the pelvic vessels and occur around the aorta and the vena cava. These nodes can be anterior, lateral, or posterior to the vessels.

**The Abdominal Wall**

Knowledge of the layered structure of the abdominal wall allows the surgeon to enter the abdominal cavity with maximum efficiency and safety. A general summary of these layers is provided in Table 7.3. The abdomen's superior border is the lower edge of the rib cage (ribs 7 through 12). Inferiorly, it ends at the iliac crests, inguinal ligaments, and pubic bones. It ends posterolaterally at the lumbar spine and its adjacent muscles.

**Skin and Subcutaneous Tissue**

The fibers in the dermal layer of the abdominal skin are oriented in a predominantly transverse direction following a gently curving concave upward line. This predominance of transversely oriented fibers results in more tension on the skin of a vertical incision and in a wider scar.

Between the skin and musculoaponeurotic layer of the abdominal wall lie the subcutaneous tissues. It is made of globules of fat held in place and supported by a series of branching fibrous septa. In the more superficial portion of the subcutaneous layer, called Camper’s fascia, the fat predominates, and the fibrous tissue is less apparent. Closer to the rectus sheath, the fibrous tissue predominates relative to the fat in the region known as Scarpa’s fascia. Camper’s and Scarpa’s fasciae are not discrete or well-defined layers but represent regions of the subcutaneous. Scarpa’s fascia is best developed laterally and is not seen as a well-defined layer during vertical incisions.

**Musculoaponeurotic Layer**

Deep to the subcutaneous tissue is a layer of muscle and fibrous tissue that holds the abdominal viscera in place and controls movement of the lower torso (Figs. 7.26 and 7.27). Within this area are two groups of muscles: vertical muscles in the anterior abdominal wall and oblique flank muscles. The rectus abdominis muscle is found on either side of the midline.
and the pyramidalis muscle is located just above the pubes. Lateral to these are the flank muscles: the external oblique, internal oblique, and transverse abdominal. The broad, sheet-like tendons of these muscles form aponeuroses that unite with their corresponding member of the other side, forming a dense white covering of the rectus abdominis muscle properly called the rectus sheath (rectus "fascia").

Rectus Abdominis and Pyramidal Muscles

Each paired rectus abdominis muscle originates from the sternum and cartilages of ribs 5 through 7 and inserts into the anterior surface of the pubic bone. Each muscle has three tendinous inscriptions. These are fibrous interruptions within the muscle that firmly attach it to the rectus abdominis sheath. In general, they are confined to the region above the umbilicus, but they can be found below it. When this happens, the rectus sheath is attached to the rectus muscle there, and these two structures become difficult to separate during a Pfannenstiel incision.

The pyramidal muscles arise from the pubic bones and insert into the linea alba in an area several centimeters above the symphysis. Their development varies considerably among individuals. Their strong attachment to the midline makes separation of their attachment here difficult by blunt dissection.

Flank Muscles

Lateral to the rectus abdominis muscles lie the broad, flat muscles of the flank. The aponeurotic insertions of these muscles join to form the conjoined tendon, or rectus sheath, which covers the rectus abdominis. Because of its importance, it is discussed separately subsequently.

The most superficial of these muscles is the external oblique. Its fibers run obliquely anteriorly and inferiorly from their origin on the lower eight ribs and iliac crest. Unlike the external oblique muscle's fibers, which run obliquely downward, the fibers of the internal oblique muscle fan out from their origin in the anterior two thirds of the iliac crest, the lateral part of the inguinal ligament, and the thoracolumbar fascia in the lower posterior flank. In most areas, they are perpendicular to the fibers of the external oblique muscle, but in the lower abdomen, their fibers arch somewhat more caudally and run in a direction similar to those of the external oblique muscle.

As the name transversus abdominis implies, the fibers of the deepest of the three layers have a primarily transverse orientation. They arise from the lower six costal cartilages, the thoracolumbar fascia, the anterior three fourths of the iliac crest, and the lateral inguinal ligament. The caudal portion of the transverse abdominal muscle is fused with the internal oblique muscle. This explains why, during transverse incisions of the lower abdomen, only two layers are discernible at the lateral portion of the incision.

Although the fibers of the flank muscles are not strictly parallel to one another, their primarily transverse orientation and the transverse pull of their attached muscular fibers place vertical suture lines in the rectus sheath under more tension than transverse ones. For this reason, vertical incisions are more prone to dehiscence.
Cross section of lower abdominal wall.

**Neurovascular Supply of the Abdominal Wall**

**Rectus Sheath (Conjoined Tendon)**

The line of demarcation between the muscular and aponeurotic portions of the external oblique muscle in the lower abdomen occurs along a vertical line through the anterolateral iliac spine (Fig. 7.28). The internal oblique and transverse abdominal muscles extend farther toward the midline, coming closest at their inferior margin, at the pubic tubercle. Because of this, fibers of the internal oblique muscle are found underneath the aponeurotic portion of the external oblique muscle during a transverse incision. In addition, it is between the internal oblique and transverse abdominal muscles that the nerves and blood vessels of the flank are found and their injury avoided.

In forming the rectus sheath, the conjoined aponeuroses of the flank are separable lateral to the rectus muscles but fuse near the midline. As they reach the midline, these layers lose their separate directions and fuse. Many specialized aspects of the rectus sheath are important to the surgeon. In its lower one fourth, the sheath lies entirely anterior to the rectus muscle. Above that point, it splits to lie both ventral and dorsal to it. The transition between these two arrangements occurs midway between the umbilicus and the pubic tubercle. Because of this, fascia of the transverse abdominal muscle are found underneath the aponeurotic portion of the external oblique muscle during a transverse incision. A vertical peritoneal incision cuts the posterior sheath. The linea alba, unites these two layers. Sharp dissection is usually required to separate these layers during a Pfannenstiel incision. A vertical peritoneal incision cuts the posterior sheath. The lateral border of the rectus muscle is marked by the semilunar line of the rectus sheath. Above the arcuate line, this is the level at which the anterior and posterior layers of the sheath split. Below it the transversalis fascia fuses with the sheath. The semilunar line is not always where the three layers of flank muscles join. During a transverse lower abdominal incision, the external and internal oblique aponeuroses are often separable near the midline.

The inguinal canal lies at the lower edge of the musculoskeletal layer of the abdominal wall. Through the inguinal canal, in the woman, the round ligament extends to its termination in the labium majus. In addition, the ilioinguinal nerve and the genital branch of the genitofemoral nerve pass through the canal.

**Transversalis Fascia, Peritoneum, and Bladder Reflection**

Inside the muscular layers, and outside the peritoneum, lies the transversalis fascia, a layer of fibrous tissue that lines the abdominopelvic cavity. It is visible during abdominal incisions as the layer just underneath the rectus abdominis muscles superficially. It is separated from the peritoneum by a variable layer of adipose tissue. It is frequently incised or bluntly dissected off the bladder to take the tissues in this region "down by layers."

The peritoneum is a single layer of serosa. It is thrown into five vertical folds by underlying ligaments or vessels that converge toward the umbilicus. The single median umbilical fold is caused by the presence of the urachus (median umbilical ligament). Lateral to this are paired medial umbilical folds that are raised by the obliterated umbilical arteries that connected the umbilical cord to the umbilical cord in fetal life, and the corresponding lateral umbilical folds caused by the inferior epigastric arteries and veins.

The reflection of the bladder onto the abdominal wall is triangular in shape, with its apex blending into the medial umbilical ligament. Because the apex is highest in the midline, incision in the peritoneum lateral to the midline is less likely to result in bladder injury.

**Vessels of the Abdominal Wall**

Knowing the location and course of the abdominal wall blood vessels helps the surgeon anticipate their location during abdominal incisions and during the insertion of laparoscopic trocars (Fig. 7.29). The blood vessels that supply the abdominal wall can be separated into those that supply the skin and subcutaneous tissues and those that supply the musculoskeletal layer.
Although there is only one set of epigastric vessels in the subcutaneous tissues (superficial epigastric), there are both superior and inferior epigastric vessels in the musculoaponeurotic layer, so care must be taken in using these terms to avoid confusion.

The superficial epigastric vessels run a diagonal course in the subcutaneous from the femoral vessels toward the umbilicus, as a single artery that branches extensively as it nears the umbilicus. Its position can be anticipated midway between the skin and musculoaponeurotic layer, in line between the palpable femoral pulse and the umbilicus. The external pudendal artery runs a diagonal course from the femoral artery medially to supply the region of the mons pubis. It has many midline branches, and bleeding in its territory of distribution is heavier than that from the abdominal subcutaneous tissues.

The superficial circumflex iliac vessels proceed laterally from the femoral vessels toward the flank.

The blood supply to the lower abdominal wall’s musculoaponeurotic layer parallels the subcutaneous vessels. The branches of the external iliac, the inferior epigastric, and the deep circumflex iliac arteries parallel their superficial counterparts (Fig. 7.29). The circumflex iliac artery lies between the internal oblique and transverse abdominal muscles. The inferior epigastric artery and its two veins originate lateral to the rectus muscle. They run diagonally toward the umbilicus and intersect the muscle’s lateral border midway between the pubis and umbilicus. Below the point at which the vessels pass under the rectus, they are found lateral to the muscle deep to the transversalis fascia. After crossing the lateral border of the muscle, they lie on the muscle’s dorsal surface, between it and the posterior rectus sheath. As the vessels enter the rectus sheath, they branch extensively, so that they no longer represent a single trunk. The angle between the vessel and the border of the rectus muscle forms the apex of the Hesselbach triangle (inguinal triangle), the base of which is the inguinal ligament.

Lateral laparoscopic trocars are placed in a region of the lower abdomen where injury to the inferior epigastric and superficial epigastric vessels can occur easily. The inferior epigastric arteries and the superficial epigastric arteries run similar courses toward the umbilicus. Knowing the average location of these blood vessels helps in choosing insertion sites that will minimize their injury and the potential hemorrhage and hematomas that this injury can cause. Just above the pubic
symphysis, the vessels lie approximately 5.5 cm from the midline, whereas at the level of the umbilicus, they are 4.5 cm from the midline (Fig. 7.30). Therefore, placement either lateral or medial to the line connecting these points minimizes potential vascular injury. In addition, the location of the inferior epigastric vessel can often be seen (Fig. 7.31) by following the round ligament to its point of entry into the inguinal ring, recognizing that the vessel lies just lateral to this point.

Nerves of the Abdominal Wall

The innervation of the abdominal wall (Fig. 7.30) comes from the abdominal extension of intercostal nerves 7 through 11, subcostal nerves (T12), iliohypogastric nerves (T12 and L1), and ilioinguinal (L1) nerves. Dermatome T10 lies at the umbilicus.

After giving off a lateral cutaneous branch, each intercostal nerve pierces the lateral border of the rectus sheath. There it provides a lateral branch that ends in the rectus muscle. The anterior branch then passes through the muscle and perforates the rectus sheath to supply the subcutaneous tissues and skin as the anterior cutaneous branches. Incisions along the lateral border of the rectus lead to denervation of the muscle, which can render it atrophic and weaken the abdominal wall. Elevation of the rectus sheath off the muscle during the Pfannenstiel incision stretches the perforating nerve, which is sometimes ligated to provide hemostasis from the accompanying artery. This may leave an area of cutaneous anesthesia.

The iliohypogastric and ilioinguinal nerves pass medial to the anterosuperior iliac spine in the abdominal wall. The former supplies the skin of the suprapubic area. The latter supplies the lower abdominal wall, and by sending a branch through the inguinal canal, it supplies the upper portions of the labia majora and medial portions of the thigh. These nerves can be entrapped in the lateral closure of a transverse incision and may lead to chronic pain syndromes.

The genitofemoral (L1 and L2) and femorocutaneous (L2 and L3) nerves can be injured during gynecologic surgery. The
genitofemoral nerve lies on the psoas muscle (Fig. 7.31), where it innervates the psoas or by too much flexion of the hip in the lithotomy position, causing anesthesia over the anterior thigh.

**BEST SURGICAL PRACTICES**

- Important anatomic relationships of the ureter include:
  - The ureter lies medial to the ovarian vessels at the bifurcation of the internal and external iliac arteries entering the pelvis.
  - The ureter courses under the uterine artery approximately 1.5 cm lateral to the cervix.
  - The ureter lies directly on the anterior vaginal wall very near the place where the vagina is detached from the cervix during the hysterectomy.
  - Branches of the ilioinguinal and iliohypogastric nerves run in the region of the abdominal wall involved in lower abdominal transverse incision and can be involved with nerve entrapment syndromes after these incisions.

- Support of the pelvic organs comes from the combined action of the levator ani muscles that close the genital hiatus and provide a supportive layer on which the organs can rest and by the attachment of the vagina and uterus to the pelvic sidewalls.

- The internal iliac vessels supply the pelvic organs and pelvic wall and gluteal regions. The complexity of these multiple branches varies from individual to individual, but the key feature is the multiple areas of collateral circulation that come into play immediately after internal iliac artery ligation so that blood supply to the pelvic organs has diminished pulse pressure but continues to have flow even after the ligation.

- The blood supply to the female genital tract is an arcade that begins at the top with input from the ovarian vessels, lateral supply by the uterine vessels, and distal supply by the vaginal artery. There is an anastomotic artery that runs along the entire length of the genital tract. For this reason, ligation of any single one of these arteries does not diminish flow to the uterus itself.

CHAPTER 8 ■ PREOPERATIVE CARE
SANFORD M. MARKHAM AND JOHN A. ROCK

DEFINITIONS
Preoperative care—The patient management period during which time gynecologic pathology, defects, and injury are assessed and diagnosed; an accurate decision is made for a surgical intervention; the patient is appropriately apprised of the problem and need for surgery as well as options available; and necessary preoperative evaluation and preparation is accomplished.

Preoperative evaluation—The assessment of a patient before surgery for the purpose of detecting factors that could affect surgical outcome and may include, in addition to a thorough physical examination, laboratory testing, imaging procedures, and consultations.

Preoperative physical examination—A complete physical examination of the whole body with special emphasis directed toward the breast, abdomen, and the pelvis and rectum.

Preoperative laboratory and imaging assessment—An assessment that is limited to those tests that are statistically important in detecting factors that could/would alter surgical outcome and are selected based on the patient's individual history and physical examination and not on a predetermined panel for all patients.

Preoperative gynecologic surgery assessment category—A complexity categorization of gynecologic surgical cases for purposes of selecting necessary preoperative testing and predicting surgical outcome. Categories include uncomplicated gynecologic pathology with an uncomplicated medical/surgical status, complicated gynecologic pathology with uncomplicated medical/surgical status, and uncomplicated or complicated gynecologic pathology with a complicated medical/surgical status.

A thorough review of medical sources does not yet provide sufficient controlled trial data to make evidence-based decisions on most preoperative laboratory and imaging testing for gynecologic surgery. The Cochrane Library contains recent controlled trial studies on individual gynecologic surgical procedures, but it does not currently contain controlled trial studies that relate to cost-effectiveness of any gynecologic preoperative testing or procedures. However, significant other case series data do exist that support the need for minimal preoperative testing in the uncomplicated gynecologic patient as well as specific preoperative testing and imaging for the complicated case.

This chapter is designed to provide to gynecologic surgeons an in-depth understanding of the essential features of preoperative care from the preoperative examination in the office, or emergency room, to the time of surgery. Included are suggestions relating to appropriate preoperative testing and evaluation based on the experience of gynecologic surgeons and anesthesiologists. Also included are accumulated data that demonstrate the benefits of preoperative evaluation to patient care. Foremost, it is essential to keep in mind that each woman must be considered individually, based on her medical findings and needs, and that no suggestions can be completely adapted to all women preparing for gynecologic surgery.

IMPORTANT OF PREOPERATIVE CARE
Successful surgical outcomes of operative gynecologic procedures occur as the result of several factors in addition to good surgical skills and techniques. These factors include:

1. An appropriate preoperative evaluation (the ability to accurately assess and diagnose gynecologic pathology, defects, and injury)
2. An appropriate patient selection (the ability to determine when surgical intervention is a necessary course of action)
3. An appropriate discussion with the patient regarding the benefits and risks of the surgery (the ability to communicate to the patient both short- and long-term complications in a manner that can be understood)
4. An ability to work with MCO organizations in terms of obtaining preoperative approval and complying with individual health care plan guidelines

Once a gynecologic pathology or defect has been detected and surgical intervention is thought to be the appropriate course of action, surgical planning should be instituted. In nonemergent cases, this planning should include a specific time for preoperative evaluation. The purpose of the preoperative evaluation is to accomplish the following tasks as described by Fischer: (a) decrease surgical morbidity, (b) minimize expensive delays and cancellations on the day of surgery, (c) evaluate and optimize patient health status, (d) facilitate the planning of anesthesia
and perioperative care, (e) reduce patient anxiety through edu-
cation, and (f) obtain informed consent. Although these objec-
tives were presented in the context of accomplishing the tasks
in a setting of a preoperative evaluation clinic, they are equally
applicable to surgical planning in smaller communities where
preoperative evaluation clinics are not available, provided that
the major components of the operating team, specifically the
gynecologist, anesthetist, surgeons, and consultants are available.

The importance of effective preoperative evaluations should not
be underestimated. Many studies have repeatedly shown that
preoperative patient conditions are significant predic-
tors of postoperative morbidity. It is essential that all women
undergoing preoperative assessment have a complete history
and thorough physical examination as a key element in their
workup. This examination is of importance to determine fac-
tors that could affect surgical outcome. When medical status
questions arise that cannot be answered by the gynecologist,
then laboratory testing and imaging procedures, as well as con-
sultations, become essential to promote optimal outcomes.

In the past, preoperative testing developed around the use of
a history and physical examination. Batteries of “routine”
individual and multiphasic laboratory tests and imaging proce-
dures were used to detect subclinical or presymptomatic med-
ical problems that might affect the outcomes of the surgical
procedure. Additionally, it was felt that less than desirable out-
comes of gynecologic surgical procedures could be minimized
through the use of a wide battery of tests to prove or disprove
normalcy before surgery. It was also felt that this reduction
in less-than-desirable outcomes might also provide some legal
protection.

Unfortunately, the use of multiple “routine” tests has re-
sulted in considerable additional costs for surgery and has cre-
ated a problem as to what should be done when preoperative
tests results are found to be unexpectedly abnormal. It has been
reported that data from the last two decades indicate 60% to
70% of laboratory tests ordered preoperatively are not re-
quired based on a review of the history and/or physical exami-
nation. Other studies suggest that only 1% or less of routinely
ordered preoperative tests revealed abnormalities that might
have influenced perioperative management. Furthermore, be-
tween 30% and 60% of all unexpected abnormalities detected
by preoperative laboratory tests were not actually noted or in-
vestigated before surgery. This fact alone suggests that not only
does the ordering of multiple “routine” tests not provide legal
protection but quite possibly it also sets up an opportunity for
increased legal liability. Finally, the cost of accomplishing these
unnecessary preoperative “routine” tests adds many millions
of dollars to health care costs each year without any proven
benefit to patient care.

Using this information and applying it to the preoperative
assessment of gynecologic surgery patients in the future, a pre-
operative evaluation should strive to answer the following three
questions as outlined by Rosen.

1. Is the patient in optimal health?
2. Can, or should, the patient’s physical or mental condition
   be improved before surgery?
3. Does the patient have health problems or use any med-
ications that could unexpectedly influence perioperative
events?

Therefore, all preoperative assessment and care should be di-
rected toward obtaining answers to these three pre-
operative testing modalities that are expected to give informa-
tion that leads to answers, as opposed to the random “routine”
batteries of tests used in the past.

Additionally it is most important to dedicate a portion of
the preoperative care time to a discussion with the patient of
options for management of her gynecologic problem, includ-
ing both short- and long-term potential complications. All pa-
tients must be given sufficient medical information to allow
them to make an educated decision about whether to proceed
with the planned surgery. Examples of gynecologic issues that
suggest the need for further discussion include the recently
reported significant increase in urinary incontinence following
hysterectomy (60%) or the higher than previously reported
failure rate of tubal sterilization (CREST [Collaborative Re-
view of Sterilization] study: 10-year accumulative failure rate
of 18.3 per 1,000), or the common occurrence of abnormal uter-
ine bleeding leading to a subsequent hysterectomy in women
with a history of abnormal uterine bleeding controlled by oral
contraceptive pills who elect to undergo a tubal sterilization
(relative risk 1.8). Not only is the discussion time useful in fos-
tering a good physician–patient relationship, but it becomes
extremely important if outcomes of surgery are less than ex-
pected, particularly if the discussion was documented in the
patient’s record.

HISTORY AND PHYSICAL EXAMINATION

History

Preoperative care of a patient always begins by carefully tak-
ing a complete history and doing a thorough preoperative ex-
amination. For the surgeon, the process of the history and the
physical examination are fundamental to good surgical results.
The physical and mental preparation of the patient are key to
patient satisfaction after surgery. It is essential that the oper-
atng gynecologist personally take the history. This personal
contact with the patient is of value to both the patient and sur-
geon. During this time, the gynecologist can gain an individual
perspective of not only the gynecologic problems but also the
patient’s general status. The patient can, in turn, ask direct
questions relating to the surgical procedure as well as express
her concerns. This interchange gives the surgeon a unique im-
pression of the problem and allows the surgeon to better assess
the pathology or defect that requires surgery. This also places
the gynecologist in a much better position to arrive at an ac-
curate diagnosis, determine the essential preoperative testing
that will be needed, and select the most appropriate surgery to
manage the problem.

Good history taking and a thorough physical examination
require time and patience, neither of which is easily available
given the expanded demands of gynecologic practice. How-
ever, the reward for the gynecologist who takes the time to
listen to the patient and accomplish a complete physical exami-
nation is the avoidance of unnecessary surgery. Unnecessary
operations, particularly for patients already troubled by some
difficult problem of life, may prove to be unsuccessful in re-
lying the patient’s symptoms and also concentrate attention
unnecessarily on the pelvic organs. If the condition is not ur-
gent, do not make a firm decision regarding recommendation
for major pelvic surgery on the first consultation.

Emergent and urgent conditions, by necessity, require a dif-
f erent approach of rapid assessment and action. In most gyneco-
logic cases, however, the patient is counseled on the need for
surgery only after all physical and psychological aspects of her
case are thoroughly evaluated. The surgeon who does not ask
questions and offer explanations, and who does not carefully consider choices, usually has less than desirable outcomes. A patient's history should be concise, but accuracy should not be sacrificed for the sake of brevity. It has become a common practice to use a preprinted form or a computer template, if using electronic medical records, when obtaining a history. Unfortunately, no medical form is applicable to every case. Maximum efficiency can be achieved by using a standard patient-completed history form (Fig. 8.1) along with a physician-completed history and physical examination form or electronic record template (Figs. 8.2 and Fig. 8.3). The physician can use the patient-completed form to efficiently assimilate the information and direct the history and physical examination process. The physician's history and physical examination form serve as a structured reminder of the essentials of the history-taking process as well as summarize the patient's medical history to facilitate the decision to accomplish surgery. The electronic record template can be tailored to include sub-sections of any portion of the history or physical examination. These forms additionally serve as a record for Current

The University of Iowa Hospitals and Clinics requests this information for the purpose of providing patient care. Some questions may seem personal or appear to be unrelated to your care, but your responses are important. Yor information will help your health care providers deliver a safe and high standard of care. Your health problems are affecting your daily life, and we feel confident they can best help you if your strengths and weaknesses are also known. Please answer all questions to the best of your ability. The blank codes (in parentheses) will be completed at the time of your visit on the form. Please talk with your health care provider if you have any questions about your answers. The information you give will be used to help you, other patients, and the University of Iowa Hospitals and Clinics improve the quality of health care.

**GYNECOLOGIC/ObSTETRIC HISTORY**

1. Age: ______
2. When was the first day of your last period? ______/______
3. Date of most recent period onset? ______/______ normal/abnormal (please circle)
4. Date of most recent Pap smear? ______/______ normal/abnormal (please circle)
5. Date of most recent mammogram? ______/______ normal/abnormal (please circle)
6. **No** (______): Have you ever been told you had an abnormal Pap smear? **Yes**: when? ______
7. How old were you when you first started your periods? ______
8. Usually, your periods come every ______ days; last ______ days.
9. Are your periods usually: ______ Regular ______ Late ______ Very early ______ Irregular ______ Very early ______
10. **No** (______): Do you have bleeding between periods? **Yes**: describe ______
11. Describe any problems you are currently having (in bed) with your periods ______

12. **No** (______): Do you need a birth control method today? **Yes**: for gynecology appointment only ______
13. Which method do you want today? ______
14. List noncontraceptive birth control methods (please): ______

Procedural Terminology (CPT) coding documentation, as well as for later clinical research. Experience has shown that important omissions are much less frequent when information is compiled on a standard form. Care should be taken, however, not to allow such a form to restrict the accurate recording of the present illness. Forms always can be expanded to document an event in the patient’s history that might have an important bearing on the present illness.

A few points should be stressed concerning proper gynecologic history taking. The menstrual history must be accurate and detailed. The clue to a correct diagnosis of the gynecologic condition for which surgery is being considered often appears in the pattern of menstrual irregularity, whether the menstrual disturbance results from an organic lesion or a dysfunctional cause. In fact, differentiation between dysfunctional and early organic disease is one of the most common and difficult clinical distinctions that must be made before surgery. Accurate dates of the last and previous menstrual periods are of major importance. When there is a discrepancy between menstrual dates and pelvic findings in a patient of reproductive age, pregnancy
should be suspected and a pregnancy test accomplished. A discrepancy between menstrual dates and pelvic findings in a patient with suspected pregnancy requires a serum quantitative human chorionic gonadotropin (hCG) testing to identify appropriate progression of the pregnancy, along with a pelvic ultrasound when the pelvic examination and hCG test results are at odds.

Good gynecologic history taking can also provide valuable clues relating to findings in the physical examination. In a woman younger than 50 years of age with a history of maternal diethylstilbestrol (DES) exposure, attention should be paid to the potential presence of a variety of anatomical defects of the müllerian duct system such as a "T-shaped" uterus, vaginal adenosarcoma, or cervical defects ("cock’s comb" cervix). A documented history of Type II herpes simplex viral infection of the lower genital tract has long-term implications for future recurrences and symptomatology. Of equal importance in postmenopausal women is obtaining an accurate date of the menopause. Some women are now cycling well into their fifties. Variations in vaginal bleeding in these patients may be of far different significance than vaginal bleeding in a woman 10 to 15 years postmenopausal.
The patient’s reproductive history is also of great importance, particularly a history of previous pregnancies and complications of pregnancy such as dystocia, cesarean section, postpartum infection, abortion, urinary tract infections, excessive infant size, vaginal lacerations, deep vein thrombophlebitis, and pulmonary embolization. A well-taken marital history may reveal dyspareunia and/or unsatisfactory sexual relations, which may explain some symptoms that resemble organic pelvic disease.

Because the symptoms of urinary tract disease so closely resemble those of reproductive tract disease, a urologic history is important, along with laboratory investigation of the urinary tract before a final diagnosis is determined and a decision made regarding surgery. Too often the symptoms of urinary frequency, urgency, and dysuria have been diagnosed as a mechanical support defect of the urinary bladder and treated by surgical repair with plication of the bladder neck, although the real problem of chronic urinary tract infection or neurogenic dysfunction of the bladder remains undiagnosed. Put in another way, a disorder of the lower urinary tract can produce symptoms suggestive of reproductive tract disease and vice versa.

For this reason, basic urologic training is advocated for every gynecologist. The gynecologist who is adept with a urologic workup, including cystoscopy and cystometrics, can evaluate a case better than one who must depend entirely on consultation and urology reports.
Symptomatology of gastrointestinal tract disease can also mimic disease of the reproductive tract. Thus, a proper gastrointestinal tract history along with appropriate laboratory investigation make a significant contribution toward arriving at a correct diagnosis and treatment plan before gynecologic surgical intervention. Constipation, irritable bowel syndrome, colitis, Crohn’s disease, and diverticulitis can cause abdominal and pelvic pain that is not dissimilar to the pain of endometriosis, pelvic adhesions, or ovarian neoplasms. Therefore, basic gastrointestinal training is also advocated for all gynecologists. The gynecologist experienced in accomplishing sigmoidoscopy is better prepared to assess gynecologic cases being considered for surgery than the gynecologist who lacks such experience.

Because abnormal uterine bleeding can result from a variety of endocrine and metabolic disorders, a history of hypothyroidism, hyperprolactinemia, insulin metabolism errors, as well as other endocrine and metabolic defects in the patient and in her family are of considerable importance in assessing and treating menorrhagia and metrorrhagia. A positive history followed by appropriate endocrine testing can give physicians significant insight into the etiology of the problem and allow...
them to institute proper management without always requiring surgery.

Musculoskeletal and neurologic defects of the low back, pelvis, and hips can result in pain similar to that found in gynecologic pathology and disease. Therefore, an orthopedic and neurologic history is an important addition to a thorough gynecologic history.

Finally, the common use of herbal therapy and dietary supplements have resulted in some unanticipated problems during surgery. For this reason, a gynecologic history is not complete without inquiring as to the use of herbs and dietary supplements. Experience has shown that garlic, ginger, ginkgo, and ginseng can potentiate an anticoagulant effect, and bilberry, dandelion, and garlic can potentiate hypoglycemia.

Other herbs, such as ephedra, guarana, and ginseng, can potentiate stimulants, and valerian, kava, and St. John’s wort can potentiate sedation. Knowledge of herbal and dietary supplement use in the preoperative period allows time to discontinue the therapy before surgery and thus avoid a potential adverse reaction.

General Health Examination

Experience has shown that the obstetrician/gynecologist often is the only physician to whom a patient consults, particularly if the symptoms of her problem seem to involve the reproductive tract. As such, preoperative care requires a complete
FIGURE 8.3. Physician's electronic record template history and physical form. (From: University of Iowa Hospitals and Clinics, with permission.)
physical examination and not just a focused examination on the lower abdomen and pelvis. This complete physical examination should include blood pressure assessment, weight and height measurement, temperature recording, thyroid and neck examination, auscultation of the heart and lungs, examination of the breasts, neurologic and orthopedic assessment, and examination of the abdomen and pelvis. During the physical examination, the breast should be examined for signs of abnormal sexual development; abnormal growth of hair on the face, chest, abdomen, extremities, back, and pubic regions; and to sexual ambiguity of the external and internal female genitalia. In addition, it is the responsibility of the gynecologist to carry out a critical evaluation of cardiac and pulmonary function before the accomplishment of any surgery. The need for additional medical and/or anesthesia consultation must be determined before surgical scheduling to complete the preoperative care assessment.

In any patient who presents with gynecologic disease and has symptoms remotely suggestive of urinary tract infection and/or disease, a meticulously collected, midstream clean-catch, or catheterized urine specimen should be examined and cultures obtained. Past data have suggested that complications of a single catheterization in terms of urinary tract infection or significant bacteriuria is minimal, whereas the complication of performing a gynecologic surgery in the presence of an undetected preexisting urinary tract infection offers a somewhat higher risk. Doing a transurethral catheterization in gynecologic patients with urinary tract symptoms is not considered to be a hazard to the normal bladder and can provide valuable information for the total assessment of gynecologic symptoms.

**Gynecologic Examination**

The gynecologic examination includes a thorough inspection and palpation of the breasts, abdomen, pelvis, and rectum. Ample time should be dedicated to this portion of the preoperative evaluation because defects detected during this examination affect surgical planning. This examination should be completed by the gynecologist performing the surgery rather than by other physicians or staff. In some institutions, however, a gynecologic team approach is used in the preoperative care process, and in such cases, the operating gynecologist may not always be the preoperative evaluation gynecologist. In this situation, the evaluating and the operating surgeon together must review the completed preoperative evaluation and plan, along with the patient's concerns and wishes. The operating surgeon must then make time before the surgery to meet the patient, review the plan of management with her, and respond to all of her questions.

**Breast Examination**

The breasts are inspected for symmetry, size, condition of the nipples, the presence of gross lesions, and the presence of discharge. Normal breast tissue, which feels rather spongy to the fingertips, is often erroneously suspected to be tumorous by the patient and is sometimes even misjudged by the physician who is unfamiliar with the proper method of breast palpation. The breasts are examined in both the upright and supine positions for symmetry, contour, and a palpable mass. The supine position of the breast being examined should be raised slightly to bring the lateral aspect of the breast tissue level with the remaining portion of the breast. The arm is then raised above the head to flatten the breast against the thoracic cage. This action permits easy examination of the full thickness of the breast tissue. Examination using the flat ventral surface of the fingers and palm almost always allows identification of an existent significant lesion. Any suspicious lesion is evaluated by mammography, ultrasonography, aspiration, and/or biopsy to confirm or discount the existence of significant breast pathology. The nipples and adjacent areolar tissue are gently compressed to detect the presence of discharge or secretion (galactorrhea). Cytologic examination of breast secretions has been reported in the past to be useful in the diagnosis of very early breast carcinoma before the clinical detection of a gross lesion. Current imaging techniques, along with fine needle biopsy, offer diagnostic accuracy before abnormal breast secretion is usually experienced, however. Nonetheless, the observation of bilateral secretion showing only the presence of fat cells on an unstained microscopic examination is reassuring and can be accomplished in an office setting. Minimal galactorrhea is not uncommon, particularly in parous women and those in early pregnancy. Other causes of galactorrhea must be considered and include prolactin-secreting tumors of the pituitary, dopamine-agonist medications, birth control pills, and primary hypothyroidism. In these cases, galactorrhea is usually found to be bilateral. Unilateral secretion should be evaluated by placing a drop of the secretion on a slide and sending the slide to cytology for examination and diagnosis. The importance of a thorough breast examination is not only to detect a previously undiagnosed breast pathology but also to detect other medical problems (galactorrhea) that could affect the outcome of a planned gynecologic surgery.

**Abdominal Examination**

Examination of the abdomen requires both visual inspection and palpation. Percussion and auscultation also may be useful. Bulging of the flanks suggests free abdominal fluid, but thin-walled ovarian cysts and irregularly shaped uterine leiomyomas can give a similar clinical picture. Although large ovarian cysts and leiomyomas most often cause protrusion of the anterior abdominal wall, there are a number of confusing exceptions. Palpation for a fluid wave in the lateral quadrants of the abdomen is useful. Palpation for a fluid wave in the lateral quadrants of the abdomen is useful. Percussion for areas of flatness or tympany and for shifting dullness can help determine whether distention is due to intraperitoneal fluid or to intestinal gas. Auscultation is especially useful to differentiate between a large tumor, a distended bowel, or an advanced pregnancy as the cause of abdominal enlargement. When physical findings are conflicting or inconclusive, imaging procedures such as abdominal-pelvic ultrasound, abdominal computed tomography scan, or magnetic resonance imaging are quite helpful in completing the assessment of an abnormal abdominal examination.

**Pelvis and Rectum Examination**

An accurate evaluation of the female reproductive tract is essential to establish the underlying cause of gynecologic symptoms. Although a detailed description of a pelvic examination is not provided in this chapter, it is important to stress a few of...
the steps necessary for proper evaluation of the female pelvis. Before an adequate pelvic examination can be performed, the bladder must be emptied by voiding. A clean-catch specimen is obtained for complete urinalysis and for culture and antibiotic sensitivity studies, if indicated. On the other hand, reports of urinary incontinence require examination with a full bladder in the lithotomy and in the erect position to demonstrate stress incontinence of the urethral sphincter. Inspection of the vulva for gross lesions includes examination of the Bartholin and Skene glands for evidence of cyst formation and purulent exudate as sources of gynecologic infection. Particular attention is given to the mons pubis and labia majora and minora for subtle changes in skin pigmentation, for vesicle formation, and for small, raised lesions that may be evidence of viral or bacterial infection or of early neoplasia. Particular attention is given to the mons pubis and labia majora and minora for vesicle formation, and for small, raised lesions that may be evidence of viral or bacterial infection or of early neoplasia. The outlet is closely inspected for relaxation of the anterior and posterior vaginal walls and for uterine descensus now referred to as pelvic organ prolapse. The vaginal mucosa is observed for any visible lesions, evidence of infection, and for estrogen effect. The patient is asked to bear down and cough without the use of a tenaculum to demonstrate the degree of relaxation of the anterior and posterior vaginal walls and the extent of uterine descensus. The urethra is compressed along its entire length to assess the possibility of a suburethral diverticulum, which often is manifested by a purulent discharge from the urethral meatus or a tender suburethral mass.

The cervix is evaluated for abnormal gross pathology, particularly ulceration, neoplastic growths, inflammation, and abnormal discharge. A Papanicolaou smear is obtained by a combined sampling of cells taken from the portio of the cervix by means of a flat stick, and from the endocervical canal by means of a small circular brush or by use of a cervical broom for liquid-based assessment. This type of combined cytologic smear or liquid-based cytology is extremely valuable in detecting cervical and endocervical lesions and is always a part of a complete gynecologic examination. Pelvic surgery always should be preceded by a recent cytologic study of the cervix. Patients with abnormal Papanicolaou smears showing repeated mild dysplasia, moderate to severe squamous cell dysplasia (CIN II–III), or high-risk human papillomavirus (HPV) should be evaluated by colposcopy, and suspicious lesions should be biopsied. Abnormal smears showing glandular cell dysplasia require both an endocervical and endometrial evaluation, such as an endocervical curettage and endometrial biopsy, before proceeding to pelvic surgery. A negative Papanicolaou smear does not, however, exclude the possibility of a cervical, endocervical, or endometrial neoplasm. False-negative cervical smears have been reported. Because 89% to 90% of all preclinical malignancies of the cervix demonstrate no significant gross lesion, it is impossible to be certain of the condition of the cervix without a Papanicolaou smear or a colposcopy and a colposcopically directed cervical biopsy if lesions are identified. The use of 3% acetic acid or Lugol’s (strong iodine solution) staining of the cervix may be beneficial in identifying lesions for biopsy. Some pathologists, however, caution against the use of Lugol’s because of the effect that it has on cervical cells, which sometimes interferes with an accurate pathological assessment.

The uterus is examined bimanually by the abdominal-vaginal route for position, size, mobility, irregularity, and tenderness to motion. Both adnexal regions are evaluated vaginally and by rectovaginal examination. The rectal examination should never be omitted from the routine pelvic examination. Rectal examinations provide information that cannot be obtained through the vaginal examination alone. The rectal examination provides insight into the competence of the anal sphincter as well as the presence of lesions of the anal canal and lower rectum. The rectal and vaginal examinations together are an effective method for detecting pelvic pathology and are especially useful for evaluating the broad and uterosacral ligaments, cul-de-sac of Douglas, uterus, and adnexa. The index finger is inserted into the vagina while the middle finger is inserted into the rectum to a higher level than is possible with the vaginal index finger (Fig. 8.4). This method offers the most effective opportunity of evaluating the ovaries, posterior cul-de-sac, and posterior aspect of the broad ligament. When pelvic findings are doubtful or inconclusive, imaging techniques may be helpful in determining the preoperative diagnosis. When imaging techniques are inconclusive or unavailable, however, a more adequate examination may be performed under general anesthesia before a final decision for or against gynecologic surgery.
is made. Indeed, a complete pelvic examination always should precede any gynecologic surgery, whether it be major or minor. The pelvic organ findings of this examination should be described carefully in the operative note for future reference. Suspected pelvic pathology frequently can be ruled in or out after a thorough preoperative pelvic examination, and needless laparotomy or laparoscopy can be avoided. The most common area of clinical confusion occurs in determining the presence of an ovarian cyst, which can be confused with bowel, bladder, or uterine leiomyomas. If a normal ovary is palpated and a cyst not identified by imaging techniques such as pelvic ultrasound, an unnecessary operative procedure frequently can be spared.

LABORATORY ASSESSMENT

Before the era of evidence-based medicine, most patients undergoing gynecologic surgery were assessed by a thorough history and physical examination followed by a battery of laboratory tests, the purpose of which was to detect a medical disease or defect that could adversely affect surgical outcome. These tests were accomplished on almost all patients, irrespective of age or concurrent medical or surgical pathologies, and might include (a) blood count with hemoglobin and hematocrit, (b) urinalysis, (c) coagulation studies, (d) chemistry panel, (e) chest x-ray, and (f) electrocardiogram. This relatively universal use of “routine” preoperative testing has not proven to be beneficial in terms of good patient care and, additionally, it has added significantly to the high cost of medical care. In one study, an average of 72.1% of preoperative tests ordered by surgeons were considered unnecessary based on a review of the patient’s history and physical examination. This same study suggested a medical care savings of between $4 billion and $10 billion per year in the United States by eliminating these unnecessary tests with no adverse effect on outcome.

Over the last 10 to 15 years, data have surfaced allowing gynecologists to better assess needed preoperative tests from those that in the past were labeled “routine” tests. Because of the presence of information such as this, and because of pressures from MCOs, the volume of preoperative testing has been reduced. With this reduction in the ordering of unnecessary tests, however, comes a reduction in the ordering of necessary tests. This finding emphasizes the need to accurately differentiate between indicated preoperative testing and the past practice of routine blanket testing of gynecologic patients preparing for surgery. A large portion of the remainder of this chapter focuses on the best-practice routine testing of gynecologic patients preparing for surgery. A large case series data to help guide the gynecologist when ordering appropriate preoperative tests based on the individual patient’s history and physical examination.

Key to the understanding of appropriate preoperative testing is an understanding of (a) the risk category of the patient and (b) the degree of complexity of the planned surgery. The risk category of any preoperative gynecology patient may be assessed risk of the patient based on her age, history and physical examination. In this case, an understanding of (a) the risk category of the patient and (b) the degree of complexity of the planned surgery may be divided into one of six different classes as established by the American Society of Anesthesiologists (Table 8.1). The degree of complexity of the planned surgery may be divided into one of three separate types as identified by Rozen and colleagues (Table 8.2). Preoperative testing should be planned around the assessed risk of the patient based on her age, history and physical examination.

examination, and the degree of complexity based on the invasiveness of the proposed surgery. Current data as well as experience suggest that, rather than a routine set of tests, all preoperative testing should be inextricably related to the type and complexity of the proposed gynecologic surgery and to the presence of the confounding medical or surgical condition.

**Asymptomatic Patients**

In an extensive review of currently available evidence on the value of routine preoperative testing in healthy or asymptomatic patients, Monto and colleagues (1997) found that there were no controlled trials assessing the value of basic tests previously thought to be essential in presurgical evaluation and care. These tests included chest x-ray, electrocardiogram, blood counts and hemoglobin, coagulation studies, blood chemistries, and urinalysis. The authors further noted that all currently available evidence on preoperative testing of healthy or asymptomatic patients came only from case series studies. After reviewing all of the available case series data, they concluded that the power of preoperative tests to predict adverse postoperative outcomes in asymptomatic patients is either weak or nonexistent.

Conclusions such as these have resulted in (a) a marked reduction in the recommendation of routine testing and (b) the suggestion that the amount of routine testing of preoperative healthy asymptomatic patients be related to the patient’s age. Currently, in this category of patients, it has been recommended that a hemoglobin or hematocrit be accomplished on all patients older than the age of 40 years, an electrocardiogram (ECG) on all patients older than the age of 60; and a blood urea nitrogen (BUN) test and a glucose test on all patients older than the age of 65. Additionally, a pregnancy test should be accomplished on all reproductive-age women who are at risk of early pregnancy (sexually active, no contraception, or questionably effective contraception) (Table 8.3).

**Symptomatic Patients and Patients with Medical or Surgical Pathologies or Defects**

Women considered for gynecologic surgery who are symptomatic and/or have other medical or surgical pathologies or defects must be considered in a different light from asymptomatic, healthy women during their preoperative evaluation and testing. Preoperative testing should be accomplished to determine the current status of medical or surgical pathologies and provide data on the potential effect that the compound- ing problem will have on the outcome of the proposed surgery. This would allow, if possible, for necessary medical correction or improvement of the problem before surgery in an attempt to minimize adverse outcomes of surgical intervention.

Despite the lack of an evidence-based preoperative evaluation plan to guide preoperative testing, evidence supports adopting a diagnosis-based preoperative testing protocol when planning any gynecologic surgery. A number of diagnosed- based or clinical condition-based protocols have been suggested. Because the diagnosed-based preoperative testing evaluation recommended by Fischer (1999) considers both clinical outcomes as well as cost-effectiveness, it is most appropriate in the preoperative evaluation of gynecologic patients who are other than healthy and asymptomatic (Table 8.4). This approach links necessary preoperative laboratory and imaging testing with concurrent medical disease—including cardiovascular, pulmonary, and endocrine pathologies—as well as with malignancies and the use of many common drug therapies.

The outcome of pelvic surgery depends largely on four preoperative factors:

1. The skill and judgment of the gynecologic surgeon
2. The ability to surgically correct the gynecologic abnormality or disease process
3. The severity, stability, and reversibility of concurrent medical/surgical pathologies
4. The availability of experienced support professionals for consultation as indicated, specifically from anesthesiology, medicine, and surgery.

Preoperative evaluation and care of the women undergoing gynecologic surgery must include not only a thorough physical examination but also correction or stabilization of any concurrent medical or surgical pathologies that could adversely affect the surgical outcome. A skilled and appropriate gynecologic surgical procedure can have an undesirable outcome because of an unstable condition or incompletely prepared patient.

For this reason, when the preoperative history, physical examination, or laboratory testing reveals instability of the cardiovascular, pulmonary, renal, or hematologic systems, a consultation should be considered. The intent is to achieve maximal stabilization before surgery. If the patient cannot be stabilized, then delaying or postponing the surgery must be considered based on the risk and benefit of the surgical procedure for the patient. A preoperative diminished cardiac, pulmonary, or renal reserve; a blood coagulopathy; or dehydration and/or hypovolemia can play a critical role in the outcome of the surgery.

Particular attention must be given to the senior gynecologic patient. Not only does this group of women represent the fastest-growing segment of gynecologic patients, but they also are more frequently prone to have other medical issues that can affect the outcome of gynecologic surgery. The U.S. Department of Health and Human Services (DHHS) has recently noted that the U.S. population older than the age of 65 was growing faster than the population as a whole. They stated that currently 13 out of every 100 Americans are 65 years of age or older.

...age or older, and in 2030 this number will increase to 20 out of 100. They additionally noted that there were significantly more women than men in this older population, with women composing 59% of the group aged 65 years and older and 71% of those aged 85 years and older. DHHS data from 2004 indicated that women born in 2002 will live to an age of 79.9 years. Additionally, if a women reached age 65 in 2002, she can expect to live an additional 19.5 years, and if she reached age 75 in 2002, she can expect to live an additional 12.4 years. Considerable data as well as experience have shown that this group of senior gynecologic patients has significantly greater health care problems and therefore will require a greater effort in the preoperative evaluation in terms of laboratory evaluation and consultation.

With this increase in concurrent medical and surgical problems, and the resulting increase in operative risks of gynecologic...
surgery in the senior population, it is important to note that chronicologic age, by itself, is not always an accurate indicator of organ function. Atherosomatous changes of the cardiovascular system are uncommon in women until well past menopause. This biologic phenomenon is just one of the many factors that promote female (compared with male) longevity. As a consequence of increased longevity, a high percentage of women are in the postmenopausal period of their life when gynecologic disease becomes more prevalent and surgery becomes more necessary. In spite of the increased concurrent medical and surgical problems and greater operative risks, excellent surgical skills, meticulous medical control of concurrent disease, and anesthesiology carefully attuned to the physiologic requirements of the senior gynecologic patient have kept the risk of surgery at a level not much greater than that for the premenopausal patient. Age alone should therefore not be a contraindication for surgery.

Guidelines for the preoperative evaluation of the gynecologic patient may be divided into three separate areas.

1. Uncomplicated gynecologic pathology with an uncomplicated medical/surgical status
2. Complicated gynecologic pathology with uncomplicated medical/surgical status
3. Uncomplicated or complicated gynecologic pathology with a complicated medical/surgical status

The following preoperative evaluation recommendations are made based on the most current data from case series studies, evidence-based medical data, and consensus opinions of gynecologic preoperative care.

### Preoperative Evaluation, Uncomplicated Gynecologic Pathology, Uncomplicated Medical/Surgical Status

A gynecologic patient who has an uncomplicated gynecologic pathology and no concurrent medical or surgical conditions that would affect surgical outcome should undergo the following preoperative evaluation.

1. Thorough history
2. Complete physical examination
3. Hematocrit or hemoglobin if older than 6 months of age
4. Electrocardiogram if older than 40 years of age
5. Blood urea nitrogen and glucose if older than 65 years of age
6. Pregnancy test if in the reproductive age, sexually active, and not on contraception or if using questionable effective contraception
7. Sexually transmitted diseases testing (chlamydia, gonococcus, syphilis, hepatitis, and human immunodeficiency virus (HIV)) with suspected or documented exposure
8. Blood type and screen if the potential exists for more than minimal surgical blood loss

### Preoperative Evaluation, Complicated Gynecologic Pathology, Uncomplicated Medical/Surgical Status

A gynecologic patient who has a complicated gynecologic pathology and no concurrent medical or surgical conditions that would additionally affect surgical outcome should undergo the following preoperative evaluation (complicated gynecologic pathology includes past abdominal/pelvic surgery with evidence of or anticipation of pelvic adhesive disease, tumors, or cysts of a size making surgery more difficult or complicated; suspected or proven cancerous lesions; concurrent infection of the reproductive tract; or active or chronic bleeding from the reproductive tract, resulting in a demonstrated or highly probable hemodynamic instability).

1. Thorough history
2. Complete physical examination
3. Laboratory testing listed under uncomplicated gynecologic pathology
4. Complete blood cell (CBC) count with suspected or evidence of pelvic infection, hemorrhage, or anemia
5. Prothrombin time (PT), activated partial thromboplastin time (APTT), and either a platelet function analysis (PFA-100) or a bleeding time with hemorrhage or anemia
6. Liver function tests and renal tests with any suspected hepatic or renal pathology
7. Type and cross match in an anticipated high blood loss surgery, otherwise only a type and screen
8. Anesthesia consultation

### Preoperative Evaluation, Uncomplicated or Complicated Gynecologic Pathology, Complicated Medical/Surgical Status

A gynecologic patient who has either an uncomplicated or complicated gynecologic pathology and a concurrent medical or surgical problem offers the greatest risk for gynecologic surgery (complicating medical or surgical problem includes cardiac, pulmonary, vascular, renal, intestinal, endocrine, neurologic, and orthopedic pathologies, as well as use of medications for these defects). These patients should undergo the following preoperative evaluation:

1. Thorough history
2. Complete physical examination
3. Laboratory testing listed under uncomplicated gynecologic pathology
4. Laboratory testing listed under complicated gynecologic pathology
5. Prothrombin time (PT) and an International Normalized Ratio (INR) in women with a history of venous thrombosis or pulmonary embolism on warfarin
6. Factor V Leiden, prothrombin 20210A gene mutation, antithrombin, lupus anticoagulant, and antiphospholipid antibodies in women with a suspected thrombophilia
7. Liver function tests, renal function tests, electrolyte and/or blood sugar tests in women with renal, liver, or intestinal disease; on diuretics; with an unexplained fever; with endocrine disease, including diabetes, hypoglycemia, parathyroid disease, or adrenal and pituitary disease; or with a recent history of radiation or chemotherapy
8. Electrocardiogram with suspected or known cardiac pathology
9. Anesthesia consultation
10. Medicine, cardiology, pulmonary medicine, endocrinology, urology, and surgery consultation as indicated

### PREOPERATIVE MANAGEMENT AND PREPARATION

Preoperative care includes not only preoperative evaluation and laboratory testing, but also any medical or gynecologic evaluation and treatment in the months preceding the surgical
procedure to help achieve maximal physical status. Achieving this goal is rewarded by a less complicated surgical procedure with better outcomes. Examples of this medical or gynecologic management include a number of treatments. Ovarian suppression through the use of a gonadotropin-releasing hormone agonist in the 2 to 3 months before surgery has proven to be beneficial in hysteroscopic resection of uterine submucous leiomyomata larger than 2 cm in size and in myomectomies when the uterine volume is equivalent to or larger than a 12-week pregnant uterus size. A similar suppression is also useful in decreasing the thickness of the endometrial lining in an endometrial ablation, although an endometrial suction curettage can achieve a somewhat similar result.

Preoperative antibiotic treatment of postmenopausal women undergoing reparative surgery for genital prolapse can be beneficial in reducing recurrent cystitis but has not been shown to significantly alter the outcome of surgery.

Use of preoperative vaginal estrogen cream starting 4 to 6 weeks before surgery may help in controlling uropathogens as well as thickening the vaginal mucosa, which results in an easier dissection of the vagina and in reducing postoperative morbidity. Routine preoperative endometrial sampling before hysterectomy has not been found to be cost-effective unless there is suspicion of endometrial pathology, such as manifested by abnormal perimenopausal or menopausal bleeding or the presence of abnormal glandular cells on Papanicolaou test. In the latter case, endocervical sampling additionally is necessary.

Another area of preoperative planning requiring an experienced decision by the gynecologist and possibly the anesthesiologist is the regulation of medications taken by the patient before surgery. When and how to modify insulin in diabetic women, surgery on women taking anticoagulants, and discontinuation or discontinuation of oral contraceptive pills are some examples of issues that must be addressed in the preoperative period and conveyed to the patient in a manner that she understands. Because of the uniqueness of each patient, it is not possible to provide a table of preoperative medication management that can be applied to every patient. However, some general suggestions serve as guidelines in the preoperative management of the more common concurrent diseases.

Preoperative insulin control in patients with diabetes is thought to be essential to achieve good surgical outcome. Older animal data have shown a relationship between hyperglycemia and wound healing with reduced tensile strength and wound failure. Experience has suggested a similar relationship in the gynecologic patient. It is therefore important to continue each diabetic woman undergoing gynecologic surgery with her primary care physician or internist to achieve this optimal control, and once achieved, to continue this insulin regimen right up to the time of surgery. Every attempt should be made to schedule the diabetic patient’s surgery as a first morning case to minimize the time period between the patient’s last oral intake and the onset of the surgical procedure. A protocol for patient preoperative management of insulin regulation may be found in Table 8.5. Some patients may present with an insulin pump, in which case a decision will need to be made regarding continuing the pump at a basal rate and transitioning to an intravenous (IV) infusion, or discontinuing the pump after a subcutaneous injection of a long-acting insulin. Planning for complex insulin preoperative management should be accomplished in conjunction with the patient’s medical physician and with anesthesia. Patients who are scheduled for gynecologic surgery who are on Coumadin (warfarin), heparin, or low-molecular-weight heparin (LMWH) represent another preoperative management issue. A number of options are available for converting the patient from warfarin to heparin. Experience has suggested that stopping the warfarin 3 days before the planned gynecologic surgery and converting to low-dose heparin 3,000 U subcutaneously every 12 hours 4 days preoperatively provides satisfactory anticoagulation protection. As an alternative, it has been recommended by some anesthesiologists that heparin be instituted only when the INR for prothrombin falls below 2. The low-dose heparin can be continued postoperatively until the patient is back on oral feeding, at which time the warfarin can be reinitiated. It is further suggested that these women use elastic stockings or intermittent pneumatic compression (IPC) hose at the beginning of the surgery and continue with this mechanical support through to the point of full postoperative ambulation.

Another preoperative medication issue involves the continuation or discontinuation of oral contraceptive pills before gynecologic surgery. Studies in the 1970s suggested a relationship between use of preoperative oral contraceptive pills and intraoperative or postoperative venous thrombosis. For this reason, in the past it has been the practice to discontinue oral contraceptive pills 2 to 4 weeks before surgery and convert to mechanical contraception. This practice, however, is unsupported by any current prospective controlled studies and places the patient at risk for unwanted pregnancy as well as menstrual irregularities. Therefore, routine discontinuation of oral contraception before gynecologic surgery is not recommended, but instead mechanical venous support, such as elastic stockings or IPC, be used at the time of surgery.

The immediate preoperative preparation of the patient includes the preoperative examination by the gynecologic surgeon and the anesthesia assessment in the anesthesia preoperative clinic or by an individual anesthesiologist. In most cases, the assessment for anesthesia risks is accomplished before the day of surgery. If significant anesthesia risk is present, such as cardiovascular or pulmonary pathology, this allows time for relevant information to be obtained, additional testing accomplished, other consultation carried out, and treatment instituted in an attempt to have the patient in optimal condition on the day of surgery. In some cases involving low-risk

**Table 8.5**

**RECOMMENDATION FOR PREOPERATIVE INSULIN MANAGEMENT: CLASSIC “NONIGHT CONTROL” REGIMEN OF ROIZEN**

1. Day before surgery: Patient should be given nothing by mouth after midnight; a 13-ounce glass of clear orange juice should be at the bedside or in the car for emergency use.
2. At 6 a.m. on the day of surgery, institute intravenous fluids using plastic cannula and a solution containing 5% dextrose, infused at a rate of 125 mL/h/70 kg body weight.
3. After institution of intravenous infusion, give one-half the usual morning insulin dose (and usual type of insulin) subcutaneously.
4. Continue 5% dextrose solutions through operative period, giving at least 125 mL/h/70 kg body weight.
5. In recovery room, monitor blood glucose concentration and treat on a sliding scale.

ambulatory procedures, however, the anesthesiologist regarding the planned surgery is an essential element in achieving a successful outcome with the lowest patient risk.

Most gynecologic surgical patients are admitted on the day of surgery. Because preoperative preparation and instructions for patient activity and actions at home are important and need to be made clear to every patient. The goal is to have the patient rested and in the optimal physical condition with an empty stomach and reduced contents in the lower gastrointestinal tract at the time of surgery. There is no evidence to support the idea that marked reduction of activity on the day before surgery is beneficial; however, it would be reasonable to recommend planning activities so that the patient is not over-stressed. Food intake on the day before surgery need not be restricted except for the evening meal before the morning of surgery, which should be light and easily digestible. An over-loaded intestinal tract during surgery is particularly hazardous not only because it poses an anesthetic risk but also because it increases postoperative nausea and gas formation. The patient should be instructed to not eat or drink after midnight on the evening before surgery unless the surgery is scheduled for the late afternoon. Some exceptions to this rule might occur with the taking of indicated medications with water. Such an exception should be discussed between the gynecologist and the anesthesiologist in the preoperative evaluation sessions. Women who are scheduled for a late afternoon surgery may have a light breakfast of a liquid diet if taken no fewer than 6 hours preoperatively.

Women undergoing major abdominal surgery in which bowel entry or injury is anticipated (or is a high probability) should undergo a complete bowel prep. This complete bowel preparation should consist of the single use of a commercially available cleansing preparation such as GoLYTELY or NuVITYLE (Braintree Laboratories, Inc., Braintree, MA). This impression is not universally supported, however. A 2005 Cochrane Review of bowel preparation before colon surgery failed to demonstrate convincing evidence that mechanical or complete bowel preparation reduced the rates of common complications. Nevertheless, a cleansing preparation continues to be standard of care in gynecologic surgeries involving bowel resection or repair. In all other major abdominal cases, the lower colon should be cleansed by a preoperative enema the evening before surgery. If the colon is not completely emptied, then a repeat enema may need to be given before performing the operation, allowing adequate time for evacuation. The patient needs to be given careful instructions for the use of enemas at home and the possible need for a repeat enema in the hospital before surgery. This issue is often overlooked in preoperative care and results in a more difficult surgical procedure because of space limitation and a less comfortable patient in the postoperative period. An adequate night’s rest before surgery is also important for the patient. In some cases, the use of a mild sedative may be considered.

Preoperative prophylactic broad-spectrum antibiotics or surgical antimicrobial prophylaxis has frequently been used in gynecologic surgery on the basis of the potential for vaginal flora contamination of the operative field and because of the close proximity of the rectum and intestinal tract. Data do not support the routine use of preoperative broad-spectrum antibiotics in uncomplicated, routine gynecologic laparoscopic or hysteroscopic surgery. Data, as presented in the 2003 Compendium of the American College of Obstetricians and Gynecologists, do, however, support the use of preoperative broad-spectrum antibiotics in vaginal hysterectomy or abdominal hysterectomy. In these procedures, the occurrence of postoperative cuff cellulitis and pelvic abscess has been significantly reduced with use of a preoperative antibiotic. First-, second-, or third-generation cephalosporins (e.g., cefazolin, cefotetan, or cefoxitin, 2 g IV) are effective as a prophylactic coverage. As an alternative, metronidazole 500 mg IV may be utilized. When used, the prophylactic antibiotic should be given as a single dose approximately 1 to 2 hours before beginning surgery and may be repeated if the operation lasts longer than 3 hours or if there is significant blood loss (in excess of 1,500 mL). If the preoperative examination and testing identifies vaginal infections such as bacterial vaginosis, treatment before surgery with metronidazole 500 mg orally 2 times a day for 7 days, or metronidazole intravaginal gel (0.75%) one 5-g applicator intravaginally daily for 5 days, or clindamycin vaginal cream (2%) one 5-g applicator intravaginally daily for 7 days should be accomplished. In like manner, any sexually transmitted disease discovered during preoperative examination and testing should be fully treated before surgery.

Infections occurring after surgery in the female reproductive tract arise from the introduction of normal vaginal flora into the surgical field. Surgery on the reproductive tract accomplished through a bacteriologically contaminated field (e.g., the vagina) seeds bacteria into the pedicles and surgical margins of pelvic tissues and provides an excellent nidus for infection in devitalized tissue beds. Therefore, pelvic surgery provides an ideal condition for aerobics (principally polymicrobial rather than monomicrobial) infections. Tissue destruction and sutures lower the tissue oxidation-reduction (redox) potential. Lower tissue oxygen levels enhance the growth of facultative anaerobes that normally inhabit the vagina. As tissue hypoxia progresses, primary bacterial flora become predominant and postoperative infections arise. Therefore, the more common postoperative infection in the vaginal vault, although initially polymicrobial, usually can be prevented with the use of the prophylactic antibiotic antibioticsonly the vaginal apex has been opened during a vaginal or abdominal hysterectomy.

Although prophylactic antibiotics are effective in reducing the incidence of postoperative infectious morbidity, they should never be used as a substitute for the time-honored principles of adequate hemostasis and gentle handling of tissue. Despite Wangensteen’s disparaging statement that “antibiotics will turn a second-class surgeon into a first-class surgeon,” current data suggest that even in the hands of a highly skilled surgeon, prophylactic preoperative antibiotics offer improved outcomes in gynecologic pelvic surgery such as vaginal and abdominal hysterectomy.

Preoperative Procedures in the Operating Suite

Just before surgery, the patient is brought to the operating theater and transferred either directly to the operating table in the operating room or to an operating table in the anesthesia room adjoining the surgical suite. Preoperative preparation includes any trimming of pubic hair, preparation of abdominal and vaginal skin, and placement of a catheter, if indicated. Preoperative shaving of pubic and abdominal hair before gynecologic surgery is generally not recommended. In fact, preoperative shaving is associated with a significantly higher surgical site infection (SSI) rate, particularly if completed the night before the operation. These guidelines note studies showing SSI rates of 5.6% in patients who had hair
TABLE 8.6
RECOMMENDATIONS FOR PREOPERATIVE PREPARATION OF THE PATIENT TO PREVENT SURGICAL SITE INFECTIONS

1. Whenever possible, identify and treat all infections remote to the surgical site before elective operation, and postpone elective operations on patients with remote site infections until the infection has resolved.

2. Do not remove hair preoperatively unless hair at or around the incision site will interfere with the operation.

3. If hair is removed, remove immediately before the operation, preferably with electric clippers.

4. Adequately control serum blood glucose levels in all diabetic patients, and particularly avoid hyperglycemia perioperatively.

5. Encourage tobacco cessation. At a minimum, instruct patients to abstain for at least 30 days before elective operation from smoking cigarettes, cigars, pipes, or other form of tobacco consumption.

6. Do not withhold necessary blood products from surgical patients as a means to prevent surgical site infections.

7. Require patients to shower or bathe with an antiseptic agent on at least the night before the operative day.

8. Thoroughly wash and clean at and around the incision site to remove gross contamination before performing antiseptic skin preparation.

9. Use appropriate antiseptic agent for skin preparation.

10. Apply preoperative antiseptic skin preparation in concentric circles, moving toward the periphery. The prepared area must be large enough to extend the incision or create new incisions or drain sites, if necessary.

11. Keep preoperative hospital stay as short as possible while allowing for adequate preoperative preparation of the patient.

12. No recommendation to taper or discontinue systemic steroid use (when medically permissible) before elective operation. ( unresolved issue)

13. No recommendation to enhance nutritional support for surgical patients solely as a means to prevent surgical site infection. ( unresolved issue)

14. No recommendation to preoperatively apply mupirocin to nares to prevent surgical site infection. ( unresolved issue)

15. No recommendation to provide measures that would enhance space oxygenation to prevent surgical site infections. ( unresolved issue)

removed by shaving compared with 0.6% in those who had no hair removed. Furthermore, shaving the night before surgery resulted in a significantly higher rate of SSI than shaving just before the operative procedure (7.1% versus 3.1%). Experience has shown that in some gynecologic procedures, removal of pubic and abdominal hair is useful, and in these situations, hair clipping is recommended immediately before the surgery.

After hair trimming and catheterization, the patient is usually sufficiently anesthetized for a careful bimanual pelvic examination, at which time the surgeon can obtain very valuable information not easily obtainable when the patient is awake. Detection of reduced mobility, identification of cysts or masses not previously known, and determination of the position of pelvic organs not appreciated in past examinations may prejudice the gynecologist to alter the planned surgical approach or incision type. After the pelvic examination, the perineum and vagina are cleaned, followed by the abdominal preparation.

The pelvic cleansing should be accomplished before all pelvic or abdominal surgery. There is always the possibility that findings at the time of operation may make a total abdominal hysterectomy advisable, even when the preoperative plan did not include such an extensive procedure. It is extremely disconcerting to find that a total abdominal hysterectomy must be performed at the time of a laparotomy if the vagina is not properly prepared. For this reason, it is strongly recommended that preoperative vaginal preparation be accomplished as a routine procedure. To clean the perineum and vagina, the vulva and perineum are first scrubbed by a nurse or surgical assistant with a sponge soaked in surgical soap or a povidone-iodine solution using a gloved hand. Before this preparation, Kelly pads should be placed under the buttocks and low back to catch wash and preparation solutions, and the perineum and vulva washed and wiped free of gross contamination (mucus, blood, bowel content). These pads should be removed before draping the patient to prevent contaminated fluids and concentrated iodine wash solutions from pooling and remaining under the buttocks during the operative procedure. After the perineal and vulvar preparation, the vagina is next scrubbed with a soapy sponge or a povidone-iodine sponge stick held in the gloved hand. After the vaginal scrub, the nurse or operative assistant inserts his or her fingers in the vagina and spreads the fingers to enlarge the vaginal outlet. At the same
time, the perineum is depressed to allow the soapy water or povidone-iodine solution to run out of the vagina. This solution is then flushed away with sterile water poured into the vagina. After this, the remaining cleanup is accomplished with a sterile sponge on a sponge forceps, which is used several times to clean the vagina with an appropriate antiseptic solution.

When the vaginal, vulvar, and perineal cleanup, the abdomen is prepared with a 5-minute scrub using a povidone-iodine or similar solution or with a three- to four-round application of a povidone-iodine gel sponge stick. Particular attention should be paid to cleansing the umbilicus with a Q-tip/cotton swab applicator. The surgically prepared area should extend superiorly from the inferior rib cage to the midhigh inferiorly. The lateral margins of the skin preparation should extend to the anterior iliac crest and the anterior axillary line. The actual skin washing and preparation should be accomplished using concentric circles moving toward the periphery. To additionally protect the incision from contamination, many surgeons use a clear plastic adhesive (3M Steri-Drape Ioban 2 or similar product) placed over the skin at the site of the incision.

The Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention has published Guidelines for Prevention of Surgical Site Infection (1999), which are important in gynecologic surgery and should be noted (Table 8.6).

Universal Precautions for the Prevention of Seropositivity for Acquired Immunodeficiency Syndrome

Because surgeons are at risk for acquiring seropositivity for the acquired immunodeficiency syndrome (AIDS) through contamination from body fluids and blood products, certain precautions should be taken at the time of surgery. In 1988, the Centers for Disease Control published a document recommending that blood and other body fluid precautions be consistently used for all patients, regardless of their blood-borne infectious status. This extension of blood and other body fluid precautions to all patients is referred to as Universal Blood and Fluid Precautions, or simply Universal Precautions. Under universal precautions, blood and body fluids of all patients are considered potentially infectious for human immunodeficiency virus (HIV), hepatitis B virus (HBV), and other blood-borne pathogens.

Universal precautions are intended to prevent parenteral, mucous membrane, and nonintact skin exposure of the surgeon to blood-borne pathogens. Immunization with HBV vaccine is also recommended as an important adjunct to the universal precautions for surgeons who are exposed to the risks. Protective barriers reduce the risk of exposure of the surgeon’s skin or mucous membrane to potentially infectious materials. In the operating room, protective barriers include gowns, gloves, masks, and protective eyewear. Masks and protective eyewear or face shields reduce the incidence of contamination of mucous membranes of the mouth, nose, and eyes. Gloves reduce the incidence of contamination of the hands, but they cannot prevent penetrating injuries, such as puncture by a needle or other sharp instrument. Special care must be taken to prevent any injury by needles, other sharp instruments or devices. Should a contamination occur in spite of these precautions, immediately and thoroughly wash the hands and other skin surfaces that have been contaminated and institute the medical institution’s policy on rapid antigen testing to determine if the surgeon should consider prophylaxis for HIV.

Gynecologic surgery encompasses a wide variety of surgical procedures from minimally invasive operations to radical and extensive dissections of pelvic pathology. No matter what the extent of the procedure, all gynecologic surgery should be considered to have three separate parts: (a) the preoperative care and management phase, (b) the surgical procedure itself, and (c) postoperative care and management phase. Each part is intricately related to the others, and each part is vital in the overall outcome of the gynecologic pathology being managed. Preoperative care and management sets the stage for a successful surgical procedure. Best outcomes are linked to a patient being in optimal physical and medical status before surgery. The preoperative process begins with an accurate diagnosis and an appropriate decision to operate. The preoperative evaluation serves to assess the patient’s overall medical status and specific gynecologic problem by a thorough history, a complete physical examination, and the ordering of appropriate laboratory testing to support the safety of the planned procedure. The preoperative evaluation additionally serves to identify other pathologies and problems that could interfere with optimal surgical outcome and to implement corrections before surgery. Suggestions for accomplishing a thorough history and physical examination have been outlined in this chapter. Preoperative testing should be based on the patient’s age, history, physical examination, and the degree of complexity of the proposed surgery. Suggestions for appropriate testing for both uncomplicated and complicated gynecologic patients have been made. Additional suggestions for management of gynecologic patients in the immediate preoperative period have also been made. Finally, of great importance is the open dialog between the gynecologic surgeon and the anesthesiologist regarding surgical planning, with consultation of other specialists when complicated medical or surgical issues are present. As a result of these actions and efforts, the gynecologic surgeon and the patient arrive in the operating room with little doubt as to the pathology, the overall medical status, and the plan for surgical correction.

BEST SURGICAL PRACTICES

• Successful surgical outcomes of operative gynecologic procedures occur as a result of several factors, including (a) appropriate preoperative evaluation, (b) appropriate patient selection, (c) appropriate discussion with the patient regarding the benefits and risks of surgery, and (d) ability to work with managed care organizations so as to obtain required approvals.

• Preoperative patient conditions are significant predictors of postoperative morbidity. It is essential that all women undergoing preoperative assessment have a complete history and thorough physical examination as a key element of their workup.

• Key to the understanding of appropriate testing is an understanding of (a) the risk category of the patient and (b) the degree of complexity of the planned surgery.

• A close dialog should exist between the gynecologic surgeon and the anesthesiologist as well as with other medical/surgical specialties providing consultative support for the patient.

CHAPTER 9 ■ POSTANESTHESIA AND POSTOPERATIVE CARE
ALEXANDER DUNCAN, IRA R. HOROWITZ, AND KENNETH KALASSIAN

POSTOPERATIVE CARE

POSTOPERATIVE CARE

DEFINITIONS

Hospital-acquired pneumonia (HAP)—Pneumonia that develops 48 hours or more after hospital admission because of organisms that were not incubating at the time of admission.

Hypoxic pulmonary vasoconstriction—Local reflex in the lung that diverts blood away from poorly oxygenated regions.

Low-molecular-weight heparin (LMWH)—Product that acts by inhibiting factor Xa.

Tissue plasminogen activator (t-PA)—Compound used for nonsurgical thrombolysis.

Venous thrombotic event—A venous thromboembolism that includes vascular clots, such as deep vein thrombosis, pulmonary embolism, and arterial thromboembolism.

Virchow’s triad—Factors that increase risk of vascular thromboembolism, e.g., hypercoagulability, stasis, trauma to vessels.

V/Q abnormalities—Ventilation/perfusion abnormalities, including increased shunting to increased dead space in the lung.

Postoperative complications are the most important factors in defining the outcome of the first 72 hours following a patient’s surgical procedure. It is critical to monitor basic physiological parameters—such as renal, cardiovascular, and respiratory functions—and laboratory tests to optimize and sustain recovery from surgery and anesthesia.

Postoperative morbidity can be minimized by an appropriate preoperative assessment of the surgical patient. This should include emphasis on identifying the patient at risk for venous thromboembolism, e.g., hypercoagulability, stasis, trauma to vessels, embolic stockings and intermittent pneumatic compression stockings have significantly reduced the risk of PE in the moderate- and high-risk patients. Clarke-Pearson and colleagues, using univariate and regression analysis, designed a prognostic model to evaluate the risk of postoperative VTE for an individual patient. In a group of 411 gynecology patients, the prognostic factors they identified included type of surgery, age, leg edema, non-Caucasian ethnicity, severity of varicose veins, previous radiotherapy, and a prior history of DVT.

More than 130 years ago, Rudolph Virchow conceptualized the factors leading to postoperative thrombosis. These included venous stasis, changes in the blood constituents, and impaired function of the vessel wall. The blood clotting process is complicated (Fig. 9.1), but it is initiated by the actions of tissue factor (TF) in factor VII after injury to vessels exposes the subendothelium and promotes platelet adhesion and aggregation to form a primary platelet plug. The process is completed by the actions of multiple components and factors in the blood that generate thrombin, the potent platelet-aggregating enzyme, which then interacts with fibrinogen and factor XIII to form an insoluble clot (Fig. 9.2).

When patients have cancer or sustain venous damage from the surgical procedure, such as occurs with skeletonization of the pelvic vasculature, the up-regulation of thrombin generation has more profound effects. TF, fibrin, and thrombin all have angiogenic properties that can interfere with tissue properties by degrading matrix metalloproteinases, promoting cell migration, and enhancing metastasis. Tumors also up-regulate the production of TF and plasminogen activator inhibitor-1 (PAI-1), again promoting the generation of procoagulant activity. This multifactorial activity helps to explain the high incidence of VTE in the gynecological cancer patient.

These tumorigenic effects on coagulation occur in addition to the typical acute postsurgical reaction of any of the hemostasis proteins. These include increases in fibrinogen, factor V, factor VIII, and von Willebrand’s factor, which promotes platelet adhesion and function. There is usually an increase in
Venous stasis is thought to be the cornerstone of postoperative thrombosis. Venous stasis in the pelvis and lower extremities results in platelet activation, promoting the adhesion of platelets to the endothelial cells lining the vessel, which are already stressed in a procoagulant mode. This results in conditions that encourage the development of a thrombus. These physiological changes in venous hemodynamics occur in the pre-, peri- and postoperative periods. Doran has shown that venous return from the lower extremities is decreased by half during surgical procedures because of the impact of muscle relaxation from anesthetic agents. Scanning using I125 fibrinogen has demonstrated that venous thrombosis is initiated during the surgery in 50% of patients who subsequently manifest a DVT. Lower-extremity blood flow has been shown to decrease to about 75% of the normal drainage flow in the immediate postoperative period. This is an important reflection of Virchow’s triad on the role of adequate vessel flow. This reduction in flow persists for about 14 days after surgery because of the loss of muscle-pumping function in the legs. The major site of thrombus formation is the soleal venous sinuses of the calf, a portion of the venous arcade that joins the posterior tibial and plantar veins draining the soleal muscle. Thrombi from these sinuses often occur posterior to valves located at the junction where these sinuses drain into the collecting veins. Thrombi often occur in these sinuses and in valve cusps in bedridden patients. Another contributing factor to venous stasis during prolonged surgery is the use of tight packing of the intestines in the upper abdomen with obstruction of the underlying vena cava. The type and length of operation are directly related to the incidence of postoperative VTE, as outlined in Table 9.1.

**Diagnosis of Venous Thromboembolism**

The traditional clinical methods used to diagnose venous thrombosis of the lower extremities are of limited value, with error rates approaching 50% for both false-negative and false-positive rates. Most of the diagnostics problems occur because of the insidious nature of venous thrombosis in the lower extremity, which takes place in the soleal veins. Modern imaging methods have evolved considerably in recent years, ranging from I125 fibrinogen scanning to venography to Doppler duplex ultrasound and impedance plethysmography. Although venography remains the gold standard, compression ultrasonography is widely used, having a good negative predictive value (98%) for proximal DVT and slightly lower (96%) for calf DVT. However, it is still inferior to venography, which remains the reference source (Table 9.2).

**Venography**

The venogram has had the most extensive and rigorous use in clinical practice of all imaging techniques. However, it is not routinely used because it is invasive, uses contrast dye, has limitations, and provides an increased risk in many patients who have renal compromise.

**1125-Labeled Fibrinogen Scanning**

This technique was first developed in the 1960s and used widely for many years. It involves the intravenous injections of isotope-labeled fibrinogen, which is expected to be incorporated into the evolving thrombus and can be imaged by a scintillation scanner. Because of the use of isotopes, it is technically cumbersome and rarely used, despite many large studies

Validating its use in the 1970s and 1980s and a high correlation to venography.

### Impedance Plethysmography

Impedance plethysmography (IPG) is based on the principal of electrical resistance in specific areas of the body. When there is resistance to blood flow that is due to a thrombus, there is marked reduction in the electrical resistance over that vessel. IPG is most useful in proximal venous thrombosis, but is relatively poor in visualizing thrombi below the knee because of the small caliber and slow flow rates through the soleal sinuses. The technique is only about 50% accurate compared with venography in detecting DVT below the popliteal vessels.

Huisman and colleagues evaluated 471 outpatient patients clinically suspected of acute onset DVT. Four sequential IPGs were obtained on days 1, 2, 5, and 10 of the study. Of the 137 patients with abnormal results, 117 (85%) had abnormal results on day 1, with the other 20 patients becoming positive by day 10. When compared with venography, serial IPG had a specificity of 92% and a sensitivity of 100%. The use of serial testing clearly improved the ability to diagnose DVT. Another similar study by Vaccaro and associates involving 252 patients using single-test IPG gave a sensitivity of 84% and a specificity of 78%, confirming the superiority of the serial testing protocol. Given the short length of hospital stays now, it is unlikely that serial IPG would be possible despite its high correlation with venography.

### Doppler Ultrasound

The use of Doppler ultrasound, often with computer color enhancement, has become the most widely used imaging technique for diagnosis of DVT. Its major physiological use is in the measurement of flow velocity in larger blood vessels. In this technique, a reflected sound signal is converted to both an audible form and visual image on a computer screen. In the presence of a thrombosis, there is a decrease in the reflected signal that can be heard or, more likely, can be visualized. Most modern ultrasound machines use color enhancement to identify arteries (red) and veins (blue). This technique is again very useful to identify DVTs in the iliac, femoral, or popliteal veins, but again, its sensitivity falls off markedly when applied to the small vessels in the calf, usually to less than 60%.

### Real-Time Ultrasound

Real-time ultrasound has been compared with venography, and in a study by Aitken and associates, it demonstrated a sensitivity of 94% and a specificity of 100% in a small study of 46 patients. In a slightly larger study of 121 patients by Appelman and colleagues, the sensitivity was found to be 96%, and specificity was 97%.

---

**Compression Ultrasound**

This technique has been used in some large DVT trials, such as the PREVENT trial, but there have been few studies directly comparing it with venography. In a recent small study by Tomczowski and colleagues involving 160 medically ill patients, 12 patients had venographically proven DVT. Compression ultrasound technique had a sensitivity of 28% and a specificity of 98%, but despite the small numbers of venographically confirmed patients, the method performed poorly, having both false-positive and -negative findings.

**Duplex Doppler Ultrasound**

This is a combination technique using real-time and Doppler methods in a procedure known as B mode or duplex Doppler imaging. It allows a radiologist to visualize the vessel and identify any thrombus in it. In a study by Langfeld and colleagues, 451 patients were examined; 86 patients had a DVT. This gave a sensitivity of 100%, but two false positives dropped the specificity to 78%. Technical issues may have given one incorrect result, the second patient was pregnant, and the study was considered falsely positive because of aortocaval compression from the pregnant uterus.

In a study by Kristo and associates comparing duplex Doppler, venography, and single bilateral IPG, the respective sensitivities and specificities were as follows, respectively: ultrasound, 92% and 100%; venography, 100% and 75%; and IPG, 50% and 83%. For many reasons, duplex B mode imaging has become the noninvasive imaging method of choice, essentially replacing venography as the “practical” gold standard.
Light Reflection Rheography

Light reflection rheography (LRR) uses infrared light directed at the skin. The backscattered rays are quantitated, which allows an estimation of blood volume. A decreased venous emptying rate of 0.35 is considered positive for DVT. In a study in patients with gastrointestinal problems in which 69 limbs were tested by venography and LRR, the sensitivity for LRR was 96%, the specificity was 83%, the positive predictive value was 79%, and the negative predictive value was 97%. LRR could prove to be a low-cost, sensitive tool for DVT detection. Further studies are needed to determine if the technique fulfills its early promise. However, in one study of 411 asymptomatic pregnant women in second and third trimesters who did not have DVT, the use of LRR denoted a significant false-positive rate of 25% and an inadequate study rate of 19%. This gave an overall specificity of only 45%, indicating that LRR is not for use in DVT diagnosis in pregnant women.

Radiosotope Imaging

Various imaging methods have been tried using radiosotopes to try to detect thrombus in both arteries and veins by labeling components of the clotting system, such as platelets or fibrinogen. These components would be incorporated into the developing thrombus, and the focused radioactivity would then allow “visualization” by a detector. Radioactive-tagged antibodies to both platelets and factors have also been used for DVT diagnosis.

Indium111-labeled platelets have demonstrated good success with high sensitivity and specificity. The same is true for fibrinogen125- and technetium99m-labeled platelets. Although all of these radiosotope-labeled methods have some proponents, the advances in computer and ultrasonic methods will probably outweigh significant development of radiosotopic methods for routine clinical VTE diagnosis.

Indirect Computed Tomography Venography

The new and evolving technique of indirect computed tomography (CT) venography, using intravenous contrast medium injection followed by CT scanning of the limbs or chest, has a high potential for detecting DVT or PE. Some early studies have indicated detection of thrombosis at least to calf level and perhaps lower. There are few studies comparing CT venography and CT pulmonary angiography. A recent study by Nchimi evaluated 1,408 patients with both techniques for PE detection and CT pulmonary angiography. A recent study by Wells and associates comparing ICG and D-dimer with contrast venography, the combination of ICG and a negative (normal) D-dimer test gave a negative predictive value of 97%. In this same study, the combination of positive ICG and positive D-dimer had a positive predictive value of 93% for any DVT and 90% for proximal DVT.

The use of an appropriate D-dimer assay in isolation has been shown to have about 95% negative predictive value for exclusion of DVT. Despite numerous studies, there is still no proven consistent correlation between a positive D-dimer assay and venous thrombosis. Because the diagnosis of PE can be difficult in many older patients, especially those with heart failure or other cardiovascular complications, some preliminary studies have been done using combinations of D-dimer, B-type natriuretic peptide (BNP), and cardiac troponins to determine if a better distinction can be made between a PE and an underlying cardiac complication. These studies are likely to be the forerunners for other combinations of lab tests to identify more specific negative or even positive predictive markers for VTE.

Risk Factors for Vascular Complications

Several clinical factors are known to identify the patient with an increased risk for VTE (Table 9.3). The most prevalent and important include age >40 years, obesity >20% above ideal weight, prolonged surgery, and immobility in the pre-, peri-, and postoperative periods. Pelvic malignancy, prior VTE, known thrombophilia risk, severe diabetes, heart failure, prior radiation therapy, and chronic obstructive pulmonary disease all increase the VTE risk.

Age

An autopsy study by Sevitt and Gallagher demonstrated that DVT was most prevalent in patients older than 60 years. Several studies have shown a linear risk of fatal PE with increasing age. Approximately 10% of hospitalized patients’ deaths are due to PE, and only about 33% of these are diagnosed ante mortem. Contributing factors include degenerative changes in the vascular tree, increases that occur in the concentration of many coagulation factors, and, possibly, increased platelet adhesiveness.

Mobility

Prolonged inactivity in the preoperative patient promotes an impairment of venous flow in the lower extremities. Many diagnostic techniques also produce a decrease in muscle tone with a secondary decrease in venous flow. These hemodynamic changes promote shedding of red cells and activation of platelets, setting the stage for VTE during the operative period. This is one of the main risk factors described by Virchow for the etiology of thrombosis.

Studies done using 125I fibrinogen scanning pre- and immediately postsurgery have indicated that in 50% of patients who subsequently developed VTE, the initiation of clot formation occurred during the surgical procedure. This is amplified...

*Highest risk.

during prolonged anesthesia, with generalized muscle relaxation further promoting venous stasis in the lower extremities, which compounds the thromboembolic risk. For this risk, the judicious use of prophylactic anticoagulation in the high-risk patient should include the operative phase and continue at a minimum until the patient is fully ambulatory.

Postoperative immobility also promotes VTE risk by continuing venous stasis, and studies have shown that 66% of patients who develop a DVT do so in the first 48 hours after surgery. Other compounding issues include sitting with legs crossed or dangling over the bed or the exaggerated Fowler position. These positions all produce impairment of lower extremity venous return. Postoperative patients should be ambulated early and aggressively; if ambulation is not possible, they should have their legs elevated to 15 degrees above the horizontal.

**Other Factors**

Other factors include previous VTE, varicose veins, severe diabetes, cardiac failure, chronic obstructive pulmonary disease, and underlying thrombophilia. Given the high incidence of factor V Leiden (5%) and the G20210A prothrombin gene mutations (3%) in the Caucasian populations, which are well-recognized risk factors for venous thrombosis (Table 9.4), these genetic risk factors are common enough to make a major contribution to preoperative thrombosis, even in the patient with no prior VTE history.

Underlying malignancy is a huge contributor to risk, most likely because of the significant up-regulation of TF that is known to occur with many malignancies. Up-regulation of TF increases thrombin generation by several mechanisms and promotes platelet activation and angiogenesis, as discussed earlier.

A review of these risk factors clearly identifies the high-risk VTE patient, and it is essential that these surgical risk variables are identified and understood in designing appropriate thromboprophylaxis and monitoring parameters to prevent venous thrombosis.

and underlying thrombophilia. Given the high incidence of factor V Leiden (5%) and the G20210A prothrombin gene mutations (3%) in the Caucasian populations, which are well-recognized risk factors for venous thrombosis (Table 9.4), these genetic risk factors are common enough to make a major contribution to preoperative thrombosis, even in the patient with no prior VTE history.

Underlying malignancy is a huge contributor to risk, most likely because of the significant up-regulation of TF that is known to occur with many malignancies. Up-regulation of TF increases thrombin generation by several mechanisms and promotes platelet activation and angiogenesis, as discussed earlier.

A review of these risk factors clearly identifies the high-risk VTE patient, and it is essential that these surgical risk variables are identified and understood in designing appropriate thromboprophylaxis and monitoring parameters to prevent venous thrombosis.

**Prophylaxis**

Prevention remains the most effective tool in the treatment of VTE. Between 5% and 45% of gynecological surgery patients develop DVT in their legs; of these, 20% have popliteal or femoral involvement; and of these, 40% will progress to PE with its high mortality. It is imperative that methods for prophylaxis are planned and implemented before surgery (Table 9.5).

At the sixth American College of Chest Physicians (ACCP) Consensus Conference, Geerts and colleagues—in a review of PE in 7,000 gynecologic surgery patients in prospective clinical trials—reported a reduction in the rate of fatal PE of 75% using thromboprophylaxis (Table 9.6).

**Low-Dose Unfractionated Heparin**

Low-dose unfractionated heparin (UFH) has been the mainstay of prophylactic treatment for many years, with numerous prospective randomized clinical trials validating a risk reduction in DVT incidence from 35% to 45% to about 7% in the high-risk patient. In one large study by Kakkar and colleagues (Table 9.7) incorporating 4,000 patients at multiple centers, patients were randomized to 5,000 units USP calcium heparin subcutaneously starting 2 hours before surgery and subsequently every 8 hours thereafter for the next 7 days. The
reduction in VTE between the control group (25%) and the treatment group (8%) was highly significant. The most important finding was the decrease in fatal PE from 16 patients in the control group to two in the treatment group confirmed by autopsy. Because there is no change in the activated partial thromboplastin time (APTT) because of the low level of subcutaneous heparin, there was no increase in postoperative bleeding. This is because the main impact of the low-dose heparin is exerted via antithrombin through factor Xa, as well as directly on thrombin. There is also a secondary effect in which heparin releases tissue factor pathway inhibitor (TFPI), which also helps to down regulate factor Xa by forming a complex involving TF:F Xa:F VIIa:TFPI.

These studies, as well as those shown in Table 9.8, clearly validate the efficacy of low-dose UFH in reducing VTE in

surgical patients using an initial dose of 5,000 units 2 hours before surgery, and then 5,000 units every 12 hours for the next 5 days. For the truly high-risk patient, such as those with a prior VTE or multiple risk factors, 5,000 units every 8 hours should be used.

Low-Dose Unfractionated Heparin/Dihydroergotamine

The combination of low-dose UFH and dihydroergotamine (DHE) treatment was shown to work well by adding the known effect of DHE as a selective venous vasoconstricting agent to the anticoagulant properties of UFH. The data in Table 9.9 support the use of this treatment modality, but none of these products are now sold in the United States.

Dextran 70/Dextran 40

In 1972, Bonnar and Walsh described the use of dextran 70 to prevent thrombosis after pelvic surgery. A subsequent study by Birnstein and colleagues involving radical hysterectomy patients using dextran 70 as prophylaxis showed a decrease in DVT incidence from 33% to 5%. Dextran works by interfering with platelet function, interacts with factor V and VIII, and inhibits fibrinolysis. Despite some comparable studies between dextran and low-dose UFH, the Sixth ACCP Consensus Conference in 2001 recommended against using dextran products in VTE prophylaxis.

Low-Molecular-Weight Heparins

LMWHs act by primarily inhibiting factor Xa with a small component of activity against thrombin. They now have become the mainstay of prophylaxis treatment and are continuing to replace all other forms of drug therapy. The drugs have a longer half-life than UFH and are much more biopredictable. If LMWH levels are measured in patients using an anti-Xa assay, there is a remarkable homogeneity of response. This has led the U.S. Food and Drug Administration (FDA) to recommend against the need to monitor when used LMWHs are for VTE prophylaxis. There are currently four LMWH drugs available in the United States (Fragmin, Lovenox, Innohep, and Arixtra). They are subtly different in molecular weights and in manufacturing processes, but in essence, they are almost identical in clinical efficacy. They are not, however, dosed in the same way, some using milligrams and other units, or even units per kg. Pharmacies can provide accurate dosage information about any of the products available.

Multiple studies reported in the literature essentially show equivalence or better for the LMWHs compared with UFH in the prevention of VTE, but almost all of these show a much lower bleeding risk for the LMWH treatment groups, even with hard data for bleeding risk being quantitated by transfusion requirements. LMWHs have also been compared with dextran and used in combination with DHE with good outcomes, but the reality is that in normal clinical practice, LMWHs by themselves provide adequate protections with minimal complications. One other advantage of the LMWH preparations is their much lower incidence of heparin-induced thrombocytopenia (HIT) when used as de novo therapy. However, if a patient has had HIT in the past, these preparations should not be used because there is about a 90% cross-reactivity between UFH and LMWH for the antibody causing HIT. One exception to this is Arixtra, the synthetic factor Xa inhibitor, which has not been shown to cause clinical HIT to date. It is highly likely, given the once-per-day dosage requirement and the lack of HIT risk, that LMWHs will continue to dominate in uses for thromboprophylaxis in VTE.

Compression Modalities

As long ago as 1944, Stanton et al. used static compression to decrease venous stasis by decreasing the luminal diameter of the veins, increasing blood flow velocity. In the mid-1970s, Segel

and colleagues showed an increase in blood velocity of 20% using graduated compression stockings but a 200% increase in velocity using intermittent sequential compression.

Mittelmann and colleagues showed that uniform intermittent calf compression was not as effective as intermittent sequential compression at increasing thigh blood flow. This is another example of a component of Virchow's triangle, namely, stasis being involved in the VTE protection mechanism.

It is possible that another component of the triad—the coagulation system—is also influenced by intermittent pneumatic compression (IPC) because several groups have shown that it stimulates fibrinolysis, perhaps by increasing prostacyclin production. Prostacyclin is a potent natural vasodilator and antiplatelet agent released from endothelial cells. Guyton and colleagues found increased quantities of 6-keto prostaglandin F1α in patients undergoing IPC compared with controls. The 6-keto prostaglandin F1α is a specific breakdown product of prostacyclin. Frango and associates have shown a 16-fold increase in prostacyclin production in cultured endothelial cells submitted to pulsatile shear stress compared with a twofold increase with contact shear stress.

Graduated Compression Stockings. Initial studies evaluating antithrombotic stockings proved inconclusive and relied on several different methods to diagnose VTE, which compounded the uncertainty. Sagel and colleagues designed a compression thromboembolism deterrent (TED) hose with graduated pressures of 18, 14, 12, 10, and 8 mm Hg from the ankle to the upper thigh. Scurr and associates evaluated TED hose in a study of 75 patients older than 40 years undergoing major abdominal

surgery in which only one leg had TED hose applied. Using fiberbrinogen scanning as the diagnostic tool, 15 patients had DVTs in the control leg, and only 1 had a DVT in the TED hose leg. A subsequent similar study by Inadla and colleagues found a DVT frequency of 14.5% in the control leg and only 3.6% in the TED leg. Malignancy is a powerful predisposition to VTE secondary to stasis and TF production by the tumor. In a study by Allan and associates assessing the efficacy of TED stocking in patients undergoing abdominal surgery for malignant and benign diseases, the incidence of DVT in the benign disease group was 24.5% in the control limb and 6.1% in the TED limb. However, in the malignant disease group, the incidence of DVT was only slightly increased in the control limb at 27.9%, but the incidence of DVT in the TED limb was significantly higher at 11.5%, clearly amplifying the impact of the tumor on the DVT risk. The Sixth ACCP Consensus Conference suggested that TED hose with early ambulation was an acceptable and effective means of VTE prophylaxis in the low-risk gynecology surgery patient.

External Intermittent Pneumatic Compression. These techniques also promote increased blood flow in the lower extremities that is due to decreased stasis and improved fibrinolysis. Nicolaidis and colleagues compared intermittent sequential pneumatic compression, nonsequential (one chamber) pneumatic compression, and UFH in the prevention of DVT. Using pressures of 35, 30, and 20 mm Hg sequentially for 12 seconds at the ankle, calf, and thigh, they observed a 240% increase in peak blood velocity. In contrast, using the single-chamber device at 35 mm Hg, the increase was only 180%. The single-chamber device was more effective than the single-chamber device and was as effective as 5,000 units of UFH every 12 hours in preventing DVT. In addition, the intermittent sequential device increased the time interval for clot formation proximal to the calf compared with UFH. In another study, the same authors compared electrical calf stimulation, low-dose UFH, intermittent sequential compression, and TED hose in 150 patients older than 30 years undergoing major abdominal surgery. The incidence of proven DVT was 18%, 9%, and 4%, respectively. In a similar study in patients undergoing surgery for gynecological malignancy comparing no thromboprophylaxis to nonsequential external compression, the control group had a VTE frequency of 34.6%. In the compression treatment group, the VTE incidence was reduced to 12.7%. Diagnostic tools for VTE were IIP and I131.

**Treatment of Venous Thrombosis**

The initial treatment of VTE in most hospitals still involves the use of intravenous UFH, although some LMWHs are approved for treatment of VTE. Given the potential variability of the hypercoagulable state in these patients, continuous intravenous infusion UFH still remains the easiest drug to use. Most patients are now treated using a weight-based heparin nomogram and are given a loading dose of 80 units/kg to a maximum of 10,000 units. They are maintained on a constant infusion of 18 units/kg, and the first APTT or factor Xa assay should be done at 4 to 6 hours after the initiation of therapy. Because of the large thrombus burden these patients may have, they can or clear use UFH at an accelerated rate; thus, they are often heparinized. Patients with malignancies will typically require higher-than-average doses until the cancer has been surgically removed or treated. Care must be taken to reduce the infusion, or these patients are susceptible to bleeding that is due to heparin overtreatment. There is little place for intermittent bolus treatment with UFH in modern anticoagulation practice.

If the APTT is used to monitor efficacy of UFH therapy, it should be used in conjunction with the laboratory heparin monitoring nomogram. Because APTT reagents can vary widely between institutions, the old concept of using a ratio of 1.5 to 2 times some poorly defined control APTT value is completely outmoded and can lead to erroneous and inadequate anticoagulation therapy.

Standard clinical practices—such as leg elevation to minimize or treat leg edema after a DVT—are still appropriate. Patients should probably not be aggressively mobilized as long as they have significant leg edema. Most patients will require 3 to 7 days of UFH or LMWH treatment, and the modern trend is to rapidly introduce oral anticoagulation, usually within 24 to 48 hours after initiation of heparin therapy. This will not always be possible in this population, but any UFH or LMWH treatment should be continued until the international normalized ratio (INR) is in the therapeutic range of 2 to 3 for several days. Oral anticoagulation is usually continued for 3 to 6 months or longer, depending on the circumstances and any other complicating factors (i.e., prior VTE or congenital thrombophilia).

The patient who is found to have an asymptomatic DVT of the lower extremity poses a dilemma for some physicians. Some feel that this is not a significant risk and should not be treated, but the risk of thrombus extension into the proximal and popliteal veins remains high and is a possibility. Although this is still a small risk for most patients, the longer-term complications of postphlebitic syndrome from the damaged valves in those veins can produce significant morbidity for such patients, leading to chronic leg edema and venous stasis ulceration. For that reason, most practitioners would elect to anticoagulate women with asymptomatic DVT. With the onset of widespread DVT prophylaxis in many hospitals, the problem of whether to treat asymptomatic DVT may become moot.

**POSTOPERATIVE PULMONARY COMPLICATIONS**

Postoperative pulmonary complications (PPCs) after abdominal surgery remain an important cause of increased morbidity, mortality, and resource use. Arterectomy, pneumonia, and pulmonary thromboembolic disease following abdominal surgery continue to occur frequently despite continuing advances in anesthetic, surgical, and postoperative treatment. The incidence of PPCs has surpassed that of postoperative cardiac complications, and PPCs have a greater impact on postoperative outcomes. Gynecologic surgery is increasingly performed in patients with advanced age, multiple comorbid conditions, and increased risk for the development of PPCs. Risk factors for PPCs in patients undergoing a gynecologic surgery procedure vary among studies, but are consistent with other patient groups undergoing abdominal surgical procedures (Table 9.10). The most important PPCs in terms of incidence, morbidity, mortality, and resource use are arterectomy, pneumonia, respiratory failure, and pulmonary thromboembolic disease.

An understanding of the physiology that predisposes to PPCs, the risk factors for their development, and the preventive
The reduction in FRC is multifactorial and includes cranial movement of the diaphragm, chest wall relaxation with reduction in thoracic volume, reduction in respiratory compliance, and shift of central blood volume from the thorax into the abdomen. Reduction in FRC can have marked adverse effects on perioperative gas exchange, especially the development of hypoxemia.

Atelectasis is defined as the absence of gas from a part or the whole of the lungs that is due to the failure of expansion or resorption of gas from the alveoli. It occurs in the dependent areas of the lungs within 5 minutes of anesthetic induction in a patient with healthy lungs. Atelectasis may be caused by compression, gas resorption, or surfactant impairment. Compression occurs when the distending pressure in the alveolus is reduced to a level that causes the alveolus to collapse. In the setting of general anesthesia, compression occurs mainly as a result of impairments in diaphragmatic position and function. In addition to the cephalad movement of the diaphragm that is due to relaxation from anesthesia as described above, increased intrabdominal pressure from bowel edema, peritoneal fluid, and hematoma forces the diaphragm cephalad and contributes substantially to compressive atelectasis. The contractile function of the diaphragm is not altered as a result of an effect of anesthesia itself because diaphragmatic dysfunction, which almost always presents after upper abdominal surgery, does not arise after lower abdominal surgery.

Other factors contributing to postanesthesia pulmonary complications include reabsorption atelectasis, hypoxic pulmonary vasoconstriction, and ventilation/perfusion abnormalities.

Although most gynecological surgery is done in the pelvis, upper abdominal operations are sometimes done by gynecologic oncologists, and extension of the surgical incision and operative procedure into the upper abdomen produce increased respiratory effects. Respiratory muscle dysfunction is the major effect of upper abdominal surgery on respiratory physiology (Table 9.12).

An important change following upper abdominal surgery is a shift in respiratory pump function from the diaphragm to accessory inspiratory and expiratory muscles of respiration. This shift results in a change in the work of breathing which is proportional to the increase in the respiratory force produced per unit of oxygen consumed.

### Perioperative Respiratory Physiology

#### Effects of Anesthesia

General anesthesia results in important alterations in respiratory physiology (Table 9.11). Anesthetic agents influence not only the ventilatory response to oxygen and carbon dioxide but also the pattern of respiration. Inhalational agents and intravenous agents both result in a reduction of the ventilatory response, but differ in their effects on respiratory pattern. The classic breathing pattern produced by inhalational anesthetics is a rhythmic, rapid, and shallow pattern of respiration with no intermittent sighs, whereas intravenous anesthesia is associated with slow, deep respirations. Little metabolism of inhalational anesthetics occurs during surgery, with most of the anesthetic agents stored in the tissues, such as muscle and fat.

At the conclusion of anesthesia, most of the stored anesthetic agent is eliminated via the lungs. As a result of tissue stores, significant concentrations of the anesthetic agent may be present well into the recovery phase, particularly after high anesthetic doses, long anesthetic times, or the presence of cardiopulmonary disease. This prolonged anesthetic effect can lead to clinically significant respiratory depression in the postoperative period.

The number of functional alveolar units participating actively in gas exchange is directly related to the functional residual capacity (FRC). General anesthesia is associated with a reduction in FRC by approximately 16%. This reduction occurs irrespective of the anesthetic techniques used. The cause of the reduction in FRC is multifactorial and includes cranial movement of the diaphragm, chest wall relaxation with reduction in thoracic volume, reduction in respiratory compliance, and shift of central blood volume from the thorax into the abdomen. Reduction in FRC can have marked adverse effects on perioperative gas exchange, especially the development of hypoxemia.

Postanesthesia and Postoperative Care 143
results in a rapid shallow breathing pattern of respiration. The contractile function of the diaphragm is impaired by inhibition of phrenic nerve output by stimulation of visceral and somatic nerve pathways during manipulation of the abdominal viscera and the peritoneum. The less efficient accessory muscles of inspiration, such as the intercostals and neck muscles, assume an increased share of the respiratory effort. Tonic and phasic contraction of the expiratory abdominal muscles also occurs. The net effect on respiratory mechanics is a reduction in lung volumes, including the FRC (which leads to atelectasis), V̇A/Q abnormalities, and hypoxemia. These changes may be aggravated by hypoventilation that is due to the residua of general anesthesia, postoperative sedative-hypnotic therapy, and pain. In addition to a submaximal voluntary activation of inspiratory muscles, pain may also have a direct effect, through unknown mechanisms, on inspiratory muscle function.

Atelectasis

Clinically significant atelectasis occurs in 15% to 20% of patients undergoing abdominal surgery. The pathophysiologic effects of atelectasis include decreased respiratory compliance, increased pulmonary vascular resistance, predisposition to acute lung injury, and hypoxemia. Atelectasis may also be a precursor to more serious PPCs, such as postoperative pneumonia. The definition of atelectasis is not uniform across clinical studies, with most investigations incorporating a global definition of a PPC that includes atelectasis. However, generally accepted criteria for the diagnosis of atelectasis include impaired oxygenation in a clinical setting where atelectasis is likely, unexplained temperature of greater than 38 °C, and chest radiographic evidence of volume loss or new airspace opacity. Risk factors implicated in the development of atelectasis after abdominal surgery include advanced age, obesity, intraperitoneal sepsis, prolonged anesthesia time, nasogastric tube placement, and smoking.

The risk of atelectasis may be reduced by a number of interventions (Table 9.13). Preoperative smoking cessation is effective in reducing respiratory function. Whether postoperative administration of opioid analgesia is superior to patient-controlled analgesia, there is inconclusive evidence as to whether selective gastric decompression is superior to on-demand narcotic analgesia in reducing PPCs. Laparoscopic procedures reduce postoperative pain scores, as well as have a lesser effect on postoperative respiratory function. Through these mechanisms, atelectasis is reduced with a laparoscopic as opposed to open abdominal surgical procedure. Irrespective of the procedure used, postoperative gastric decompression should be used selectively rather than routinely for postoperative nausea, symptomatic abdominal distention, or inability to tolerate oral intake. Routine nasogastric tube use significantly increases rates of atelectasis with- out reducing risk of aspiration in comparison with selective decompression.

Postoperative Pneumonia

Hospital-acquired pneumonia (HAP) is defined as pneumonia that develops 48 hours or more after hospital admission because of an organism that was not incubating at the time of hospitalization. HAP after abdominal surgery has a high attributable mortality, increases hospital length of stay by approximately 11 days, and is associated with a fourfold increase in risk of discharge to a skilled nursing facility. Women have a risk of developing HAP after abdominal surgery that is twice that of men. HAP is caused by a wide spectrum of bacterial pathogens and is occasionally due to viral or fungal pathogens in immunocompetent patients (Table 9.14). Common pathogens

include the aerobic Gram-negative bacilli and S. aureus species. Early-onset HAP, defined as occurring within the first 4 days of hospitalization, is usually associated with a better prognosis and is more likely to be caused by antibiotic-susceptible pathogens. Late-onset HAP (occurring on or after 5 days of hospitalization) is more likely to be caused by multidrug-resistant (MDR) pathogens, which are associated with increased morbidity and mortality. The risk of HAP that is due to MDR pathogens is related to characteristics of the patient, the healthcare environment, and the prescribed medical treatment (Table 9.15).

Bacterial colonization of the lower respiratory tract under conditions that promote bacterial invasion is necessary for HAP to develop. Sources of colonization include air, water, equipment, fomites, and direct transfer from healthcare providers. Among conditions that promote invasion are severity of underlying illness, comorbid conditions, prior exposure to antimicrobials, and exposure to invasive devices, such as nasogastric tube. Risk of colonization may be modified by several means (Table 9.16). Infection control procedures, including guidelines for alcohol-based hand disinfection and appropriate barrier precautions, should strictly be observed. Early removal of invasive devices, in particular nasogastric tubes, and avoidance of endotracheal intubation when noninvasive ventilation is feasible, will reduce the risk of HAP. As one of the mechanisms for initial colonization of the lower respiratory tract includes microaspiration of gastrically residing bacteria, measures to minimize aspiration and to reduce gastric bacterial overgrowth are important preventive measures. All patients should be maintained in a least a semirecumbent position with the head elevated to 30 to 45 degrees. Restriction of the use of stress ulcer prophylaxis to patients who meet criteria (i.e., receiving mechanical ventilation or coagulopathy/therapeutic anticoagulation) is critical in controlling a possible risk factor for HAP. Implementation of a restrictive red blood cell transfusion strategy, in patients without evidence of active bleeding, is proven to reduce infectious complications of all kinds, including HAP. Adherence to such a strategy not only reduces infectious complications but reduces overall in-hospital mortality and may reduce recurrence of malignancy. In patients younger than age 55 and with an APACHE II score less than 25, a hemoglobin target of 7.0 should be adopted, with a hemoglobin target of 9.0 reserved for patients who do not meet these criteria. Strict control of hyperglycemia has been widely adopted as a means of reducing morbidity and mortality, including the risk of infection. Although the optimal glucose target and the means of achieving that target remain controversial, an attempt to limit capillary blood glucose to less than 150 mg/dl in both diabetic and nondiabetic patients appears warranted.

The clinical definition of HAP includes a new opacity on chest radiograph (posterior-anterior and lateral views preferred) plus two of the following: fever greater than 38°C, leucocytosis or leukopenia, and purulent respiratory secretions. The diagnosis of HAP should be supported by sampling of lower respiratory tract secretions, with either an endotracheal aspirate or a bronchoscopic specimen, before the initiation of empiric antibiotic therapy. The initial step in choosing antibiotic therapy for suspected HAP is determination of the patient’s risk of infection with an MDR pathogen (Fig. 9.3). One of the consequences of increasing antimicrobial resistance is an increased probability of inappropriate initial empiric treatment. Inappropriate or delayed empiric treatment results in a substantial excessive attributable mortality and hospital length of stay. Prompt institution of appropriate empiric therapy based on risk stratification for the presence of a possible MDR pathogen is crucial to improving patient outcome in HAP.

Initial therapy should be administered intravenously, with a switch to the enteral route of administration in selected patients with a good clinical response and a functional gastrointestinal tract. Combination therapy should be used initially if patients are at high risk of being infected with an MDR pathogen. Monotherapy is appropriate for those patients deemed to be low risk. Duration of therapy should be based on clinical response and may often be safely terminated before the traditional 14- to 21-day treatment period. Provided the etiologic pathogens is not Pseudomonas aeruginosa, clinical improvement usually takes 48 to 72 hours, and therapy should not be changed during this time unless there is a rapid clinical decline. The responding patient should have therapy tailored to the most focused regimen possible on the basis of microbiologic studies. The nonresponding patient should be evaluated for drug-resistant organisms, complications of pneumonia (e.g., parapneumonic effusion or empyema), extrapulmonary sites of infection, or noninfectious causes of symptoms and signs of pneumonia (e.g., drug fever with drug-induced lung injury).

Respiratory Failure

Respiratory failure denotes either the inability to maintain normal tissue oxygen transport or the normal excretion of carbon dioxide. Clinically, respiratory failure is usually diagnosed by levels of arterial PO2 and PCO2, although the levels that constitute the threshold for respiratory failure are arbitrary. An arterial PO2 of less than 60 mm Hg or an arterial PCO2 of greater than 45 mm Hg generally indicates significant
respiratory compromise in patients without preexisting lung disease. The diagnostic and therapeutic approach to the patient with respiratory failure is dictated by the underlying mechanism of abnormal gas exchange (Table 9.17).

Algorithm for initiating empiric antibiotic therapy for hospital-acquired pneumonia (HAP).
the need for prolonged bladder drainage is anticipated, such as after radical hysterectomy. Increased CO₂ production is a by-product of overall increases in metabolism. Fever, delirium with marked agitation, severe sepsis, overfeeding, and hyperthyroidism would be examples of clinical states associated with increased CO₂ production. Increased dead space is a hallmark of severe chronic obstructive pulmonary disease; in patients with normal lung function, increased dead space is usually due to either pulmonary thromboembolic disease or a change in respiratory pattern. Rapid shallow breathing as a result of the physiologic changes induced by anesthesia, and upper abdominal surgery produces an increase in the proportion of ventilation to the anatomic dead space and a decrease in effective alveolar ventilation. In addition to anesthesia and upper abdominal surgery as causes of respiratory pump dysfunction in the postoperative patient, any other cause of respiratory muscle weakness may result in ventilatory failure. Endocrine disorders, such as myasthenia gravis or hypothyroidism, as well as electrolyte abnormalities, such as hypophosphatemia, are examples of conditions that could significantly contribute to respiratory muscle weakness and pump dysfunction.

Treatment of acute respiratory failure depends on the underlying cause and is best accomplished in an appropriately monitored environment, such as the intensive care unit with the aid of a specialist in critical care medicine, as mechanical support of ventilation—via either conventional endotracheal intubation/mechanical ventilation or noninvasive positive pressure ventilation—may be necessary (Fig. 9.4). Management of mechanical ventilation and its consequences has acquired a level of complexity that mandates subspecialist care and is beyond the scope of this chapter.

**POSTOPERATIVE CARE OF THE URINARY BLADDER**

The most common postoperative problem in the female bladder is atony caused by overdistention and the reluctance of the patient to initiate the voluntary phase of voiding. After abdominal/pelvic surgery, the patient is often unwilling to contract the abdominal muscles to produce sufficient intraabdominal pressure against the dome of the bladder to initiate the voiding reflex. After anterior colporrhaphy, spasms, edema, and ten-derness of the pubococcygeal muscles may obstruct the process of voiding. The operative trauma from plication of the pubovesical fascia causes edema of the urethral wall and submucosa, especially at the urethrovaginal junction, thus contributing to the urinary obstruction.

For spontaneous voiding to occur, the parasympathetic function of the bladder detrusor must be coordinated with the voluntary motor function of the abdominal wall and the levator muscles. In the past, it was customary to insert an indwelling urethral catheter for 5 or more days after vaginal plastic surgery. Although this technique is still used in many clinics, a suprapubic catheter has proved to be an effective alternative. The suprapubic technique was developed and introduced to the gynecologic literature in 1964. When inserted at the time of suprapubic bladder drainage.

**POSTOPERATIVE GASTROINTESTINAL TRACT MANAGEMENT**

Dysfunction of the gastrointestinal tract remains a challenge in postoperative management. Each patient should be treated as an individual and not placed on a standard protocol for

advancing diets. Patients who have had uncomplicated surgery may be given a regular diet on the first postoperative day if bowel sounds are present, if abdominal examination reveals no distention, and if the patient is no longer nauseated from her anesthesia. Seriously ill or malnourished patients or patients requiring extensive bowel surgery may benefit from preoperative and postoperative parenteral nutrition.

It is important to differentiate between postoperative ileus and postoperative obstruction (Table 9.18) if proper therapy is to be initiated promptly with beneficial results. The distinction may be difficult. This is because partial bowel obstruction is often accompanied by a secondary ileus as part of the clinical picture. Only by close clinical monitoring of the bowel sounds, serial abdominal radiographic studies, and frequent white blood cell counts can one clearly separate these two postoperative complications. Adynamic ileus is the more common clinical entity, a fact that may mislead the surgeon into a false sense of security unless he or she remains acutely aware of the

| TABLE 9.18 | DIFFERENTIAL DIAGNOSIS BETWEEN POSTOPERATIVE ILEUS AND POSTOPERATIVE OBSTRUCTION |
|-------------|---------------------------------|---------------------------------|---------------------------------|
| Clinical feature | Postoperative ileus | Postoperative obstruction |
| Abdominal pain | Discomfort from distention but not cramping pains | Cramping progressively severe |
| Relation to previous surgery | Usually within 48–72 h of surgery | Usually delayed, may be 5–7 d for remote onset |
| Nausea and vomiting | Present | Present |
| Distention | Present | Present |

or hyperlipidemia, administering low-nitrogen TPN to patients ing fat emulsion in patients with severe cardiovascular disease. TPN modification can include decreasing or eliminating or renal disease, hyperlipidemia, diabetes, and thyroid attension should be paid to identifying patients with cardiovas- obtained before parenteral nutrition is initiated. Particular at- tention to improving a poor one, the decision to use TPN should not be with renal failure, and increasing the insulin dosage in patients with diabetes mellitus.

The patient's degree of malnutrition should be assessed by taking measurements of several physical indicators, such as actual body weight (ABW) and ideal body weight (IBW), usual body weight (UBW; preillness), creatinine to height index, triceps skin fold thickness (TSFT), and arm circumference (AC). The arm muscle circumference (AMC) is calculated and used as an index of nutritional status.

Fat stores are reflected in the triceps skin fold measurement, whereas somatic proteins are evaluated by measuring muscle mass, such as the AMC. The Frisancho standards (1984) are used to interpret body weight (kg), triceps (mm), and bone-free arm muscle area (cm²). Patients found to be in the 5th to 10th percentiles are severely malnourished and require an an- abolic environment. Weight loss is significant when the (UBW – ABW)/UBW is >10%. Weight loss during starvation occurs at a rate of 0.4 kg/d. Survival also is com- promised when the ABW falls below the 70th percentile of the IBW. In addition to the preceding physical measurements, a thorough evaluation of chemical indicators is required (Table 9.19) before initiating TPN. Extensive monitoring is required while the patient is receiving TPN (Table 9.20).

### Total Parenteral Nutrition

Nutritional support has proved efficacious in patients under- going major surgery and in patients with impaired bowel func- tion, inadequate oral intake, or cancer. A few patients require total parenteral nutrition (TPN) for prolonged periods sec- ondary to their inability to obtain adequate calories orally. Parenteral nutrition may be administered through a peripheral or central access, depending on the patient's initial nutritional status and the time required on TPN.

Hospitalized patients may require TPN for disease pro- cesses such as gastrointestinal tract obstruction, prolonged ileus, short-bowel syndrome, radiation enteritis, intraabdomi- nal abscess, pancreatitis, regional enteritis, and enterocuta- neous fistula. A patient with any condition that prevents oral intake of adequate amounts of food for more than 7 to 10 days probably requires central parenteral nutrition. Because it is much easier to maintain an adequate nutritional state than to improve a poor one, the decision to use TPN should not be delayed.

TPN is not without complications. Many of these pertain to the need for central venous access. Catheter tip infection is one of the more frequently encountered problems. Meticulos- ous aseptic technique when placing the central venous catheter and adherence to aseptic technique when using the catheter mini- mizes the risk of infection. Antibiotic-coated central venous catheters have been around for more than a decade and are coming more into favor as compelling data surface suggesting decreased infection rates with their use. At the Emory Univer- sity Hospital, central venous catheters coated with chlorhex- idine and silver sulfasalazine are being used. Other potential problems with central venous catheters include catheter or air embolism and pneumothorax or hemothorax. TPN itself can cause fluid overload, electrolyte abnormalities, or metabolic disturbances.

### Patient Evaluation

A complete medical history and physical examination must be obtained before parenteral nutrition is initiated. Particular at- tention should be paid to identifying patients with cardiovas- cular or renal disease, hyperlipidemia, diabetes, and thyroid disease. TPN modification can include decreasing or eliminat- ing fat emulsion in patients with severe cardiovascular disease or hyperlipidemia, administering low-nitrogen TPN to patients.
TABLE 9.21

DESIGN OF PARENTERAL NUTRITION PROGRAMS: EXAMPLES

Nonobese patient weighing 60 kg; assume basal Harris-Benedict equation estimate of daily caloric requirements of 1,250 kcal/d

Patient characteristics
1. Euvolemic, normal urine output, and no unusual gastrointestinal losses; therefore, appropriate initial estimate of daily fluid requirement is 30 mL/kg body weight
2. Moderately stressed with normal renal and hepatic function; therefore, appropriate to provide 1.2 g protein per kg body weight
3. Nonobese; therefore, appropriate to provide Harris-Benedict estimate plus 20% for calories, i.e., 1,250 kcal plus 20% = 1,500 kcal

Program design
1. Fluid requirement: 30 mL × body weight; 30 × 60 = 1,800 mL
2. Caloric requirement: Harris-Benedict estimate plus 20%; 1,250 kcal + 250 kcal = 1,500 kcal
3. Protein requirement for moderately stressed patient: 1.2 g/kg body weight; 60 × 1.2 = 72 g protein
4. Fat requirement: 30% of total calories; 30% × 1,500 kcal = 450 kcal
5. Carbohydrate requirement: caloric requirement minus the sum of protein and fat calories; 1,500 – (280 + 450 kcal) = 770 kcal
6. Therefore, consider the following parenteral nutrition formula: 1.5 L amino acids, 5%; dextrose, 15%; plus 250 mL of 20% fat emulsion, which provides 1,250 mL, 1,460 calories, 70 g protein, 200 g carbohydrate, and 500 fat calories

The physical and chemical measurements of malnutrition are subject to many influences during illness and should be treated as confounding variables. For example, albumin values less than 3.2 g/dL are frequently used to indicate malnutrition. Starker and colleagues observed that in hospitalized patients, albumin and body weight measurements in conjunction provided better indications of sodium balance and extracellular fluid volume. In addition, albumin serum levels are required for maintenance of the intravascular colloid oncotic pressure and as a carrier protein. The half-life of albumin is 20 days and thus reflects a depletion of visceral proteins of at least 3 weeks’ duration. Transferrin, with a half-life of 8 to 9 days, provides the clinician with a measurement of recent protein status changes. Because transferrin is required to bind Fe^{2+}, its level is affected by intravascular iron status and can increase during pregnancy, in patients with hepatitis, and in patients receiving estrogen supplementation. Serum protein content can be reduced in protein-losing enteropathy, nephropathy, chronic infections, uremia, and during catabolism. Transferrin reflects recent losses and remains a better indicator of protein status and change than albumin. Total lymphocyte counts of less than 1,500 ml are indicative of an immunocompromised patient. Immunologic skin testing for recall antigens and total lymphocyte counts have been correlated with both nutritional status and morbidity and mortality. Its usefulness in the assessment of nutritional status is limited to confounding variables such as cancer, side effects of cancer treatment protocols, stress of trauma or surgery, and infection. Phosphorus and the trace elements are thoroughly evaluated before initiating TPN and during TPN because they are often depleted with many disease states and are required when alimenting (Tables 9.7, 9.8, 9.9, and 9.19–9.22).

Nutritional Requirements

TPN consists of six components: carbohydrates, fat, protein, electrolytes, vitamins, and trace elements. The Harris-Benedict basal energy expenditure (BEE) accounts for two thirds of the total daily energy requirements, with the remaining one third obtained from protein. Daily requirements for protein are between 1.5 and 2.5 g/kg/day. Patients receiving TPN who are

#### Principles of Anatomy and Perioperative Considerations

Severely malnourished and stressed require larger amounts of protein daily.

The basal energy expenditure (BEE) is calculated as follows:

$$\text{BEE (kcal/d) } = 655 + 9.26(\text{wt}) + 1.83(\text{ht}) - 4.68(\text{age})$$

Height is in cm; weight is in kg.

Once the patient has reached the estimated daily calorie goal, a 24-hour nitrogen balance study is performed by obtaining a 24-hour urine collection and an a.m. electrolyte panel. If a large quantity of fluid from the nasogastric tube, ileostomy, fistula, or wound is present, this also should be collected and sent for nitrogen measurements. Iodine uptake is calculated as follows:

$$\text{Iodine uptake } = \frac{\text{Iodine in } \text{in} - \text{Iodine out}}{\text{Iodine in}}$$

Adding 4 to the N₂ out value accounts for nitrogenous losses in the stool and skin. This does not include an estimate of the
losses from the gastrointestinal tract and wound, as previously described.

\[
\begin{align*}
N_2 (g) \text{ balance} &= N_2 (g) \text{ in} \times \left[N_2 (g) \text{ out} + 4\right] \\
N_2 (g) \text{ out} &= \text{urine volume (mL)} \times \\
&= g \text{ protein/g nitrogen}
\end{align*}
\]

Patients with normal renal and liver function are started on standard total hyperalimentation solution THAS (Table 9.19). Each liter provides a total of 1,020 kcal, including 41 g of amino acids and 230 g of dextrose. The osmolality of this solution is 1,830 mOsm, which therefore necessitates a central venous access. The calories-to-nitrogen ratio of this solution is 137:1 and is optimal in nonstressed patients. The addition of lipids also is effective in promoting a positive nitrogen balance. The total daily sodium concentration should be equivalent to that of normal saline (150 mEq/L). This can be altered to accommodate patients who require sodium restriction or loading. Table 9.23 outlines the recommendation for daily electrolyte requirements. It should be noted that acetate serves as a precursor to bicarbonate, because the latter is not compatible in the THAS solution. Multivitamins are added daily to 1 L of THAS, whereas trace elements are divided equally in the volume to be infused during a 24-hour period. The recommended daily allowances for both fat- and water-soluble vitamins are outlined in Table 9.24.

Blood glucose levels in patients receiving TPN should be between 100 and 200 mg/dL. A minimum of 10 IU should be added to each liter when required. This permits about 50% to adhere to the plastic tubing. This can be supplemented with subcutaneous doses of regular insulin to obtain the desired blood glucose level. About one half to two thirds of the previous day’s requirements are added in divided doses to the THAS solutions.

Intravenous lipids provide a nonprotein source of energy and serve as a source of essential fatty acids. Ten percent fat emulsions (550 kcal/500 mL) and 20% fat emulsions (1,000 kcal/500 mL) are commercially available. In patients receiving standard TPN, 500 mL of 10% fat emulsion are infused twice weekly at a rate of 42 mL/h. However, when fat emulsion is used with peripheral THAS, the patient requires 2 L of peripheral THAS and 1 L of 10% fat emulsion daily. Twenty percent fat emulsions also can be used for calories in patients with glucose intolerance or patients who require a decreased protein-calorie percentage.

Patients deficient in fatty acids present with dermatitis, homocystinemia, thrombocytopenia, elevated liver enzymes, and poor wound healing.

To improve glucose tolerance, the first liter should be started at a rate of 42 mL/h. On the second day, the solution can be increased to 84 mL/h; on day 3, it can be increased to 124 mL/h. If the patient is unable to tolerate this schedule, increments can be decreased to 21 mL/h each day. Treatment monitoring is outlined in Table 9.20. Total nitrogen balance should be recalculated if there is a marked change in the patient’s condition or in the parenteral nutrition administered.

Recent data in the surgical literature suggest that supplementing TPN with glutamine dipeptides improves nitrogen balance, preserves intestinal permeability and absorptive function, and improves recovery of lymphocytes. These authors also demonstrated a shorter hospital stay in postoperative patients receiving glutamine dipeptide-enriched TPN compared with controls receiving TPN alone.

**Initiating Total Parenteral Nutrition**

Safe venous access is required for initiating TPN. A reliable intravenous catheter should be placed into a large central vein with the catheter tip located so that blood flow dilutes the highly concentrated nutritional fluids. The insertion site should also allow easy fixation of the catheter at the entrance site, minimum catheter movement during body movements, and easy dressing changes. A subclavian vein approach satisfies the requirements for safe catheter placement, but neither internal jugular vein nor antecubital fossa placement is optimal. The internal jugular vein should be used only if the subclavian approach has failed. Movement of the head and neck results in an increased incidence of occluding venous access when the internal jugular vein has been cannulated.

**Anatomy of Infraclavicular Subclavian Vein**

In 1952, Aubaniac, a French physician, was among the first to advocate use of the subclavian vein for intravenous infusions. Wilson and colleagues cannulated the superior vena cava through a percutaneous puncture of the subclavian vein. They reported a high percentage of successful cannulations and a low incidence of complications.

As Figure 9.6 shows, the subclavian vein is located within the costoclavicular-scapular triangle, which is bounded anteriortly by the medial end of the clavicle, posteriortly by the upper surface of the first rib, and laterally by the anterior scalene muscle. The anterior scalene muscle separates the subclavian vein from the subclavian artery, which lies beneath and along the lateral aspect of the muscle. The subclavian vein is covered by 5 cm of the clavicle medially and joins the internal jugular vein near the median border of the anterior scalene muscle to form the innominate vein. The innominate vein descends behind the sternum and joins with the opposite innominate vein to form the superior vena cava. The subclavian vein, which is about 3 or 4 cm long, continues as the auxiliary vein below the clavicle en route to the axilla. Several other significant structures occupy this region. The phrenic nerve courses across the anterior surface of the anterior scalene muscle near its attachment to the first rib and courses medially to lie posterior to the subclavian vein. It can be injured if the posterior wall of the vessel is penetrated. The internal thoracic nerve and apical pleura are in contact with the posterior surface of the subclavian vein at its junction with the internal jugular vein. The roots of the brachial plexus form by the fifth, sixth, seventh, and eighth cervical and first thoracic nerves lie lateral to the anterior scalene muscle on the lateral side of the subclavian artery. If a cannulating needle is directed too far laterally, the brachial nerve plexus could be injured or the subclavian artery could be injured.

The allowances, expressed as average daily intakes over time, are intended to provide for individual variations among most normal persons as they live in the United States under usual environmental stresses. Diets should be based on a variety of common foods in order to provide other nutrients for which human requirements have been less well defined.

Weights and heights of Reference Adults are actual medians for the US population of the designated age, as reported by NHANES II. The median weights and heights of those under 19 years of age were taken from Hamill PV et al. *Am J Clin Nutr* 1979;32:607–629. The use of these figures does not imply that the height-to-weight ratios are ideal.

Retinol equivalents. 1 retinol equivalent = 1 mg retinol or 6 mg β-carotene.

As cholecalciferol. 10 mg cholecalciferol = 400 IU of vitamin D.

α-Tocopherol equivalents. 1 mg d-α-tocopherol = α-TE = 1.49 IU.

posterior surface of the clavicle to ensure that the pleura is protected from puncture. By applying suction constantly, the needle passes beneath the skin and immediately aspires dark red blood, which confirms entry into the vein. If the vein is not entered, the needle is withdrawn and readvanced in a similar manner but in a slightly more cranial or caudal direction. As soon as a free flow of blood is obtained, the introduced Teflon sheath is advanced far enough to be certain that it is securely placed within the vein. The sheath is held in place by the connector, the finger is placed over the end of the needle to prevent air embolism, and the internal needle is replaced (Fig. 9.7B) by the silicone infusion catheter that accompanies the central venous pressure kit (Fig. 9.7C). A thin wire stylet inside the infusion catheter allows the catheter to be advanced easily; occasionally, the stylet must be withdrawn slightly to advance the catheter as far as possible into the innominate vein and superior vena cava. The silicone infusion catheter is advanced until the attached connector can be securely wedged into the connector of the Teflon sheath (Fig. 9.7C). After the infusion catheter is connected to an intravenous fluid line, the Teflon

![FIGURE 9.7. Insertion of subclavian catheter for monitoring central venous pressure. A: After locally anesthetizing the puncture site, the needle with overlying introducer catheter is directed medially between the first rib and the clavicle at the junction of the middle and inner third of the clavicle. The needle is held parallel to the anterior chest wall and advanced along the undersurface of the clavicle. Entry into the vein is evident with aspiration of blood in the attached syringe. B: The needle and syringe are removed from the Teflon sheath, and a finger is held over the end of the open catheter to prevent entry of air. C: The silicone infusion catheter is inserted through the introducer catheter until the two connectors meet and lock firmly. D: The intravenous fluid line is connected to the silicone infusion catheter. E: The suture sleeve is advanced to the skin surface, where the catheter is sutured firmly to the skin.]
sheath is carefully withdrawn from the vein, remaining par- 
tially in the subcutaneous tissue while leaving an ample length of the infusion catheter in the vena cava (Fig. 9.7D). A suture sleeve on the introducer sheath is slid down to the puncture site and sutured to the skin (Fig. 9.7E). The tip of the catheter is preferably positioned in the superior vena cava and should not be advanced into the right atrium or ventricle, where it could cause accidental trauma to the heart wall or cardiac arrhythm- 
as. To ensure its continued sterility and proper function, the subclavian vein should be allowed to fill with blood fluids or withdraw blood for laboratory studies, if it is at all possible to avoid these uses. A central venous line for hyperalimentation is an exception to this rule. The dressing should be changed daily, and the catheterization site cleaned with povidone-iodine or a similar antimicrobial solution.

Cardiac and Respiratory Insufficiency

Patients with congestive heart failure require decreased sodium and decreased total fluid volume. The best solution can be pre-
pared from the most concentrated solutions of glucose, amino 
acid, and fat available. Fluid-restricted solutions also may be 
beneficial for patients with respiratory failure, who should re-
ceive less total glucose in favor of more fat because the respira-
tory quotient (CO2/O2) of glucose (1.00) is greater than that of fat (0.70) and because excess glucose will increase the load of CO2, the lungs must excrete. Excessive total caloric intake resulting in fat synthesis from glucose substrate may severely compromise respiratory function because large amounts of CO2 are released (respiratory quotient 8.0).

Discontinuing Total Parenteral Nutrition

Before discontinuing TPN, the patient should tolerate an en-
teral diet that provides adequate calories. It is permissible to al-
iment patients with an enteral diet before decreasing the THAS 
solution. An abrupt discontinuation of central parental nu-
trition results in rebound hypoglycemia. Our recommendation is to decrease the THAS stepwise to 42 mL/h before contin-
uation. Some institutions recommend that the patient receive 10% dextrose for an additional 12 hours once central par-
tenteral nutrition has been discontinued.

The Team Approach to Total Parenteral Nutrition

TPN can now be safely administered to patients in many hos-
pitals because of the existence of a team of physicians, nurses, 
and health care professionals. Although the composition and 
exact function of the team members vary between hospitals, 
most teams consist of a physician, nurse, pharmacist, and nu-
tritionist. The role of the team varies in each institution from 
consultation to complete management of the patient’s nutri-
tional needs. The team approach by either method is highly 
beneficial because it provides a high concentration of personnel 
with knowledge, expertise, and interdisciplinary communica-
tion at the patient’s bedside. Team members can provide con-
tinuing education on nutrition therapy, continuously audit and 
collect quality control data, and investigate ways to improve 
the safety and efficacy of TPN as a treatment modality. Most teams operate with a standardized protocol that covers patient 
assessment, catheter insertion techniques, solutions used, and 
monitoring functions performed.

Enteral Nutrition

Enteral nutrition is preferable to TPN. The old adage “if the gut works, use it,” applies for several reasons. Ease of admin-
istration, economic considerations, and decreased number of complications are all advantages of enteral feeding over par-
enteral nutrition. Several studies have shown TPN and enteral 
nutrition equally efficacious in achieving nitrogen balance. Pa-

tients with good bowel function should receive enteral feedings. Relative contraindications to enteral feeding include gastroin-
testinal bleeding, diarrhea, and intestinal obstruction. Small-
bore nasal feeding tubes are placed in the stomach, duodenum, 
or jejunum. An abdominal radiograph should be obtained to con-
firm placement. Failure to obtain appropriate studies may result in tube placement in the trachea. Alternatively, a gas-
trostomy or jejunostomy tube could be placed for long-term 
enteral nutrition (Table 9.25). Several products are commer-
cially available (Table 9.26). Enteral tube feedings are routinely 
administered by pump, with either bolus feeds to the stomach 
or continuous feeds to the small bowel, and should be adminis-
tered by pump at 25 to 30 mL/h with gastric residuals evaluated 
every 4 hours. Table 9.27 shows the essential and nonessential 
amino acids.

### TABLE 9.25

<table>
<thead>
<tr>
<th>PROTOCOL FOR ENTERAL TUBE FEEDING</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nasogastric route: Use small-bore, flexible tube (8F preferred); obtain radiograph after placement to confirm position. Use feeding pump for continuous feeding. Begin with full-strength formula at 25–30 mL/h and, if tolerated, increase by 25–30 mL/h at 12-h intervals until desired total volume is reached. Check gastric residuals every 4 h; if greater than 100 mL, hold feeding, and repeat at hourly intervals until residuals are less than 100 mL before resuming feeding. Irrigate with 30–50 mL of water after each residual check or after any medications are given. (If patient requires additional free water, use greater volumes of water for irrigation.)</td>
</tr>
<tr>
<td>If patient experiences diarrhea or intestinal cramping, slow rate of feeding or decrease concentration of formula.</td>
</tr>
</tbody>
</table>

*When using hypertonic formulas or feeding into the jejunum with a nasojejunal or jejunostomy tube, diluting the formula to one-half or three-quarter strength may improve tolerance initially. The concentration then can be increased after the desired volume is reached.*

### ROUTINE ORDERS

When the patient has fully recovered from the anesthetic and is ready for return to the nursing floor and routine postoperative care, we have found the basic postoperative orders shown in Figure 9.8 to be useful. They are a general outline. This list should be expanded to include the special needs of each postoperative patient.

It is imperative that each patient be evaluated before being transferred from the recovery room. If the patient is not ready for transfer, additional efforts are made to stabilize the patient.

or transfer her to an intensive care bed. On transferring, the frequency of physicians’ rounds should be based on the severity of the patient’s condition. All patients should be evaluated on the evening of surgery and appropriate documentation made in the chart. A thorough evaluation of the vital signs, catheter drainage (nasogastric, peritoneal, and Foley), and pulmonary status is required, and abdominal examination is performed. Each physician has a desired protocol for postoperative management. The routine orders outlined in this chapter provide the clinician with a framework to design patient care plans that address the individual patient’s requirements. Laboratory and radiographic evaluation of the postoperative patient also is tailored to the individual patient. Unfortunately, many physicians are predominantly concerned with quantitative test values. However, it is just as important to develop a close rapport with the patient, the patient’s family, and the nursing staff. Only through good communication can the gynecologic surgeon deliver optimum medical care.

#### BEST SURGICAL PRACTICES

- Ten percent of hospital deaths in the United States are secondary to a PE.
- Tumors up-regulate the production of TF and PAI-1, which promotes coagulation and VTE.
- Anti-factor Xa assay can be used to monitor patients who are anticoagulated with LMWHs.
- General anesthesia is associated with a reduction of FRC by approximately 16%.
- Atelectasis occurs in 15% to 20% of patients undergoing abdominal surgery.
- An arterial PO2 of less than 60 mm Hg or an arterial PCO2 of greater than 43 mm Hg indicates significant respiratory compromise in patients without preexisting lung disease.
- Increased CO2 production is a by-product of increased metabolism (i.e., fever, marked agitation, severe sepsis, overfeeding and hypothyroidism).
- During stress, urinary nitrogen levels may increase greater than or equal to 20 g in 24 hours, corresponding to a loss of 600 g of hydrated body protein.

#### BASIC POSTOPERATIVE ORDERS

WATER, ELECTROLYTE, AND ACID–BASE METABOLISM

CHAPTER 10 WATER, ELECTROLYTE, AND ACID–BASE METABOLISM

JACK B. BASIL

DEFINITIONS

Anion gap—A concept used to estimate anion and cation levels in serum and conditions that influence them. It is estimated by subtraction of the sum of the chloride and bicarbonate anions from the sodium cations \([\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)]\).

Extracellular fluid (ECF)—The compartment outside of cells that contains approximately one third of the volume of body water.

Henderson-Hasselbach—An equation for stating the expression for the dissociation constant of an acid. This equation may be expressed in terms of the bicarbonate, where

\[ \text{pH} = 6.1 + \log \text{HCO}_3^- / \alpha \text{[HCO}_3^-] \]

where \( \alpha = 0.03 \text{mM/L/mm Hg at } 38^\circ \text{C} \).

At normal blood pH 7.4, the ratio of \( \text{HCO}_3^- / \alpha \text{[HCO}_3^-] \) is 20 to 1.

Metabolic acidosis—Acidosis resulting from increase in acids other than carbonic acid.

Metabolic alkalosis—Alkalosis in which plasma bicarbonate is increased and there is a rise in plasma concentration of CO2.

Oncotic pressure—The total influence of the protein on the osmotic activity of plasma water.

Osmotic pressure—The pressure that develops when two solutions of different concentrations are separated by a semipermeable membrane.

Respiratory acidosis—Acidosis secondary to pulmonary insufficiency resulting in retention of carbon dioxide.

Respiratory alkalosis—Alkalosis with an acute reduction in the partial pressure of carbon dioxide. Proper management of fluids and electrolytes in the gynecologic surgical patient is of extreme importance. Gynecological surgical patients can differ in age, baseline nutritional status, and in the complexity of medical problems that they possess. The stresses of surgery and the bodies’ complex responses to that stress need to be understood to best care for these patients. The tendency to standardize postoperative care for all patients should be avoided.

The human body is about 60% water by weight (Table 10.1). An exchange of approximately 2 liters of fluid per day exists normally. This is a balance between an intake of 1,500 mL orally and 500 mL from foodstuffs, and an output of between 750 and 1,300 mL of urine, 500 mL in insensible losses, and 300 mL in stool. Thus, total body water, body weight, osmolality, and oncotic pressure are critical concepts if one is to understand water metabolism. Comprehension of renal physiology, electrolytes, and acid-base metabolism is also important. This chapter discusses these concepts in detail.

RENAI PHYSIOLOGY

Blood enters the glomerulus by way of afferent arterioles. The filtration process begins with the filtrate passing into Bowman’s space. Filtration depends on hydrostatic pressure, which forces the filtrate out of the capillary, and oncotic pressure, which holds the filtrate in. The oncotic pressure in the glomerulus usually is negligible, resulting in net flow into Bowman’s space.

The filtrate then passes into the proximal tubule, where an isosmotic solution of sodium bicarbonate, glucose, water, and amino acids is absorbed. The filtrate (urine) enters the descending portion of the loop of Henle, where it becomes hypertonic secondary to absorption of water into the interstitium. As urine flows up the ascending limb, sodium and chloride are absorbed, making the urine more dilute. Urine then enters the distal convoluted tubule, where active absorption of sodium occurs with exchange of potassium. Under the control of antidiuretic hormone (ADH), water is absorbed from the urine (in the collecting tubule and duct) into the interstitium, causing concentration of urine. Hydrogen ions secreted from tubular cells into the lumens of the tubules help maintain pH balance. Carbonic anhydrase in the renal tubular cells causes the transformation of water and carbon dioxide to bicarbonate and free hydrogen ion (Fig. 10.3). In acidic states, bicarbonate is reabsorbed into the bloodstream, and hydrogen ions are excreted into the tubular lumen. In alkalotic states, the opposite occurs.

OSMOTIC FORCES (OSMOLALITY AND OSMOTIC PRESSURE)

If a solute is added to pure water, then the presence of the second molecular species interferes with the normal activity of water molecules. As a result, water diffuses more slowly through the solution, and the solution has a higher boiling point and lower freezing point. These effects of solute on the colligative properties of water are related principally to the number of molecules present per unit volume rather than to the specific kind of molecule or the total weight of solute present. The determination of osmolality is a measure of the number of molecules in the solution that is effective in reducing the concentration and, therefore, the chemical properties of water. The slower rate of diffusion of water caused by the solute accounts for the fact that water diffuses from zones of low osmolality (high water concentration) to zones of high osmolality (low water concentration). The hydrostatic pressure that must be applied...
FIGURE 10.1. Passive model of the concentrating mechanism in the inner medulla. Arrows indicate movements of water (H₂O), sodium chloride (NaCl), and urea between the tubule and the interstitium. In the vaso estra, there is perfect exchange between the two limbs. [From: Jamison RL, Buerkert J. The urinary concentrating mechanism. N Engl J Med 1976;295:1039, with permission.]

*The intravascular water space is about one fourth of the extracellular water space. The intravascular volume is substantially larger than the extracellular water space because of the additional space occupied by blood cell and plasma proteins. The intravascular volume (blood volume) is about 7% of body weight or slightly less than 4 L in a 60-kg person.

Just as crystalloids in solution, such as Na⁺, Cl⁻, and urea, reduce the concentration of water, so do colloids, such as albumin and globulins. In biologic solutions, however, the contribution of proteins in lowering the effective concentration of water is far less than that of crystalloids, because there are far fewer protein molecules than crystalloid molecules. One gram of albumin (molecular weight [MW] 68,000) theoretically yields 0.015 mOsm ([(1,000 mg/68,000 mg mOsm/L) × 1 mOsm mmol/L], whereas 1 g of sodium chloride theoretically yields 34.3 mOsm [(1,000 mg/58.5 mg mmol/L) × 2 mOsm mmol/L]. Thus, gram for gram, sodium chloride is theoretically 2,100 times more effective in increasing the osmolality of a solution than albumin. The oncotic pressure of solutions is expressed in millimeters of mercury (mm Hg) for the same reason that osmotic forces are expressed in units of hydrostatic pressure.

Although oncotic forces are small in relation to osmotic forces, they are important in biologic systems because plasma proteins are selectively retained in the intravascular space. Thus, the effective concentration of water and electrolytes is selectively reduced in the intravascular space compared with the interstitial space. All other things being equal, this results in diffusion of water and electrolytes from the interstitial to the intravascular space. At the capillary level, however, where these oncotic forces are at work, the capillary blood hydrostatic pressure opposes an inward diffusion of water and electrolytes. At the arterial end of the capillary, the effect of capillary blood hydrostatic pressure (1–35 mm Hg) pushing fluid outward is greater than the effect of capillary blood oncotic pressure (equivalent to 25 mm Hg), causing outward diffusion of each of these solutes to plasma osmolality can be directly determined in the clinical laboratory by measuring freezing point depression or by calculation. Calculation of plasma osmolality (P_{\text{osm}}) from the known concentration of solutes is as follows:

\[
P_{\text{osm}} = 2 \times [\text{Na}] \text{ mEq/L} + \text{glucose mmol/L} + \text{urea mmol/L} + \text{osmolar concentration of other solutes}
\]

For normal plasma:

\[
P_{\text{osm}} = 2 \times 140 \text{ mEq/L}
\]

\[
+ (900 \text{ mg glucose/L}/180 \text{ mg glucose/mOsm}) + \text{other solutes (negligible in normal plasma)} = 290 \text{ mOsm/L}
\]

Most laboratories use different units, and the formula can be shortened to:

\[
P_{\text{osm}} = 2 \times [\text{Na}] \text{ (mEq/L)} + \text{glucose (mg/dL)}
\]

\[
+ \text{BUN (mg/dL)} \times 8 = \text{mOsm/L}
\]

The osmolalities of intracellular fluid (ICF) and ECF are equal because cell walls (except for the collecting duct of the kidney) are always freely permeable to water. Potassium is the major intracellular cation and is found in concentrations of about 150 mEq/L of cell water. Thus, potassium and its accompanying anions—principally phosphate and protein—account for almost all of the osmolality of ICF. In health, Na⁺ is excluded from cells and K⁺ is maintained in cells in most cases because of the cellular Na⁺–K⁺ pump.

**ONCOTIC FORCES (ONCOTIC PRESSURE AND COLLOID OSMOTIC PRESSURE)**

Water, Electrolyte, and Acid–Base Metabolism 163
of fluid. Therefore, net outward movement of water and electrolytes occurs. At the venous end of the capillary, the capillary blood oncotic pressure (equivalent to ~23 mm Hg) exceeds capillary blood hydrostatic pressure (now ~15 mm Hg); therefore, net inward movement of water and electrolytes occurs. In health, the rate of fluid outflow from the arterial end of the capillary equals the rate of uptake at the venous end of the capillary.

**REGULATION OF WATER AND ELECTROLYTE DISTRIBUTION BETWEEN INTRACELLULAR AND EXTRACELLULAR COMPARTMENTS**

Osmotic forces regulate the distribution of water between ECF and ICF. Under all steady-state conditions, ECF osmolality equals ICF osmolality. The implications of these principles when water or solute is added to body fluids are discussed in the following sections.

**Effect of Addition of Water on Extracellular and Intracellular Fluid Volume and Osmolality**

The ingestion of water or the intravenous (IV) infusion of water, as a 5% solution of dextrose in water (D5W), results in expansion of all body fluid compartments. Because the osmolality of all body compartments is the same, the water is distributed in the body water compartments in proportion to their size. For example, 1,000 mL of D5W is infused into a normal 60-kg person with a plasma osmolality of 290 mOsm/L, an ECF of 25% of the body water, and a serum sodium level of 140 mEq/L. Assuming that no excretion of electrolytes occurs, the change in volume of the body water compartments (Table 10.1) when complete mixing has occurred is as follows: The ICF is increased by about 666 mL, and the ECF is increased by about 333 mL. The intravascular water, which is 25% of the ECF, is increased by only about 83 mL. Plasma osmolality decreases by about 2%. This is sufficient to completely suppress ADH release and cause a maximum water diuresis in a normal person.

**Effect of Addition of Solute on Extracellular and Intracellular Fluid Volume and Osmolality**

If solutes that penetrate cells slowly (e.g., glucose) are ingested, infused, or actively excluded from cells (e.g., Na+), water is obligated to remain with these solutes in the ECF so that conditions of osmotic equilibrium between ECF and ICF are met. If these solutes are given in isotonic solutions (i.e., if the osmolality of the solution equals that of body fluids), conditions of osmotic equilibrium are met without shifts of water between ECF and ICF. Thus, the ECF is selectively expanded. On the other hand, if these solutes are ingested without water or given as hypertonic solutions, ECF osmolality rises as these solutes move into the ECF, and water diffuses from ICF to ECF until osmolality in the two compartments is equal. Thus, the ECF expands as the ICF contracts.

Although certain other solutes, such as urea and ethyl alcohol, increase plasma osmolality, they do not affect the steady-state distribution of water between ECF and ICF because these solutes readily penetrate cells and rapidly distribute throughout the body water space. Nevertheless, in non-steady states, such as rapid removal of urea by hemodialysis, transient redistribution of water between ECF and ICF does occur. Such shifts of fluid in brain tissue can lead to significant changes in brain function.

**Regulation of Water and Electrolyte Distribution between the Intravascular and Interstitial Compartments**

As discussed, the regulation of fluid and electrolyte transfer at the capillary level is determined by the balance among oncotic forces, hydrostatic forces, and capillary permeability to plasma proteins. These forces can be perturbed in the following ways. Hyposalbuminemia results in a fall in plasma oncotic pressure, a rise in the effective concentration of water and electrolytes into the intravascular space, and, all other things being equal, net movement of water and electrolytes into the interstitial space. As a consequence, intravascular volume (IVV) decreases, and the kidney responds by retaining sodium and water in an attempt to restore IVV to normal. If the hyposalbuminemia is sufficiently pronounced (≤2.3 g/dL) and the expected renal retention of sodium and water occurs, edema develops before a new equilibrium between outflux and influx of fluid at the capillary level is achieved.

The sequence of events that leads to edema formation is depicted in Figure 10.2. The stimulus to renal sodium and water retention in hyposalbuminemia is a decrease in IVV. In many hyposalbuminemic patients, the retention of sodium and water does not completely restore IVV to normal. In fact, in some patients with marked hyposalbuminemia, massive edema (expansion of the interstitial volume) may be present, yet the IVV may be dangerously low, even to the point of shock. Marked edema also can develop in the presence of extensive lymphatic obstruction, distal to a venous obstruction, or because of ischemic injury. In these situations, the edema sediment accumulates at such a rate that a serious decrease in IVV becomes clinically evident. Once the edema in such patients is established, the IVV and the renal, endocrine, and hemodynamic factors regulating the IVV usually return to normal. Thus, if diuretic therapy is used to reduce the lymphedema, it can do so, but IVV is decreased below normal, possibly adversely affecting hemodynamics.

![FIGURE 10.2. Sequence of events leading to edema formation in hyposalbuminemia.](image)
REGULATION OF WATER AND SODIUM EXCHANGES WITH THE EXTERNAL ENVIRONMENT

The following discussion focuses on the normal response of the kidney to perturbations of sodium or water balance because an examination of the state of renal sodium and water excretion often is key to the understanding of the pathogenesis of a disorder of fluid and electrolyte balance and usually provides the basis for planning appropriate fluid and electrolyte therapy.

Water Balance

Water balance equals water intake minus water output. Sometimes it is assumed that the measurement of fluid intake and output, as it is performed clinically, is a measure of water balance. The difficulty in assessing the state of water balance based on the measurement of intake and output is indicated in Table 10.2, which lists all the sources of intake and output of water from the body. It is evident from this table that only a few of the important components of water balance are included in the measurement of intake and output. For this reason, some serious disturbances of water balance may not be reflected in the intake and output record. Fortunately, the accurate measurement of water balance does not require that special techniques be used to measure the various sources of intake and output of water from the body. Instead, in most clinical situations, changes in water balance can be assessed simply by followings changes in body weight. In the management of a compromised postoperative patient, it is imperative to follow daily weights.

In most clinical situations, changes in water balance occur secondarily to changes in sodium balance. For example, in the pathogenesis of fluid retention in congestive heart failure (CHF), the primary event is positive sodium balance because of a decreased renal capacity to excrete sodium. The ingested water is retained as a secondary event to maintain plasma osmolality at some level set by the thirst mechanism. If sodium had not been retained, water would not have been retained. For this reason, the key to preventing fluid retention in such patients is the regulation of sodium intake and output, not water intake.

Less commonly, a change in water balance is the primary event, and changes in sodium balance are secondary to the change in water balance. To recognize such situations, it is necessary to understand the normal renal response to primary changes in water balance. Because the capacity of the kidneys to concentrate and dilute the urine is commonly evaluated by measurement of the specific gravity of urine, it is first necessary

*Water balance = water intake – water output.*
to consider the relation between urine osmolality (U_{osm}) and specific gravity.

\[
\text{specific gravity} = \frac{W_s}{W_{H_2O}}
\]

where:

\[W_{H_2O} = \text{weight of an equal volume of water; and}
\]
\[W_s = \text{weight of the solution.}
\]

On the average, in normal urine, a linear relation exists between urine osmolality and specific gravity, as shown in Figure 10.3. This relation is disturbed when molecules that have molecular weights much higher than the predominant normal urinary solutes are excreted in large amounts. Thus, in the presence of large numbers of molecules with high molecular weight, specific gravity is no longer a reliable index of osmolality. The normal, predominant urinary solutes are sodium, potassium, chloride ions, and urea, which have molecular weights of 23, 39, 35, and 60, respectively. The commonly encountered urinary solutes that cause large increases in specific gravity but small increases in urine osmolality are glucose (MW 180), mannitol (MW 181), dextran (MW 20,000 to 40,000), iodine-containing radiographic contrast (MW 600 to 800), and protein (but only with heavy proteinuria). If these substances are absent, urine specific gravity can be relied on to reflect urine osmolality. If these substances are present, urine osmolality must be measured directly to determine the true extent to which the kidneys have concentrated or diluted the urine.

Normal Renal Response to Water Deprivation

The permeability of the collecting duct to water is markedly increased when ADH is released. Thus, as the tubular fluid enters the collecting duct, water diffuses from the collecting duct into the hypertonic medullary interstitium, resulting in a marked reduction in urine volume and a marked increase in urine osmolality. In health, the osmolality of the medullary interstitium is 900 to 1,200 mOsm/L. Thus, in states of maximum water conservation, the urine osmolality approaches 900 to 1,200 mOsm/L. In such circumstances, urine flow rates approach 0.5% or less of the normal glomerular filtration rate (GFR), resulting in urine flow rates of about 20 mL/h, or 500 mL/day, when kidneys function normally. Elderly people are unable to concentrate their urine, with maximum osmolalities among the aged often below 800 mOsm/L.

FIGURE 10.3. Approximate relation between specific gravity and osmolality in normal urine.

Normal Response to Water Loading

The administration of water or hypotonic solutions results in a reduction in the osmolality of body fluids. A 2% reduction in plasma osmolality (e.g., plasma osmolality from 290 to 284 mOsm/L, serum sodium from 140 to 137 mEq/L) is sufficient to completely suppress ADH secretion. In an average, healthy adult, the ingestion of 1 L of water is more than enough to elicit such a response and to cause the formation of a maximally dilute urine. When ADH secretion is inhibited and renal function is normal, urine specific gravity usually is less than 1.005, urine osmolality is less than 100 mOsm/kg, and urine flow rates approach 13% to 20% of the GFR (i.e., 10 to 15 mL/min, 600 to 900 mL/h). Elderly patients also cannot dilute their urine as well as young persons, with the minimum osmolality being 200 mOsm/L or slightly higher.

Sodium Balance

Sodium balance equals sodium intake minus sodium output. The components of sodium balance are shown in Table 10.3. From this table, it is evident that the kidneys play the central role in the regulation of sodium balance by adjusting sodium excretion to match sodium intake. Unless there are abnormal losses of sodium through the skin or gut, sodium balance can be assessed simply by determining dietary sodium intake and by measuring the urinary excretion of sodium. These measurements usually are not necessary because if the patient has free access to water and an intact thirst mechanism, water is ingested and retained in proportion to the level of sodium retention. Thus, changes in sodium balance are reflected by changes in body weight. Occasionally, the measurement of urine sodium concentration is useful. For example, when body weight and serum sodium concentration are stable and there are no abnormal extrarenal sodium losses, the measurement of the 24-hour urinary excretion of sodium accurately reflects sodium intake.

Normal Renal Response to Sodium Restriction and Sodium Loading

When sodium intake is abruptly reduced from a normal level (e.g., 170 mEq/24 h) to a very low level (e.g., 10 mEq/24 h), it takes 3 or 4 days until maximal renal sodium conservation occurs. During this period of adjustment, renal sodium output exceeds intake, and water is lost with sodium in isosmotic proportion from the ECF. One to two liters of ECF usually is lost in the change from a normal to a very low sodium intake. Thus, normal people come into balance on a low sodium intake, but the ECF volume then may be regulated at a suboptimal level. This is potentially dangerous because the patient may be vulnerable to the potential hypotensive effects of anesthesia or additional volume losses that can occur during surgery.

The normal renal response to salt loading is analogous to that of salt restriction in that it takes several days for the renal excretion of sodium to increase in response to the higher level of sodium intake. Thus, when balance is finally achieved, ECF volume is being regulated at an expanded level, which can be
effective IVV is greater than normal. That is, because of the stance, the actual IVV could be less than normal, whereas the venous pressure (CVP) and cardiac output. Under this circumstance can develop, resulting in an abnormal increase in central example, in acute metabolic acidosis, increased venoconstriction states, the actual IVV is different from the effective IVV. For change in direct proportion, in a number of important clinical situations and can be expected to maintain an optimal cardiac output and thus maximize tissue perfusion. Although the actual IVV and the effective IVV are the same in many clinical situations and can be expected to change in direct proportion, in a number of important clinical states, the actual IVV is different from the effective IVV. For example, in acute metabolic acidosis, increased venoconstriction can develop, resulting in an abnormal increase in central venous pressure (CVP) and cardiac output. Under this circumstance, the actual IVV could be less than normal, whereas the effective IVV is greater than normal. That is, because of the increase in venous tone, an IVV that is lower than normal can maintain a normal effective IVV.

Acute changes in venous tone induced by drugs (e.g., morphine, furosemide, norepinephrine), changes in acid-base status, and the presence of bacterial endotoxin also can disrupt the normal relation between the actual IVV and the effective IVV.

The most reliable clinical means for assessing the status of the effective IVV is the pulmonary capillary wedge pressure. This measurement is an estimate of the pulmonary capillary pressure, which is a measure of the filling pressure of the left ventricle. Factors that increase pulmonary capillary wedge pressure tend to increase cardiac output by increasing capillary outflux. When effective IVV is considered within these constraints, it becomes clear that under virtually any physiologic or pathophysiologic circumstance, an optimal effective IVV is one that results in a pulmonary capillary wedge pressure that is high enough to promote optimal cardiac output but low enough to prevent pulmonary edema.

Fortunately, in most clinical situations, it is not necessary to resort to measuring pulmonary wedge pressure to assess whether a disturbance of ECF composition is associated with an effective IVV that is abnormally high, abnormally low, or normal. Instead, an accurate assessment of the effective IVV usually can be made by a careful clinical assessment using the criteria listed in Table 10.4. This table lists the bedside and laboratory means to assess volume status according to whether the findings are consistent with an effective IVV that is less than normal or an effective IVV that is nearly normal or expanded.

Also shown in Table 10.4 are the conditions under which the given means for evaluating the IVV must be qualified (i.e., the conditions that may render the meaning of the finding indeterminate with respect to the evaluation of IVV). For example, the relation between an increase in weight and a change in IVV is rendered indeterminate if, at the same time, the patient has additional fluids are administered.

**CLINICAL ASSESSMENT OF DISORDERS OF WATER AND ELECTROLYTE METABOLISM**

Disorders of ECF electrolyte composition may be detected by measurement of the serum electrolyte concentrations. Identification of the process (or processes) behind the disturbance of electrolyte composition and the planning of subsequent therapy are critically dependent on the clinician’s ability to accurately assess whether the disturbance in ECF electrolyte composition is associated with volume expansion, volume contraction, or a normal volume.

In the evaluation of a patient's ECF volume status, it must be kept clearly in mind that the critical volume is that portion of the IVV that is effective in determining the filling pressure of the ventricles and, hence, the cardiac output. Hereafter, this theoretic volume is referred to as the effective IVV.

In light of this definition, the most effective IVV is that which maintains an optimal cardiac output and thus maximizes tissue perfusion. Although the actual IVV and the effective IVV are the same in many clinical situations and can be expected to change in direct proportion, in a number of important clinical states, the actual IVV is different from the effective IVV. For example, in acute metabolic acidosis, increased venoconstriction can develop, resulting in an abnormal increase in central venous pressure (CVP) and cardiac output. Under this circumstance, the actual IVV could be less than normal, whereas the effective IVV is greater than normal. That is, because of the

**DATABASE FOR ASSESSMENT OF EFFECTIVE INTRAVASCULAR VOLUME**

**Body Weight**

All patients should be weighed on admission to the hospital and then periodically during their hospital stay. In patients undergoing surgery, or in whom problems in fluid and electrolyte balance are anticipated, weight must be measured daily. Alterations in body weight are the result of changes in body water content plus solid tissue content (fat, protein, bone). Gains or losses of solid tissue are almost always related to changes in caloric intake and seldom exceed 0.25 kg/24 h. For example, a patient who takes no calories for 24 hours is forced to develop a third space, as in bowel obstruction. In this instance, the entire weight gain could be caused by the accumulation of fluid outside the IVV. Thus, the finding of weight gain in this setting cannot be used as evidence of an increase in effective IVV.

I suggest that the evaluation of effective IVV, using the criteria in Table 10.4, be approached in the following manner. First, whenever a finding can be significantly qualified, it should not be used in arriving at a final decision. Second, as many independent means as practical should be used to assess the effective IVV to minimize the effect of possible error on the final decision. The greater the number of independent, unqualified findings that agree in favor of a given clinical decision, the more likely it is that the decision is correct. If such a systematic approach to clinical decision making is used, it should be possible to arrive at an accurate evaluation of volume status in most circumstances.
to consume her endogenous stores of fat and protein to meet the energy requirements for continued life. The complete oxidation of fat yields 9 cal/g, and protein yields 4 cal/g. It can be readily calculated that the complete oxidation of 0.25 kg of solid tissue (an approximation, a mixture of about 87% fat, 13% protein) yields enough calories to meet basal daily energy needs. Thus changes in weight exceeding 0.25 kg/day are almost always attributable to changes in water balance. Although the relation between body weight and effective IVV can be variable, usually the relation between changes in body weight and IVV can be correctly assessed by the application of the two guidelines. The first is that a decrease in body weight below normal (for the patient), and not explained on the basis of inadequate caloric intake, can be assumed to be accompanied by a decrease in IVV. The second is that an increase in body weight above normal not explained by increased nutrition can be assumed to be accompanied by an increase in IVV except when the weight gain develops in association with the following conditions.

- Significant hypoalbuminemia: serum albumin less than 3 g/dL.
- Venous obstruction or congestion
- Development of third spaces (e.g., obstructed or ischemic bowel)

Under these three general conditions, an increase in body weight may not reflect an increase in the effective IVV.

### Renal Function

Creatinine, a byproduct of muscle energy metabolism, is produced at a constant rate that is related to muscle mass. Normal men produce 20 to 25 mg/kg (ideal body weight)/24 h, and women produce 15 to 20 mg/kg (ideal body weight)/24 h. Nearly all of the creatinine produced is excreted by glomerular filtration. Therefore, changes in the concentration of serum creatinine reflect changes in the GFR, and the clearance of creatinine (Ccr) is an index of the GFR.

\[
\text{Ccr} = \frac{\text{Ucr} \times \text{V}}{\text{Scr}} = \text{GFR}
\]

where:
- \( \text{Scr} \) = serum creatinine,
- \( \text{Ucr} \) = urinary creatinine concentration;
- \( \text{V} \) = urine volume per unit time.

Thus, by rearranging this equation:

\[
\text{Scr} = \frac{\text{Ucr} \times \text{V}}{\text{Ccr}}
\]

Normally, as muscle mass (which is proportional to \( \text{Ucr} \times \text{V} \)) increases, the GFR increases proportionately less. Therefore, on the average, children have lower serum creatinine values than do adults, and large adults have higher serum creatinine levels than do small adults. Because of these considerations, a single range of serum creatinine values cannot be applied on the average, children have lower serum creatinine values than do adults, and large adults have higher serum creatinine levels than do small adults. Because of these considerations, a single range of serum creatinine values cannot be applied to everyone. The suggested normal ranges of serum creatinine for adults, according to ideal body weight, are shown in Table 10.5. Creatinine clearance for men can be estimated, using the formula derived by Cockcroft and Gault, from the patient’s age, body weight, and serum creatinine level as follows.

\[
\text{Ccr in mL/min} = \left( \frac{140 - \text{age}}{72} \times \text{weight in kg} \right) - 0.85 \times \text{Scr in mg/dL}
\]

This result multiplied by 0.85 provides a better estimate for women because of their relatively smaller muscle mass. Azotemia is arbitrarily defined here as a serum creatinine level greater than the upper limit of normal for body size, as shown in Table 10.5. The blood urea nitrogen level is influenced by dietary protein intake, tissue metabolism, and urine flow rate, in addition to GFR, and should not be relied on to assess changes in GFR.

The following guidelines are suggested for the evaluation of the IVV in light of the state of renal function. The azotemia can be assumed to result from decreased renal perfusion if the serum creatinine level is elevated, the urine is concentrated (\( \text{U}_{\text{osm}}/\text{P}_{\text{osm}} \) ratio greater than 1.5; specific gravity higher than 1.015), and renal sodium conservation is present (\( \text{UNa} \), level >20 mEq/L) on a random and untimed urine sample. The fractional excretion of sodium is based on serum and random urine concentrations of sodium and creatinine. If below 1%, azotemia can be attributed to decreased IVV, unless the patient has severe liver or cardiac disease.

\[
\%E = \frac{\text{U}_{\text{Na}}}{\text{Scr}} \times 100
\]

where:
- \( \text{S}_{\text{Na}} \) = serum sodium concentration in mg/dL;
- \( \text{S}_{\text{Na}} \) = serum Na+ concentration in mEq/L;
- \( \text{U}_{\text{Na}} \) = urine sodium concentration in mEq/L;
- \( \text{U}_{\text{cr}} \) = urinary Na+ concentration in mEq/L.

If severe cardiac failure and severe liver failure (hepatorenal syndrome) can be excluded, the decreased renal perfusion can be assumed to be caused by a decreased effective IVV.

### Edema, Ascites, and Pleural Effusion

Effective IVV is increased when edema, pleural effusion, or ascites occurs in the setting of CHF. Increased effective IVV cannot be assumed in the presence of edema, ascites, or pleural effusion if there is significant hypoalbuminemia or venous obstruction, or if the accumulation of fluid is in a relatively small area of capillary injury (e.g., pleural effusion caused by pulmonary infarction).

### Tissue Turgor

Tissue turgor is a function of the elasticity of the solid components of tissue and the degree of distention of the tissues by interstitial fluid. If tissue is depleted of interstitial fluid, it becomes less elastic (i.e., it less readily returns to its original shape after being deformed). Skin turgor is best assessed on the forehead and anterior chest. In patients less than 50 years of age, the turgor of the dorsum of the hand also can be used. In older patients, the elasticity of the solid components of tissue

is decreased, and the turgor of the skin becomes unreliable in interpreting changes in interstitial volume.

Central Venous Pressure

The measurement of CVP is a relatively simple but useful means for monitoring cardiac function and cardiovascular status. For the valid measurement of CVP, the catheter must be placed in the large intrathoracic vena cava near the right atrium (as assessed by chest radiograph), and the catheter must be patent (as assessed by the cyclic variation of CVP with ventilatory movements) to decrease CVP during inspiration, increased CVP during expiration).

In normal adults, CVP is about 5 to 12 cm H₂O. CVPs below 3 cm H₂O are commonly seen in children and young adults who have no evidence of a decreased effective IVV. In older adults and elderly persons, CVP of less than 3 cm H₂O can be assumed to reflect a significant decrease in effective IVV.

CVP is an index of the filling pressure of the right atrium, which, in turn, is an index of the filling pressure of the right ventricle. In uncomplicated circumstances, expansion of the IVV results in increased CVP, whereas contraction of the IVV results in decreased CVP. CVP cannot be used to assess the adequacy of left ventricular function in patients in whom left ventricular function may be impaired relative to right ventricular function. CVP also is unreliable when lung disease is present, because it is normally elevated. In such patients, left ventricular function can be monitored by observing for signs and symptoms of left ventricular failure (dyspnea, development of an audible third heart sound, or pulmonary edema), or by direct measurement of pulmonary capillary wedge pressure. Under normal circumstances, the pulmonary capillary wedge pressure is about equal to the CVP plus 6 mm Hg.

Pulmonary Capillary Wedge Pressure

Technical refinements of the Swan-Ganz catheter make it possible to measure pulmonary artery systolic and diastolic pressures, CVP, pulmonary wedge pressure, and cardiac output using the thermodilution technique with the same catheter. This permits a definitive assessment of the volume status of the patient, because it can be determined whether the cardiac output is appropriate for a given pulmonary wedge pressure. Specific guidelines for the interpretation of the relation between pulmonary wedge pressure and cardiac output are discussed in the following sections.

Patients with Normal Volume Status

Pulmonary wedge pressure can be expected to be between 8 and 12 mm Hg in a patient with a normal cardiopulmonary system and a normal effective IVV. Cardiac output is normal. Pulmonary wedge pressure can be less than 8 mm Hg without indicating volume contraction; in this circumstance, the cardiac output is normal despite the unusually low pulmonary wedge pressure.

Patients Who Are Volume Contracted

Patients who have a normal cardiopulmonary system but who are significantly volume depleted usually have a pulmonary wedge pressure below 8 mm Hg and their cardiac output is less than normal. In patients with chronic pulmonary hypertension (e.g., those with chronic left ventricular failure), a higher than normal pulmonary wedge pressure is needed to drive a satisfactory cardiac output. Thus, in such patients, pulmonary wedge pressure can be above the normal range but be inappropriately low for the patient. This situation can be identified by showing that: (a) cardiac output is less than normal, despite the elevated pulmonary wedge pressure; (b) volume infusion causes an increase in cardiac output toward a more favorable range; and (c) despite further increase in pulmonary wedge pressure with volume expansion, pulmonary function does not deteriorate. (Pao₂ does not decrease, Paco₂ does not increase, and pulmonary compliance does not worsen.)

Patients Who Are Volume Expanded

In patients with a normal cardiopulmonary system, pulmonary wedge pressure usually is above 18 mm Hg when volume expansion is substantial. Cardiac output is above normal. If cardiac function is impaired, cardiac output will be inappropriately low for the level of pulmonary wedge pressure.

When a given pulmonary wedge pressure is being interpreted, the serum albumin level also should be taken into consideration, because this opposes the effect of capillary hydrostatic pressure to cause migration of fluid from the capillary lumen to the interstitial space. Thus, at any given elevated pulmonary wedge pressure, pulmonary edema develops more rapidly in a patient who is hypoalbuminemic than in one who has a normal serum albumin concentration. In some patients, it is not possible to obtain a reliable pulmonary wedge pressure. In most of these patients, the pulmonary artery diastolic pressure is a good estimate of the pulmonary wedge pressure. If pulmonary hypertension is present, then pulmonary vascular resistance is increased; thus, pulmonary artery diastolic pressure may not be a good index of the pulmonary wedge pressure. In such patients, it is important to be able to obtain a wedge pressure. Finally, in patients who are being ventilated with high levels of positive end-expiratory pressure, pulmonary wedge pressure may become unreliable because the high intrapulmonary pressures may cause obstruction of the catheter orifice. Patients must be briefly taken off the ventilator for accurate measurements. Other circumstances in which pulmonary artery wedge pressure measurements may be inaccurate include the presence of mitral stenosis or pulmonary venous obstruction.

Blood Pressure

The following guidelines are suggested for the evaluation of the effective IVV from measurement of blood pressure.

1. A nearly normal or expanded effective IVV can be assumed in patients with hypertension that is demonstrated in the sitting or standing position.
2. Effective IVV may be decreased in patients who previously were hypertensive but who have become normotensive.
3. Effective IVV may be decreased in patients who develop orthostatic hypotension (a drop in systolic pressure greater than 10 mm Hg in changing from the supine to the sitting or standing position).

Orthostatic hypotension also can be present, in the absence of volume contraction, as a result of prolonged bed rest, during the use of such antihypertensive agents as methyldopa (Al-domet) or of vasodilators (Prazosin, Minoxidil). If the pulse rate does not rise as blood pressure falls when a patient stands,
autonomic neuropathy should be considered as a cause of postural hypotension.

Systemic Vascular Resistance

Other measurements of hemodynamic importance derived from Swan-Ganz readings include calculations of resistance across the pulmonary and systemic vascular beds. The calculations are as follows:

\[
\text{PVR} = \frac{\text{Paw}}{\text{QT}} \times 80
\]

\[
\text{SVR} = \frac{\text{PSA} – \text{Pra}}{\text{QT}} \times 80
\]

where:

- \( \text{Paw} \) = mean right atrial pressure;
- \( \text{Pra} \) = mean pulmonary artery wedge pressure;
- \( \text{PVR} \) = pulmonary vascular resistance;
- \( \text{PSA} \) = mean systemic arterial pressure;
- \( \text{QT} \) = cardiac output in liters per minute; and
- \( \text{SVR} \) = systemic vascular resistance.

Normal values are 60 to 150 dyne-s/cm for pulmonary vascular resistance and 800 to 1,200 dyne-s/cm for systemic vascular resistance. Pulmonary vascular resistance is elevated in hypovolemic shock, cardiogenic shock, pulmonary embolism, or airway obstruction; it is diminished in septic shock. Systemic vascular resistance is elevated in hypovolemic shock, cardiogenic shock, pulmonary embolism, and sometimes in right ventricular infarct and cardiac tamponade; it is decreased in end-stage liver disease and septic shock.

Clinical Assessment of Disorders of Extracellular Fluid Composition

Hyponatremia

The schema for the evaluation of a hyponatremic patient depends on the assessment of volume status. That is, it must first be determined whether the patient’s hyponatremia is associated with an effective IVV that is decreased, normal, or increased. Once this is decided on the basis of the assessment of IVV, a further separation, based only on the state of renal sodium and water excretion, is made. Each of the final categories contains relatively few diagnostic possibilities, and the presence or absence of each of these conditions in a given patient usually can be readily determined. The scheme for the evaluation of a hyponatremic patient is analogous, except that it depends on the assessment of the state of renal water excretion.

Clinical Assessment

In the discussion that follows, only patients with true hyponatremia are considered (i.e., hyponatremia in which serum osmolality is decreased in proportion to the reduction in serum sodium concentration, after appropriate correction for any elevation in the plasma urea nitrogen). By making this distinction, hyponatremia caused by accumulation of ECF solutes such as glucose or mannitol can be excluded. In this type of hyponatremia, the decreased concentration of ECF sodium is the result of the shift of water from cells to the ECF in response to the osmotic gradient caused by the accumulation of the solute. As a consequence, the hyponatremia is associated with an increased plasma osmolality. These patients also can be readily identified either by the presence of hyperglycemia sufficient to explain the decrease in serum sodium concentration or by a history of administration of large amounts of mannitol (0.100 g in adults), usually in the presence of a decreased capacity to excrete mannitol (decreased GFR).

Also to be excluded are patients with spurious hyponatremia that results from the abnormal accumulation of plasma lipids or proteins. In such circumstances, the concentration of sodium in plasma water is normal; however, the concentration of sodium expressed per liter of whole plasma is reduced because an abnormally large volume of whole plasma is occupied by the lipids or proteins, which do not contain plasma water and electrolytes. Thus, when aliquots of hyperlipemic or hyperproteinemic plasma are analyzed, a lower amount of sodium is determined to be present in a given volume of whole plasma. Plasma osmolality, however, is normal because lipids and proteins do not contribute importantly to plasma osmolality (see section on osmotic forces). Patients with spurious hyponatremia can be readily identified by the presence of markedly elevated total serum protein levels (e.g., multiple myeloma) or grossly hyperemic serum. The distinction can be readily made if lipemic serum is subjected to centrifugation and the lipoprotein layer is removed before evaluation, if flame photometry is being used for measurement of serum Na⁺. Spurious hyponatremia is no longer a consideration in most laboratories, because serum Na⁺ concentration is determined by ion-specific electrodes, and increased levels are not affected by lipemic serum. Symptoms of hyponatremia include increased tendon reflexes, lethargy, mental confusion, and muscle twitching, which are followed by convulsions, coma, and possibly death if levels fall beneath 115 mEq/L.

Hyponatremia and Volume Depletion Associated with Renal Sodium Wasting

The normal renal response to volume depletion and hyponatremia is the virtual elimination of sodium from the urine (Fig. 10.4; see section on Sodium Balance). Thus, the presence of an excessive amount of urinary sodium under these conditions indicates that renal sodium loss is the cause or a major contributory factor to the state of sodium depletion. A spot urine sodium concentration greater than 40 mEq/L, a %E/FNa above 1%, or a urinary sodium excretion rate greater than intake indicates such renal sodium wasting. The conditions discussed in the following sections are associated with hyponatremia, IVV depletion, and renal sodium wasting.

Chronic Renal Disease. All types of renal disease can be associated with renal salt wasting. In adults with such a disorder, the serum creatinine level is virtually always above 2 mg and usually much higher before a significant salt leak develops. These azotemic patients usually require 85 to 170 mEq of sodium daily (3 to 10 g of sodium chloride) to maintain salt balance at a normal effective IVV. Thus, if sodium intake is decreased in azotemic patients by anorexia or vomiting, or if additional sodium losses occur (e.g., diarrhea or diuretic therapy), the inability of the diseased kidneys to conserve sodium and water normally may rapidly lead to the development of significant sodium and water deficits. Water intake usually continues; therefore, sodium balance is more adversely affected than water balance. As a consequence, the patient becomes contracted with hyponatremia. With the onset of CHF or the nephrotic syndrome, the salt leak of chronic renal failure usually disappears, and salt intake must be restricted.
Hypotonic fluid losses from the skin also can occur after burns or other skin injuries. These are isotonic losses of sodium and lead to hyponatremia if the water losses are more adequately replaced than the sodium losses.

Diuretic Therapy. The diuretics include thiazide agents or loop diuretics, such as furosemide, bumetanide, and ethacrynic acid. Diuretics induce a renal salt-wasting state, and if the urinary output of sodium exceeds intake, sodium depletion ensues. Rarely, diuretics cause hyponatremia without evidence of volume depletion if severe potassium depletion has resulted from their use (Fig. 10.4).

Adrenal Insufficiency (Addison’s Disease). Destruction of the adrenal gland or sudden withdrawal of chronic, daily glucocorticoid therapy results in inadequate adrenal function. The lack of mineralocorticoid causes wasting of renal salt but retention of renal potassium and leads to sodium depletion. The lack of glucocorticoid results in a decreased capacity to excrete a water load and leads to hyponatremia but not to volume depletion or hyperkalemia.

**Hypotonic Fluid Losses**

- Gastrointestinal losses
  - If losses of fluid from the upper gastrointestinal tract (e.g., vomiting, gastric aspiration) cause the hyponatremia, and if the gastric juice is normally acid, metabolic alkalosis is present. If diarrheal losses cause the hyponatremia, metabolic acidosis may be present. In patients with gastric achlorhydria, upper gastrointestinal losses also can lead to metabolic acidosis.

- Losses of Sodium from the Skin
  - Sweat contains about 50 mEq/L of sodium and is a hypotonic fluid. If sweat losses are not replaced, then hypernatremia can develop. In most situations, the water losses from the skin are replaced more adequately than the sodium losses. Thus, most patients with significant sodium losses that are due to sweating become hyponatremic. Skin losses of fluid and electrolytes also can occur after burns or other skin injuries. These are isotonic losses of sodium and lead to hyponatremia if the water losses are more adequately replaced than the sodium losses.
losses of sodium from prior diuretic therapy. The natriuretic action of most diuretics lasts less than 24 hours. Hyponatremia is made worse if water intake is excessive.

**Hyponatremia and Normal Volume Status Associated with Water Diuresis**

In a patient with normal renal function who has become hyponatremic as a result of the administration or ingestion of excessive amounts of water, intravascular and ECF volume are normal to slightly expanded, and high rates of urine flow in association with maximally, or nearly maximally, dilute urine can be expected (see section on Water Balance). In a patient with preexisting renal functional impairment, water loading also increases urine flow rate and dilution of the urine; however, maximally dilute urine cannot be formed. Hyponatremia secondary to water loading may occur in compulsive water drinkers, who usually are severely neurotic or psychotic, or after excessive IV administration of hypotonic fluids. Many of these patients also have high levels of ADH for various reasons (e.g., drugs, psychosis). Without this elevation of ADH, presuming normal renal function, consumption of 20 L of water a day would be necessary for development of frank hyponatremia.

**Hyponatremia and Normal to Slightly Elevated Volume Status Associated with Water Conservation**

As discussed, it is appropriate to observe a brisk water diuresis in a patient with normal renal function who is hyponatremic and has evidence of normal or slightly elevated IVV without edema. When high flow rates of hypotonic urine are not observed, the patient is exhibiting an inappropriate antidiuresis. This may result from the inappropriate release of ADH, although other mechanisms also can be involved (e.g., decreased renal blood flow, certain drugs). Another characteristic of such patients is that administered sodium is promptly excreted in the urine, perhaps because of the effect of atrial natriuretic factors. On the other hand, when sodium intake is curtailed, renal sodium conservation is observed. These patients also exhibit normal adrenal and renal function, and are not edematous.

The syndrome of inappropriate antidiuresis has been associated with various clinical states, including malignant tumors (e.g., in the lung or pancreas), central nervous system (CNS) disorders (e.g., head trauma, meningitis), infections (e.g., tuberculosis, bacterial pneumonias), the postoperative state, hypopituitarism, and myxedema, as well as with many drugs (Table 10.6). Infusion of oxytocin to induce uterine contraction also can cause hyponatremia because of the antidiuretic effects of oxytocin.

Within the category of hyponatremia associated with normal IVV are three special categories. The feature that sets these apart is that patients may exhibit evidence of water conservation when water is withdrawn or an appropriate or nearly appropriate water diuresis when water is administered. That is, it appears that osmoregulation has been reset to “defend” a lowered plasma osmolality. The first special category includes patients who have an unusual response to diuretic therapy, characterized by hyponatremia, severe potassium depletion, and metabolic alkalosis. Despite the hyponatremia and normal IVV, exchangeable sodium is nearly normal, suggesting intracellular movement of sodium. Potassium replacement must be accomplished before specific treatment of hyponatremia. The second category involves patients with an unusual manifestation of a chronic illness, such as pulmonary tuberculosis, that resets the osmostat. The third category includes patients with sodium depletion resulting from any cause in whom the depletion in effective IVV is minimized by excessive water intake and retention. This effect of excessive water intake can occur in any of the causes of sodium depletion.

**Hyponatremia Associated with Increased Effective Intravascular Volume or Increased Extracellular Fluid Volume (Edema or Ascites)**

**Congestive Heart Failure.** When hyponatremia develops spontaneously in the course of chronic CHF (i.e., is not the result of excessive water administration or diuretic therapy), it usually is indicative of severe cardiac insufficiency and has a poor prognosis. The cause of the hyponatremia in such patients has been ascribed to a decreased capacity to increase renal free water clearance perhaps because of (a) increased fractional reabsorption of glomerular filtrate proximal to the renal diluting sites of the distal nephron and (b) an elevated ADH level.

**Cirrhosis of the Liver.** Patients with cirrhosis and ascites have a decreased capacity to excrete a water load, possibly because of the same mechanisms at work in patients with CHF.

**Excessive Administration of Hypotonic Fluids.** This usually is an iatrogenic situation and must be especially guarded against in postoperative patients whose ADH levels are elevated because of stress, pain, hypovolemia, or drugs, as well as in elderly patients who are unable to maximally dilute their urine.

**Hypernatremia**

All patients with hypernatremia are volume contracted, except those in whom the disorder develops as a result of excessive administration of hypertonic saline or sodium bicarbonate and the rare patients with essential hypernatremia (Fig. 10.5). The following discussion considers only the first group of patients; the latter section on treatment discusses all forms of hypernatremia. Patients with hypernatremia usually have CNS deficits, and they may also have confusion and neuroseizures. Autopsy findings often reveal hemorrhages or thromboses of brain tissue.
FIGURE 10.5. Approach to the assessment of a hypernatremic patient. This approach does not consider patients with hypernatremia secondary to excessive administration of hypertonic saline. ADH, antidiuretic hormone.

Hypernatremia Associated with Formation of Concentrated Urine

The normal renal response to decreased intake of water or increased extrarenal losses of water is the formation of maximally concentrated urine (see section on Water Balance). In most clinical situations in which hypernatremia is the result of water depletion, the expected renal response is a Uosm:Posm ratio greater than 1.5 and a specific gravity above 1.015. Thus, the finding of hypernatremia with evidence of renal conservation of water indicates that the hypernatremia is caused by excessive nonrenal losses of water or solute diuresis.

1. **Low urine output (e.g., < 35 ml/hr).** Hypernatremia is due to nonrenal losses of water (e.g., skin, lung, gut) and failure of water intake to keep pace with later losses (sensible and insensible). Sodium deficits are also usually present.

2. **Normal urine output (e.g., > 35 ml/hr).** Hypernatremia is due to solute diuresis in face of inadequate water intake (i.e., solute intake requiring renal excretion is high), thereby necessitating a high urine output relative to intake (e.g., high-protein tube feeding mixture given with inadequate amounts of "free water"), Sodium deficits are also usually present.

Hypernatremia Associated with Formation of Dilute Urine

The finding of hypernatremia in combination with isotonic or hypotonic urine indicates that, at least in part, the hypernatremia results from failure of normal renal conservation of water. Failure to concentrate the urine under these conditions may result from the lack of ADH (diabetes insipidus) or impaired renal tubular function that interferes with the development of a hypertonic medullary interstitium (renal tubular damage).

Central diabetes insipidus or nephrogenic diabetes insipidus should be suspected immediately in a patient with hypernatremia when the urine is very dilute (a Uosm:Posm ratio < 0.5, or specific gravity < 1.005).

In patients with renal tubular damage, the ability to concentrate and dilute the urine is decreased. As a result, under all conditions, the urine is isotonic or nearly isotonic with plasma. Hypertension can supervene when water losses exceed sodium losses and water intake does not keep pace with water losses. Despite the hypernatremia, significant sodium deficits usually are present because renal sodium wasting also usually is a feature of these disorders. The following sections are examples of

---

Hypernatremia Associated with Formation of Dilute Urine

The finding of hypernatremia in combination with isotonic or hypotonic urine indicates that, at least in part, the hypernatremia results from failure of normal renal conservation of water. Failure to concentrate the urine under these conditions may result from the lack of ADH (hypothalamic–pituitary diabetes insipidus) or impaired renal tubular function that interferes with the development of a hypertonic medullary interstitium (renal tubular damage).
clinical situations in which renal tubular damage can be associated with hypernatremia.

**Diuretic Phase of Acute Renal Failure.** Occasionally, in a patient recovering from acute renal injury, tubular function is more severely affected than glomerular function. Thus, an inordinately large fraction of the glomerular filtrate escapes reabsorption, resulting in high urine flow rates. The period of inappropriate diuresis can persist for a few days to several weeks.

**Postobstructive Diuresis.** The sudden release of chronic urinary tract obstruction often is followed by several days or weeks in which urine flow rates are abnormally high. Short-lived nephrogenic diabetes insipidus develops in some patients.

**MANAGEMENT OF WATER AND ELECTROLYTE BALANCE**

Water requirements should be carefully monitored, especially in hospitalized patients. Patients with known fluid deficits or excesses should be approached as demonstrated in Tables 10.7 and 10.8. Maintenance requirements can be calculated from two simple formulas.

</tr>
<tr>
<td>Gastric fluid</td>
<td>Rates of loss from nasogastric suction usually are 1–2 L/24 h but can be much greater. Normal composition of gastric juice is about H⁺ 100 mEq/L; sodium 40 mEq/L; potassium 10 mEq/L; and chloride 150 mEq/L. Replace with 0.45 normal saline and potassium chloride (usually 20–40 mEq/L/L), as needed.</td>
<td></td>
</tr>
<tr>
<td>Diarrheal fluid</td>
<td>Losses can vary from trivial to several liters daily. In adults, diarrheal fluid usually resembles extracellular fluid except that the bicarbonate concentration is higher (about 30–50 mEq/L) and chloride concentration is lower (about 80 mEq/L). Potassium concentration is variable (10–40 mEq/L). Replace with 0.45 normal saline and 50 mEq of sodium bicarbonate/L and potassium chloride (usually 20 mEq/L), as needed.</td>
<td></td>
</tr>
<tr>
<td>Urine in acute renal failure</td>
<td>Because of tubular injury, urine sodium concentration is largely independent of urine flow rate.</td>
<td></td>
</tr>
</tbody>
</table>

*The rate of potassium replacement usually is determined by the serum potassium concentration rather than the rates of potassium loss. For example, even though a patient in acute renal failure may be losing 30 mEq/24 h potassium in the urine, it may not be necessary to replace this amount, since potassium may be entering the extracellular fluid at an even faster rate because of catabolism of cellular proteins. On the other hand, the potassium losses in gastric fluid may amount to only 10 to 20 mEq/24 h, yet far greater amounts of potassium may have to be administered to maintain a normal serum potassium level, since gastric aspiration may lead to metabolic alkalosis, causing renal potassium wasting and extensive diffusion of potassium into extracellular fluid.

The first is the 4–2–1 rule (Table 10.9). A more simplified method of calculation using this formula in adults would be to administer 60 mL/h of fluid for the first 20 kg of body weight. Subtract 20 from the patient’s weight (in kg), and add this difference to calculate the hourly rate. For example, a patient who weighs 65 kg has a maintenance requirement of 105 mL/h.

The second method is to calculate the body surface area and multiply by 1,000. A patient with a body surface area of 1.5 m² would require 1,500 mL of fluid daily.

Intraoperative Fluid Administration

The guidelines for fluid replacement during the perioperative period are dictated by (maintenance) basal requirements, deficits, intraoperative losses, and third-space losses. The basal requirement has been discussed. Deficits include actions of general or spinal anesthesia on effective blood volume, intestinal losses (bowel obstruction or diarrhea), perspiration, and blood loss. In some cases, a CVP or Swan-Ganz catheter may be needed to assess IVV.

Intraoperative losses of fluid occur through several routes. Evaporation from peritoneal surfaces occurs, but quantifying it is difficult. The most obvious source of fluid loss, blood loss, is first assessed by looking into the suction canister. Fluid from irrigation should be subtracted. A soaked lap pad contains about 50 mL of blood, and a 4 × 4 pad contains about 5 mL. These are crude approximations. For instance, a moistened lap pad absorbs less than a dry one. Most researchers recommend a replacement rate of 3 to 1 for blood loss using crystalloid suspension and 1 to 1 using colloid suspension. While anesthetized, patients experience third-space loss. This phenomenon is the movement of isotonic fluid from the intravascular space to the interstitial space. A replacement of 2 to 4 mL/kg/h is usually adequate to accommodate third-space losses. Actual total intraoperative losses may be difficult or impossible to monitor.
be used in the perioperative setting. Although D 5W solutions contain less sodium than lactated Ringer solution does should not be used over the following conditions:

1. Large amounts of crystalloid are needed to maintain normal hemodynamics.
2. Assessment of circulatory status is difficult.
3. The patient has an elevated pulmonary capillary wedge pressure.
4. The colloid pressure is below 12.

Colloid oncotic pressure may be difficult to ascertain in a routine clinical setting; therefore, total protein or albumin levels can be used to give a rough approximation of colloid pressure. If blood loss is more than 25% of total blood volume (in an otherwise healthy patient), transfusion of red cells must be considered. Hemoglobin concentrations can help. If the patient is elderly or suffers from lung, heart, or renal disease, then the transfusion trigger point is higher.

Experience has shown that hemoglobin levels between 7 and 8 are generally well tolerated in healthy adults. Primate experiments have demonstrated adequate perfusion of tissues with hemoglobin levels of 5 as long as the blood pressure, urine output, and pulse are satisfactory. During long and difficult surgical procedures, monitoring of vital signs and urine output (optimal, 0.5 ml/kg/h) is extremely important. Sometimes invasive monitoring can be used to guide the clinician.

Crystalloid solutions contain only sugars and electrolytes (Table 10.10). Lactated Ringer solution is usually used because its composition more closely resembles the extracellular component than does normal saline. Generally, solutions that contain less sodium than lactated Ringer solution does should not be used in the perioperative setting. Although D 5W solutions have an osmolality greater than 250, they are unsuitable as routine perioperative replacement because the sugar is metabolized. Normal saline is another popular crystalloid solution. It is preferred over lactated Ringer solutions in the perioperative period when the patient is hypotensive or if brain injury is present. Hypertonic saline is rarely used in the perioperative setting. Because water tends to follow sodium, its theoretic advantage is that water is drawn into the intravascular space from the interstitial space; hence, smaller volumes of hypertonic solution than isotonic solution are needed to provide the same intravascular expansion. Crystalloid solutions are preferentially used over colloid solutions for perioperative fluid replacement.

Colloid solutions include albumin, hetastarch, and dextran. Blood is also a colloid but is discussed in another chapter. Colloids are used primarily when patients have a low colloid oncotic pressure or when large amounts of crystalloids have been infused. For example, if a patient has suffered a significant protein loss from ascites secondary to pelvic malignancy, colloids should be used early in the fluid replacement process. If a patient’s blood pressure becomes difficult to maintain after infusion of sufficient crystalloid, colloids should be used. Albumin, hetastarch, and dextran are three commonly used colloid solutions. Albumin is the most popular of the colloid solutions. It is a blood product but has the advantage of complete absence of infectious agents. In addition, it is treated with heat, eliminating the possibility of transmission of hepatitis or human immunodeficiency virus (HIV). It comes in 5% and 2.5% concentrations. Hetastarch consists of large polymer molecules and comes in a solution of saline. It is synthetic; therefore, its use does not affect the blood supply. There is no risk for vascular transmission. Hetastarch is metabolized by the kidney and some must be used judiciously in those who have renal disease. Other disadvantages include potential volume overload, dilution hypoprothrombinemia, and decreased coagulation. The half-life of hetastarch can be as long as 13 days. Dextran is similar to hetastarch in mode of action. Additional problems with this substance are interference with cross matching and histamine release. Dextran and hetastarch should be carefully monitored. Usually no more than 1,500 ml of hetastarch or 1,000 ml of dextran should be infused during a 24-hour period.

In summary, crystalloids should be used primarily for perioperative volume replacement. Colloid solutions should be used under the following conditions:

1. Large amounts of crystalloid are needed to maintain normal hemodynamics.
2. Assessment of circulatory status is difficult.
3. The patient has an elevated pulmonary capillary wedge pressure.
4. The colloid pressure is below 12.

Colloid oncotic pressure may be difficult to ascertain in a routine clinical setting; therefore, total protein or albumin levels can be used to give a rough approximation of colloid pressure. If blood loss is more than 25% of total blood volume (in an otherwise healthy patient), transfusion of red cells must be considered. Hemoglobin concentrations can help. If the patient is elderly or suffers from lung, heart, or renal disease, then the transfusion trigger point is higher.

Experience has shown that hemoglobin levels between 7 and 8 are generally well tolerated in healthy adults. Primate experiments have demonstrated adequate perfusion of tissues with hemoglobin levels of 5 as long as the blood pressure, urine output, and pulse are satisfactory.

Correction of Volume Deficits

**Estimating the Magnitude of Sodium or Water Deficits**

If the patient has been weighed daily, the magnitude of the water deficit owing to external losses of water can be estimated from the decrease in body weight. The coexisting sodium deficits can be estimated by examining the weight deficits in light of the serum sodium concentration. For example, if the patient has acutely lost 3 kg and the serum sodium concentration is within 10% either way of normal serum sodium concentration (i.e., 126 to 154 mEq/L), little error is incurred by assuming that the patient has lost 3 L of ECF (i.e., isotonic saline); therefore, replacement therapy should be about 3 L of 0.9% saline (155 mEq/L). Using an equivalent amount of lactated Ringer solution offers no advantage, because the kidneys adjust electrolyte excretion to make up for small differences between the composition of the ECF and the isotonic saline.

**Correction of Volume Deficits**

**Estimating the Magnitude of Sodium or Water Deficits**

If the patient has been weighed daily, the magnitude of the water deficit owing to external losses of water can be estimated from the decrease in body weight. The coexisting sodium deficits can be estimated by examining the weight deficits in light of the serum sodium concentration. For example, if the patient has acutely lost 3 kg and the serum sodium concentration is within 10% either way of normal serum sodium concentration (i.e., 126 to 154 mEq/L), little error is incurred by assuming that the patient has lost 3 L of ECF (i.e., isotonic saline); therefore, replacement therapy should be about 3 L of 0.9% saline (155 mEq/L). Using an equivalent amount of lactated Ringer solution offers no advantage, because the kidneys adjust electrolyte excretion to make up for small differences between the composition of the ECF and the isotonic saline.

**Correction of Volume Deficits**

**Estimating the Magnitude of Sodium or Water Deficits**

If the patient has been weighed daily, the magnitude of the water deficit owing to external losses of water can be estimated from the decrease in body weight. The coexisting sodium deficits can be estimated by examining the weight deficits in light of the serum sodium concentration. For example, if the patient has acutely lost 3 kg and the serum sodium concentration is within 10% either way of normal serum sodium concentration (i.e., 126 to 154 mEq/L), little error is incurred by assuming that the patient has lost 3 L of ECF (i.e., isotonic saline); therefore, replacement therapy should be about 3 L of 0.9% saline (155 mEq/L). Using an equivalent amount of lactated Ringer solution offers no advantage, because the kidneys adjust electrolyte excretion to make up for small differences between the composition of the ECF and the isotonic saline.
In patients in whom sodium and water deficits cannot be documented by changes in body weight, or in whom the losses are from the IVV into internal third spaces, approximate but useful guidelines are available to estimate the magnitude of the IVV deficit. These guidelines are as follows.

1. A loss equivalent to 15% of ECF volume (about 2 to 3 L in the average adult) results in a decrease in tissue turgor, but blood pressure and renal function, as judged by serum creatinine level, usually are normal.

2. Losses of sodium and water in excess of 15% of ECF volume usually are accompanied by decreased tissue turgor, orthostatic or frank hypotension, and significant elevation of serum creatinine level.

**Correction Rates and Criteria for Assessment**

Sodium and water losses great enough to result in hypotension represent a medical emergency, and rapid IV administration of isotonic saline is indicated until the hypotension is reversed.

Therapeutically, the rate of IV therapy is guided by the adequacy of the IVV as assessed by other criteria, particularly the measurement of blood pressure and pulse in the supine and sitting positions, urine flow rate, and CVP or pulmonary wedge pressure. In patients with less severe degrees of volume depletion, salt and water deficits often can be corrected by increasing oral intake. Salt can be added to food (the salt packets commonly present on hospital trays provide slightly more than 1 g of sodium chloride), or plain sodium chloride tablets can be given, with unrestricted water allowance, letting the patient’s thirst mechanism dictate water intake. As a guide to the amount of sodium chloride that should be added to the diet to restore the deficits, 1 L of ECF contains 140 mEq of sodium, or about 9 g of sodium chloride. The adequacy of replacement therapy can be assessed over the ensuing days by measurement of change in body weight and blood pressure and by the decrease in serum creatinine level.

**Correction of Volume Excess**

Expansion of effective IVV sufficient to precipitate pulmonary edema is a medical emergency and requires the usual treatment of pulmonary edema, including placement of the patient in the sitting position or elevation of the head of the bed and administration of oxygen, vasodilators—such as nitrates, hydralazine, or angiotensin-converting enzyme inhibitors (e.g., captopril, enalapril, lisinopril)—diuretics, and loop diuretics, as needed. If the pulmonary edema does not improve, then phlebotomy may be required to relieve the vascular congestion. If the volume excess is less severe (e.g., simple edema), the problem usually can be controlled by decreasing salt intake, adding a diuretic drug, or both. The effectiveness of treatment can be guided by the decrease in body weight and periodic measurement of serum electrolyte and creatinine levels.

**Correction of Hyponatremia**

The approach to the correction of hyponatremia depends on (a) whether the patient has significant CNS symptoms as a result of the hyponatremia (coma or seizures) and (b) the cause of the hyponatremia. If the patient has coma or seizures as a result of hyponatremia, the serum sodium level is commonly below 125 mEq/L and the reduction usually has occurred rapidly, over a few hours to days. In these situations, regardless of the cause of the hyponatremia, the serum sodium level should be rapidly raised toward normal by the IV administration of 3% saline.

The serum sodium level should be raised to 125 mEq/L at a rate of 1 to 2 mEq/h. The rate of replacement can be slowed once the serum sodium level reaches 123 mEq/L, because neurologic symptoms are rare above this concentration. Rapid elevation of the serum sodium concentration to normal or hypernatremic levels must be avoided, because it may cause central pontine myelinolysis. The correction using 3% saline (513 mEq/L) can be calculated as follows:

\[
\text{volume TBW} = 0.67 \times \text{total body weight in kg} - 60.5
\]

or

\[
\text{volume TBW} = 0.6 \times \text{total body weight in kg} - 62.5
\]

where:

\[
\text{[Na\textsuperscript{+}]} = \frac{\text{desired [Na\textsuperscript{+}]} - \text{actual [Na\textsuperscript{+}]}}{0.67 \times \text{total body weight in kg} - 60.5}
\]

or

\[
\text{[Na\textsuperscript{+}]} = \frac{\text{desired [Na\textsuperscript{+}]} - \text{actual [Na\textsuperscript{+}]}}{0.6 \times \text{total body weight in kg} - 62.5}
\]

Therefore, this patient requires 1 L of 3% saline to raise her serum sodium level by 12 mEq. The liter of hypertonic saline is administered over 6 to 12 hours. Serum electrolyte levels should be checked every few hours and rates of replacement readjusted as necessary. The infusion of hypertonic saline results in diffusion of water from ECF to ICF until isomotic conditions are restored. This results in reduction of cell volume and an increase of ECF osmolality toward normal as well as in an expansion of ECF volume. The expansion of the ECF by the hypertonic saline may precipitate or worsen CHF. Therefore, patients who receive hypertonic saline should be carefully observed for signs of pulmonary edema and, if such signs are present, vigorously treated with a loop diuretic.

**Hyponatremia Associated with Volume Depletion**

The administration of isotonic saline in amounts sufficient to replace existing sodium deficits usually results in complete correction of the hyponatremia, as discussed, in connection with the treatment of volume depletion, because restoration of effective IVV toward normal allows a water diuresis. If specific disease states, such as adrenal insufficiency or diarrhea, are associated with the development of the hyponatremia and volume depletion, these also require treatment.

**Hyponatremia Associated with Normal Intravascular Volume**

If the hyponatremia is associated with excessive intake of water, restricting water intake to normal corrects the problem. If the hyponatremia is owing to an inappropriate antidiuresis, water intake must be restricted below normal—for example, to about 800 mL of measured liquid intake daily in an average-sized adult (Table 10.2). This usually results in negative water balance, a fall in body weight, and a rise in serum sodium concentration toward normal. Excess total body water can be calculated as follows:

\[
\text{actual TBW} = 0.6 \times \text{total body weight in kg} - \text{actual serum [Na\textsuperscript{+}]} \times \text{actual TBW}
\]

where:

\[
\text{[Na\textsuperscript{+}]} = \frac{\text{desired [Na\textsuperscript{+}]} - \text{actual [Na\textsuperscript{+}]}}{0.6 \times \text{total body weight in kg} - \text{actual TBW}}
\]

\[
\text{desired TBW} - \text{actual TBW} = \text{excess TBW in L}
\]
where:
\[ [Na^+] \text{ is expressed in mEq/L} \]

If a specific cause for the inappropriate antidiuresis can be identified, it should be eliminated (Table 10.6).

**Hyponatremia Associated with Expanded Intravascular Volume and Extracellular Fluid**

The spontaneous development of hyponatremia in the course of severe congestive heart or liver failure is an ominous sign. The hyponatremia usually does not cause any clinical symptoms and although it can be successfully treated by water restriction, clinical improvement usually does not follow. Furthermore, during such treatment, patients complain bitterly of thirst. Thus, water restriction should be restricted, however, to prevent the serum sodium concentration from decreasing to less than 120 mEq/L in an effort to prevent possible CNS symptoms of hyponatremia.

**Correction of Hyponatremia**

**Hypernatremia Secondary to Water Depletion**

The amount of water needed to correct the serum sodium concentration toward normal is given in the following equation:

\[ \text{actual TBW} = 0.6 \times \text{total body weight in kg} \]
\[ \text{actual serum [Na']} = \text{actual TBW} \times \text{desired TBW} \]
\[ \text{desired TBW} = \text{water necessary to lower serum [Na']} \]

where:
\[ [Na^+] \text{ is expressed in mEq/L} \]

The rate of correction usually is 1 to 2 mEq/L. This deficit would be corrected with administration of hypotonic fluid over 24 to 48 hours along with the water and electrolytes needed to maintain day-to-day water and electrolyte balance. The underlying cause of the hyponatremia also must be corrected if possible.

**Hypernatremia Secondary to Excessive Administration of Hypertonic Saline**

In the rare instance of hypernatremia secondary to excessive administration of hypertonic saline, which occurs when intraarteriostic infusion of hypertonic saline is used to induce abortion, hypernatremia is owing solely to positive sodium chloride balance. Therefore, treatment involves simply inducing a state of negative sodium chloride balance while maintaining a slightly positive water balance. If the hyponatremia is associated with impairment of CNS function (Na' usually exceeds 160 mEq/L), 2 to 3 L of 5% solution of glucose in water should be given IV, along with sufficient furosemide to induce a urine flow rate of about 10 to 20 mL/min. About 100 mg of IV furosemide is an appropriate initial dose. This results in the excretion of urine containing about 140 mEq/L of sodium and chloride and 10 mEq/L of potassium. If, at the same time, only the water and potassium are replaced, e.g., replacement of each 1,000 mL of urine with 1,000 mL of 5% solution of glucose in water plus 10 to 20 mEq of potassium chloride, given IV, the patient is selectively depleted of sodium chloride, and plasma electrolytes can be restored to normal within several hours. During this period of correction, serum and urine electrolyte levels must be monitored frequently to assess the adequacy of IV replacement therapy, particularly the rate of potassium administration.

**POTASSIUM METABOLISM**

Disorders of potassium metabolism frequently coexist with disorders of sodium and water balance. For example, sodium and potassium losses often accompany gastrointestinal losses of water and electrolytes. The recognition and management of potassium depletion under these circumstances were discussed earlier in connection with the management of disorders of sodium and water balance. Even small movements of potassium into and out of cells can cause significant changes in the serum potassium since more than 90% of potassium resides intracellularly. It also is important to recognize disorders in which disturbances of potassium balance are the primary abnormality or the major feature of the electrolyte disturbances.

**Hyperkalemia**

Hyperkalemia is defined as a serum potassium level greater than 5 mEq/L. Serum potassium levels between 5 and 6 mEq/L usually cause little or no functional abnormality, but such levels indicate that an abnormality of potassium regulation is present. This sign should be bred and its cause investigated, because further small elevations in serum potassium concentration can seriously impair cardiac and skeletal muscle function. At a serum potassium level of 6 or 7 mEq/L, the electrocardiogram (ECG) begins to show tall, peaked T waves, and skeletal muscle weakness may be present. At a serum potassium level greater than 7 mEq/L, severe ECG abnormalities may be present, including complete suppression of atrial activity and an idioventricular rhythm that can then lead to ventricular tachycardia and fibrillation. Profound skeletal muscle weakness leading to respiratory arrest also may develop. If serious hyperkalemia is suspected, an ECG should be obtained immediately along with a blood specimen for potassium measurement. The ECG findings establish whether life-threatening hyperkalemia is present.

Table 10.11 lists the principal clinical conditions associated with hyperkalemia. Pseudohyperkalemia can result from hemolysis of red blood cells as a result of the mechanical trauma of venipuncture. Such pseudohyperkalemia should be readily recognized, because both potassium and hemoglobin are released by the damaged cells. If the serum potassium level has been significantly raised by in vitro hemolysis, the serum is easily pink because of the presence of free hemoglobin. Patients with extraordinarily high white blood cell counts or platelet counts also can exhibit pseudohyperkalemia as the result of excessive traumatic in vitro lysis of these cells. Pseudohyperkalemia can be avoided by drawing venous blood samples under low pressure into a heparinized syringe.

**Management**

**Life-Threatening Hyperkalemia.** ECG shows sine waves or loss of atrial activity and a broad QRS complex. Serum potassium level usually is higher than 7 mEq/L.

1. Infuse 10 mL of 10% calcium gluconate intravenously over a few minutes with ECG monitoring to observe for reversal of ECG changes toward normal. The same infusion of 10 mL of 10% calcium gluconate can be repeated once. Calcium ions directly antagonize the effects of potassium on...

myocardial metabolism. The onset of action is a few minutes. If the patient is taking digitalis, consider not giving the calcium, and proceed on to the next step.

2. Infuse 50 g of glucose, 10 units of regular insulin, and 50 mEq of sodium bicarbonate. The onset of action is about 15 minutes. Additionally, an IV infusion of glucose, insulin, and sodium bicarbonate (e.g., 500 mL of 10% dextrose in water plus 15 units of regular insulin plus 50 mEq of sodium bicarbonate) may be started. Infuse over several hours. This maneuver causes potassium to move intracellularly. The amount of glucose infused must be altered or omitted in hyperglycemic diabetic patients.

3. Nebulized albuterol at a dose of 10 to 20 mg is recommended. The peak action is approximately 90 minutes.

4. As soon as practical, give sodium polystyrene sulfonate (Kayexalate) by mouth, nasogastric tube, or retention enema (e.g., 20 to 50 g of Kayexalate every 2 to 4 hours). An equal number of grams of sorbitol should be given if the Kayexalate is administered into the upper gastrointestinal tract. Sorbitol, a sugar that is poorly absorbed from the intestine, causes an osmotic diarrhea and prevents concretions of Kayexalate from forming within the gut. Kayexalate is an ion-exchange resin that removes potassium by binding potassium and releasing sodium into body fluids.
5. Hemodialysis may be required in patients in whom these measures fail.

Moderate Hyperkalemia. ECG shows only peaked T waves; serum potassium level usually is below 7 mEq/L.

1. Reduce potassium intake (normal potassium intake is 60 to 100 mEq/24 h). Reducing dietary potassium to 50 to 60 mEq/24 h usually is sufficient to correct mild hyperkalemia.
2. Kayexalate may be needed periodically to control the serum potassium level.
3. Correct metabolic acidosis if present.

4. Stop administration of medications that can contribute to hyperkalemia, such as angiotensin-converting enzyme inhibitors, nonsteroidal antiinflammatory drugs, and potassium-sparing diuretics.

Hypokalemia

Hypokalemia is defined as a serum potassium level below 3.5 mEq/L (Table 10.12). Significant symptoms usually do not result from hypokalemia unless the serum potassium level is less than 3 mEq/L. An important exception is in patients who are receiving digitalis preparations. In such patients, hypokalemia, or

even low-normal serum potassium levels, can increase myocardial irritability and lead to serious arrhythmias. In addition to increasing myocardial irritability, hypokalemia can cause profound muscle weakness and ileus. Chronic severe hypokalemia also can cause metabolic alkalosis and decreased capacity to concentrate the urine. The ECG in hypokalemia often shows U waves, although this finding is not diagnostic of hypokalemia.

Management

Mild Asymptomatic Hypokalemia. This usually can be corrected simply by eliminating the cause of the potassium wasting or by increasing potassium intake. If the hypokalemia is caused by diuretic therapy, potassium depletion usually can be avoided by administering spironolactone or triamterene. Potassium supplementation also can be used, but if the patient is on a low sodium chloride intake, the potassium supplement must be given as potassium chloride. The use of other, more palatable potassium salts (e.g., gluconate, citrate, acetate) and all forms of potassium in food is much less effective in correcting hypokalemia, and this treatment is used primarily in patients on a normal sodium chloride intake.

Severe or Symptomatic Hypokalemia. This usually requires IV administration of potassium chloride. In general, the use of IV solutions that contain more than 40 mEq/L of potassium should be avoided, because infusing high concentrations of potassium can cause hyperkalemia or cardiac disturbance. In correcting even severe potassium deficits, it is seldom necessary to infuse more than 120 to 160 mL/24 h of potassium chloride. When higher rates are used, frequent monitoring of the patient’s ECG and serum potassium level is essential. Intravenous replacement of potassium should never run at a rate of greater than 10 mEq/h. The oral route of potassium replacement should be used whenever possible.

Calcium

Approximately 99% of body calcium is contained in bone. Up to 40% of the extracellular calcium that circulates in the bloodstream is bound to plasma proteins. However, the unbound or ionized form of calcium is the form that exerts physiologic activity. Total calcium is a measure of both the bound and unbound or ionized form. Serum albumin levels affect the total serum calcium, as albumin in the plasma protein to which the majority of calcium is bound.

Corrected calcium in mg/dL = measured calcium + [(4 – albumin in g/dL) ÷ 0.8]

Ionized or unbound calcium can be measured if specifically requested. Its concentration is affected by the serum pH. With alkalosis when the pH is increased, a decrease in ionized calcium results from the increased protein binding of calcium. Conversely, with acidosis, a decrease in protein binding causes an increase in ionized calcium.

The homeostasis of calcium is quite complex, and calcium serves many important functions. Calcium plays a role in regulation of muscle contraction and nerve conduction. Additionally, it functions in the coagulation cascade. The majority of calcium is stored in bone; however, calcium is under the control of several other organ systems, including the integument, musculoskeletal, endocrine, and renal systems. Parathyroid hormone (PTH) appears to be the major hormone effecting calcium homeostasis. Vitamin D must be present, however, for it to exert its maximal effect. PTH causes the following.

■ Mobilization of calcium and phosphorus from bone
■ Increased renal tubular reabsorption of calcium
■ Increased intestinal absorption of calcium
■ Decreased renal tubular reabsorption of phosphorus

Hypocalcemia

Clinical manifestations of hypocalcemia (defined as a calcium level below 8 to 8.5 mg/dL) are characterized by neuromuscular irritability. Symptoms can include numbness, muscle cramping, paresthesias, Chvostek (twitching of facial muscles) and Trousseau (carpal spasm) signs, tetany, and seizures. Patients can also experience psychos and sensory disturbances. On physical examination, patients may have hyperactive deep tendon reflexes. ECG findings of hypocalcemia include a prolonged QT interval, which can lead to heart block or ventricular fibrillation. Causes of hypocalcemia are shown in Table 10.13.

Treatment of hypocalcemia should be directed at its underlying cause. A low total calcium level with a normal ionized calcium level signifies a low level of plasma proteins. These patients usually are asymptomatic, and calcium replacement in this setting usually is not necessary. For patients with acute symptomatic hypocalcemia, calcium gluconate or chloride should be given intravenously. These may cause a local cellular or tissue necrosis if infiltation occurs. If infiltation occurs, especially with the chloride solution in emergent situations, 10 mL of 10% calcium gluconate can be administered intravenously over 15 minutes. In addition, 10 to 20 mL of calcium gluconate can be placed in 1 L of D5W and administered over 24 hours. If the serum albumin level is below 2 mg/dL, then it may be prudent to replace albumin, especially if the urine output is low. Because albumin is heat sensitive, there is no risk of hepatitis or HIV exposure. In cases of symptomatic hypocalcemia, magnesium levels must be checked and corrected if necessary. In those patients with metabolic acidosis and hypocalcemia, the hypocalcemia should be treated initially followed by the correction of the acidosis.

Long-term treatment of hypocalcemia involves adequate nutritional supplementation of calcium, vitamin D, or both. If the serum phosphorus level is high, hyperparathyroid disease must be suspected and the patient treated accordingly. If the serum phosphorus is normal or low, then primary bone disease (hugly bone) must be considered. It is imperative that magnesium levels be checked because replenishment of calcium cannot be accomplished in a patient who is hypomagnesemic.

Hypercalcemia

The clinical manifestations of hypercalcemia usually are seen when the total serum calcium is greater than 12 mg/dL. Common presenting symptoms include weakness, fatigue, nausea, vomiting, constipation, polyuria, polydipsia, lethargy, and confusion. Psychiatric disturbances and coma can be seen in severe hypercalcemia.

182 Principles of Anatomy and Perioperative Considerations
cases of hypercalcemia. ECG changes include prolongation of PR and QR intervals with a shortening of the QT interval. Complete heart block and cardiac arrest can occur in profound hypercalcemia. Additional laboratory abnormalities can include elevations in serum amylase and creatinine levels. The phosphorus level is critical in establishing the cause of hypercalcemia. A phosphorus level below 3.5 mg/dL suggests hyperparathyroidism, whereas an elevated phosphorus level suggests an underlying malignancy.

Hypercalcemia, unlike many other electrolyte disturbances, is rarely arteriographically induced. There are several causes of hypercalcemia. The majority of hospitalized patients with hypercalcemia have an underlying malignancy, whereas the most common etiology of hypercalcemia in the ambulatory setting is hyperparathyroidism. Additional causes of hypercalcemia include thiazide diuretics, lithium, vitamin D intoxication, hyperthyroidism, and sarcoidosis. In the setting of gynecology, hypercalcemia is most often seen with malignancy. In patients with cancer, hypercalcemia results from increased bone resorption and decreased renal excretion. Metastasis to the bony skeleton causes an increase in osteoclastic activity that increases bone resorption. Some gynecologic tumors, however, may cause hypercalcemia by production of a substance similar to PTH, causing bone resorption without evidence of bony metastasis.

Volume expansion is crucial in the treatment of acute hypercalcemia. Replacement with normal saline solution decreases calcium reabsorption in the proximal renal tubule, thus improving renal function. Initial IV fluid therapy should be aggressive, with rates of 250 to 500 mL/h, as most patients are volume contracted. Addition of loop diuretics such as furosemide may aid in increasing urinary calcium excretion, but caution must be used because these drugs may result in volume contraction. After initial volume is restored, 3 to 6 L/d of normal saline solution should be given. Close monitoring of daily patient weights, intake and output, and frequent monitoring of serum electrolytes is necessary in patients with hypercalcemia.

Bisphosphonates are commonly used for the treatment of hypercalcemia. This class of drugs inhibits osteoclast precursors and induces osteoclast cytoxicity, thereby decreasing serum calcium levels. Etidronate disodium (Didronel) is given at a dose of 7.5 mg/kg IV over 2 hours daily for 3 to 7 days. Alternatively, pamidronate (Aredia) is given as a single dose of 60 to 90 mg IV over 4 to 24 hours. Peak onset of action with these medications is usually seen in 24 to 96 hours and may last 2 to 3 weeks. The single dose of 90 mg IV of pamidronate is recommended for severe cases of hypercalcemia because of its effectiveness.

Zoledronic acid (Zometa) is a new-generation, nitrogen-containing bisphosphonate that has been shown to be superior to pamidronate at inhibiting the induction of hypercalcemia of malignancy. Zometa can be given over 5 minutes in a 4-mg dose for the initial treatment of hypercalcemia and an 8-mg dose for relapsed or refractory hypercalcemia. The duration of response with zoledronic acid is approximately 32 days with a 4-mg dose and 43 days with a 8-mg dose compared with 18 days with a 90-mg dose of pamidronate.

Calcitonin increases renal excretion of calcium and inhibits osteoclastic activity. In patients with hypercalcemia, calcitonin can be given at a dose of 4 to 8 IU/kg intramuscularly (IM) or subcutaneously (SC) every 6 to 12 hours. Commercial calcitonin preparations are generally from salmon. It has a rapid onset of action, and serum calcium levels may decrease within several hours. Its effect usually subsides after several days but may be potentiated by concomitant glucocorticoid administration.

Calcitonin has minimal side effects. Tachyphylaxis is seen with calcitonin, limiting its repeated usage and causing it to be less consistently effective compared with other available hypercalcemic treatments.

Glucocorticoids decrease the intestinal absorption of calcium, promote urinary excretion of calcium, and may lower calcium levels by a direct cytolytic effect on some tumor cells. Lowering of serum calcium by glucocorticoids may take 5 to 10 days. Dosages may vary from 20 to 100 mg of oral prednisone or its IV equivalent per day. Side effects limit the long-term use of glucocorticoids for hypercalcemia.

Another potent inhibitor of bone resorption is gallium nitrate. Its onset of action is usually seen in 1 to 2 days, with a peak at 5 to 10 days after administration. Gallium nitrate is administered in a dose of 100 to 200 mg/kg per day for 5 days in a continuous drip. It is important to maintain a saline diuresis of at least 2 L/d during this therapy. Side effects are relatively uncommon, but renal toxicity may be seen. Gallium nitrate in early studies was significantly more effective than calcitonin with or without the addition of corticosteroids. Its obvious disadvantage over the bisphosphonates is that it requires continuous IV infusion over 4 to 5 days.

Oral and IV phosphorus has been used successfully to treat hypercalcemia. It has fallen out of favor, however, because it causes decreased excretion of calcium from the kidneys. Intravenous phosphorus can also lead to soft-tissue deposition of calcium compounds and renal failure. It was used in patients with serum phosphorus levels less than 3 mg/dL and normal renal function. For patients with extremely high calcium levels and severe symptoms (e.g., coma, arrhythmia), renal dialysis may be necessary for rapid correction of hypercalcemia.

Plicamycin (Mithramycin) is an antibiotic that blocks bone resorption, thus lowering serum calcium. The recommended dose of plicamycin in the treatment of hypercalcemia is 25 mg/kg IV over 4 to 6 hours and may be repeated every 24 to 48 hours. Its onset of action is relatively quick, and peak action is usually noted in 2 to 3 days. Side effects can be severe and include nausea, vomiting, bleeding, thromboctopenia, renal failure, and hepatotoxicity. These side effects are more common with repeated doses of plicamycin. Because of these side effects, plicamycin usually is reserved for hypercalcemia of malignancy or hypercalcemia refractory to other therapies.

Magnesium

Magnesium has several functions in the human body. Its primary role is in neuromuscular function, but it also serves as an enzyme cofactor in protein and carbohydrate metabolism. The majority (60%) of magnesium in the body is contained within the bone. Most of the remainder is found intracellularly, with only about 1% found in the extracellular fluid. Normal serum magnesium levels are between 1.2 and 2.2 mEq/L. Magnesium metabolism depends on potassium and calcium levels. The kidney serves as the organ primarily responsible for magnesium homeostasis. Magnesium is filtered at the glomerulus and reabsorbed in the ascending loop of Henle and to a lesser degree in the proximal and distal tubules.

Hypomagnesemia

Hypomagnesemia is more common than hypermagnesemia. Hypomagnesemia results from decreased gastrointestinal absorption of magnesium, increased urinary excretion, or both. Microalbuminuria, which is an indicator of renal dysfunction, is associated with low magnesium levels. Patients with hypomagnesemia may experience symptoms such as fatigue, weakness, and muscle cramps. Hypomagnesemia can also affect cardiac function, leading to arrhythmias and cardiac arrest. Treatment of hypomagnesemia typically involves intravenous magnesium replacement or oral supplements, depending on the severity of the condition.
absorption with conditions such as chronic diarrhea, malabsorption syndromes, and nasogastric suction. Increased renal and gastrointestinal losses from osmotic diuresis, hypercalcaemia, and medications such as cisplatin, diuretics, and aminoglycosides also can cause hypomagnesemia. Hypomagnesemia can result from decreased intake in malnutrition. For example, 10% to 15% of hospitalized patients and more than half of patients in intensive care units exhibit low magnesium levels. Lastly, patients with heavy alcohol use may have hypomagnesemia.

Symptoms and signs of hypomagnesemia are usually nonspecific but may be manifested by neuromuscular excitability, cramps, tremors, fasciculations, and seizures. Typical ECG findings are prolonged PR and QT intervals; however, atrial and ventricular arrhythmias can result.

The treatment of hypomagnesemia involves the replacement of magnesium. Mild or chronic cases may be treated with oral magnesium supplements. Oral repletion is also preferred in asymptomatic patients. This is accomplished by giving 240 mg of elemental magnesium one to four times a day. Diarrhea is the most common side effect. For severe or acute cases, IV magnesium is indicated. Obstetricians and gynecologists are familiar with the 4-g magnesium load mixed with 50 mL of D5W to infuse over 30 minutes. Deep tendon reflexes should be evaluated frequently because hyperreflexia suggests hypermagnesemia and renal insufficiency. Long-term oral therapy can be provided with magnesium oxide, 300 mg/d. Patients should receive proper nutritional counseling and be warned to avoid alcohol. Any underlying medical disorder that may contribute to magnesium losses should be treated. Hydration status should be evaluated because overhydration can lead to mild forms of hypomagnesemia. Gastrointestinal tract losses and alcohol consumption also should be addressed in the evaluation of this disease process.

**Hypermagnesemia**

Hypermagnesemia is rare and usually iatrogenic. Causes of hypermagnesemia include therapy with magnesium-containing antacids or laxatives and secondary to administration of parenteral hyperalimentation. Often hypermagnesemia is seen in patients with some degree of renal insufficiency. Lastly, it can be seen in preclamptic or preterm labor patients treated with IV magnesium. Mild to moderate hypermagnesemia usually is asymptomatic, but patients with severe cases may present with several clinical manifestations. Clinical manifestations are normally seen if magnesium levels are greater than 4 mEq/L. Signs and symptoms include nausea, vomiting, weakness, lethargy, and somnolence. A prolonged PR interval, widening of the QRS complex, and increased T-wave amplitude can be seen with levels greater than 5 mEq/L. Areflexia occurs at levels above 6 to 7 mEq/L. Respiratory arrest, bradycardia, and hypotension can be seen when levels are higher than 10 to 11 mEq/L. Finally, cardiac arrest can occur when serum magnesium is above 14 mEq/L. Discontinuation of magnesium intake is the primary therapy for symptomatic hypermagnesemia. Patients with severe cases should be given 10%calcium gluconate, 10 to 20 mL IV over 10 minutes. The calcium therapy antagonizes the effects of magnesium and is cardioprotective. Supportive therapy and mechanical ventilation may be necessary in those with respiratory failure. Hemodialysis may be required in patients with hypermagnesemia and renal insufficiency.

**Phosphorus**

As with magnesium, the majority of phosphorus is contained with the bony skeleton and the intracellular space, and only 1% is found in the extracellular fluid. As a result, serum phosphate levels may not accurately reflect total body phosphate stores. A normal range for serum phosphorus is 3 to 4.5 mg/dL. Phosphorus serves as an important energy source by means of high-energy phosphates. It is a key component to protein and lipid structure, and is a vital component for carbohydrate metabolism.

**Hypophosphatemia**

Causes of hypophosphatemia defined as a serum phosphate below 2.5 mg/dL include a redistribution of phosphate into the cells, a decrease in intestinal absorption, or an increase in renal excretion. Several causes of hypophosphatemia are listed in Table 10.14. Most patients with mild hypophosphatemia are asymptomatic. Moderate to severe hypophosphatemia causes neuromuscular abnormalities, including weakness, rhabdomyolysis, paresthesias, confusion, seizures, and coma. Erythrocyte, leukocyte, and platelet dysfunction also can be seen because of a depletion of cellular adenosine triphosphate (ATP) and 2,3-diphosphoglycerate.

Most patients with serum phosphate levels between 1 and 2.5 mg/dL usually are asymptomatic. Treatment is aimed at correcting the underlying cause. In cases of chronic hypophosphatemia, oral repletion can be instituted at a dose of 500 to 1,000 mg of elemental phosphorus two to three times per day, and the most common side effect is diarrhea. This can be given in the form of sodium/potassium phosphate tablets called Neutra-Phos or Neutra-Phos K (each contains 250 mg of elemental phosphorus). Parenteral administration of phosphorus is indicated when serum phosphate levels are below 1 mg/dL. Infusion at a dose of 2.5 to 5 mg elemental phosphorus/kg given every 6 hours is recommended. When the serum levels are greater than 1.5 to 2 mg/dL, patients may be switched to oral supplements. Care must be taken to avoid hypophosphatemia. Also, concomitant calcium supplementation often is needed to prevent hypocalcemia. Serum magnesium, calcium, and potassium levels should be monitored closely.

**Hyperphosphatemia**

Hyperphosphatemia is relatively rare and is seen with either an increased endogenous or exogenous phosphate load or with a decrease in renal clearance of phosphate. Renal failure is the most common cause of hyperphosphatemia.

Elevated phosphorus levels also may be seen secondary to rhabdomyolysis, tumor lysis syndrome, hyperparathyroidism, and respiratory or metabolic acidosis. Clinical manifestations include numbness, tingling, muscle cramps, paresthesias, and tetany and are caused by hypocalcemia. Hyperphosphatemia causes hypocalcemia by decreasing calcium absorption from the gastrointestinal tract. Addressing the underlying cause is the cornerstone of management for hyperphosphatemia. In acute cases, saline diuresis can be used in patients with normal renal function. Additionally, administration of glucose and insulin causes a shift in phosphorus from extracellular fluid to the intracellular space. Dialysis may be required if renal failure is present. Oral phosphate binders such as calcium carbonate can be used in patients with chronic hyperphosphatemia.

**ACID–BASE METABOLISM**

Chemicals that are able to provide a hydrogen ion (H+) such as HCl and H2CO3 are defined as acids. Bases are defined as chemicals with the ability to accept a (H+). The acidity of a solution is governed by the concentration of hydrogen ions it contains. The pH of a system is defined as the negative logarithm of hydrogen ions expressed in moles per liter (mol/L). The normal pH of human ECF ranges from 7.35 to 7.45.

**Buffer Systems**

In order for optimal cellular function to occur within the body, the pH must remain in this range. Humans have the ability to absorb excess acids or alkali in circumstances of abnormal pH. The lungs correct for acid-base disorders in an acute setting until the kidneys can compensate. In acidotic states, patients will hyperventilate to decrease CO2 levels in the blood. Conversely, in alkalotic states, patients will hypoventilate, driving up the level of CO2 in the blood. Renal function will gradually compensate by retaining or releasing bicarbonate and hydrogen ions. The most important human buffer system is the bicarbonate system. It is the principal extracellular buffer. This buffer system is described by the Henderson-Hasselbach equation.

\[
pH = 6.1 + \log (\text{HCO}_3^-) / (\text{PaCO}_2)
\]

where:

- 6.1 = pK a = 0.03 mmol/L/mm Hg at 38°C (solubility coefficient).

Organic phosphates, bicarbonate, and peptides are the major intracellular buffers.

Table 10.15 shows the directional changes in acid-base parameters for the primary acid-base disorders. If the kidney detects a respiratory acidotic state, CO2 and H2O in renal tubule cells are converted by carbonic anhydrase to carbonic acid (H2CO3). This dissociates into H2CO3 which is secreted back into ECF and H2O, which is exchanged for sodium from the renal tubule. This in effect causes excretion of the hydrogen ion into the urine, where it is buffered with ammonium and phosphate ions or acted on by carbonic anhydrase (in the tubule) to ultimately form CO2 and H2O. The CO2 is absorbed back into the cell, where more bicarbonate can be generated to buffer ECF acidosis. If a patient has a respiratory alkalosis, available levels of CO2 are low, causing a decrease in hydrogen excretion. Figure 10.6 shows the expected range of arterial pH, PaCO2, and bicarbonate concentrations for primary acid-base disturbances. Figure 10.7 shows a simplified means of determining the acid-base status of patient given pH and PaCO2. A line is drawn between the pH and PaCO2 lines and extended to the line marked “fixed acids.” If the patient has a pH of 7.1 and a PaCO2 of 70, she has a respiratory acidosis, because the line

</table>
drawn falls within the normal range of fixed acids. If, however, she has a pH of 7 and a Pa\textsubscript{co\textsubscript{2}} of 38, she would have a pure metabolic acidosis with no compensation. A pH of 7.3 with a Pa\textsubscript{co\textsubscript{2}} of 27 characterizes a patient with respiratory alkalosis with metabolic compensation.

### Anion Gap

The definition of anion gap is \(\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)\). The normal anion gap is approximately 12 ± 2 mEq/L. In most circumstances, the difference between serum Na\textsuperscript{+} and the combination of serum Cl\textsuperscript{−} and HCO\textsubscript{3}\textsuperscript{−} is a general measure of the combination of serum proteins, sulfate anions, inorganic phosphates, and organic acids. Anion gap calculation may aid in determining the underlying cause of both simple and mixed forms of acid/base disturbances.

### Primary Acid–Base Disorders

#### Metabolic Acidosis

Metabolic acidosis begins as a reduction in plasma HCO\textsubscript{3} and a rise in H\textsuperscript{+}. In response to these changes, alveolar ventilation is increased, resulting in a decrease in Pa\textsubscript{co\textsubscript{2}} and restoration of H\textsuperscript{+} toward normal (see Fig. 10.6 for appropriate decrease in Pa\textsubscript{co\textsubscript{2}} for given HCO\textsubscript{3}– reduction in metabolic acidosis).

Metabolic acidosis can be divided into normal anion gap and increased anion gap acidosis. Table 10.16 shows the major causes of metabolic acidosis.

**Increased Anion Gap.** Renal failure, either acute or chronic, can result in an increased anion gap metabolic acidosis resulting from the kidneys’ inability to excrete inorganic acids, such as phosphate and sulfate. Organic acid accumulation also results in an increased anion gap metabolic acidosis. In the case of lactic acidosis, cellular respiration is disturbed. This occurs as a result of anaerobic glycolysis in muscle, red blood cells, and other tissues. Conditions such as shock, hypoxemia, and septicemia can produce lactic acidosis by causing inadequate oxygen delivery to tissues. Conditions such as diabetic ketoacidosis, alcoholic ketoacidosis, and starvation cause an accelerated rate of organic acid production by lipolysis and ketogenesis. Ingestion of substances such as salicylates, methanol, ethylene glycol, and paraldehyde can result in an increased anion gap metabolic acidosis.

**Normal Anion Gap.** Normal anion gap metabolic acidosis occurs with abnormal increases in net bicarbonate losses. This can occur when the kidney fails to reabsorb bicarbonate in proximal renal tubular acidosis. The administration of carbonic anhydrase inhibitors can also cause normal anion gap metabolic acidosis. Excessive diarrhea or small bowel/pancreatic drainage can cause bicarbonate losses from the gastrointestinal tract. Hyperchloremic acidosis occurs when the kidney fails to regenerate bicarbonate in conditions such as distal renal tubular acidosis and hyporeninemic hyperaldosteronism. Lastly, administration of acid salts can result in chloremic acidosis.

### MANAGEMENT

The treatment for metabolic acidosis depends on the severity of acidosis and the underlying cause. A clinical manifestation of metabolic acidosis is hyperventilation. In the surgical patient, metabolic acidosis is commonly due to hypoxia secondary to inadequate tissue perfusion and subsequent accumulation of...
Metabolic Alkalosis

Metabolic alkalosis occurs when extracellular bicarbonate concentration is increased and renal excretion of this excess bicarbonate is decreased. This cascade may begin with the loss of a hydrogen ion. The major causes of metabolic alkalosis are listed in Table 10.17.

One of the most common causes of metabolic alkalosis is vomiting or gastric suction. Volume contraction ensues, and bicarbonate is saved in the kidneys. Hypercalcemia can result in an increase in proximal tubular bicarbonate reabsorption. The mechanism for alkalosis in these conditions is an increase in bicarbonate via mineralocorticoid excess condition such as hyperaldosteronism, Bartter syndrome, Liddle syndrome, and Cushing syndrome can cause metabolic alkalosis. The mechanism for alkalosis in these conditions is an increase in bicarbonate via the kidneys. Hypercalcemia can result in an increase in proximal tubular reabsorption of bicarbonate leading to metabolic alkalosis.

### Table 10.17

</tr>
</tbody>
</table>

Alkalosis can be reversed with adequate ventilation. Inadequate alveolar ventilation leads to respiratory acidosis. As the pH drops, the bicarbonate rises. This is easily reversed by adequate ventilation. The treatment for respiratory acidosis is to increase alveolar ventilation by endotracheal intubation, mechanical ventilation, or bronchodilation. Within minutes, severe respiratory acidosis can be reversed with adequate ventilation.
In patients with chronic respiratory acidosis, severe posthyperventilatory alkalosis develops if the Paco\textsubscript{2} is rapidly restored to normal and the patient is unable to initiate and sustain a bicarbonate diuresis. This inability usually results from sodium chloride or potassium chloride deficits. If sodium chloride or potassium chloride is provided to correct volume contraction and intracellular potassium deficits, a bicarbonate diuresis ensues, and correction of metabolic alkalosis is achieved.

**Respiratory Alkalosis**

Respiratory alkalosis occurs when hyperventilation decreases Paco\textsubscript{2}, resulting in an increase in pH. Hyperventilation may be secondary to conditions such as pulmonary embolism and CHF, which can cause hypoxia. Fever, sepsis, salicylate toxicity, and hepatic failure all can increase alveolar ventilation and cause respiratory alkalosis. This condition can also be iatrogenically induced by mechanical ventilation. Chronic hyperventilation can be seen in pregnancy, exposure to high altitudes, and underlying pulmonary disease.

**Management**

The symptoms of acute respiratory alkalosis (e.g., paresthesia, lightheadedness, tetany) can be rapidly controlled by raising Paco\textsubscript{2} to normal (e.g., by rebreathing into a paper bag). If the patient is being supported on a ventilator, the dead space can be increased, or tidal volume and respiratory rate can be decreased while oxygenation is maintained. Definitive treatment consists of removing the cause of hyperventilation. Respiratory alkalosis also can cause tetany and seizures and predispose to cardiac arrhythmias (by causing an intracellular shift of potassium), particularly in patients receiving digitalis. If the patient is septic, aggressive measures should be taken to alleviate this. She should be treated with appropriate antibiotics and adequate volume replacement. Surgery may be necessary if the patient has an abscess.

Mixed acid–base disturbances can commonly be seen in severely ill patients. Arterial blood gas measurements and careful evaluation of compensatory changes in the pH, HCO\textsubscript{3}–, and Pae\textsubscript{CO}\textsubscript{2} are necessary in the workup and management of these patients. The treatment of mixed acid–base disturbances is aimed at the underlying disease process.

**BEST SURGICAL PRACTICES**

- Maintenance fluids in a hospitalized patient should be calculated by one of two formulas. The 4–2–1 rule recommends administering 60 mL/kg of fluid for the first 20 kg of body weight, then subtracting 20 from the patient’s weight in kg and adding this difference to calculate the hourly rate. The alternative method for calculating maintenance fluids is to take the body surface area and multiply by 1,000 to come up with the daily fluid requirement in mL.

- The initial step in correcting either hyponatremia or hypernatremia is an accurate assessment of the patient’s volume status (decreased, normal, or increased).

- In severe life-threatening hyperkalemia (ECG showing sine waves and broad QRS complexes), patients should first receive 10 mL of calcium gluconate IV for cardioprotective purposes. These patients should then receive an amp of D50, 10 units of regular insulin, and 50 mEq of sodium bicarbonate. Subsequently, these patients should then receive 20 to 50 g of Kayexalate every 2 to 4 hours and infusions of glucose and insulin.

- In the treatment of severe hypokalemia, potassium should never run at a rate greater than 10 mEq/h, and solutions should not contain more than 40 mEq/L of potassium.
Magnesium metabolism is closely related to potassium and calcium levels. In cases of symptomatic hypocalcemia, mag- nesium and potassium must be checked and corrected ac- cordingly.

For any acid-base disturbance, it is important to elucidate the underlying cause for both the diagnosis and treatment to be effective and successful.

**ACKNOWLEDGMENT**

This chapter is based on material from Water, Electrolyte, and Acid–Base Metabolism by Claire M. Fritsche, Lee A. Hebert, and Jacob LeMann Jr., which appeared in the seventh edition of Te Linde’s Operative Gynecology.

**Bibliography**

CHAPTER 11  ■  POSTOPERATIVE INFECTIONS: PREVENTION AND MANAGEMENT

W. DAVID HAGER AND JOHN W. LARSEN

DEFINITIONS

Bacteremia—Infection of the bloodstream can complicate any pelvic infection, but is seen more frequently in association with abscesses, peritonitis, and septic pelvic thrombophlebitis.

Cuff cellulitis—A soft tissue infection of the surgical margin in the upper vagina where the uterus was removed.

Drug fever—Elevated temperature that is due to an allergic reaction to medications.

Febrile morbidity—A temperature of 38°C (100.4°F) or greater recorded on two occasions, at least 6 hours apart, more than 24 hours after the surgical procedure.

Necrotizing fasciitis—A severe synergistic bacterial infection of the fascia, subcutaneous tissue, and skin that is usually caused by group A hemolytic streptococci, often in combination with other bacteria.

Surgical wound class—The surgical wound infection rate per 100 operations in the United States by wound class is 2.1% for clean, 3.3% for clean-contaminated, 6.4% for contaminated, and 7.1% for dirty or infected cases.

Urinary tract infection (UTI)—A collection of blood originating from an oozing vascular pedicle or along the vaginal cuff. If the collection becomes infected, it is an abscess.

Vaginal cuff hematoma/cuff abscess—A walled-off collection of blood originating from an anastomizing vascular pedicle or along the vaginal cuff. If the collection becomes infected, it is an abscess.

Wound cellulitis—Soft-tissue infection localized to the skin and adipose tissue above the fascia that is characterized by erythema, warmth, and swelling, as well as tenderness.

Wound seroma—A collection of serous fluid beneath the skin surface.

Infection complicating surgical procedures has been the conundrum of gynecologists since the first operations were performed. Even when medical and surgical care are beyond reproach, infectious morbidity can complicate the postoperative course. Unfortunately, using antibiotics prophylactically at the time of surgery does not eliminate this risk of infection.

It is imperative that the gynecologic surgeon understand basic infectious disease concepts to treat infected patients appropriately. Diagnosis and treatment are not guess work but depend on understanding basic principles.

In evaluating the incidence of postoperative infection in published studies, it is important to consider whether infectious morbidity or febrile morbidity was used to define infection, what the socioeconomic status of the population studied was, whether antibiotic prophylaxis was used, and whether there

Certain risk factors play a role in increasing postoperative infection rates. Knowledge of these factors can enable the surgeon to take action to alter those risks. There are various types of postoperative infection, each with its own unique time of onset and usual bacterial etiology. Knowledge about likely causes of a disorder can facilitate decision making when an antibiotic is empirically selected to treat the patient.

Appropriate patient evaluation, including proper culturing techniques, is critical to this diagnostic process. Steps to prevent infection must become routine with every surgeon on every case. These steps are necessary not only for the operator, but also for all personnel participating in the surgical and medical treatment of the patient. These steps are described later in this chapter.
were other confounding variables that might have influenced infection rates (e.g., multiple surgical procedures, experience of the surgeon, or site of the study).

Prospective studies report the incidence of acute pelvic infection after abdominal hysterectomy to be 3.9% to 50%. The range for infection after vaginal hysterectomy is 1.7% to 64%. The incidence of septic pelvic thrombophlebitis (SPT) after gynecologic procedures is 0.1% to 0.3%.

**VAGINAL FLORA**

The most frequent source of bacteria that cause postoperative pelvic infection among women is the vagina. The vagina is colonized by large numbers of a variety of bacteria that normally exist in a symbiotic relationship. Several factors influence the vaginal flora, including age, sexual activity, stage of the menstrual cycle, use of antibiotic or immunosuppressive agents, and any invasive procedure.

Mean bacterial counts in vaginal secretions are $10^5$ to $10^8$ bacteria/mL, with three to six different species present. The most frequent aerobic bacteria are *Lactobacilli*, *Gardnerella vaginalis*, *Staphylococcus epidermidis*, *Corynebacterium sp*, *Enterococcus faecalis*, *Enterobacteriaceae*. Anaerobes outnumber aerobes and include *Peptostreptococcus sp*, *Peptococcus sp*, *Prevotella bivia*, *Prevotella disiens*, and members of the *Bacteroides fragilis* group (Table 11.1). These same bacteria are frequently isolated from sites of pelvic infection among women who have undergone gynecologic surgery. This indicates, as Schottmueller proposed at the turn of the century, that pelvic infections are principally a result of endogenous sources of bacteria. The concepts of antibiotic prophylaxis and antiseptic douching before surgery or prophylactic and antiseptic gel are related to reducing these rates.

Prospective studies report the incidence of acute pelvic infection after vaginal hysterectomy to be 0.1% to 0.5%. The incidence of septic pelvic thrombophlebitis (SPT) after gynecologic surgery is 0.1% to 0.3%.

**RISK FACTORS FOR POSTOPERATIVE INFECTION**

Several factors may increase the infectious morbidity of postoperative patients (Table 11.2). Of all the factors mentioned, the most basic appears to be immunocompromise. Anything that plays a role in altering the host’s own defense mechanisms can result in a greater chance of infectious morbidity.

Some risk factors can be controlled by the surgeon, whereas others cannot be influenced by the surgeon or operative team and must be dealt with as they occur. Lower socioeconomic status is a risk factor for infection in gynecologic surgery. Although economic status is convenient for epidemiologic studies, the clinical effect is believed to be a result of inadequate nutrition and poor hygiene. Obesity is another risk factor for infection, probably reflecting poor hygiene, altered nutrition, risk of diabetes, and prolonged operative time. These result in altered wound healing and greater possibilities for infection.

When a hysterectomy is performed through an infected operative site, there is an increased risk of postoperative infection. Likewise, contamination of the operative field by break in sterile technique or injury to the bowel promotes infection. Young age has been considered a risk factor for posthysterectomy infection, although the exact reason is unclear. This increased risk in younger patients may result from the presence of more virulent bacteria in the vagina or increased vascularity and difficulty in obtaining adequate hemostasis. Other factors are not as clear-cut and may result from interacting effects. For example, duration of surgery is considered to be a risk for infection in most studies, but this actually may reflect experience of the operating surgeon, complexity of the case, or a greater chance of inadequate hemostasis. Lack of adequate hemostasis results in an increased risk of postoperative infection, especially of abdominal incisions. No data, however, have indicated that raising the volume of red blood cells decreases the rate of infection. Leaving an excessive amount of devitalized tissue (e.g., large, ligated pedicles) can predispose to a greater risk of infection. Pedicles should

All women have bacteria colonizing the vagina in greater or lesser numbers. Women without symptoms have a mean of 4.2 species present. It is these same bacteria normally existing in a symbiotic relationship that ultimately can invade tissue altered by surgery, leading to clinical infection. The virulence of the bacteria and the volume inoculated are countered by the host’s immune defense mechanisms and may be aided by prophylactic antibiotics to combat the occurrence of infection.

The bacteria listed in Table 11.3, which are responsible for postoperative infection after gynecologic surgery, are the same organisms that can be recovered from vaginal cultures of women before hysterectomy, according to Hemsell. The volume of bacteria present and their proximity to the operative site promote a polymicrobial infection in women who experience posthysterectomy infectious morbidity. Aerobic bacteria may initiate the infectious process; as tissue is devitalized and undrained collections of blood are ideal sites for infection to occur. Once the infection has begun, the body’s host immune defense mechanisms initiate an inflammatory response and attempt to wall off and localize the infection. Infected hematomas and abscesses can result.

**CATEGORIES OF INFECTION**

Not all women who have temperature elevation after gynecologic surgery are infected, and not all of those who are infected have the same clinical syndrome. It is important to categorize the infectious process because treatment can vary accordingly.

**Cuff Cellulitis**

Cuff cellulitis is an infection of the surgical margin in the upper vagina where the uterus was removed. Symptoms and signs of cellulitis usually begin late in the hospital course or even after discharge from the hospital. These patients’ immediate post-operative course may have been completely benign. There is always an element of induration, erythema, and edema in the vaginal cuff immediately after hysterectomy. If the patient becomes infected, she will often have initial symptoms of lower abdominal pain, pelvic pain, back pain, fever, and abnormal vaginal discharge. Examination may reveal persistent hyperemia, induration, and tenderness of the vaginal cuff and possibly purulent discharge along with fever. The parametrial and adnexal areas are nontender. The white blood cell count usually is mildly to moderately elevated. Gram-positive aerobes, facultative Gram-negative aerobes, and obligate anaerobes can all contribute to the cause of cuff cellulitis. Single- or multiple-agent broad-spectrum coverage is effective in treating this infection, although single agents usually are preferred to reduce costs and the likelihood of an allergic reaction.

**Infected Vaginal Cuff Hematoma or Cuff Abscess**

Hysterectomy can result in small amounts of oozing from vascular pedicles or along the vaginal cuff. This bleeding may result in a walled-off collection of blood called a hematoma. If this localized mass above the vaginal cuff becomes infected, an abscess may result. Bacteria, especially anaerobes, flourish in this environment. Women with a vaginal cuff abscess present with fever that is usually early in the postoperative period. Other symptoms include chills, pelvic pain, and rectal pressure. Clinical findings include temperature elevation; lower abdominal and vaginal cuff tenderness; the presence of a tender, fluctuant mass near

</table>
the cuff, and, occasionally, purulent drainage from the cuff. The pain and tenderness is often more predominant on one side.

As an infected cuff hematoma actually can present later in the postoperative course because an abscess is usually associated with a drop in the hemoglobin and hematocrit levels. The hematoma may not be readily palpable but can be delineated on pelvic ultrasound or computed tomographic (CT) scan.

Postoperative Ovarian Abscess

The patient who develops fever and abdominal and pelvic pain late in the postoperative hospital course or after hospital discharge may have a pelvic abscess, possibly of ovarian origin. If there is a sudden increase in abdominal or pelvic pain, a rupture may have occurred. A ruptured abscess should be managed as a surgical emergency with a laparotomy and excision or drainage of the infected mass. The inciting site for an ovarian abscess is a place of recent follicle expulsion or a site of surgical trauma to an ovary in a premenopausal woman. Ovaries should not be aspirated or probed at the time of hysterectomy for fear that bacteria from the vagina may penetrate the ovary and initiate infection. Once again, anaerobes are the predominant bacteria in an ovarian abscess.

If an ovarian abscess is suspected, then a CT scan should be ordered. The CT scan not only identifies the size and location of the abscess but also allows for visualization and evaluation of the ureters, bladder, and colon. A pelvic ultrasound also may be useful to localize the abscess. Many abscesses respond to broad-spectrum antibiotic therapy; but if a tender, fluctuant mass persists, drainage is necessary. A radiologic interventionist may be able to accomplish percutaneous drainage with a needle or catheter using CT or ultrasound guidance, or colpotomy drainage may be possible. For colpotomy drainage to be accomplished safely, the abscess must be fluctuant, fixed to the cul-de-sac, and dissecting the upper third of the rectovaginal septum. With either approach, a closed-suction drain should be placed to ensure complete and continued evacuation during the next 2 to 3 days.

Septic Pelvic Thrombophlebitis

Septic pelvic thrombophlebitis (SPT) complicates gynecologic surgery in 0.1% to 0.5% of procedures. It is usually a diagnosis of exclusion, made when a postoperative patient with febrile morbidity does not respond to appropriate parenteral antibiotic therapy in the absence of an undrained abscess or infected hematoma. The development of SPT is enhanced by venous stasis (e.g., obesity, diabetes), vascular injury, or bacterial contamination of pelvic vessels.

Two forms of SPT have been described. The classic form is seen in association with abdominal surgery. This form occurs 2 to 4 days after surgery and is characterized by fever, tachycardia, gastrointestinal distress, unilateral abdominal pain, and, in 50% to 67% of cases, a palpable abdominal cord resulting from acute thrombus formation. The enigmatic form complicates parturition or pelvic surgery and is characterized by spiking temperatures despite clinical improvement on antibiotics; tachycardia during the temperature spikes; and small, diffusely scattered thrombi in small pelvic vessels. Pelvic findings are minimal in both forms. The diagnosis often may be confirmed by CT scan or magnetic resonance imaging.

The traditional mainstream of treatment for SPT is anticoagulation with heparin for 7 to 10 days. Some experts recommend changing antibiotics or extending coverage before heparin is considered. All patients should be treated with antibiotics effective against heparinase-producing Bacteroides sp. Long-term anticoagulation is not required unless septic pulmonary emboli have occurred. Lysis of fever may occur 24 to 48 hours after starting heparin, yet other cases may require much longer for complete resolution. Treatment should be continued until the patient is afebrile for 48 hours and clinically well.

Osteomyelitis Pubis

Osteomyelitis pubis rarely complicates gynecologic procedures adjacent to the symphysis pubis, such as retroperitoneal renal suspension, radical vulvectomy, or pelvic exenteration. Direct or contiguous seeding of the peristium from pelvic bacteria results in a delayed-onset infection 6 to 8 weeks after the original procedure. Patients report pain and tenderness along the symphysis pubis, especially with ambulation. Low-grade fever, an elevated erythrocyte sedimentation rate, and a moderate leukocytosis have been reported, as well as positive cultures from blood or the bone itself. Aggressive antibiotic therapy covering *Staphylococcus aureus* and facultative Gram-negative bacilli is essential for adequate recovery. If the response is not adequate, surgical debridement of the pubis is necessary.

Wound Infection

Surgical wound infection is possible with any transabdominal gynecologic procedure, but especially with those that are contaminated. Extensive study of the epidemiology of wound infections resulted in a classification of operative wounds in relation to contamination and increasing risk of infection. Because the vagina is entered during hysterectomy, even an uninfected hysterectomy is classified as a clean-contaminated operation. Fortunately, prophylactic antibiotics and minimally invasive, laparoscopic procedures have greatly reduced the risk of severe, surgical wound infections.

The rates of wound infection according to case classification of the operative wound are summarized in Table 11.5. Culver and colleagues, using the National Nosocomial Infections Surveillance System, reported the percentage of operations in the United States by wound class and the surgical wound infection rate per 100 operations to be 2.1% for clean, 3.3% for clean-contaminated, 6.8% for contaminated, and 7.1% for dirty or infected cases. The more contaminated the operative site, the greater is the risk of wound infection. Fortunately, despite polymicrobial contamination by bacteria from the vagina when it is entered at the time of hysterectomy, prophylactic antibiotics, adequate host resistance, and good surgical technique result in most patients avoiding wound infection.

The Centers for Disease Control and Prevention (CDC) definitions of surgical wound infection were modified by Horan et al. This system divides infections into two major categories: (a) an organ/space surgical site infection (SSI), and (b) superfi- cial and deep incision infection. An SSI may be in any anatomic area that was opened or manipulated during a surgical procedure other than the incision itself. This would include most of the infections that develop after hysterectomy. It must develop within 30 days of the procedure and be accompanied by one of the following: diagnosis by a surgeon or attending

Wound Cellulitis
Abdominal wound infections are categorized by their location and severity. The least severe are localized to the skin and subcutaneous tissue. Wound cellulitis is characterized by erythema, warmth, and swelling, as well as tenderness. If there is no purulent drainage, antibiotic therapy alone with a cephalosporin or augmented penicillin often is effective. Staphylococcus aureus, coagulase-negative staphylococci, and streptococci cause most of these infections.

Wound Seroma
A collection of serous fluid beneath the skin surface is a seroma. A small amount of serous drainage may be managed with limited opening of the incision, drainage, and cleansing. Larger collections may require more extensive incision and drainage.

Deep Wound Infection
When purulent drainage is noted, the wound should be opened widely to allow drainage and removal of necrotic tissue. If the fascia is intact, healing is hastened by mechanical debridement followed by loose, wet-to-dry packing with gauze moistened with saline; dilute hydrogen peroxide (1:1 mixture with saline) or Dakin's solution, 0.5%. Povidone-iodine is to be discouraged because it does not promote the development of granulation tissue. An antibiotic effective against anaerobes must be used.

Necrotizing Fascitis
This severe complication results from synergistic bacterial infection of the fascia, subcutaneous tissue, and skin. This rapidly progressive infection is characterized by cyanosis of the skin and frequently blistering necrosis. It is most commonly caused by group A, beta-hemolytic streptococci, but may be a polymicrobial, synergistic infection with anaerobic bacteria or Clostridium perfringens. It is seen more frequently in diabetic and immunocompromised patients. Patients present with severe pain in the area of involvement; clinical signs of sepsis; and a viscous, cloudy, malodorous drainage. The wound edges may be purple or even necrotic. If gangrene occurs in the area of fascitis, bullae of the skin and crepitations in the subcutaneous tissue may be seen. Treatment includes antibiotics effective against streptococci and anaerobes, plus prompt and extensive resection of the tissue involved.

Urinary Tract Infection
Infection of the lower urinary tract is a frequent complication of gynecologic surgery. The patient may have low-grade fever, dysuria, frequency, and urgency, but in many situations has no symptoms. The criterion for defining a urinary tract infection
tibiotics or anesthetics, pyrogenic reactions to tissue trauma, include pulmonary atelectasis, hypersensitivity reactions to an-
fever are not infectious in origin. Possible noninfectious causes
and/or tenderness around the incision, drain, or intravenous
infusion site; leg pain; tenderness or swelling; costovertebral
angle (CVA) tenderness; cough; or dysuria. When any of these
or other signs or symptoms alerts the surgeon to the possibil-
ity of a postoperative infection, an appropriate workup is indi-
cated. A diagnosis of infection should be made or at least a high
probability of infection should be present before antibiotics are
started.

**Drug Fever**
This diagnosis should be considered when appropriate par-
enteral antibiotics have been used and there are no localizing
signs of infection and no undrained collection of fluid. Fevers
are usually steady but can fluctuate. Many patients exhibit an
eosinophilia. The antibiotic(s) should be discontinued.

**EVALUATION OF THE PATIENT WITH SUSPECTED INFECTION**
Fever is the most common sign of postoperative infection, but it is important to remember that fever is not always, or indeed
not usually, caused by infection in the postoperative patient (Table 11.6). In a large study of 537 women who underwent
major gynecologic surgery, Fanning et al. found that 39% de-
veloped postoperative fever, but only 17 patients (8%) actu-
ally had a documented infection. Other signs and symptoms
of postoperative infection can include erythema, induration,
and/or tenderness around the incision, drain, or intravenous
infusion site; leg pain; tenderness or swelling; costovertebral
angle (CVA) tenderness; cough; or dysuria. When any of these
or other signs or symptoms alerts the surgeon to the possibil-
ity of a postoperative infection, an appropriate workup is indi-
cated. A diagnosis of infection should be made or at least a high
probability of infection should be present before antibiotics are
started.

**History**
Careful history taking often can be the source of helpful clues to
the cause of postoperative infection. The time of onset of the
complicating infection is important. Ledger emphasized that
the interval between surgery and the onset of fever is helpful
in determining the cause of infection. For example, Garibaldi
and colleagues suggested that most cases of early postoperative
fever are not infectious in origin. Possible noninfectious causes
include pulmonary atelectasis, hypersensitivity reactions to an-
tibiotics or anesthetics, pyrogenic reactions to tissue trauma,
or hematoma formation. Infectious causes of early postopera-
tive fever include aspiration pneumonia, group A beta-hemolytic
streptococcal wound infection, or surgery in a previously in-
fected site (e.g., pelvic inflammatory disease or recent D&C or
cone biopsy). Other important aspects of history include the surgical procedures performed (e.g., abdominal versus vaginal
approach, whether ovaries were invaded), risk factors encoun-
tered (pelvic abscess, bowel injury), use of antibiotic prophyl-
axis, symptoms, and whether the patient had any ancillary
illnesses (smoking history, history of cardiac valvular disease, immuno suppression).

**Physical Examination**
Gynecologic surgeons tend to focus on the pelvis as the source of
all postoperative infections. Instead, a comprehensive eval-
uation of the entire patient should be carried out. The upper
respiratory tract should be examined to rule out otitis, pharyn-
gitis, and bronchitis and the lower respiratory tract to rule out
pneumonia. The gastrointestinal tract should be checked to
evaluate bowel function, distention, and tenderness. Breast
examination is usually only important in postpartum patients.
The urinary tract should be evaluated, and the possibility of
pyelonephritis must be considered. Intravenous access, espe-
cially central lines or other indwelling foreign bodies, should
be carefully inspected and palpated for evidence of infection.
The surgical wound must be examined carefully, and if the
site of infection has not been identified or symptoms suggest
a pelvic infection, a pelvic examination should be carried out.
The pelvic examination should evaluate the vaginal cuff for
discharge, erythema, and induration. Palpation for tenderness
and for masses should be done and cultures obtained if pus is
identified.
Laboratory and Imaging Evaluation

In recent years, it has become clear that a routine postoperative "fever workup"—including a variety of studies, such as a complete blood count, urine analysis, chest X-rays, and multiple cultures—is largely unwarranted in identifying the site of postoperative infections. A careful history and physical examination are the best guides to which laboratory tests, if any, are indicated. In a retrospective review of 257 patients who underwent major gynecologic surgery, Lyon et al. found that a urine culture was positive in only 9% of the patients who were febrile and only 1.5% of all febrile patients having a significant finding. Similar results were described by Fanning et al., who also noted that none of the 77 blood cultures in their series of 211 febrile postoperative patients was positive.

In a follow-up study, Schwandt et al. outlined a protocol for evaluating postoperative gynecological patients as follows: (a) record temperatures every 4 hours; (b) for temperatures greater than 38°C (100.4°F), evaluate the patient by history and physical examination; (c) when no significant signs or symptoms are identified, order no tests, and observe the patient. Antibiotics are not started at this point. The authors felt that this protocol of selectively ordering lab tests to evaluate a postoperative fever did not compromise patient care and saved considerable resources. Similar findings also have been reported in a retrospective review by McNally et al.

Although current practice discourages the use of "routine" testing to evaluate a postoperative fever, the clinician must be sensitive to special circumstances, unusual signs or symptoms, or persistent fever or other warning signs. Special circumstances could include a patient who was at high risk for infection because of immunosuppression, gross bacterial contamination at surgery, infection already present before surgery, or patient in such a frail or unstable condition that any postoperative infection could be fatal. Unusual signs or symptoms, which may provide evidence of deep-seated fasciitis or gas-forming organisms and, most common of all, persistence of fever or other signs or symptoms of infection, definitely warrant a more exhaustive evaluation and, in most cases, prompt aggressive therapy.

A complete blood count with differential usually is indicated, and electrolytes, renal function tests, and liver-associated tests may be useful if sepsis is anticipated, prior damage to these organs exists, and/or antibiotics excrated or metabolized by these organs may be used. Acute pancreatitis can be ruled out by a normal serum amylase and lipase.

Blood cultures are not frequently indicated; but in patients with high fever, those with persistent fever despite antibiotics, or those who are immunocompromised, they may be useful. This is particularly true when patients have indwelling central lines for longer than a few days, especially if these lines have been used for several functions (blood transfusions, antibiotics, electrolytes, etc.), and/or the patient had bacteremia that could seed the tip of the line. In these cases, at least one culture should be taken through the central line catheter. Other cultures of pus from an abdominal incision, the vaginal cuff, an undrained collection, or a drainage tube occasionally may be helpful in a patient who is not responding to antibiotics or in whom an unusual infection (actinomycoses) is suspected. A spumon Gram stain should be rare, but should be considered in a symptomatic, immunosuppressed patient who could have tuberculosis, coccidioidomycosis, or some other atypical pneumonia.

A number of different imaging techniques may be useful in special circumstances. A CT scan of the abdomen/pelvis should identify an abscess. In many cases, CT-guided percutaneous catheter drainage in combination with intravenous antibiotics is the treatment of choice. Renal function always should be satisfactory before administering intravenous contrast for a CT or intravenous pyelogram. Ultrasound can be used to scan the abdomen at incision and post for an abscess or hematoma. Ultrasound of the heart can diagnose valvular vegetations associated with bacterial endocarditis. It also is useful for evaluation of the jugular vein for venous thrombosis. Pelvic or abdominal vein thrombosis can be diagnosed easily in most cases using CT scanning. Radioactive-tagged white blood cell scans can be useful for localizing occult infections, but these have largely been replaced by CT scans.

TREATMENT

The following factors must be considered when making antibiotic choices for the treatment of postoperative infections.

1. Pelvic infections are polymicrobial in etiology.
2. The most frequent causative organisms are aerobic, Gram-positive cocci (streptococci, S. epidermidis, S. aureus), facultative Gram-negative rods (Escherichia coli, Klebsiella sp, Enterobacter sp), anaerobic cocci (peptostreptococci), and anaerobic rods (Prevotella sp, Bacteroides sp, B. fragilis).
3. Enterococci may occasionally cause sepsis or be a sole isolate but usually accompany other bacteria and are not principal pathogens.
4. The choice of an antibiotic is made empirically before culture results are available.
5. The timing of onset of the infection may be an indicator of a pathogen group.
6. Resistance to frequently used antibiotics is developing.
7. Single agents may be as effective as multiple agents in treating postoperative infections.

The polymicrobial nature of postoperative pelvic infections results in about 20% aerobic Gram-positive cocci, 20% Gram-negative rods, and 60% anaerobes. Infections that occur in the first 24 hours after surgery usually are caused by Gram-positive cocci or occasionally by facultative Gram-negative rods. Infections that occur after the first 48 hours more frequently have an anaerobic component. The effect of timing should be considered in making the initial choice of an antibiotic because an extended-spectrum penicillin or cephalosporin may be the best choice in early-onset infections (Table 11.7).

The gold standard for treating gynecologic postoperative infections has been gentamicin, 2 mg/kg loading dose, followed by 1.5 mg/kg maintenance dose for patients with normal renal function, plus clindamycin, 900 mg administered parenterally every 8 hours. Unfortunately, increasing resistance among anaerobic rods to clindamycin is altering the effectiveness of this regimen. The fear of nephrotoxicity or ototoxicity when gentamicin is used for short treatment courses in young, healthy women has not been borne out. Aminoglycoside serum levels may be obtained if the treatment is expected to last more than 72 hours. The addition of ampicillin to the previous combination extends the spectrum of coverage to include enterococci.

To overcome the resistance of anaerobes to clindamycin, metronidazole may be used in combination with a penicillin (ampicillin, amoxicillin, or both). Metronidazole in combination with levofloxacin, 500 mg daily, is also used frequently. The dose of metronidazole is 500 mg every 6 hours. The oral

NA, not applicable.

Absorption of this antibiotic is such that blood levels are equivalent to parenteral administration. Metronidazole is only effective against anaerobes and has minimal to no aerobic spectrum.

Investigators have studied various extended-spectrum penicillins and cephalosporins as single agents for the treatment of mild to moderately severe postoperative pelvic infections. These agents have an extended spectrum of in vitro antibacterial activity and β-lactamase stability. Single agents—such as cefoxitin, cefotetan, cefuroxime, ticarcillin/clavulanic acid, and piperacillin/tazobactam—avoid the problems of admixture with multiple agents and the potential for aminoglycoside toxicity. In our experience, persistence of infections despite these single agents usually is caused by anaerobic infection.

If an abscess is present and medical management is used to attempt to eradicate it or allow for stabilization before drainage is undertaken, meropenem, a carbapenem, is an excellent choice in a dose of 500 mg given IV every 6 to 8 hours. Metronidazole is a good option when anaerobes are suspected. If the patient has evidence of clinical improvement and decrease in size of the abscess, antibiotics should be continued; if there is no improvement by 48 to 72 hours, surgical drainage is indicated.

Parenteral antibiotics should be continued until the patient is afebrile and clinically well for 24 to 48 hours. At that point, antibiotics may be discontinued and the patient discharged. Several studies show no benefit to the continuation of oral antibiotics after successful parenteral therapy or observing the patient for an additional 24 hours in the hospital.

If there is not a good response to appropriate antibiotic therapy within 72 hours, the patient should be completely reevaluated. After another review of the history and physical examination, imaging studies should be considered. Perhaps a chest x-ray may indicate new consolidation or an abdominal and pelvic CT scan may identify a collection or abscess or even septic thrombophlebitis. If a fever persists, antibiotics may be discontinued, and the patient recultured before new antibiotics are started. SPT should be considered.

**PREVENTION OF INFECTION**

In this modern era of antibiotics, we have become somewhat lax in our efforts to prevent infection because we assume that if infection occurs, we can easily and effectively treat it. This ignores the potential for morbidity in the patient and the tremendous economic burden imposed by postoperative infections. In a 5-year study of wound infections after abdominal hysterectomy, Kandula and Wenzel found that women with infections were hospitalized an average of 3.53 days longer, resulting in a significant financial impact. It is important to implement specific strategies aimed at preventing postoperative infection and to use these with every patient. In doing so, a significant number of infections can be prevented. Identifying risk factors is important preoperatively. Major risks are obesity, bacterial vaginosis, radical surgery, and excessive blood loss (>1,000 cc).

Some guidelines apply to all situations, and some are specific to certain types of infection. Careful hand washing, avoiding contact with septic patients before proceeding to the operating...
Prevention of Postoperative Pneumonia

All patients who undergo general endotracheal anesthesia are at risk for retention of pulmonary secretions, alveolar collapse, and in turn, atelectasis and possible pneumonia. Atelectasis is frequently a cause of immediate postoperative fever. To help prevent this complication, all patients undergoing surgery, and especially those with chronic obstructive airway disease, should be encouraged to discontinue or decrease smoking and have any upper respiratory infections treated before operation. Postoperatively, coughing, deep breathing, and devices to encourage alveolar expansions should be used. Adequate analgesia control pain that interferes with respiratory effort should be administered. Early ambulation should be encouraged.

Prevention of Urinary Tract Infection

UTIs can complicate gynecologic surgery because of the proximity of the urethra to the operative site in the vagina. This effect is augmented by the placement of an indwelling urinary catheter. To limit UTIs, appropriate placement and management of catheters is essential. Personnel should be instructed in the proper sterile placement of catheters, maintained as a closed drainage system without traction on the device. Catheters should be placed only when necessary and should be removed as soon as feasible. Routine culture of terminal urine specimens when catheters are removed has not proven cost-effective in our institution.

Prevention of Operative Site and Wound Infections

Other Considerations

Multiple studies have demonstrated that antibiotic prophylaxis significantly reduces infectious morbidity following both vaginal and abdominal hysterectomy. These results do not preclude that the important surgical principles that have been shown to reduce morbidity can be ignored, but the use of prophylactic antibiotics in many gynecologic surgical procedures has reduced the incidence of postoperative surgical site infections from 30% to 50% to about 15% in most series.

Theory of Antibiotic Prophylaxis

At the time of hysterectomy, vaginal or cervical bacteria are inoculated into the surgical site, and it is hypothesized that antibiotics in these tissues at this time augment host defense mechanisms to reduce the incidence of clinical infections. For antibiotic prophylaxis to work effectively, several important criteria must be fulfilled. First, the operative procedure must have a significant risk of bacterial contamination and, in the absence of prophylactic antibiotics, an appreciable incidence of operative site infection. Hysterectomy or other gynecologic procedures involving the cervix, vagina, or vulva all qualify for antibiotic prophylaxis to work effectively, several important criteria must be fulfilled. First, the operative procedure must have a significant risk of bacterial contamination and, in the absence of prophylactic antibiotics, an appreciable incidence of operative site infection. Hysterectomy or other gynecologic procedures involving the cervix, vagina, or vulva all qualify for antibiotic prophylaxis.

First, the operative procedure must have a significant risk of bacterial contamination and, in the absence of prophylactic antibiotics, an appreciable incidence of operative site infection. Hysterectomy or other gynecologic procedures involving the cervix, vagina, or vulva all qualify for antibiotic prophylaxis.
Choice of Antibiotics for Prophylaxis

As noted, the antibiotic selected for a given procedure should be effective, have few side effects, be administered in a way that results in a minimal risk of antibiotic-resistant infections, and be inexpensive. In a metaanalysis of 25 prospective, randomized trials of prophylactic antibiotics for abdominal hysterectomy, Mittenndorf et al. reported a reduction of serious postoperative infections from 21.1% to 9%. The most commonly used antibiotic for hysterectomy is cefazolin, because it meets the preceding criteria and has a relatively long half-life of 1.8 hours. Recommended prophylactic antibiotic regimens for various gynecologic procedures are listed in Table 11.9.

Cephalosporins generally should not be given to patients with a history of penicillin allergy. Metronidazole and clindamycin have been particularly effective when anaerobic contamination is anticipated in penicillin-sensitive patients. In women with damaged or artificial heart valves or others at increased risk for bacterial endocarditis, combination antibiotics such as ampicillin (2 g) and gentamicin (1.5 mg/m²) are recommended. If the patient is allergic to penicillin, vancomycin (1 g over 1 to 2 hours) is substituted for ampicillin. Unlike prophylactic antibiotics given for operative site infections when only a single dose is administered, it is recommended that a second dose be given 6 hours later.

Adverse Reactions

Although reactions to cephalosporins occur from 1% to 10%, severe side effects such as anaphylaxis have been reported in only about 0.02% of patients. The majority of reactions are skin rashes and urticaria, which usually are resolved by the time the patient has recovered from anesthesia postoperatively. Diarrhea secondary to pseudomembranous colitis associated with β-lactam antibiotics has been reported in up to 15% of patients, but it is probably not so common in women with an antiinfective agent the night before, or even immediately before surgery. Although this practice has been recommended for many years, and povidone-iodine solution gel and gel have been demonstrated to decrease vaginal bacterial counts to undetectable levels 10 minutes after application, the bacterial flora gradually return to approximately one half pretreatment levels in 2 hours. The benefit of vaginal cleansing with an antifungal agent the night before, or even immediately before surgery, has not been evaluated in a prospective, randomized trial.

aα-hemolysin-positive staphylococcus is now recognized to be a major cause of contamination and subsequent wound or surgical site infection, having the bowel prepared whenever possible bowel involvement is suspected is beneficial. The Condon bowel prep includes adequate use of a cathartic plus oral neomycin and erythromycin in three doses the day before surgery. The use of a povidone-iodine douche or insertion of gel has been recommended for the night before admission or the day of surgery. Although this practice has been recommended for many years, and povidone-iodine solution gel and gel have been demonstrated to decrease vaginal bacterial counts to undetectable levels 10 minutes after application, the bacterial flora gradually return to approximately one half pre-treatment levels in 2 hours. The benefit of vaginal cleansing with an antifungal agent the night before, or even immediately before surgery, has not been evaluated in a prospective, randomized trial.
Bacterial vaginosis has been found to be a risk factor for postoperative infection when present before surgery in women undergoing hysterectomy. In a prospective study of 173 women who underwent major gynecologic surgery, Lin et al. found a 36% incidence of postoperative febrile morbidity in patients who had bacterial vaginosis preoperatively and only a 20% incidence of fever among the women who had a lactobacillus-dominated vaginal flora (odds ratio = 0.045). Although some data support the benefit of treating pregnant women with bacterial vaginosis to decrease the rates of preterm labor, premature rupture of the membranes, and intraamnionic infections, no data have shown a beneficial effect of preoperative treatment of hysterectomy patients. In light of the obstetric data, some gynecologists recommend screening hysterectomy patients preoperatively and treating those who are infected with metronidazole because anaerobes play such a significant role in postoperative gynecologic infections.

All gynecologists should employ careful hand-washing techniques or Avagard use preoperatively and when seeing patients. Appropriate gowns and eye coverings should be worn. Wearing double gloves is an effective way to decrease the chances of percutaneous injury. Careful surgical technique is essential to minimize postoperative infections. Adequate hemostasis should be obtained whenever possible. The amount of dead space should be limited. Large areas of necrotic tissue should be excised, and vascular pedicles should be short. Closing the subcutaneous space has no benefit, and using suture there can actually increase the rate of superficial wound infection. If the case is dirty, consideration should be given to delayed wound closure. If drains are used, they should be closed-suction drains, not gravity drains. Draining the subcutaneous space often is helpful in large patients to eliminate serous and bloody fluid.

Multiple studies have shown that double gloving significantly reduces the risk of blood contamination to the surgeon and other members of the operative team. In a large study from Finland, Laine and Aarnio reported a 7.4% glove perforation rate for single gloves in 3,020 surgery uses. When double gloves were used, the inner glove was perforated in only 0.52% of 1,148 uses. Overall, someone in the surgical team had a glove perforation during 18.5% of the operative procedures, and the literature quotes rates of up to 63% in orthopedics and trauma surgery. The most common site of perforation is the index finger of the left hand of the surgeon; but all members of the team are at risk, and gloves can be torn in clamps or retractors as well as punctured by needlestick injuries. Manufacturing defects in the gloves themselves are uncommon but do occur and may go unnoticed until blood is seen on the finger or hand. Although double gloving does reduce dexterity and tactile sensation, it also reduces the potential for blood contamination almost 10-fold. It is a good general practice and always should be used in high-risk situations.

**UNIVERSAL PRECAUTIONS**

The epidemics of acquired immunodeficiency syndrome and hepatitis B viral infection have brought to light the risks of lethal infection of the surgeon or other members of the operative team by blood or tissue fluids in association with surgery. Believing that all at-risk situations can be identified by history, physical examination, or laboratory data is naive and dangerous. To overcome this prevalent thought, universal blood and body fluid precautions were developed. This concept treats all patients’ blood and certain other body fluids capable of transmitting blood-borne pathogens as potentially infectious. Universal precautions include the following requirements: (a) the use of gloves when touching blood and body fluids, mucous membranes, or broken skin, or when handling items or surfaces soiled with blood or body fluids; (b) the use of masks and eye protection during procedures that can generate splashing or droplets in the air; (c) the use of a gown or plastic apron if splashing of blood is anticipated; (d) careful hand washing if hands are contaminated with blood or body fluids; (e) extraordinary care in handling needles or other sharp objects, and proper disposal of sharp objects in puncture-resistant containers; (f) the availability of emergency resuscitation devices to minimize the need for emergency mouth-to-mouth resuscitation; and (g) the exclusion from patient care of personnel with exudative lesions or weeping dermatitis until these conditions are resolved. Multiple studies have shown that every patient is potentially infected, using specific protocols for the safe use of invasive procedures and taking steps to avoid any and all risk-taking behavior by medical personnel can help to prevent nosocomial infections.
Some surgeons would leave the skin open for delayed closure; others would close it primarily. The use of unusual precautions to minimize the risk of the surgeon, surgical team, or health care worker acquiring a potentially fatal human immunodeficiency or hepatitis B viral infection from the patient is strongly encouraged. Although high-risk patients may be identified, all patients pose a risk to the surgeon.

Principles of Anatomy and Perioperative Considerations

CHAPTER 12 ■ SHOCK IN THE GYNECOLOGIC PATIENT
HARRIET O. SMITH AND HEATHER M. GREENE

DEFINITIONS

Cardiogenic shock—Shock in which there is intrinsic pump failure.

Class I hypovolemia—Blood losses of less than 15% of the total blood volume with no measurable changes in blood pressure, resting pulse, or respiratory rates.

Class II hypovolemia—1,000 mL of blood loss, consistent with tachycardia; however, resting blood pressure is generally preserved.

Class III hypovolemia—Blood loss equivalent to 30% to 40% of plasma volume marked by insufficient perfusion, tachycardia, tachypnea, severely diminished urinary output, and cold clammy skin.

Class IV hypovolemia—Acute blood loss of more than 2,000 mL or more than 40% of circulating volume, which is immediately life threatening.

Distributive shock—Shock in which total body water is normal or slightly decreased but is pooled into the intracellular fluid compartment, resulting in intravascular volume depletion.

Extracardiac obstructive shock—Shock in which the heart is intrinsically normal and total volume is adequate, but mechanical factors interfere with pump performance.

Hypovolemic shock—Shock in which there is an inadequate circulating blood volume resulting from hemorrhage or acute volume depletion.

Infection—A pathologic process caused by the invasion of normally sterile tissue or fluid by pathogenic or potentially pathogenic microorganisms.

Neutropenic fever—Presence of three oral temperatures >38°C (100.4°F) coexistent with a low absolute neutrophil count (ANC, less than 500/mm³).

Septic shock—Sepsis with hypotension that persists despite adequate fluid resuscitation, leading to derangements in cellular and organ system function.

Systemic inflammatory response syndrome—Presence of a hyperdynamic phase of shock but no site of infection can be found.

Shock states are among the most formidable conditions that the gynecologist is likely to encounter. The morbidity and economic impact of shock are enormous, considering the costs of primary treatment, the management of multorgan failure syndrome, and providing care for long-term disabilities that may result from partial or total loss of organ function. In the United States annually, septic shock alone affects 100,000 to 200,000 patients at an annual cost of $5 billion to $10 billion. Although recent studies indicate improvements in survival, 50% to 60% of those affected with septic shock will not survive despite aggressive therapy and significant expenditure. In obstetrics, two of the three most common causes of maternal mortality are complications from hemorrhage and sepsis. Therefore, it is critical for the practicing obstetrician-gynecologist to understand the pathogenesis, clinical signs and symptoms, and management of shock because prompt recognition and early intervention significantly reduces morbidity and mortality.

Although shock can be defined as a condition in which tissue perfusion is incapable of sustaining aerobic metabolism, in practical terms shock is best defined as an acute clinical syndrome characterized by hypoperfusion and severe dysfunction of organs vital for survival. These manifestations result from an acute generalized disturbance in the normal cardiovascular circulation. Cardiac output and circulatory blood volume may be compromised by direct myocardial injury or from hypovolemia. Clinical manifestations include mean arterial hypotension and circulatory collapse. Severe hypovolemia can occur as a direct result of uncontrolled hemorrhage or, as in septic shock, may result from the pathological redistribution of circulating volume.

CLASSIFICATION AND ETIOPATHOGENESIS

Based on the underlying cause, shock can be divided into four main categories (Table 12.1):

1. Hypovolemic shock, in which there is an inadequate circulating blood volume resulting from hemorrhage or acute volume depletion.

2. Distributive shock, in which total body water is normal or slightly decreased, but is “pooled” into the intracellular fluid compartment, resulting in intravascular volume depletion.

3. Cardiogenic shock, in which there is intrinsic pump failure.

4. Extracardiac obstructive shock, in which the heart is intrinsically normal and total blood volume is adequate, but mechanical factors interfere with pump performance.

Often, shock results from more than one of these circulatory disturbances, and the apparent cause of persistent cardiovascular dysfunction can change with time and intervening therapy. For example, septic shock is generally considered the result of tissue hypoperfusion; however, endotoxins and mediators released from injured cells have additional direct myocardial depressant effects. Thus, the cardiac presentation is similar for both hypovolemic shock and cardiogenic shock from intrinsic cardiac disease. Cardiogenic shock is characterized by a low systemic blood pressure (<80 mm Hg) associated with a severely reduced cardiac index (usually <1.8 L/min/m²) and a high left ventricular filling pressure (usually >18 mm Hg). Pulmonary edema may be present or absent.
Clinical manifestations of hemorrhagic shock can vary greatly, depending on the rate and the total volume lost, and red cell loss as measured by hemoglobin and hematocrit which do not take into account total or plasma volume. Therefore, these patients may be hypovolemic, euvoicmic, or hypervolemic. Recent studies of acute hypovolemic anemia using tagged red blood cell (RBC) studies have found that in the first few hours after surgery, the hematocrit is transiently elevated by as much as 5% because of failure of the plasma volume to decrease or correct in accordance with blood loss. When the rate of loss has been gradual, as might be found with an unruptured ectopic pregnancy or a retroperitoneal bleed, plasma refilling and other compensatory mechanisms can ensure an adequate circulating volume, and the resuscitative requirements can be severely underestimated. Once initial fluid resuscitation is begun, close observation and frequent reassessment are required as these patients remain at risk for circulatory collapse.

Obstructive shock is characterized by the inability of the ventricle to fill during diastole, which severely reduces stroke volume and cardiac output. In the gynecologic patient, massive pulmonary embolus is the most common example.

Regardless of the precipitating event, hypotension results from an inadequate circulating volume caused by cardiac insufficiency, loss of sympathetic tone, inadequate plasma volume, or a combination of these factors (Fig. 12.1). Prolonged hypotension and organ hypoperfusion leads to cellular injury that, if left unchecked, culminates in cardiovascular collapse and death or organ system failure. Because the most common types of shock encountered in obstetrics and gynecology are from hypovolemia (usually, resulting from hemorrhage) or sepsis, this chapter will focus on the recognition and management of these forms of shock.

### Hypovolemic Shock

Hypovolemic shock may be subdivided into four classes based on presenting signs and symptoms (Table 12.2). This classification schema is useful for understanding the pathophysiologic mechanisms responsible for the clinical presentation with progressively greater increments of blood loss and for estimating initial fluid losses or blood requirements. The clinical manifestations of hemorrhagic shock can vary greatly, depending on the rate and the total volume lost, and red cell loss as measured by hemoglobin and hematocrit which do not take into account total or plasma volume. Therefore, these patients may be hypovolemic, euvoicmic, or hypervolemic. Recent studies of acute hypovolemic anemia using tagged red blood cell (RBC) studies have found that in the first few hours after surgery, the hematocrit is transiently elevated by as much as 5% because of failure of the plasma volume to decrease or correct in accordance with blood loss. When the rate of loss has been gradual, as might be found with an unruptured ectopic pregnancy or a retroperitoneal bleed, plasma refilling and other compensatory mechanisms can ensure an adequate circulating volume, and the resuscitative requirements can be severely underestimated. Once initial fluid resuscitation is begun, close observation and frequent reassessment are required as these patients remain at risk for circulatory collapse.

Class I hypovolemia is associated with losses of less than 15% of the total blood volume (Table 12.2); usually, there are no measurable changes in blood pressure, resting pulse, or respiratory rates. Transcapillary refill and other compensatory mechanisms usually restore plasma volume within 24 hours. With class II hypovolemia, or up to 1,000 mL blood loss, the most consistent clinical finding is tachycardia. The increase in heart rate is often associated with a narrowed pulse pressure (the difference between systolic and diastolic pressures). The resting blood pressure, however, is generally preserved by compensatory mechanisms, including the renin-angiotensin system and the hypothalamic–hypophyseal–adrenal system. In response to a decrease in wall tension or sodium, or sympathetic activation, the juxtaglomerular cells release renin into plasma. Renin converts angiotensinogen into angiotensin I, an inactive polypeptide, which is metabolized in the liver to angiotensin II, a potent vasoconstrictor that stimulates aldosterone secretion from the renal cortex. Aldosterone, along with the pituitary release of antidiuretic hormone, promotes sodium and water retention. These mechanisms increase venous return and, consequently, stroke volume, cardiac output, and blood pressure. Thus, oliguria is a common manifestation of hypovolemic shock. In response to hypovolemia, norepinephrine and epinephrine are locally and systemically released. Catecholamine-mediated effects are inotropic and chronotropic, resulting in increased cardiac output. Venocclusion enhances venous return, which also increases stroke volume and cardiac output. In response to the catecholamine-mediated increase in peripheral vascular resistance, the diastolic blood pressure is increased, which leads to a narrowed pulse pressure. Typically, the resting blood pressure is normal; however, when blood pressure and pulse are recorded in the standing, sitting, or reclining position, a narrowed pulse pressure is usually observed. This is the major clinical distinction between class I and class II hypovolemic shock. As long as these compensatory mechanisms remain intact, shock is almost always eventually reversible, hence the frequently used descriptive term early shock.

Although patients with losses of 20% to 30% of their blood volume may ultimately require RBC replacement for immediate resuscitation, crystalloid is usually adequate. Crystalloid replacement is guided by the 3:1 rule: 300 mL crystalloid per 100 mL of blood (plasma volume) lost. In normal adults, approximately two thirds of the total body water is intracellular, and the remaining one third in the extracellular fluid compartment is disproportionately distributed between the intracellular extracellular compartments, with intravascular and intracellular compartments in a 3:1 ratio. Collod oncotic pressure, the effective osmotic pressure between the interstitial and intravascular compartments, is dependent on
transcapillary hydrostatic and oncotic pressures, and the relative permeability of capillary membranes that divide these spaces. Because of these forces, within 24 hours of intravenous crystalloid administration, approximately two thirds will disperse into the interstitial compartments. Although the principal determinant of oxygen delivery is hemoglobin, tissue oxygenation remains adequate as long as intravascular volume is adequate, and cardiac output appropriately increases despite major reductions in hemoglobin (<7 g/dL). This is because oxygen delivery is not dependent on hemoglobin concentration alone. However, in class III hypovolemic shock (Table 12.2), which is associated with a blood loss equivalent to 30% to 40% of the plasma volume, the physiologic compensatory mechanisms previously described begin to fail. Patients almost always present with classic signs of insufficient perfusion, including marked tachycardia, tachypnea,

bMeasure heart rate and blood pressure in standing, sitting, and recumbent positions with 5 minutes between measurements to permit equilibration. Orthostatic change (+ tilt) is a postural increase in pulse of 10 to 15 beats/minute or a drop in systolic blood pressure of at least 10 mm Hg.

severely diminished urinary output, and cold, clammy skin. Importantly, in uncomplicated shock, 1,500 to 2,000 mL is the smallest amount of blood loss that is consistently associated with a drop in the systolic blood pressure. Arterial hypotension and a fall in cardiac output diminish oxygen delivery to peripheral tissues. This is shown by the following formula:

\[
\text{DO}_2 = \text{CaO}_2 \times \text{Qt} \times \text{SaO}_2/100 \times 1.39 \times \text{Hb} + 0.003 \times \text{PaO}_2
\]

Where:
- \( \text{DO}_2 \) = oxygen delivery;
- \( \text{Qt} \) = cardiac output;
- \( \text{CaO}_2 \) = arterial oxygen tension;
- \( \text{SaO}_2 \) = hemoglobin saturation; and
- \( \text{PaO}_2 \) = amount of oxygen physically dissolved in arterial blood.

As is illustrated, arterial oxygen tension is a complex formula dependent on the hemoglobin concentration, saturation, and amount of oxygen physically dissolved in arterial blood. Anemia effects must be separated from the effects of hypovolemia, as both interfere with oxygen transport. Although the lower limit of tolerated acute normovolemic anemia has not been established, most normal individuals tolerate Hb of 7 g/dL, partially as a result of improved \( \text{O}_2 \) delivery facilitated by increase in 2,3-diphosphoglycerate levels in RBCs. Tissues that can maintain their oxygen consumption accomplish this by increasing their \( \text{O}_2 \) extraction, the ratio of oxygen consumption to oxygen delivery. This results in an increase in the arterial and venous oxygen difference and reduction in \( \text{O}_2 \) extraction. Eventually, under conditions of increased oxygen demand (stress, sepsis) or insufficient oxygen delivery (severely reduced cardiac output, hypovolemia, and profound anemia), these compensatory mechanisms fail, and tissue hypoxia and lactic acidosis ensue. Cerebral and cardiac functions are maintained by diverting blood flow from the skin, muscles, gastrointestinal tract, and kidneys. Complicated shock associated with loss of compensatory physiologic mechanisms is often called intermediate shock. In this phase, reversibility is dependent on prompt crystalloid and blood product replacement to avoid irreversible ischemia of vital organs.

Class IV hypovolemic shock, defined as an acute blood loss of more than 2,000 mL, or more than 40% of the circulating volume, is immediately life threatening. Survival depends on rapid transfusion of blood and crystalloid and immediate surgical intervention before cardiac and cerebral circulation fail, resulting in ischemia in these organs. When vital organs fail, total cardiovascular collapse, coma, and eventually death or multorgan failure is likely. The transition between the intermediate stage of shock and irreversible shock (late shock, cold shock) is dependent on the duration and severity of the hypovolemia; however, once cellular injury has occurred within the brain and cardiac muscle, shock is almost always irreversible and fatal.

Septic Shock

Over the past several decades, the incidence of sepsis—the precursor to septic shock and multorgan failure—has increased. In the United States alone, sepsis and septic shock affect an estimated 750,000 patients per year with an expected 1.5% annual increase in incidence at a total annual hospital cost of $16.7 billion. Annually, there are approximately 215,000 deaths from sepsis, with mortality rates for severe sepsis and septic shock of 20% to 52% and 50% to 60%, respectively. An increasing emphasis has been placed on correct identification of the degree or severity of sepsis to more effectively prescribe treatment and evaluate response.

Sepsis represents a continuum from the preshock phase or early hypodynamic phase to the late shock phase. The early hypodynamic phase is characterized by a normal or slight decrease in blood pressure and tachycardia. The slight decrease in systemic vascular resistance (SVR) is offset by a marked increase in cardiac output. In contrast, the classic features of late shock include low SVR and low cardiac output, hypoperfusion, and lactic acidosis. In 1992, the ACCP/SCCM Consensus Conference developed widely accepted and used standard definitions of sepsis and its related conditions. This was followed by the Sepsis Definition Conference (2001), which expanded the list of signs and symptoms of sepsis to reflect clinical bedside experience that reinforced clinical definitions (Table 12.3).

Infection is defined as a pathologic process caused by the invasion of normally sterile tissue or fluid by body cavity by pathogenic or potentially pathogenic microorganisms. When early hypodynamic phase of shock is present but no site of infection can be found, the process is termed the systemic inflammatory response syndrome. Sepsis is defined as a systemic response to infection manifested by two or more of the following: fever or hypothermia, tachycardia, tachypnea, and an elevated or severely depressed white blood cell count. Septic shock is sepsis with hypotension that persists despite adequate fluid resuscitation, leading to derangements in cellular and organ system function. Although helpful in differentiating categories of sepsis, Levy and colleagues note that these definitions do not allow for precise classification and staging of patients with this condition. Therefore, a rudimentary stratification scheme termed Predisposing Factors, Infection, Response, and Organ Dysfunction (PIRO) was developed to classify patients in terms of their predisposing conditions, the nature of the insult (which in the case of sepsis is the infection), and the nature and magnitude of host response and the degree of concomitant organ dysfunction (Table 12.4). Microbial factors contribute to outcome in patients with severe sepsis. Hospital-acquired bacteremia has increased coincident with the rise in predisposing risk factors: an aging population with underlying systemic disease (diabetes mellitus, cirrhosis, malignancy, lymphoproliferative disorders), invasive devices, burns, prolonged or indiscriminate use of broad-spectrum antibiotics, aggressive cytotoxic chemotherapy, and use of corticosteroids and other immunosuppressive agents. Most nosocomial infections are associated with the use of invasive devices: 83% of pneumonias in mechanically ventilated patients, 97% of urinary tract infections in catheterized patients, and 87% of bloodstream infections in patients with central intravenous lines. Although sepsis can be caused by fungi and viruses, Gram-positive bacteria and Gram-negative bacteria are the most common isolates from patients with severe sepsis. Gram-negative organisms used to account for more than half of all episodes of bacteremia, but recent studies indicate that mortality caused by Gram-positive bacteremia now equals or exceeds that of Gram-negative bacteremia. Staphylococci, mainly Staphylococcus aureus or coagulase-negative staphylococci, and streptococci such as Streptococcus pneumoniae are the most frequent microbes involved. In obstetrics and gynecology, Gram-positive aerobes account for 31% of bacteremic episodes, and Gram-positive anaerobes, mainly group B streptococci and Peptostreptococcus, 18% of septic

**Shock in the Gynecologic Patient**

Episodes: Gram-negative microbes are responsible for 41% of all septic episodes. The most commonly isolated Gram-negative bacteria are *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*, with *Escherichia coli* predominating. Less frequent isolates include *Enterobacter aerogenes*, *Acinetobacter*, *Proteus*, *Serratia*, *Aeromonas*, *Xanthomonas*, *Citrobacter*, *Achromobacter*, *Salmonella*, and *Mogella* spp.

The Gram-negative bacterial cell wall consists of an inner and outer cell membrane, the latter of which contains lipopolysaccharide (LPS), or bacterial endotoxin. LPS consists of three principal regions: the O antigen, the R core antigen, and lipid A, which is responsible for toxicity. The lipid A portion of the LPS molecule mediates the binding of CD14 and Toll-like receptors (TLRs—specifically TLR4) and perhaps other receptors with lipopolysaccharide-binding protein (LBP). This coupling enables LPS to bind to mammalian cells. Depending on the involved cell type, LPS-LBP-CD14-TLR4 receptor binding induces the release of a variety of mediators. These include cytokines, interferon-α, prothrombin, procoagulins, thromboxane A2, leukotrienes, complement component fragments (especially C3a, C5a), platelet-activating factor (PAF), and cathehalamines. Peptidoglycan and lipoteichoic acids of Gram-positive bacteria, certain polysaccharides, extracellular enzymes, and toxins are also able to induce intracellular responses similar to those of LPS (Fig. 12.2). The inflammatory cytokines interact by way of autocrine, paracrine, and endocrine mechanisms to stimulate leukocytes and vascular endothelial cells to release other cytokines, express cell-surface adhesion molecules, and increase production of arachidonic metabolites. Biologically, their effects appear to be synergistic. Tumor necrosis factor (TNF)-α in particular plays an early, critical role in cellular activation and the propagation of the inflammatory response. TNF-α levels are elevated in severe sepsis, myocardial infarction, adult respiratory distress syndrome, and multiorgan failure and correlate with increased mortality rates. In contrast, interleukin (IL)-1β levels are only slightly increased in humans with severe sepsis and do not appear to correlate with severity or outcome. However, plasma concentrations of IL-6 in plasma levels can discriminate among patients who survive or die from severe sepsis/septic shock. In women with pelvic inflammatory disease (PID), cervical as well as systemic IL-6 levels are increased, and correlate with higher erythrocyte sedimentation rate and white blood cell counts. These data suggest that measurements of specific inflammatory cytokines such as IL-6 may eventually be used to evaluate response to therapy in patients with PID.

Hemostatic effects are common in sepsis and result from vascular endothelial cell injury thought to be caused by endotoxins and phospholipid-mediated mediators. The net coagulation defects in sepsis are predominantly procoagulant and override the anticoagulant effects that concomitantly occur. Prostaglandin E2 and prostacyclin are potent vasodilators, whereas thromboxane A2 is a potent vasoconstrictor that, together with PAF, promotes platelet aggregation. Blood coagulation results from activation of the intrinsic, extrinsic, and common pathways, culminating in the generation of thrombin. Thrombosis is enhanced by impairment of antithrombin III and tissue plasminogen activator, as well as by plasminogen activator inhibitors-1, released by stimulated monocytes. Neutrophils, attracted by the injured vascular epithelium, release procoagulins that inhibit thrombin formation and elastase—free oxygen radicals, proteases, and leukotrienes that are responsible for fibrinolysis. Microcirculation is further impaired by the resulting microthrombi and the cytotoxic effects of cytokines released by inflammatory cells.
Gluconeogenesis is increased, as well as glycogenolysis. As hydrolysis of pyruvate from muscles, wounds, and monocytes. Hepatic is a significant increase in the production and release of lactate jury by a process known as aerobic glycolysis. The net result of these events is an increase in basal rate and is increased in proportion to the degree of inflammation. The liver, as well as other tissues, is a major site of protein catabolism and amino acid disposal. The transfer of amino groups to α-ketoglutarate for the synthesis of glutamate occurs in the liver and is dependent on the reduced activity of the transaminase. Subsequently, glutamate is converted to glutamine, which is released into the plasma, and then reconverted to glutamate in muscle and other tissues. The latter process, as well as amino acid transport across the blood-brain barrier, is dependent on the availability of glutamine. The liver is a major site of amino acid disposal, as well as a major source of amino acids for other tissues.

Energy expenditure is often 1.5 to 2 times the basal rate, and is increased in proportion to the degree of inflammation. The liver, as well as other tissues, is a major site of protein catabolism and amino acid disposal. The transfer of amino groups to α-ketoglutarate for the synthesis of glutamate occurs in the liver and is dependent on the reduced activity of the transaminase. Subsequently, glutamate is converted to glutamine, which is released into the plasma, and then reconverted to glutamate in muscle and other tissues. The latter process, as well as amino acid transport across the blood-brain barrier, is dependent on the availability of glutamine. The liver is a major site of amino acid disposal, as well as a major source of amino acids for other tissues.

Lipolysis and ketogenesis are also increased, and in the absence of nutritional support, long-chain fatty acid deficiency can lead to profound hypoglycemia. In diabetic patients, however, impaired gluconeogenesis and increased lactic acid. Hyperglycemia can occur, especially in diabetics, patients; however, impaired gluconeogenesis and excessive insulin release can lead to profound hypoglycemia. Lipolysis and ketogenesis are also increased, and in the absence of nutritional support, long-chain fatty acid deficiency can develop.

In patients who develop irreversible organ failure, the systemic inflammatory response is maintained long after the initial injury and response have abated. Although the mechanisms for this process are poorly understood, undetected microcirculatory dysfunction may be a critical factor. More likely, at some critical point, the perpetuation of cellular and organ system hypermetabolism becomes independent of host regulatory mechanisms.

At the cellular level, differences in ionic composition between the cellular and extracellular compartment are normally maintained by semipermeable membranes, energy-dependent cell transport mechanisms, transmembrane differences in

PRINCIPLES OF ANATOMY AND PERIOPERATIVE CONSIDERATIONS

Attraction to the damaged endothelium. This effect has been proposed as a possible mechanism for persistent organ system dysfunction. Thrombocytopenia is common. Although fulminant disseminated intravascular coagulation can eventually develop, the coagulation profile is usually consistent with compensated intravascular coagulation with fibrinolysis. That is, fibrinogen levels are normal or slightly decreased, prothrombin time (PT) and partial thromboplastin time (PTT) are normal or slightly prolonged. However, thrombin generation is increased, and fibrin formation is accelerated. Shock in the Gynecologic Patient

electrical potential, particle charge, and oncotic pressure. With the development of metabolic acidosis, coupled with a decreased production of intracellular cyclic adenosine triphosphate (the energy substrate for cell transport), the normal ionic composition within cells that is critical for mitochondrial function can no longer be maintained. There is an influx of sodium and water and an efflux of potassium, resulting in gradual hemococoncentration and hypotension. Although irreversible cellular injury and, ultimately, cell death can result from organ system dysfunction caused by
pressure and systemic vascular resistance. Depending on the severity of hypoperfusion and organ system reserve, cardiovascular collapse and death or multiorgan failure may ensue (Fig. 12.2).

In shock states, preservation of cardiac function is critical. Mild to moderate losses in blood volume (up to 1,500 mL) result in a temporary decrease in cardiac output and SVR. Venoconstriction increases venous return, enhancing stroke volume and cardiac output. As shock worsens, cardiac output decreases and severe vasoconstriction develops, leading to hypotension and organ hypoperfusion. Coronary artery perfusion is reduced, leading to myocardial ischemia, dysrhythmias, and further evidence of cardiac dysfunction. With progressive heart failure, the LVED pressure rises, resulting in impairment of gas exchange, tissue hypoxia, and pulmonary edema. The most common clinical presentation of cardiac involvement is tachycardia. This may be associated with a wide pulse pressure and bounding pulses, as with the acute hypodynamic phase of septic shock (systemic inflammatory response syndrome, or early shock). Weak, thready pulses typically accompany severe hemorrhagic shock and advanced septic shock (late shock). Unfortunately, tachycardia may not be a reliable sign of hypotension after trauma. Although tachycardia is independently associated with hypotension, its sensitivity and specificity limit its usefulness in the initial evaluation of trauma victims, and absence of tachycardia should not reassure the clinician about the absence of significant blood loss. Patients who are both hypotensive and tachycardic have increased mortality and warrant even more diligent evaluation. Signs and symptoms of coronary artery hypoperfusion include chest pain and dyspnea; clinical findings can include jugular neck vein distention, pulmonary rales and crackles, a new S3 or S4 gallop, and a middiastolic regurgitation murmur that signifies papillary muscle injury. Electrocardiogram changes may be consistent with myocardial ischemia.

Heart

In addition to a severe systemic vascular response, patients with sepsis and septic shock also develop severe derangements in cardiac function. Although these effects have been attributed to global myocardial ischemia, recent studies support the hypothesis that myocardial depression occurs in response to circulating myocardial depressant substances, such as a soluble catabolic product released by the pancreas, TNE–TNE, and IL-1β. Initially, patients may present with a normal or slightly reduced cardiac output. This is due to hypovolemia from arterial and venous dilatation and interstitial pooling. With adequate fluid resuscitation, the hemodynamic presentation is that of a marked increase in cardiac output (∼11 L/min), a low SVR, and a severely reduced ventricular ejection fraction. In surviving patients, there is usually a compensatory increase in the left ventricular end-diastolic volume (LVEDV) secondary to ventricular dilatation. Current evidence suggests that right ventricular dysfunction in septic shock closely parallels left ventricular dysfunction. Right ventricular function in both septics and septic shock is characterized by ventricular dilatation and decreased right ventricular ejection fraction, changes that resolve in 7 to 14 days. Patients who do not survive have persistent right ventricular dysfunction. Several studies also suggest the existence of significant right ventricular compliance abnormalities in patients with septic shock. However, the relative contribution of abnormalities of compliance and contractility to impaired cardiac function of the right ventricle is currently unknown.

The initial cardiac effects of septic shock include decreased contractility and, in survivors, compensatory ventricular dilatation. Because stroke volume is maintained and tachycardia is pronounced, cardiac output is almost always dramatically increased. In this setting, cardiac output is a poor measure of myocardial performance. In the recovery phase, the SVR returns to normal over 24 hours or so, and the cardiac index drops to near normal levels. In septic shock fatalities, little or no initial reduction in stroke volume or increase in LVEDV was found, suggesting that ventricular dilatation is absent in these patients, which accounts for the lack of compensatory increase in stroke volume or cardiac output needed to maintain arterial
perfusion defect can be partial or total, and tubular or cortical necrosis, or both, can result.

Skin and Mucous Membranes

When the skin is poorly perfused, its temperature falls and its color changes, so that it is cold to the touch and pale, dusky, or mottled in appearance. When hypoxemia is pronounced, the skin may become frankly cyanotic. Sympathetic stimulation results in increased sweat gland secretion; consequently, the skin may be moist, cold, or clammy. With mild hypovolemia, capillary refill, which is clinically assessed by compressing and then releasing pressure on the fingernail beds, remains normal. However, with losses of 30% or more of the circulating volume, patients nearly always demonstrate a positive capillary refill test (>2 seconds). The lips and oral cavity may appear dry or chapped. The conscious patient usually experiences intense thirst.

Lung

The pulmonary vasculature is particularly susceptible to injury. Clinical manifestations include dyspnea, progressive hypoxemia, diffuse bilateral pulmonary infiltrates, and reduced compliance. A condition is referred to as adult respiratory distress syndrome (ARDS). The combination of ARDS and Gram-negative sepsis is particularly ominous, because nearly 50% of patients diagnosed with sepsis develop acute lung injury/ARDS, contributing to mortality rates of 80% to 90%. ARDS results from increased pulmonary capillary permeability and the accumulation of extravascular lung water. Inflammatory cells spill into the alveoli, destroying the delicate type I alveolar cells. This is followed by proliferation of type II pneumocytes, thickening of the alveolar–capillary membranes, and subsequent fibrosis. Clinically, ARDS is characterized by intrapulmonary shunting, widening of the alveolar–arterial oxygen gradient, and reduced pulmonary compliance and functional residual capacity. Radiographic findings are consistent with pulmonary edema, despite a normal or low pulmonary capillary wedge pressure (PCWP). Arterial PaO2 remains low (<65 mm Hg), even with supplemental oxygen, and assisted mechanical ventilation is often required.

Liver

In sepsis, the liver plays a critical role in host defense response. Kupffer cells are important for bacterial scavenging, inactivation of bacterial products, and proinflammatory cytokine production and clearance. Cytokine receptor-mediated responses within hepatocytes include gluconeogenesis, amino-acid uptake, and increased synthesis of coagulant and complement factors and protease inhibitors. Paradoxically, the acute phase protein response also contributes to a procoagulant state, inhibiting the production and function of protein C. Primary hepatic dysfunction refers to sepsis-induced derangements that typically resolve in disseminated intravascular coagulation and bleeding. Reduced perfusion appears to be the most important initiating event. Secondary hepatic dysfunction is a more frequent, silent, and at times imperceptible dysfunction that probably results from spillover of bacterial, endotoxin, and inflammatory mediators. At this juncture, most of the liver's function is clinically intact. Liver dysfunction associated with multiorgan failure is characterized by elevated bilirubin levels, rarely exceeding 10 mg/dL, approximately 80% of which is conjugated. Hyperbilirubinemia results from the breakdown of RBCs and from hepatocellular dysfunction. Although alkaline phosphatase often is 1 to 3 times that of AST or ALT, more dramatic elevations may be observed, especially in the elderly. Patients with hepatic failure secondary to sepsis continue to demonstrate progressive worsening abnormalities in plasma albumin, fat, and amino acid metabolism. The amino acid profile is typically one of decreased branched chain and increased aromatic amino acids.

Gastrointestinal Tract

Gastrointestinal failure presents as gastrointestinal stress bleeding, which is characterized clinically by “coffee-ground” staining of gastric aspirates, or frank, bright red bleeding. In addition to blood loss, the resulting mucosal injury increases the likelihood of translocation of bacteria to the blood and liver. Bacterial translocation—the movement of viable organisms from the gut lumen across intact epithelium into the mesenteric lymph nodes, liver, spleen, lungs, or the systemic circulation—has been postulated as a potential source of bacteria and sepsis. Normally, the gastrointestinal mucosa serves as an important mechanical barrier to systemic contamination by intraluminal microflora. The normal gut flora consists predominantly of anaerobic bacteria that displace more pathogenic organisms such as Escherichia coli and Candida albicans away from the gastrointestinal mucosa, a host defense mechanism termed colonization resistance. The source of Gram-negative bacteremia after trauma and hypovolemic shock is thought to be from mucosal endothelial cell injury or from bacterial translocation. The microvascular circulation of the mesenteric vili appears to be highly susceptible to mesenteric ischemia, leading to further endothelial cell injury. As with the kidney and lung, inflammatory cells are attracted to the site of endothelial cell injury. Cytokines and oxygen free radicals are released that promote additional injury that may result in mucosal ulceration or bleeding, or both.

Summary of Shock Presentation

Clinical signs and symptoms and systemic manifestations are frequently subdivided into early, usually reversible manifestations (Table 12.3) and late findings (Table 12.6). In early stages, the clinical findings of hypovolemic and septic shock differ, but are usually reversible, whereas the clinical features are essentially the same for late or irreversible shock. When diagnosis or intervention is delayed or insufficient, shock can become irreversible, resulting in permanent organ dysfunction or death. The patient may enter a chronic condition of continued mal-function of one or more organ systems—despite adequate volume restoration, the absence of persistent infection, and other identifiable insults (Fig. 12.1) termed multiorgan failure syndrome. Multiorgan failure, depending on the number of organ systems involved, carries a mortality of 30% to 100% and is the most common cause of death from shock. In addition to continued central nervous system, cardiac, and renal dysfunction, organ system failure in its classic presentation usually involves the lungs first (24 to 72 hours after the original injury), then the liver (5 to 7 days), followed by the gastrointestinal tract (10 to 15 days) and kidneys (11 to 17 days). However, many variations in clinical presentation are seen. For example, patients...

Febrile Neutropenia

Neutropenic fever is clinically defined by three oral temperatures of 38°C (100.4°F) or a single temperature higher than 38.5°C (101.3°F) coexistent with a low ANC (less than 500/mm³). Over the past several decades, bacteremia in febrile neutropenic patients has shifted from Gram-negative to Gram-positive organisms secondary to more frequent use of indwelling catheters, which are particularly at risk for Gram-positive colonization from skin flora. Other contributing factors include use of prophylactic antibiotics, the type of chemotherapy given, and regional climatic conditions. In the early 1970s, the empirical use of intravenous broad-spectrum antibiotics in febrile neutropenic patients significantly reduced infection-related mortality; patients were typically hospitalized and treated until their ANC had recovered and they were afebrile for at least 24 hours. However, in nearly half of neutropenic patients who receive standard antibiotic therapy, no bacterial infection is identified. Recent estimates indicate that cancer patients account for 126,209 severe sepsis cases annually in the United States—16.4 cases per 1,000 people per year. Severe sepsis is associated with 8.5% of all cancer-related deaths at a cost of 3.4 billion dollars per year; the overall mortality rate for febrile neutropenia is approximately 6%. Costs of hospitalization, risks of exposure to nosocomial infections, emergence of drug resistance, and variable compliance with antibiotic regimens formed the basis for stratification of febrile neutropenic cancer patients into high- and low-risk groups. Individual studies and systematic reviews indicate that low-risk patients with neutropenic fever may be treated safely with oral antibiotics. A metaanalysis of neutropenic patients (1980–1994) found that antibiotic prophylaxis significantly reduced the risk of death over placebo or no treatment (RR 0.67, 95% CI 0.55, 0.83) and that oral fluoroquinolone prophylaxis significantly reduced mortality (RR 0.52, 95% CI 0.35, 0.77). Despite this, quinolone prophylaxis increases the risk for harboring antibiotic-resistant organisms. A subsequent metaanalysis of the Cochrane Database of Systemic Reviews found that adding anti-Gram-positive therapy did not adversely affect survival. Overuse of Gram-positive coverage has led to the emergence of resistant enterococci and, more recently, S. aureus species. Because of concern regarding the spread of vancomycin resistance, its empirical use in this setting is specifically discouraged. In one recent study, in select low-risk

*Variable in severity, depending upon the rate and volume of loss.

Febrile neutropenic patients (no clinical evidence of infection, IL-8 < 60 ng/L), withholding empiric antibiotic therapy did not increase adverse events and resulted in cost savings of $572 per patient. In hospitalized febrile neutropenic patients with hematological malignancies, piperacillin-tazobactam was found to be more effective and cost-efficient than ceftriaxone plus gentamicin. The specific management of neutropenic patients must be based on the underlying malignancy, prior prophylactic therapy, institutional/community drug-resistance patterns, and patient risk factors.

**MANAGEMENT OF SHOCK**

For the gynecologist who infrequently encounters a moribund, unstable patient in shock, it may be useful to remember to restore ORDER. The mnemonic, ORDER, outlined in Table 12.7, provides the appropriate sequence of resuscitative priorities. After immediate resuscitative measures are initiated, it is highly recommended that continued management of all but the least complicated cases be carried out in a modern critical care unit. A team approach with the benefit of staff trained in intensive care medicine can greatly improve the likelihood of survival, as well as significantly reduce morbidity. General guidelines for managing shock are provided in Table 12.8.

**Oxygenate**

For patients with minimal or no respiratory distress, oxygen delivery at 1 to 6 L/min by nasal cannula may be sufficient. When respiratory distress is evident, oxygen delivery by face mask at the recommended flow rate (8–10 L/min) will increase the inspired oxygen concentrations to 80% to 100% with an oxygen reservoir, compared with 40% to 60% without a reservoir. For patients who are disoriented or obtunded, tiring, or unable to maintain sufficient arterial oxygenation (Pao₂ < 60 mm Hg), the airway must be protected. Immediate endotracheal intubation with positive pressure ventilation should be instituted. Oxygenation in patients with increased compliance and high intrapulmonary shunt fractions (e.g., ARDS, pulmonary edema) can be improved by the addition of positive end-expiratory pressure (PEEP) at physiologic or low levels (5–15 cm H₂O). Because high levels of PEEP can reduce venous return and, consequently, reduce cardiac output, patients needing higher levels may benefit from invasive hemodynamic monitoring to determine the "best" PEEP to optimize oxygen delivery.

**Restore Circulating Volume**

Initial fluid therapy should consist of a 1- to 2-liter fluid challenge with an isotonic electrolyte solution, preferably Ringer’s lactate. Normal or half normal saline solution can also be infused; however, prolonged use of these infusions increases the risk of hyperchloremic acidosis if renal function is impaired. Because severe hypernatremia increases the risk of brain dehydration or death, hypertonic saline is not recommended except under special circumstances and is not part of the initial management. Albumin and other colloidal solutions (high- or low-molecular-weight dextran, polyethyl starches) have been advocated to restore and maintain circulation under the premise that these agents are more likely to remain in the intravascular...
In trauma and perioperative patients, hypobutermia of some degree is almost universal, and results from crystalloid administration, increases in capillary permeability, and sequestration of albumin in the interstitial compartment. Albumin has been used in edematous patients based on ratio nale that edema fluid may be “pulled” into the intracellular compartment and excreted. This practice is not supported by scientific data and may actually be harmful. Colloids can eventually “leak” across damaged pulmonary capillary epithelium, may be lifesaving in selected clinical settings, specifically patients with cirrhosis and spontaneous bacterial peritonitis. The choice of fluid replacement also has considerable cost implications, because colloids are more expensive than crystalloid administration and more expensive than hydroxyethyl starch.

In most cases, hemorrhagic shock should be managed initially by inserting one or two large-bore (14- or 16-gauge) angiocatheters for volume replacement. Central venous catheterization is not recommended for most patients. Central venous access will not improve the rate of fluid administration and carries the risk of pneumothorax and other potentially life-threatening complications. Central circulation can also be improved by elevating the feet or by placing the patient in the Trendelenburg position. Blood can be drawn for initial laboratory assessment at the time that intravenous access is obtained and should include a complete blood count with differential and platelets, electrolytes, blood urea nitrogen (BUN), creatinine, calcium, magnesium, glucose, phosphate, and, where indicated, serum human chorionic gonadotropin β, liver function studies, clotting profiles, serum lactate, and blood cultures.

In patients with distributive shock, or shock following ischemic injury from severe or prolonged hypovolemia, damage to the capillary endothelium results in increased capillary permeability and greater interstitial losses, and larger volumes of fluid are required to restore circulatory volume than may be apparent by clinical estimation of the plasma volume. For example, 6 to 7 liters of fluid may be required for what appears to be 1 to 1.5 liters of plasma volume depletion. Most of these patients have some degree of cardiac dysfunction and are at high risk for lung injury from injurious volume expansion. Because central venous pressure and PCWP are often discordant, right heart catheterization has been advocated

after immediate fluid resuscitation. Additional volume replace- ment or pressure support may then be based on determina- tions of the pulmonary artery mean and occlusive pressures, cardiac output, cardiac index, and SVR. Mixed venous oxy- gen content can be also obtained to estimate oxygen deliv- ery at the cellular level. For patients with pulmonary injury, shunt fractions and alveolar-arterial oxygen differences can be calculated to evaluate ventilatory and RBC trans- fusion requirements. Contors and colleagues, in a prospective study of 52 critically ill patients with multiorgan system dis- ease, found that clinical estimates of volume status are signific- antly different from estimates based on right heart catheter- ization parameters; in this study, major changes in therapy (altering the rate of fluid administration, or starting or stop- ping a pressor agent, or both) occurred in 48.4% of cases after catheterization.

Many cardiologists and critical care physicians believe that therapy guided by pulmonary artery catheterization (PAC) leads to improved patient outcomes. However, the “routine” use of Swan-Ganz catheters in patients with sepsis is controver- sial. One or more randomized controlled clinical trials could clarify this issue; however, attempts at randomized controlled trials have failed, mostly because of physician biases for or against their use. In the absence of controlled trials, observa- tional studies permitting, placement of right heart catheters at the discretion of the physician are being used in an attempt to clarify the risk/benefit ratios. These studies are inherently biased because the more critically ill the patient is, the more likely he is to undergo right heart catheterization, and the more likely she is to die, independent of this intervention—a selection bias has termed confounding by indication. In one observational study of 5,735 critically ill patients in five teaching hospitals, PAC use was found to be associated with increased mortality and costs with no clear benefit. A PAC Consensus Conference con- cluded that there is insufficient evidence to support the routine use of PACs in septic patients, but PAC improves outcome in patients with myocardial infarction complicated by cardio- genic shock and right ventricular infarction. In patients with respiratory failure (i.e., ARDS versus pulmonary edema), deter- minations of pulmonary artery mean and occlusive pressures, cardiac output, cardiac index, and systemic vascular resistance may be useful to determine the underlying and to guide fluid therapy, but it is uncertain that using PACs in this setting improves survival.

Specific blood component therapy has virtually replaced whole blood transfusion as the standard of care. Packed red blood cells (PRBC) have a volume of 200 to 250 mL and a hematocrit of 70%. Combined with normal saline, PRBCs are the component of choice for hemorrhagic shock. Loss of approximately 20% of blood volume is equivalent to 1,500 mL blood loss and in a normal 70-kg individual is not associ- ated with a significant reduction in oxygen-carrying capacity or ventilator filling pressures when adequate crystalloid resus- citation is given. Because the oxygen-carrying capacity is met in most healthy patients with a hemoglobin of 7 g/dL, empirical transfusion for moderate anemia (8 to 10 g/dL) is no longer recommended. Nevertheless, because most of the oxygen trans- ferred in the blood is by hemoglobin, correction of anemia is an important component in optimizing oxygen delivery at the cellular level (Table 12.8). In general, these recommendations regarding RBC transfusion have been derived from the man- agement of trauma victims that were in normal health before and at the event. In the critically ill patients and those with signif- icant underlying cardiac disease, RBC transfusions have been used liberally to maintain hemoglobin levels between 10 and 12 g/dL to reduce the potential adverse effects of oxygen debt.

The importance of weighing the benefits of RBC transfu- sion against potential adverse effects has received considerable attention. Current estimates of the risk per unit of blood in the postnuclear acid testing era are 1 in 872,000 to 7 million and in 4–8 million for hepatitis C virus and human immuno- deficiency virus (HIV), respectively. Other risks of contami- nation include human T-cell lymphotrophic virus (1/250,000– 1,000,000), acute hemolytic transfusion, delayed hemolytic (1/7,000), and transfusion-related lung inju- ry (1/5,000). Currently, bacterial contamination of platelets poses the greatest risk of transfusion transmitted disease. Of 4 million platelet units transfused annually in the United States, as many as 4,000 are bacterially contaminated, resulting in 333 to 1,000 cases of severe sepsis. Concern for infectious risks (HIV, hepatitis, shortages, and expense led many gov- ernmental agencies and advisory boards, including the Amer-ican College of Obstetricians and Gynecologists, to adopt lower thresholds for empiric transfusion. In a multicenter, ran- domized controlled clinical trial of critically ill patients, there were no differences in mortality rates when hemoglobin lev- els were maintained between 7 and 9 mg/dL compared with scheduled transfusions to maintain levels between 10 and 12 mg/dL, and mortality rates among younger (<35 years) and less acutely ill patients were significantly lower for those who were not transfused. The immunomodulation effects of blood transfusion—immune suppression, allograft tolerance, and the potential development of autoimmune diseases—probably occurs secondarily to exposure and sensitization of leukocytes. Immunosuppression may contribute to postoperative infection in transfused patients and may increase recurrence for some solid tumors. Despite these risks, the benefit of leukocyte re- duction of cellular blood components is proven. Because the cost of universal leukodepletion is in excess of $500 million, this practice is unlikely to be adopted until proven beneficial.

Preoperative autologous donation, the practice of do- nating blood before surgery, accounted for 6% of blood transfused blood in 1992 but has declined to about 2%. Pre- operative autologous transfusions are also more costly than allogeic blood transfusion. HIV and hepatitis C transmis- sion risks, which spawned the wide acceptance of this prac- tice, have dramatically declined in recent years, and autolo- gous blood donation may actually be transfused to patients and include bacterial contamination, volume overload, administra- tion error/ABO incompatibility, and perioperative anemia, ne- cessitating allogeic transfusion. This practice is also waste- ful, as up to half of the blood donated for this purpose in the United States is ultimately discarded. Advantages include the prevention of transfusion-transmitted disease, red cell al- lomunization, and transfusion reaction. To transfuse preop- erative autologous blood during shock, acute normovolemic hemodilution entails the removal of whole blood from a pa- tient immediately before surgery, and volume is restored with crystalloid or colloid. After major bleeding is controlled, the blood is infused. Relative contraindications include infection, malignancy, and contaminants (amoebic fluid/patIENTCONTENTS/ASCITES/FUS) within the operative field. Despite this, both acute normovolemic hemodilution and cell salvage can be used in women undergoing cesarean section who are at risk for profound hemorrhage (placenta percreta) who will not ac- cept blood products.

A higher threshold for blood transfusion is warranted in patients with renal, coronary artery, and/or chronic obstructive lung disease because of increased risk for acute myocardial infarction and perioperative death. Most experts recommend maintaining hemoglobin levels above 10 g/dL in these patients. Survival is also improved in cervical cancer...
patients undergoing chemoradiation therapy by maintaining the hemoglobin concentration above 12 g/dL. Epoetin alfa (Procrit; Ortho Biotech Inc., Raritan, NJ) is currently approved in the United States for the treatment of anemia in patients with nonmyeloid malignancies who receive concomitant chemotherapy. In cancer patients receiving chemotherapy, epoetin alfa 10,000 U and increased to 20,000 U three times weekly, depending on hemoglobin after 4 weeks, improved patient-reported functional capacity and quality of life independent of response to chemotherapy. Epoetin alfa has become a valuable alternative to transfusion in patients with inflammatory diseases that reduce erythropoiesis (e.g., renal failure, carcinoma) or who refuse blood products. Its use can reduce the need for transfusion when given preoperatively to anemic patients. Epoetin alfa is not effective without appropriate iron intake, preferably given with vitamin C, to enhance absorption. Although there are no adverse effects recorded in cancer patients, two recent trials have shown lower survival rates in patients treated with epoetin alpha instead of transfusion. Further studies are needed to address the presence of erythropoietin on tumor cells and its impact on tumor progression, especially in this clinical setting. Red-cell substitutes are in various stages of clinical development and may become lifesaving alternatives in military and trauma settings or for patients who refuse other options.

When blood loss exceeds 25% of the blood volume, whole blood— or, in the presence of bleeding consistent with coagulopathy, PRBCs and fresh frozen plasma (FFP) in a 4:1 ratio—has been the standard of care until recently. However, 4-5 platelet concentrates, or 1 unit of single-donor apheresis platelets, or 1 unit of whole blood provides a quantity of factors similar to 1 U FFP (except for factor V and VIII) and is usually sufficient for hemostasis. True dilutional coagulopathy, which may occur with loss of 100% of blood volume has been replaced. Therefore, it is recommended that coagulation profiles be obtained in patients with microvascular bleeding and transfusion with FFP not be given unless the PT/PTT is greater than 1.5 times normal values or, in absence of lab determinations, only for massively transfused patients with ongoing microvascular bleeding or when warfarin therapy must be given. Cryoprecipitate is concentrated FFP in a small volume of 10 to 15 mL (1 bag per 5 kg in a 70-kg individual). Because cryoprecipitate is pooled factor components from multiple donors, risk of infection is significantly increased. Cryoprecipitate should be reserved for patients with deficiencies in factor VIII, von Willebrand factor, fibrinogen factor XIII, and/or fibrinogen who fail desmopressin acetate. When desmopressin intravenous coagulation is suspected based on massive transfusion and the persistence of significant outbleeding, FFP instead of cryoprecipitate is the component of choice. To avoid the risks of hemolysis, agglutination, and clotting, all blood products should be administered through clinically filtered lines with normal saline without electrolyte or drug additives. To prevent hypothermia, warming of blood products is indicated when the volume infused exceeds 50 mL/kg/h.

When transfusion is massive (10 U PRBCs in 24 h), platelets in addition to packed cell transfusion are needed. One unit of platelet concentrate will increase the count by 3,000 to 10,000/μL. Preoperative platelet and intraoperative platelet counts of 50,000/μL or less are indications for platelet transfusion when major surgery or further bleeding is anticipated. Platelet transfusions may also be indicated for platelet dysfunction. FFP is indicated in coagulopathy, without increasing microvascular coagulation, severe liver disease, or massive transfusion and for specific clotting disturbances when the factor concentrate is not available. FFP is not indicated for volume expansion or nutritional support and should not be given empirically with PRBC transfusions.

**Drug Therapy**

**Pharmacologic Support of Blood Pressure**

Inotropic agents and vaspressors recommended in the management of hypotensive shock are outlined in Table 12.9. Except for the newer agents (inamrinone, milrinone acetate), all of these sympathomimetic agents have both inotropic and vasoconstrictive effects. With these cardiosuppressive effects, dopamine hydrochloride and dobutamine hydrochloride are the preferred agents in the initial treatment of shock. Epinephrine and norepinephrine, which are potent vasoconstrictors, are usually reserved for refractory hypotension. It is important to bear in mind that these vasoactive drugs are not indicated until adequate volume replacement has been given and are seldom of benefit in the management of hemorrhagic shock. Use of vaspressors in the face of inadequate volume resuscitation can worsen preexisting ischemia, increasing cellular and organ system injury. The judicious use of sympathomimetic agents after sufficient hydration may be useful to correct inadequate cardiac function and persistent hypoperfusion.

Because they reduce myocardial oxygen requirements and improve myocardial performance, vasodilators (nitroglycerin, nitroprusside) are generally preferred in the management of patients with cardiogenic shock who have mean arterial pressures higher than 70 mm Hg. Vasodilators are not indicated in the setting of hypovolemic and septic shock associated with low arterial pressures secondary to peripheral vasodilatation. Under these circumstances, vasodilators would serve to further reduce venous return and may intensify hypotension and further reduce coronary artery perfusion.

Dopamine is the preferred catecholaminergic agent in the management of the hypotensive patient whose MAP is less than 60 mm Hg. Dopamine stimulates dopaminergic, β₂-adrenergic, and β₁-adrenergic receptors in a dose-dependent fashion. At low doses (1-3 μg/kg/min), dopamine stimulates cerebral, renal, mesenteric, and vasoconstrictive effects. Because of their cardiotropic effects, all of these sympathomimetic agents have both inotropic and vasoconstrictive effects. Because of their cardiotropic effects, all of these sympathomimetic agents have both inotropic and vasoconstrictive effects.

IV, intravenous; AMP, adenosine monophosphate phosphodiesterase.
be associated with myocardial depression, an elevated LVESD, and an abnormally high PCWP; dobutamine may be preferred or needed in addition to dopamine. Used together at moderate doses, dopamine and dobutamine can maintain arterial pressure with less of an increase in pulmonary artery occlusive pressure or pulmonary congestion than when dopamine is used alone. Inamrinone is a phosphodiesterase inhibitor with positive inotropic and chronotropic effects. Although typically blocked by use of α, β, cholinergic-, or ganglionic-blocking agents, inamrinone decreases myocardial cyclic adenosine monophosphate phosphodiesterase (AMP) activity, thereby increasing cardiac cyclic AMP levels. Inamrinone improves lung compliance in mechanically ventilated patients with severe cardiogenic pulmonary edema and is currently recommended in the setting of severe acute congestive heart failure with a systolic blood pressure greater than 100 mm Hg. Inamrinone and milrinone are synergistic with dobutamine, and these agents are often used together for acute refractory congestive heart failure and cardiogenic shock.

Isoproterenol is a synthetic sympathomimetic amine with nearly pure β-adrenergic effects. Although its potent inotropic and chronotropic properties increase cardiac output, isoproterenol increases tachycardia and oxygen consumption and can induce or exacerbate myocardial ischemia. Isoproterenol is seldom used to treat shock. The vasopressors (phenylephrine, norepinephrine, and epinephrine) are used for refractory shock. Although epinephrine and norepinephrine have both β- and α-adrenergic effects, they differ in that epinephrine has more potent α-adrenergic activity. These potent agents increase blood pressure predominantly by increasing systemic and peripheral vascular resistance and must be used with great caution in patients with shock because they may induce or exacerbate myocardial ischemia.

Antibiotic Therapy

Antibiotic therapy should be initiated immediately, as soon as samples of blood and other suspected sites of infections have been obtained for culture. The agents selected should be based on the likely pathogens at the probable site of infection, recent antibiotic use, and the patterns of antimicrobial resistance within the hospital or community (Table 12.10). Empiric broad-spectrum therapy should cover both Gram-positive and Gram-negative organisms; anaerobic coverage is also indicated when a pelvic source is suspected (ubovarian abscess or septic abortion). Initially, these agents should be given at maximum doses, with dose modification for impaired renal function. Acceptable regimens include an extended-spectrum penicillin (azlocillin, mezlocillin, piperacillin) or third-generation cephalosporin (cefotaxime, ceftriaxone) combined with an aminoglycoside. Extended-spectrum penicillins combined with an aminoglycoside may be more effective than cephalosporin-aminoglycoside combinations for Gram-negative sepsis, and in the absence of a penicillin allergy, broad-spectrum β-lactam antibiotic–β-lactamase inhibitor combinations, or a carbapenem, or a fluoroquinolone, to prevent the rapid development of resistance. A parenteral coverage may consist of clindamycin or metronidazole (Flagyl), although dose modifications are required for hepatic failure. Because of the emergence of clindamycin-resistant B. fragilis, β-lactam antibiotic–β-lactamase inhibitor combinations and metronidazole are better agents for the empiric treatment of B. fragilis; clindamycin can be substituted after drug sensitivity is verified. The only available coverage for methicillin-resistant Staphylococcus aureus is vancomycin, which requires dose adjustments in patients with renal compromise. When the suspected source of infection is a peripheral or central venous access site, vancomycin may be added to cover for Staphylococcus epidermidis. Its effects are usually observed within 24 hours, and if the patient improves, vancomycin can be stopped.

Empiric broad-spectrum antibiotic therapy should be replaced with specific therapy as soon as possible because of the significant adverse effects. These include disruption of the normal gut mucosal barrier that increases the risk for opportunistic infections including yeast species (C. albicans), enterococcal infection, and pseudomembranous enterocolitis. Clostridium difficile–induced colitis (CDIC) is a gastrointestinal disorder that results from colonization by and overgrowth of C. difficile, a Gram-positive, spore-forming anaerobic bacillus. Exposure to oral antibiotic therapy is the most common predisposing factor; an association with clindamycin use is well established, but anyone colonized with C. difficile who receives antibiotic therapy is at risk. Associated medical comorbidities include advanced age and diabetes, recent bowel preparation, admission to an intensive care unit, and chemotherapy. C. difficile infection usually presents with mild to moderate diarrhea, sometimes associated with lower abdominal cramping; systemic symptoms are usually absent. The laboratory diagnosis is made by stool culture.

Severe colitis without pseudomembrane formation is associated with profuse, debilitating diarrhea, abdominal pain, and distension. Systemic manifestations include fever, nausea, anorexia, malaise, and dehydration, and leukocytosis and fever are commonly found. Pseudomembranous colitis is characterized by worsening symptoms, and proctosigmoidoscopy reveals characteristic adherent yellow plaques. When colitis is life-threatening, patients appear acutely ill, with abdominal tenderness and distension, fever, tachycardia and hypotension, or shock. The development of a paralytic ileus and colonic dilatation can result in a paradoxical decrease in diarrhea. When C. difficile infection is suspected, antibiotic therapy should be discontinued, or agents less likely to disrupt the normal colonic microflora—such as aminoglycosides and aminoglycoside–β-lactam antibiotic–β-lactamase inhibitor combinations and the impact of these antibiotics on the incidence of C. difficile have raised additional concerns regarding the use of quinolones in the treatment of anaerobic infections. Quinolones remain an effective therapy for infections caused by enteric Gram-negative and -positive bacteria and are an important alternative to β-lactam antibiotics. Advantages include spectrum of activity, pharmacokinetics, and once-daily oral administration. Quinolones available for clinical use have been classified into four generations, mainly based on their spectrum of activity. The second generation (fluoroquinolone) has a fluorine substitute at position 6, which markedly increases activity against Gram-negative organisms. Of the fluoroquinolones, the two most widely used are ciprofloxacin and ofloxacin; ciprofloxacin is the most active against P. aeruginosa and a valuable alternative in patients with impaired renal function. Acceptable regimens include an extended-spectrum penicillin (azlocillin, mezlocillin, piperacillin) or third-generation cephalosporin (cefotaxime, ceftriaxone) combined with an aminoglycoside therapy to cover both Gram-positive and Gram-negative organisms; anaerobic coverage is also indicated when a pelvic source is suspected (ubovarian abscess or septic abortion). Initially, these agents should be given at maximum doses, with dose modification for impaired renal function. Acceptable regimens include an extended-spectrum penicillin (azlocillin, mezlocillin, piperacillin) or third-generation cephalosporin (cefotaxime, ceftriaxone) combined with an aminoglycoside.

*Empiric antibiotic selection for invasive pneumococcal disease should be based on known antibiotic susceptibility patterns in the community.

**Empiric antibiotic selection for hospital-acquired sepsis should be based on antibiotic resistance patterns for bacteria from each specific institution or intensive care unit. Antibiotic regimen may be modified 48-72 hours later, based on culture and antibiotic susceptibility. Adapted from Simon D, Trenholme G. Antibiotic selection for patients with septic shock. Crit Care Clin 2000;16:47.

Shock in the Gynecologic Patient

renal function. Ciprofloxacin is preferable against Gram-negative bacteria, whereas moxifloxacin should be used to target Gram-positive organisms. Levofloxacin and ofloxacin show an intermediate response to Gram-positive bacteria, and non-β-lactamase is an intrinsically weak fluoroquinolone against Gram-positive organisms. The emergence of drug resistance has limited their potential against S. aureus. Quinolones are not recommended for children or breast-feeding and pregnant women and should be used with caution in the elderly.

Necrotizing fasciitis is a rare, potentially fatal infection of the subcutaneous tissue associated with progressive destruction and necrosis of fascia and fat. Culture results can differentiate the subcutaneous tissue associated with progressive destruction and should be used with caution in the elderly.

Additional Therapies

Recombinant Human-activated Protein C (Drotrecogin Alfa)

Drotrecogin alfa activated (DAA), also known as activated protein C, is an endogenous protein that promotes fibrinolysis and inhibits thrombosis and inflammation and is important modulator of coagulation and inflammation associated with severe sepsis. DAA is converted from its inactive precursor protein by thrombin coupled to thrombomodulin. The conversion of DAA is impaired during sepsis as a result of the down-regulation of thrombomodulin by inflammatory cytokines. DTTA administration of 24 μg/kg of body weight...
per hour for 96 hours has been shown to reduce coagulopathy and inflammation, decreasing mortality rates in patients with severe sepsis by 6% to 13.3%. DTTA has also been proven to decrease mortality by 15.5% in older (75+ years of age) patients. DTTA, now approved by the FDA, is marketed with the brand name Xigris (Eli Lilly and Company) and is the first therapeutic intervention specifically indicated for severe sepsis. DTTA therapy is relatively cost-effective when targeted to patients with severe sepsis of greater severity of illness and a reasonable death probability if they survive the episode of sepsis. However, the cost is high and accounts for about 9% of the average total cost of hospitalization per patient treated. Adverse effects include increased risk of bleeding or intracranial hemorrhage in patients treated with anticoagulant therapy, oral anticoagulants, glycoprotein IIB/IIa inhibitors, and low-molecular-weight heparins. Further research is needed to determine if DTTA therapy is cost-effective for patients with sepsis and less severe illness.

Intensive Insulin Therapy

Patients with severe sepsis and septic shock may develop complications associated with hyperglycemia and insulin resistance, which may increase their risks of severe infections, septicemia, and death. Recent studies have examined the effects of blood glucose normalization with intensive insulin therapy among patients with severe sepsis and septic shock. Maintaining a blood glucose level at 4 to 6.1 mmol/L compared with 10 to 11.1 mmol/L reduced the episodes of septicemia by 46% and lowered the mortality rates in patients with bacteremia from 29.5% to 12.5%.

Adrenal Replacement Therapy

The role of corticosteroid therapy in shock has recently been reevaluated. Patients with severe sepsis may develop either systemic inflammatory response syndrome (SIRS)-induced glucocorticoid receptor resistance or relative adrenal insufficiency. The prevalence of adrenal insufficiency in septic shock has been reported to be about 30%. Consequently, it has been assumed that corticosteroids could be used as antiinflammatory agents, but short courses of high-dose corticosteroids do not appear to reduce mortality from severe sepsis and septic shock. However, one intravenous dose of stress dose hydrocortisone has been shown to improve vasopressor activities in septic shock, and prolonged therapy with low-dose hydrocortisone was associated with reversal of shock state. Benefits included improvement in systemic hemodynamics, a reduction in septic shock, and prolonged therapy with low-dose hydrocortisone was associated with reversal of shock state. Benefits included improvement in systemic hemodynamics, a reduction in septic shock, and prolonged therapy with low-dose hydrocortisone was associated with reversal of shock state.

Antacids

The risks of stress ulceration of the gastric mucosa can be significantly reduced by the use of oral antacids, intravenous H2-blocking agents, or oral sucralfate. A recently described predisposing risk factor for Gram-negative pneumonia and sepsis is a reduction in the concentration of gastric secretions of antacids or H2-blockers, such as cimetidine and ranitidine, to prevent stress-induced bleeding. Driks and associates, in a prospective randomized trial, found that the use of sucralfate, which provides equivalent prophylaxis against stress bleeding without reducing gastric acid levels, was associated with approximately half the rate of pneumonia found with H2-blockers or antacid use. Evidence that sucralfate is preferable to antacids or H2-blockers is far from conclusive. Nevertheless, one of these agents should be used to protect the gastrointestinal tract from stress ulceration.

Nutrition

Malnutrition in intensive care unit (ICU) patients has been associated with increased morbidity, mortality, and length of hospitalization that is due to increased ventilator dependency, higher rates of infection, and impaired wound healing. As many as 40% of adult patients at the time of their hospital admission are affected by poor nutrition. Nutritional support should be based on laboratory assessment of preexisting nutritional status (albumin, transferrin, thyroxine-binding prealbumin, somatomedin-C). When total parenteral nutrition (TPN) is used, the usual rule of thumb is to provide between 25 and 35 nonprotein kcal/kg/day fairly equally distributed between fat and carbohydrate. Optimal assessment of caloric requirements in the patient with shock requiring mechanical ventilation is especially important. Although underfeeding can compromise pulmonary status, increased CO2 production from excessive carbohydrate loads can exacerbate hypercapnia and complicate weaning efforts. Intralipid therapy should be used judiciously in neurogenic and immunosuppressed patients because of its depressive effects on mononuclear and polymorphonuclear monocytes, and increased risks for infection. The goal of amino acid therapy is to reduce catabolic expenditure, and usually, 1 to 1.5 g/kg is sufficient. Electrolytes, BUN, creatinine, glucose, liver function studies, calcium, magnesium, and phosphate levels should be monitored as frequently as clinically indicated to adjust carbohydrate, lipid, or protein loads and to correct specific electrolyte deficits. Trace elements (zinc, copper, chromium, and manganese) should be provided. Recent reports suggest that outcomes can be improved by providing oral glutamine to patients with systemic inflammatory response syndrome. Glutamine is a nonessential amino acid that is unstable in aqueous solutions and cannot be provided by standard TPN solutions. Special attention to nutritional needs should be provided for older, critically ill patients. It is estimated that 12% to 50% of acute ill patients of age and older are malnourished as assessed by measurements such as body mass index (BMI), biochemical indices (serum albumin, prealbumin, and transferring), and clinical parameters. Reasons for this include poor dentition, loss of appetite, and in the postoperative period, the inability to actually chew and swallow food. Although often not considered by the operating surgeon, oral health and hygiene seriously affect perioperative and overall health. A number of pathogens associated with gingivitis include P. gingivalis, S. sobrinus, and S. aureus, all three of which have been associated with aspiration pneumonia. In general, enteric rather than parenteral—nutrition is preferred, even in critically ill ICU patients, because enteric nutrition is less likely to be associated with hepatobiliary dysfunction, metabolic derangements, or infection complications, and it is less expensive.

Other Therapies

Kverner and colleagues demonstrated that antibiotic prophylaxis with oral tobramycin, amphotericin B, and polymyxin E in critically ill patients requiring ventilatory support significantly reduced the incidence of nosocomial infection rates and their associated mortality. Prophylactic use of ranitidine + omeprazole

**Principles of Anatomy and Perioperative Considerations**

---
and swallow" with 5 to 10 mL of nystatin (100,000 U/mL) has been found to reduce the incidence of systemic candidiasis as well as local wound infections. Hypothermic patients should be treated with warming therapy by elevating the room temperature, using radiant heat, or using convective warming therapy.

Critically ill patients with acute renal failure may benefit from continuous renal replacement therapies such as hemofiltration or hemodialysis. Electrolyte, coagulation, and complete blood count deficits may be corrected

...vention. Electrolyte, coagulation, and complete blood count abnormalities should be obtained to affirm adequate pulmonary edema, myocardial infarction, or congestive heart failure. Those who have not responded to resuscitative efforts or who have evidence of pulmonary edema, myocardial infarction, or congestive heart failure should be considered (Table 12.9), especially in those patients who have not had dynamic monitoring, if not previously initiated, may be considered. In managing the patient with septic shock, right heart catheterization with hemodynamic monitoring, if not previously initiated, may be considered (Table 12.9), especially in those patients who have not responded to resuscitative efforts or who have evidence of pulmonary edema, myocardial infarction, or congestive heart failure. Arterial blood gases should be obtained to affirm adequate ventilation. Electrolyte, coagulation, and complete blood count results should now be available, and deficits may be corrected based on specific laboratory findings. In the face of specific organ system dysfunction, such as renal or hepatic failure, doses of antibiotics, vasopressors, and fluid support should be modified. Gastrointestinal losses should be replaced based on the electrolyte and acid-base composition of the site of loss.

Hypokalemia usually results from excessive crystalloid replacement, although renal losses can be increased secondary to a high protein intake, hyperglycemia, diuretic therapy, or acute failure. Symptoms can include coma or seizures, but hypokalemia is generally asymptomatic unless severe (serum potassium <125 mEq/L). The management of mild, asymptomatic hypokalemia associated with an expanded intravascular volume is fluid restriction. Severe hypokalemia should be corrected by raising the serum sodium level to a minimum of 125 mEq/L. Hypokalemia is usually secondary to insufficient volume replacement and can be corrected using isotonic crystalloid solution, such as half normal saline.

Hypokalemia usually occurs secondary to diuretics, digitals, β-antagonists, amnoglycosides, some penicillins, and gastrointestinal losses. Intravenous replacement may be safely accomplished with 20 to 40 mEq of potassium per liter of isotonic solution. In the intensive care setting, severe, life-threatening hypokalemia may be treated by giving intravenous KCl at a rate of 20 mEq per hour in as little as 25 to 50 mL of compatible solution. Hyperkalemia can develop secondary to renal failure, excessive potassium administration, tissue destruction, and acidsosis, which shifts intracellular potassium into the extracellular fluid compartment. Shifting potassium into the intracellular compartment by infusing insulin with glucose (10 U regular insulin after 1 ampule of 50% glucose), or insulin with sodium bicarbonate or with albuterol is effective treatment. For life-threatening hyperkalemia (serum potassium >7 mEq/L), calcium gluconate, 10 mL of 10% solution, can be given intravenously over 2 to 5 minutes, followed by a second dose if needed. Finally, calcium exchange resins, such as sodium polystyrene sulfonate (15–30 g in 50–100 mL of 20% sorbitol), bind potassium in exchange for sodium within the gastrointestinal tract and are commonly used in patients with chronic renal failure.

Metabolic acidosis usually is satisfactorily corrected with appropriate ventilatory, electrolyte, and crystalloid therapy.

---

**Evaluate Response to Therapy**

Once oxygenation and restoration of the intravascular volume have been completed, it is important to reassess the patient's response to therapy (Table 12.11). Thorough investigation to determine the underlying cause should be performed so that definitive therapy may be implemented. In managing the patient with septic shock, right heart catheterization with hemodynamic monitoring, if not previously initiated, may be considered (Table 12.9), especially in those patients who have not responded to resuscitative efforts or who have evidence of pulmonary edema, myocardial infarction, or congestive heart failure. Arterial blood gases should be obtained to affirm adequate ventilation. Electrolyte, coagulation, and complete blood count results should now be available, and deficits may be corrected based on specific laboratory findings. In the face of specific organ system dysfunction, such as renal or hepatic failure, doses of antibiotics, vasopressors, and fluid support should be modified. Gastrointestinal losses should be replaced based on the electrolyte and acid-base composition of the site of loss.

Hypokalemia usually results from excessive crystalloid replacement, although renal losses can be increased secondary to a high protein intake, hyperglycemia, diuretic therapy, or acute failure. Symptoms can include coma or seizures, but hypokalemia is generally asymptomatic unless severe (serum potassium <125 mEq/L). The management of mild, asymptomatic hypokalemia associated with an expanded intravascular volume is fluid restriction. Severe hypokalemia should be corrected by raising the serum sodium level to a minimum of 125 mEq/L. Hypokalemia is usually secondary to insufficient volume replacement and can be corrected using isotonic crystalloid solution, such as half normal saline.

Hypokalemia usually occurs secondary to diuretics, digitals, β-antagonists, amnoglycosides, some penicillins, and gastrointestinal losses. Intravenous replacement may be safely accomplished with 20 to 40 mEq of potassium per liter of isotonic solution. In the intensive care setting, severe, life-threatening hypokalemia may be treated by giving intravenous KCl at a rate of 20 mEq per hour in as little as 25 to 50 mL of compatible solution. *2000 mL Ringer’s lactate solution in adults, 20 mg/kg in children.

administration. The routine use of bicarbonate is not recommended for mild to moderate metabolic acidosis (pH 7.35–7.4). Bicarbonate use may shift the oxygen–hemoglobin dissociation curve and reduce oxygen delivery at the cellular level. Furthermore, excessive alkalinization can induce tetanus, seizures, and cardiac arrhythmias, and increase lactate production. When acidosis is severe (pH < 7.2), intravenous bicarbonate is given by a continuous infusion (1–3 ampules of 7.5% NaHCO₃ [44.6 mL/ampule] in 500–1000 mL D₂W), with the dose based on calculation of the total deficit. Approximately one half of the deficit can be replaced in 3 to 4 hours. No further replacement is necessary once the pH is 7.2 or greater. Serum potassium and calcium levels should concomitantly be monitored, because these shift into the intracellular space as the acidosis is corrected, resulting in hypokalemia or hypocalcemia.

Remedy the Underlying Cause

Although some causes of bleeding—such as a retroperitoneal hematoma developing after hysterectomy—can resolve without surgical intervention, all patients with continued intrabdominal bleeding and bleeding associated with persistent hemodynamic instability despite appropriate colloid and blood product replacement require immediate surgical intervention. Vaginal or other lacerations, if present, should be repaired. If the underlying cause is septic abortion, prompt evacuation of the uterine contents is indicated as soon as adequate serum and tissue levels of broad-spectrum antibiotics are reached. Nonhemorrhagic causes of hypovolemic shock should be identified, and specific therapy should be directed at the underlying cause.

Investigational Agents

Several studies have looked at the clinical use of antibodies that would effectively neutralize bacterial endotoxin and mitigate its effects. Polyvalent antiserum directed against a mutant strain (J-5) of E. coli was the first of these agents subjected to clinical trial. In 1982, Ziegler and colleagues found that in subgroups of patients with Gram-negative bacteremia or without shock, immunization was associated with a significant reduction in mortality. However, immunization provided protection only for patients with Gram-negative bacteremia or septic shock associated with Gram-negative sepsisemia and did not benefit patients with sepsis or shock from other causes. J-5 antiserum did not become available for clinical use because it is difficult to manufacture and, because pooled donor serum is required, it carries the risk of blood-borne infections.

The use of monoclonal antibodies has also been investigated. The first of these, immunoglobulin IgG antibody purified from pooled plasma obtained from volunteers immunized with E. coli, did not demonstrate a significant difference in survival in patients with profound septic shock. Two additional monoclonal antibodies to endotoxin have subsequently been developed with more optimistic results. One of these, E5, an IgM antibody with reactivity to lipid A, was developed from murine splenocytes immunized with J-5 mutant E. coli cells. A second, HA-1A, a human monoclonal IgG antibody that binds to the lipid A domain of endotoxin, was also developed from J-5 mutant cells. Both of these monoclonal antibodies were able to neutralize survival and cytokine adhesion molecule expression in patients with Gram-negative sepsis. Antibodies to TNF-α and a recombinant form of IL-1 receptor antagonist (a naturally occurring protein that binds to IL-1 receptors), were especially intriguing, because it was anticipated that they could be used for patients with inflammatory response syndrome in the absence of an identifiable infection. In a pilot clinical trial, Vincent and colleagues found that anti-TNF antibody improved left ventricular function in 10 patients with septic shock; however, only 3 of the 10 patients survived. More recent trials using cytokine antagonists—including PAF- and TNF-receptor antagonists—in the treatment of shock have demonstrated little benefit.

The high mobility group box protein 1 (HMGB1), a proinflammatory cytokine that plays a vital role as a delayed and potent mediator of local and systemic inflammation, has also been investigated. Secreted by necrotic cells and macrophages or passively released from necrotic cells of any tissue type, high levels of HMGB1, like TNF-α, have been shown to increase the sensitivity of animals to endotoxins, and HMGB1 levels are significantly increased in patients with severe sepsis. Administration of neutralizing anti-HMGB1 antibodies, recombinant HMGB1 A box protein, and ethyl pyruvate in septic animals has been shown to decrease mortality. Unlike TNF-α and other previously described cytokine targets, HMGB1’s delayed kinetics may provide a greater temporal treatment window for neutralization therapy.

Other cytokines of recent interest in antiinflammatory and immunomodulatory therapies include granulocyte colony stimulating factor (G-CSF) and granulocyte-macrophage colony stimulating factor (GM-CSF). G-CSF differs from GM-CSF in its specificity of action on developing and mature neutrophils, effects on neutrophil kinetics, and toxicity profile. Recombinant GM-CSF has toxicity profile consistent with the priming of macrophages for increased formation and the release of inflammatory cytokines, whereas recombinant G-CSF induces the production of antiinflammatory factors such as IL-1 receptor antagonist and TNF receptors, and is protective against endotoxin- and sepsis-induced organ injury. G-CSF and GM-CSF can augment the functional antimicrobial activities of neutrophils in addition to up-regulating multiple antimicrobial mechanisms in monocytes and macrophages, enhancing pathogen eradication. In one trial, treatment with both cytokines effectively prevented the overactivation of Kupffer cells by both Gram-negative and Gram-positive bacterial substances. Although most clinical studies have examined G-CSF and GM-CSF therapy in neutropenic patients, further trials in are needed to identify the subset of patients who may benefit from G-CSF and/or GM-CSF therapy.

Polymorphisms present in cytokine genes may influence concentration of inflammatory and antiinflammatory cytokines produced in a patient’s response to infection, suggesting that genetic factors significantly contribute to a patient’s overall outcome when infected with inflammatory and infectious diseases. Recent studies have also discovered inflammatory responses associated with neutrophil defects, including alterations in pattern recognition in molecules such as CD14 and TLRs. An increased understanding of genetic influence on susceptibility to inflammatory responses may lead to individualized therapy directed at patients that may be at greater risk for hyper- or hypoinflammatory response to infection.

Nitrergic oxide (NO) and reactive oxygen species exert multiple modulating effects on inflammation and play a key role in the regulation of immune responses. Low concentrations of nitric oxide produced by constitutive and neuronal nitric oxide synthases inhibit adhesion molecule expression, cytokine and chemokine synthesis, and leukocyte migration and transmigration. Large amounts can be toxic and proinflammatory. Actions of nitric oxide are dependent on the cellular context, concentration, and initial priming of immune cells. The effects of both
Shock in the Gynecologic Patient

Bibliography

Barr JD, Glaser MP, McCarth J, et al. Prevention of gram-negative sepsis and death in surgical patients by antibody to endotoxin core lipopoly-

nitric oxide and superoxide in immune regulation are exerted through multiple mechanisms, which include interactions with diverse cell signaling pathways. Consequently, nitrous oxide has both proinflammatory and antiinflammatory effects, and both enhances and reduces phagocyte activation and function. Drugs that interfere with nitrous oxide, including statins, angiotensin receptor blockers, NAD(P)H oxidase inhibitors, and NO synthase inhibitors, are beginning to be introduced in the treatment of inflammation and sepsis.

SUMMARY

The management of patients with systemic inflammatory response syndrome and shock states remains one of the most formidable challenges facing the practicing gynecologist. However, with early recognition, prompt intervention, and continued aggressive surveillance, a satisfactory outcome is achievable in most cases. Thus, caring for the patient in shock, although challenging, may well be rewarding.

BEST SURGICAL PRACTICES

■ Management of shock requires restoration of ORDER: oxygenation, with ventilatory support, if needed; restore circulatory volume with crystalloid and, if needed, blood products; drug therapy, with antibiotics or pressors; evaluation of response to therapy; and remedy the underlying cause.

■ Regardless of the precipitating event, the severity of hypovolemia can be estimated using guidelines established by the American College of Surgeons. Initially, crystalloid replacement should be initiated to replace volume.

■ Blood product use should be based severity of anemia, symptoms, and ongoing blood loss. In asymptomatic patients without significant cardiopulmonary or renal disease, there is no “transfusion trigger,” for which blood replacement is essential.

■ Critical care multidisciplinary teams with training and experience to address respiratory, nutritional, and other aspects of care have significantly reduced both mortality and morbidity from shock states.

■ When a patient presents with septic shock, broad-spectrum antibiotic therapy directed against Gram-positive, Gram-negative, and anaerobic organisms should be initiated after cultures are obtained. Attempt to identify the etiology; sources such as abscesses should be drained, and infected wounds should undergo debridement. Subsequent antibiotic therapy should be guided by culture results. Indiscriminate use of antibiotics has led to drug resistance; empiric use of agents such as vancomycin is discouraged because of the development of methicillin-resistant staphylococcus infections.

""

CHAPTER 13 | WOUND HEALING, SUTURE MATERIAL, AND SURGICAL INSTRUMENTATION

GARY H. LIPSCOMB

DEFINITIONS

Healing by primary intention—Wound healing that occurs if the wound layers are approximated following injury.

Healing by secondary intention—Wound healing that occurs if wounds are left open after injury and allowed to close spontaneously from the formation of granulation tissue.

Healing by third intention—Wound healing that occurs when the wound is closed after an initial period of delay of several days, also referred to as delayed primary closure.

Absorbable sutures—Sutures that lose the majority of their tensile strength before 60 days when implanted in body tissues.

Non-absorbable sutures—Sutures that maintain the majority of their tensile strength before 60 days when implanted in body tissues.

Knot-pull tensile strength—Breaking strength of a suture when tied around a plastic tube using a surgeon's flat knot and stressed from either end.

WOUND HEALING

Ideally, organic tissue lost by destruction or injury would be replaced with tissue identical in form and function. This process is known as regeneration. Although tissue regeneration does occur in lower animals (e.g., salamanders), humans have lost this ability for the most part. With the exception of the epidermis of the skin, mucosa of the intestinal tract, and liver, damaged human tissue heals by the laying down of collagen, a repair process better known as scarring.

The healing process itself directly produces disease (e.g., postoperative adhesion formation following surgical procedures or tubal occlusion after pelvic inflammatory disease). These repair mechanisms are also nonspecific. They are activated whether a wound is made with a surgical scalpel and sutured closed or by trauma and then allowed to heal without surgical closure. However, the nature of the wound influences the degree to which each individual process is involved, and this in turn can affect the ultimate success of the repair.

Inflammation

The inflammatory phase of healing is the initial response to any injury involving more than an epithelial surface. This phase can be divided into two separate but simultaneously occurring responses: a vascular and a cellular response. Both are initiated by amines, most notably histamine, as well as the kinins and proteolytic enzymes released by the injured tissue. Immediately after injury, a transient vasoconstriction of the local vasculature lasts for 5 to 10 minutes. Vasoconstriction is followed by vasodilatation and an increase in vascular permeability. Edema caused by the escape of plasma through altered vessel walls becomes clinically apparent at this point. The cellular response is characterized by the migration of leukocytes into the injured area. Although the agents responsible for this active migration of leukocytes remain unclear, chemotactic factors are thought to play a major role. Initially, the polymorphonuclear leukocytes and monocytes in the wound are present in the same concentration as in the systemic circulation. As a result, polymorphonuclear leukocytes predominate for the first 3 days. Because polymorphonuclear leukocytes are relatively short-lived compared with monocytes, the latter stages of the inflammatory phase are characterized by a predominance of monocytes that transform into macrophages. These leukocytes actively phagocytize bacteria, foreign proteins, and necrotic debris. As polymorphonuclear leukocytes die, their intracellular enzymes and debris are released into the wound and become part of the wound exudate. These released enzymes also facilitate the breakdown of material not phagocytized by the leukocytes. This accumulated exudate or pus develops even in the absence of bacteria. Even when this exudate is sterile, the presence of proteolytic enzymes, including collagenase, can interfere with epithelialization and fibroplasia, and thus, interfere with continued wound healing. Poor wound healing, however, is more common in wounds contaminated with bacteria and foreign material. In these cases, the inflammatory response may persist for long periods of time.

Physiology of Wound Healing

The healing of a wound involves several distinct biological processes: (a) inflammation, (b) epithelialization, (c) fibroplasia, (d) wound contraction, and (e) scar maturation. Although considered distinct, these processes do not occur in a strict sequence but often simultaneously with each other.

Healing may be delayed or prevented by the presence of bacteria and foreign materials. These exudates also stimulate an acute inflammatory response, characterized by an influx of leukocytes and an increase in vascular permeability. This results in the formation of granulation tissue, which is rich in fibroblasts and collagen. The healing process can be divided into four stages:

1. Inflammation
2. Epithelialization
3. Fibroplasia
4. Wound contraction

These stages may overlap, and the healing process can be complex and variable. The final outcome of wound healing depends on various factors, including the nature of the wound, the patient's health, and the presence of infections or other complications.
Epithelialization
By virtue of their exposed location, the epithelial surfaces of the gastrointestinal, urogenital, and respiratory tract as well as the skin itself are continually subjected to the physical and chemical trauma associated with the activities of daily living. An initial rapid, replacing damaged or destroyed cells through a process known as epithelialization. Epithelialization occurs by migration and subsequent maturation of immature epithelial cells from the deeper basal layers of surrounding areas. If the cellular damage is confined entirely to the epithelium, the healing response is merely an exaggerated form of the basic normal replacement process.

If an injury involves the supporting connective tissue beneath the epithelium, however, the other components of the healing processes, in addition to epithelialization, become involved. If the injury severs blood vessels, the vessels retract, and the process of hemostasis is initiated. If bleeding is not too severe, a blood clot soon forms. This clot subsequently contracts, dehydrates, and becomes a scar. Within 12 hours, basal cells from the surrounding epithelial surfaces begin migrating onto the injured surface. Epithelial cells move beneath the scar, detaching it from the wound and sealing the surface. In incised and sutured wounds, epithelialization generally produces a watertight seal within 24 hours of injury. This new layer of epithelial cells is initially thin and poorly attached to the underlying surface, rendering it susceptible to injury from even minor trauma. Final epithelial healing is accomplished by differentiation and maturation of the migrated cells and by scar formation through fibroplasia.

Fibroplasia
The process by which wounds regain strength is termed fibroplasia. Fibroplasia results in the production of the collagen necessary to form fibrous scar and ultimately determines the final strength of the healed wound. This process begins with the differentiation of mesenchymal cells into fibroblasts. Fibroblasts then migrate into the wound, apparently along fibrin strands produced during clot formation. Once at the injury site, fibroblasts multiply and manufacture the glycoproteins and mucopolysaccharides that make up the ground substance of connective tissue. Ground substance is an amorphous matrix that is believed to induce aggregation of collagen subunits and influences the final orientation of the fibers.

Once the ground substance is produced, fibroblasts begin to synthesize the basic building block of collagen—tropocollagen. Tropocollagen is a stiff elongated macromolecule of three helically intertwined chains of amino acids consisting of two identical α1 chains and one α2 chain. Within the ground substance and at the proper pH, osmolality, and temperature, tropocollagen molecules polymerize into collagen fibrils by forming covalent bonds with their neighbor. These fibrils bond with other fibrils to form collagen bundles. It is not until 4 to 5 days after injury that the wound produces enough collagen to result in a measurable increase in wound tensile strength. Before this time, the wound is held together only by fibrous adhesion. This time frame between wounding and an increase in tensile strength originally was referred to by Howes and Harvey as the “lag period” of wound healing.

Wound Contraction
The manner in which tissue heals is dependent on whether tissue integrity is simply interrupted (as in a surgical incision) or tissue is removed (as in an avulsion injury). In both types of injury, tissue seals itself, begins to reepithelialize, and synthesizes collagen for structural support. However, when large amounts of tissue are missing, the edges of the wound must be brought closer together so that the previously noted tissue responses can repair the defect. This process is known as contraction. Contraction of wound margins begins about 5 days after injury and corresponds with the fibroplasia phase of healing. Because this process can be inhibited by cytochrome poisons, such as potassium cyanide, and by smooth muscle relaxants, older theories attributing wound contraction to passive collagen changes have been discarded. Instead, wound contraction appears to be an active process produced by contractile proteins within the fibrils. If the area is too large for contraction to bring the edges together, the wound remnant covered with granulation tissue, or if small enough, it is covered with epithelium only. Epithelialization of such a wound prevents weeping, but without the normal underlying supporting stroma, it remains too fragile to provide lasting protection. Pathologic progression of skin contraction ultimately may result in restriction of joint or limb mobility. This deformity is termed contracture and should not be confused with contraction.

Scar Maturation
The bulky scar formed during the fibroplasia phase consists of randomly oriented soluble collagen fibers. This scar has little tensile strength. During scar maturation, the disordered fibers are replaced with fibers arranged in a more orderly fashion, producing a denser and stronger scar. Collagen fibers also continue to form covalent bonds within fibrils as well as between adjacent fibrils and fibers, resulting in a continued increase in wound tensile strength over time. This maturation process may continue for years.

During scar maturation and remodeling, the breakdown of old disordered collagen slightly exceeds production of new organized collagen fibers. The resulting new scar is softer and less bulky than the original scar but also is stronger because of its more organized and extensively cross-linked nature. However, if collagen production exceeds breakdown, then a keloid or hypertrophied scar results.

Surgical Wound Healing
Depending on the manner of wound closure, three types of surgical wound healing are recognized: primary, secondary, and third intention. Figure 13.1 illustrates these types of wound healing.

Primary Intention
Healing occurs by primary intention if the wound layers are reapproximated following injury. This apposition of tissue layers allows healing to occur in a minimum of time, with no separation of wound edges and with minimum scar formation. This is the desired mode of healing for surgical incisions.

Secondary Intention
It has been known for centuries that a wound has a higher resistance to infection when left open rather than closed. This was demonstrated experimentally in dogs by Bilroth, who applied dressings soaked in liquid feces and pus to wounds. Wounds left open remained healthy in appearance, whereas those that were subsequently closed became infected. As a result, contaminated or infected surgical wounds often are left unapproximated and allowed to close spontaneously. This type of wound healing is referred to as healing by secondary intention. This healing
process obviously is more complicated and prolonged than that of primary intention. The wound eventually heals by a combination of contraction and the formation of granulation tissue with the wound gradually filling in from the raw surfaces. This type of healing is slow and frequently characterized by formation of excessive scar tissue. Granulation tissue from the healing wound also may protrude above the wound margin during this process. This can prevent final epithelialization of the surface and require further treatment for complete healing.

Third Intention

Wound healing by third intention, also known as delayed primary closure, refers to the technique of wound closure after a period of delay. This method often is used after postoperative wound breakdown or as an alternative to healing by secondary intention of wounds that should not be closed primarily, such as grossly contaminated or infected wounds. The timing of closure is important. After delays of 7 to 8 days, the wound edges become increasingly difficult to approximate because of the increasing collagen content. Edlich and colleagues have suggested that closure on or after the fourth day appears to be ideal. This concept also is supported by Lowery and Curtis, who showed that wounds closed after a delay of between 3 and 6 days have the lowest infection rates. Furthermore, studies by Fogdestam revealed that wounds closed during this time frame also have greater wound strength at 20 days than wounds closed primarily.

Methods of Wound Closure

Wound dehiscence with evisceration is a serious complication of abdominal surgery. This complication is associated with prolonged morbidity and high mortality. Published mortality figures range from 18% to 33%, with a mean of 20%. Wound dehiscence occurs in 0.5% to 5% of all abdominal surgeries, but is less frequent (0.1% to 0.7%) with gynecologic abdominal procedures. Potential reasons for the decreased rate of dehiscence associated with gynecologic surgery include the use of transverse incisions, healthier patients, lower infection rates, and a lower rate of bowel enterotomies.

Traditionally, gynecologic surgeons have been taught that vertical incisions are associated with a greater likelihood of dehiscence than transverse incisions. Critical review of the earlier data supporting this conclusion reveals that significant confounding variables often were ignored. In general, vertical incisions often were performed emergently on sicker patients or those who had other risk factors for dehiscence, such as cancer. Transverse incisions typically were performed on relatively healthy patients undergoing elective surgery. At least two randomized studies by Greenall and colleagues and Stone and associates have shown no difference in hernia formation or dehiscence between vertical and transverse incisions.

Proper suture selection is critical in preventing wound dehiscence. The wound may break down if the suture has too little initial tensile strength or if the suture is absorbed too quickly before the wound regains enough strength to resist normal stress. The suture also is only as strong as the knots placed in it. The suture is tied using an improper technique or too few knots are placed, the knot can slip and the suture line fail. The issues involved with proper suture selection and knot security are discussed in detail later in this chapter. Proper surgical technique is one of the most critical factors in preventing wound dehiscence. Several studies have indicated that the most common cause of wound dehiscence is intact sutures pulling through fascia. Animal studies have confirmed that incisions closed with wide loose fascial bites have greater tensile strength than those closed using smaller fascial bites. Sanders and DiClementi also have shown that tightly tied fascial sutures result in fascial necrosis beneath the sutures. Thus, the old adage that one should “approximate and not strangulate fascia” is well taken.

Although the use of loose, wide fascial bites appears to reduce the likelihood of suture pull-through, the optimum distance sutures should be placed from the fascial edge is unknown. However, data obtained by Campbell and colleagues can provide some guidelines. When the pull-out force and
sorbed synthetic sutures has allowed the use of these sutures in the formation of suture sinuses. The development of slowly absorbable permanent suture. The use of nonabsorbable sutures for mass closure of patients at high risk for dehiscence.

The manner in which the incision is made also may influence the dehiscence rate. Although no good data are available, it has been suggested that the shearing produced when scissors are used to incise the fascia results in increased fascia necrosis and an increased breakdown rate when compared with incisions produced by a scalpel. Likewise, the use of electrosurgery to incise the fascia has been implicated by some data to result in an increase in the dehiscence rate. These factors are magnified if the fascia then is closed improperly. Because such fascia necrosis generally occurs only at the cut edge of the fascia, the use of generous fascia bites during fascial closure probably is more important in preventing fascial dehiscence than the manner of opening the fascia.

### SUTURE MATERIAL

It is unknown when humankind first learned to use strings or animal sinews to ligate bleeding vessels or approximate tissue. Any material used for this purpose is commonly referred to as suture, whereas the act of reapproximating tissue with suture is known as suturing. The first recorded use of suture and suturing dates to the 16th century B.C. in the Edwin Smith papyrus, the oldest record of a surgical procedure. Over the centuries, many different materials have been used as sutures. These materials include metals (gold, silver, and tantalum wire), plant material (linen and cotton), and animal products (horsehair, tendons, intestinal tissue, and silk).

The United States Pharmacopeia (USP) is the official compendium that defines the various classes of suture as well as sets standards for dimensions and minimum tensile strength for each class of suture marketed in the United States. Most sutures today significantly exceed the minimum tensile strength required by the USP (Table 13.1).

Sutures are divided into size categories based on diameter as defined by the USP. Sutures progressively larger than 0 are numbered in increasing numerical order; that is, 1, 2, etc. Sizes progressively smaller than 0 are indicated by an increasing number of zeros; that is, 0, 00, 000. The smaller the suture, the more zeros. For simplicity, the smaller numbers often are written numerically as 1–0, 2–0, etc., where the first numeral refers to the number of zeros.

The USP characterizes sutures based on their rate of absorption by body tissues. Sutures initially are classified as either absorbable or nonabsorbable. Absorbable sutures lose the majority of their tensile strength before 60 days when implanted in body tissues. Absorbable sutures are further subdivided by the USP into natural and synthetic sutures. Figure 13.2 illustrates the percentages of tensile strength remaining for common absorbable sutures at various postoperative time intervals.

Nonabsorbable sutures are defined as sutures that maintain the majority of their tensile strength for more than 60 days in body tissue. These sutures are further subdivided by the USP into three classes: class I is composed of silk or synthetic fibers; class II is composed of cotton or linen fibers or coated natural or synthetic fibers, with the coating forming a cast of significant thickness but not contributing appreciably to strength (these coatings typically are added to improve handling characteristics or resist degradation); and class III sutures are composed of monofilament or multifilament metal wire.

Natural Absorbable Sutures

Plain and Chromic Catgut

One of the oldest suture materials is plain catgut. Catgut consists of highly purified strands of collagen obtained from the submucosa of animals. Despite its name, catgut normally is obtained from sheep or cattle intestines. The name is believed to have originated from the Arabic term kitgut, which referred to the strings of a musical instrument known as a kir. Kitgut was made from sheep intestines and probably served as a readily available source of suture material. Over the years, the term has evolved into catgut.

Because plain catgut is a foreign protein, it elicits a marked inflammatory response in tissue. It is rapidly degraded by proteolytic enzymes released by white blood cells. This suture loses more than 70% of its tensile strength in 7 days and is totally digested by 70 days. Plain gut is used in tissue in which strength is needed for very short periods of time. It is ideal for Pomeroy tubal ligations because it dissolves rapidly and thus allows the severed ends to fall apart. Less rapidly absorbed sutures, particularly permanent suture, are associated with higher failure rates, probably because of fibrous formation.

Chromic gut is treated with chromic acid salts that bind to the antigen sites in the collagen. The resulting suture elicits a less inflammatory response and subsequently is more resistant to degradation. Chromic catgut maintains more than half of its tensile strength at 7 to 10 days, with some measurable strength remaining up to 5 months. It is suitable for tissue in which long-term strength is not needed. Examples of such tissue include serosal, visceral, and vaginal tissues. This suture should not be used in skin because the inflammatory response can cause scarring, and the suture often serves as a nidus for infection.

Because natural absorbable sutures are degraded by the proteolytic enzymes released by inflammatory cells, these sutures lose strength more rapidly in infected tissue. Because catgut is derived from animal intestines, primarily cow and sheep, there has been increasing concerns over the possibility of the transmission of transmissible spongiform encephalopathies (TSE), such as “mad cow.” Intestines are currently classified as tissues of medium infectivity with regard to TSE. Furthermore, because all inactivation processes for TSE cause severe changes to catgut, it is not possible to apply these methods to these sutures to eliminate infectious agents. Risk management is only possible by restricting sources to TSE-free herds. Because of these concerns, catgut sutures have been taken off the market in many countries of Europe as well as Japan. Where available, catgut has become progressively more expensive. Because the primary advantage of catgut over many of the synthetics has been cost, many believe use of catgut sutures will soon become obsolete.

Synthetic Absorbable Sutures

Polyglycolic Acid and Polyglactin 910

During the 1970s, two synthetic absorbable sutures (polyglycolic acid and polyglactin 910) became available in the United States. These sutures were designed to be stronger, longer-lasting, and less reactive than catgut. Both sutures are composed of braided filaments of a synthetic polymer. Polyglycolic acid (Dexon: Sherwood/Davis & Geck, St. Louis, MO) is a copolymer of glycolic acid, whereas polyglactin 910 (Vicryl: Ethicon, Somerville, NJ) is a copolymer of lactic and glycolic acid. The two sutures have very similar biologic properties.
Breakdown is by hydrolysis rather than digestion by proteolytic enzymes. The result is minimal inflammatory reaction and a constant absorption rate. There essentially is no loss in tensile strength in the first 7 to 10 days after implantation. Approximately 50% to 60% of tensile strength remains after 14 days, 20% to 30% after 21 days, and almost no tensile strength at 28 days. The initial tensile strength of both these sutures is significantly greater than catgut suture of equal size. In fact, the tensile strength of the synthetic absorbable sutures is almost equal to the tensile strength of a catgut suture one size larger.

One disadvantage of the synthetic absorbable sutures is that they do not handle as well as a catgut suture. To counter this difficulty, manufacturers have attempted to enhance the handling qualities of their products by offering versions with various surface coatings or variations with finer and more tightly woven filaments. Although these refinements improve handling characteristics, they increase the tendency of knots to slip. As a result, additional throws may be needed when using these versions of polyglycolic acid or polyglactin 910. These sutures can be used in most situations in which chronic catgut would be used and have replaced catgut almost entirely for many surgeons. Because they retain tensile strength longer than natural absorbable sutures, they are acceptable for fascial closure in patients at low risk for fascial dehiscence.

Polyglyconate and Polyoxydioxanone

Sutures of polyglycolic acid and polyglactin are by necessity composed of braided filaments because the inherent rigidity of the polymers produces a monofilament suture too stiff for general surgical use. A newer class of polymers allow the production of pliable monofilament sutures. This type of suture is represented by polyglyconate (Maxon) and polyoxydioxanone (PDS). Although subtle differences exist between the two sutures, they are similar enough to consider them together when discussing the biologic properties of this suture class.

The initial tensile strength of these monofilament sutures is lower than that of the multifilament absorbable sutures. However, this class of suture undergoes absorption at a much slower rate than other absorbable sutures. As a result, tensile strength is maintained for a longer period of time. More than 90% of initial tensile strength is maintained by the end of the first postoperative week, 80% at 2 weeks, 50% at 4 weeks, and 25% at 6 weeks. As with the other synthetic sutures, inflammatory response is minimal. An additional advantage is that these monofilament sutures lack interstices that could serve as a nidus for bacterial infection. As a result, chronic inflammation is rarely seen with this class of monofilament sutures. In comparison, infected absorbable braided sutures have been shown experimentally by Buckall to contain bacteria even after 70 days of implantation. Because of their delayed absorption profile, both polyglyconate and polyoxydioxanone are excellent choices for fascial closure. Because these sutures are composed of only one fiber, care must be taken to insure that the strand is not inadvertently damaged by instruments, needles, or other sharp-edged material. Such damage may not be easily recognized in the operating room but can seriously weaken a monofilament suture and may result in suture line disruption postoperatively. This precaution is even more critical when a continuous suture line is used.

Poliglecaprone 25 and Poligleactin 910 (Rapide)

With recent advances in polymer chemistry, it is now possible to manufacture the synthetic equivalent of surgical gut. First introduced in 1993, poliglecaprone 25 (Monocryl) has the absorption similar to chronic catgut. Unlike natural collagen, poliglecapron 25 produces a highly uniform and predictable absorption pattern. Like the other synthetic sutures, poliglecaprone 25 is absorbed by hydrolysis and thus does not induce the inflammatory response of catgut. This monofilament suture retains approximately 30% to 60% of its original tensile strength at 7 days postoperatively, 20% to 30% at 14 days, and by 21 days has lost essentially all tensile strength. This particular suture has the advantages of chronic catgut suture, but without many of the disadvantages (i.e., intense inflammatory response and somewhat unpredictable absorption rate). Although it is similar to chronic catgut in tensile strength and actually maintains its tensile strength longer than chronic catgut, it is not recommended by the manufacturer for use for fascial closure or in any tissue in which absorption under stress is required.

Poligleactin 910 Rapide (Vicryl Rapid) is identical in chemical structure to polyglactin 910 but is of lower molecular weight. The result is a braided suture with performance characteristics similar to plain catgut. Absorption is rapid, with 70% of tensile strength lost in the first 7 days. After 10 to 14 days, essentially no strength remains. It is intended for use in the superficial soft tissue where only short-term support is needed. It can be used for skin closure because of its rapid absorption and minimal inflammatory response. The sutures typically begin to fall off at 7 to 10 days. Because sutures remaining in skin longer than 7 days may cause scarring, any suture remaining at this time can be wiped off with sterile gauze or, if necessary, cut. This suture is an excellent choice for first- and second-degree episiotomy and vaginal laceration closure. Because of the intense inflammatory response produced, gau sutures are associated with more significantly postepisiotomy pain than synthetic sutures, whereas long-delayed absorbable synthetic sutures are associated with the presence of unabosorbed suture and knots after the postpartum period. Although this suture does not meet USP strength requirements for synthetic absorbable sutures, its tensile strength exceeds the tensile strength specifications for similar size natural collagen suture.

Nonabsorbable Sutures

By definition, nonabsorbable sutures are suitably resistant to the action of living mammalian tissue. These sutures, however, are not completely resistant to absorption. Over time, these sutures also lose tensile strength and in the case of natural fiber sutures eventually are completely absorbed or digested. Despite beliefs to the contrary, the initial tensile strength of many nonabsorbable sutures is less than comparable-size absorbable suture (Table 13.1). Nonabsorbable sutures, however, have the advantage of maintaining tensile strength for long periods of time. Disadvantages of nonabsorbable sutures include the potential suture-related pain, palpable sutures, and occasionally the formation of suture sinus.

Natural Nonabsorbable Sutures

Modern nonabsorbable natural fiber sutures are composed of either surgical silk or cotton. Silk suture is one of the best handling sutures. The handling and knot-tying characteristics of silk suture remain the standard against which other sutures are judged. This suture has little “memory”; that is, it does not tend to return to its original form after being bent or twisted. As a result, it handles well, ties easily, and possesses excellent knot security. Silk suture loses more than half of its
tensile strength after 1 year of implantation and frequently can-
not be found after 2 years. In this respect, it can be viewed
as a delayed absorbable suture. Because silk is a foreign ani-
mal protein, it initiates the greatest inflammatory response
of the nonabsorbable sutures. The multifilament nature and the
capillary action of this suture makes it unsuitable in contami-
nated tissue or in tissues in which the potential for infection is
high.

Cotton is the other natural nonabsorbable natural suture
material still available. It is rarely used in modern sur-
gical practice. Cotton is the weakest of the nonabsorbable su-
tures. Cotton loses 50% of its original tensile strength within 6
months of implantation, but still has 30% to 40% remaining
at the end of 2 years. Unlike silk, which loses tensile strength
when exposed to moisture, wet cotton is 10% stronger than
dry cotton. Because wet cotton also is easier to handle, it is
usually moistened before use.

Synthetic Nonabsorbable Sutures

A wide variety of nonabsorbable synthetic sutures exist.
Nylon is a synthetic polyamide polymer derived from coal,
air, and water. It is available both as a braided multifilament
suture (Neuronol, Surgelon) and as a monofilament suture
(Dermalon, Ethilon). Monofilament nylon has slightly greater
tensile strength than braided nylon, but braided nylon handles
better and has better knot security than the monofilament nylon
suture. Monofilament nylon suture incites less inflammatory
reaction and is less prone to infection than the braided nylon
sutures. However, because nylon is relatively inert, all types of
nylon suture produce minimal tissue reaction. Nylon under-
goes slow hydrolysis in tissue over extended periods of time.
It loses approximately 15% to 20% of tensile strength each
year.

Polyester sutures are produced only in braided forms. Most
sutures in the properties of these sutures are determined by
whether they are coated and by the type of coating. The un-
coated forms (Maxon, Dacron) generally offer the best knot
security. As with synthetic absorbable sutures, coatings can im-
prove the handling characteristics of the polyester sutures. Knot
security of coated polyester sutures is generally poorer than
that of uncoated sutures. Coatings currently used include poly-
tetrafluoroethylene, also known as Teflon (Polydek, Ethibux,
and Tevdek) polybutyrate (Ethibond), and silicone (Ti-Cron).
Polypropylene (Prolene, Surgilon) is a monofilament su-
ture composed of a linear hydrocarbon polymer. It has the
least tissue reactivity of all nonabsorbable sutures. Although
polypropylene has a high memory, it also exhibits a small de-
gree of plasticity. If it is tied carefully and the knots set firmly, a
flattening occurs where the strands cross. This flattening helps
lock the knot and thus provides somewhat greater knot security
than is possible with many other monofilament nonabsorbable
sutures. As with the absorbable monofilament sutures, the same
precautions to prevent damage to the tissue must be observed
with the monofilament nonabsorbable sutures.

Metal Sutures

Although silver wire was used by Sims for closure of veno-
vaginal fistulas, metal sutures are rarely used in gynecologic
surgery today. Historically, metal sutures have been used in
infected sites or for repair of wound dehiscence and vesica-
tion. Stainless steel once was used routinely by the military for
repair of wounds of the abdomen, but has been abandoned after
2 and 12 days postoperatively, with a mean occurring around
day 7 to 8. Dehiscence rarely occurs after postoperative day 12
but has been reported up to day 18. This would suggest that in
most patients, fascia has regained enough strength by day 12
after surgery to resist reasonable stresses, but that in a limited
number of patients, fascia may not regain sufficient strength to
prevent dehiscence until 3 weeks postoperatively.
FIGURE 13.3. Fascial tensile strength after surgery. (Adapted from Howes EL, Sooy JW, Harvey SC. The healing of wounds as determined by their tensile strength. JAMA 1929; 92:42.)

Using the fascia pull-out data, tensile strength as measured by the knotted-loop model following various lengths of implantation in animals, and dehiscence data, the appropriate size absorbable suture for fascial closure can now be estimated. As can be seen in Figure 13.4, both 1 and 0 polydioxanone and polyglyconate retain tensile strength greater than the fascial pull-out force for 4 to 6 weeks, but polyglycolic acid sutures of the same size maintain adequate tensile strength only for 7 to 14 days. Based on this model, a 1 or 0 polydioxanone or polyglyconate suture appears to be the most appropriate absorbable suture for fascial closure. Unfortunately, although these types of data are theoretically appealing, there are little clinical data to support these conclusions. It must be realized that in most healthy patients, fascial dehiscence does not occur, even when rapidly absorbed sutures are used. Before the development of the synthetic absorbable sutures, 1 and 0 chromic catgut sutures were frequently used for fascial closure. In fact, based on a survey of obstetrics residency programs, chromic catgut still was being used for fascial closure in 16.1% of vertical fascial incisions and 23.4% of transverse fascial incisions as of 1979. Although fascial dehiscence in healthy patients remained uncommon after fascial closure with chromic catgut, dehiscence rates of up to 11% were reported for other patient populations. Likewise, polyglycolic acid and polyglactin 910 sutures have been used for fascial closure with good success, even in patients at risk for dehiscence.

Surgical Needles

Needles are necessary to carry suture material through tissue. The specific needle required for a procedure is determined by the tissue type, its location and accessibility, and the surgeon’s personal preference. All surgical needles have three basic components: the eye, the body, and the point.

The eye of the needle is the point of attachment for suture. Eyes may be classed as closed, French, or swaged. Closed eyes are similar to those on household sewing needles, whereas French eye needles have a slit with ridges inside the slit to catch and hold the suture. Swaged or eyeless needles have the suture mechanically attached to the end of the needle to form a continuous unit. Eyed needles have several disadvantages over swaged needles, including difficulties with threading and the need to pull a double loop of suture through the tissue. Swaged needles are available with either the suture permanently attached or attached in such a manner that it can be removed from the

FIGURE 13.4. The tensile strength of various implanted suture materials over time and the point at which tensile strength is less than fascial pull-out strength (14.3 to 24.2 lb).
needle by a slight straight tug on the suture. These controlled-release needles, also known as “pop-off” needles, increase the speed at which interrupted sutures can be placed.

The shape of the body or shaft of a needle determines how easily the needle performs in different applications (Fig. 13.5). The longitudinal shape of the body may be straight, half-curved, curved, or compound. Straight needles are used commonly when tissue is easily accessible. This type of needle is rarely used by gynecologists except for skin closure. Half-curved, or ski, needles may be used to close skin, but have primarily been used in gynecology to facilitate laparoscopic suturing. Curved needles require less space for maneuvering than other needles, thus are ideally suited for most surgical procedures. Curved needles are commonly named based on the percentage of a circle they complete; that is, a \( \frac{1}{2} \) circle needle is one half of a full circle. Curved needles are available in various curvatures, with the \( \frac{3}{8} \) circle the most commonly used. The less of an arc the needle completed, the more shallow a bite the needle takes. For example, a \( \frac{5}{8} \) needle is useful in deep wounds in which a deep, narrow bite is required. Compound curve needles were originally developed for anterior segment ophthalmic surgery and are not used in gynecologic surgery.

The point of the needle begins at the widest part of the needle body and extends to the extreme tip. The two types of needle points are the cutting point and the tapered point (Fig. 13.5). Tapered points are used in easily penetrated tissue, such as bowel or peritoneum. A variation of the taper point is the blunt tip, which has a rounded blunt tip at the end of a tapered shaft. This needle tip was designed for use in friable tissue, but has been advocated by some surgeons for use with other tissues because of its reduced likelihood to penetrate the surgeon’s gloves or skin. Cutting needles are used in tough tissue, such as skin. The most common cutting needle is the reverse cutting needle. Its sharp edge is on the outside of the outer curvature of the needle. Conventional cutting points have the sharp edge on the inside of the curvature. Variations of the cutting point include spatula and lancet points and are used for specialized applications such as ophthalmology.

### Needle Holders

Straight needles can be held and pushed through tissue with the fingers. Straight needles can be used only to sew in a straight line, and only then when the tissue is easily accessible. When straight needles are used, sewing is done in a direction away from the operator.

In the depths of a wound, curved needles are needed. A needle holder is required when curved needles are used. All needle holders have a broad head with a variety of surfaces to prevent the needle from slipping or rotating. Needle holders may be large and heavy, or small and delicate, depending on the size needle to be used. Many needle holders have ring finger grips and locking mechanisms. Two common types of basic needle holders used in gynecology are Wagensteen (straight) or Heaney (angled) (Fig. 13.6). Curved needle holders are especially useful in vaginal surgery, for which the angled head allows easier needle placement. The needle is loaded so that the angled tip is pointed toward the needle eye and not the tip. Sewing, using needle drivers, is performed toward the operator.

### Surgical Knots

The surgical knot has been described as the weakest link in any knotted suture, regardless of the knot configuration and the type of suture used. If tied improperly, a surgical knot will fail before the tensile strength of the suture is reached. Even when performed perfectly, the mere placement of a knot in suture reduces its overall tensile strength by 30% to 35%. Therefore, some knowledge of surgical knots is imperative for all surgeons.

All surgical knots can be divided into two basic groups: flat knots (square, surgeon’s, and granny) and sliding knots (identical and nonidentical). (Fig. 13.7). Flat knots are formed with half hitches tied with equal tension on the ends of the suture. Surgeon’s knots are formed by adding an additional loop to the first throw of the half hitch. Sliding knots are two half hitches...
either nonidentical (square knot) or identical (granny knot), tied with greater tension on one segment than the other. The term sliding knot suggests the tendency of the knot to slip compared with the flat, but this is not completely true. Simple sliding knots of two or three throws do slip often and should not be used as surgical knots. Brouwers and colleagues have shown, however, that flat knots with only two throws also tend to slip rather than break.

The flat square knot is the most secure of all the surgical knots and theoretically the most desirable knot for tying suture. However, according to a study by Trimbos, sliding knots are used more commonly by gynecologists than are square knots. It has been shown also that many surgeons actually tie sliding knots despite being convinced they tie flat knots. Sliding knots frequently are used in actual surgical practice for two reasons. The crossing of the surgeon’s hands needed to tie square knots unavoidably releases tension on the knot, and this can lead to knot slippage. The tying of deep ligatures is mostly performed by keeping constant tension on one suture. Thus, sliding knots may be preferable to square knots in certain situations. Whichever knot is used, the operator should be aware of the knot being used and the number of throws needed to obtain maximum knot capacity.

The number of throws required for knot security is frequently debated. Too few throws and the knot is weaker than the suture; additional throws above that needed to equal the sutures tensile strength adds unneeded suture to the wound and may increase the infection rate. When flat square knots are used, Brown has shown that maximum knot-holding capacity was achieved with four throws in all noncoated suture tested. In fact, three throws were sufficient to achieve maximum knot-holding capacity except for sutures composed of nylon (both monofilament and braided). The addition of coating to improve handling characteristics also decreases knot security. In a 1983 study, Rodeheaver and colleagues showed that coated suture required two additional flat throws to equal the maximum knot-holding capacity of uncoated suture. In a similar study by Van Ruiszel and colleagues, the knot-holding capacity of a sliding knot with one extra throw equaled that of square knots in smaller gauge (3-0) suture. In larger sutures (0), square knots remained stronger than sliding knots with an extra throw, but sliding knots with more than five throws were not tested. From these studies, it appears that a surgical knot of four to six throws is adequate for most sutures. The exact number of throws required, of course, depends on the type of suture and whether a flat or sliding knot is formed.

It is common practice for some surgeons to leave suture tails long to prevent knot disruption should the knot slip. As might be expected, the usefulness of this practice is dependent on the type of suture involved. It has been shown that any knot slippage in nylon, polydioxanone, and polypropylene sutures results in total knot disruption. In other sutures (polyglactin and poliglecaprone), initial knot slippage is followed by knot recomposition. The reconstituted knot remains intact until greater force is applied. A long suture tail is only helpful in preventing knot disruption in this latter class of suture. Knot security is of utmost importance when using a continuous suture line. It is common practice for many surgeons to form the terminal knot in a continuous suture line by tying the ending single strand to the last loop of suture. This “loop-to-strand” knot is a potentially weak configuration. Unless multiple square knots are used, the single strand may slip from the knot when placed under tension. As a result, the entire suture line disrupts. At reoperation, the strand may appear broken but, in fact, one of the three terminal knot ends has slipped through what appears to be an intact knot (Fig. 13.8). A safer method for tying continuous suture is to run two sutures to the midpoint of the incision and tie the two single strands to each other, thus avoiding the “loop-to-strand” knot.

**SURGICAL INSTRUMENTATION**

A multitude of surgical instruments are designed to perform one unique function or slightly improve on the performance...
of another instrument. This section is not intended to be a comprehensive list of all instruments available, but a review of the basic surgical instrumentation needed for most common gynecologic procedures.

**Scalpel**

The scalpel is the first instrument used in most surgeries and remains the best instrument for dividing tissue with minimal trauma to surrounding tissue. Scalpel blades come in various sizes and shapes to allow performance of different tasks (Fig. 13.9). The basic scalpel blade has a straight ribbed back and an oval cutting surface. This basic blade is commonly available in sizes 10, 15, 20, and 22. The 10 scalpel blade is the most versatile and the most commonly used size. The smaller blades are used for fine dissection and when precise turns are required in making the incision—that is, plastic surgery—although the larger blades are used to rapidly perform an incision. Blades such as the 11 and 12 are designed for specific purposes. The 11 blade is bayonet-shaped and used to perform stab incisions for drains and in draining abscesses. The 12 blade is hook-shaped...
Scissors

The scissors are the second most commonly used instrument to divide tissue. In addition to cutting, scissors also can be used for blunt dissection by opening the scissors after the tips have been inserted into a tissue plane. The basic scissors designs used in gynecology surgery are the Mayo, Metzenbaum, and Iris scissors. All come in both straight and curved versions (Fig. 13.10). Curved scissors allow horizontal cutting deep in a wound and thus improve visibility. Curved scissors also are used to cut tissue in a smooth curve, such as for incising the vaginal cuff in an abdominal hysterectomy.
FIGURE 13.12. Tissue clamps. (Courtesy of Zinnati Surgical Instruments, Inc., Chatsworth, CA.)
FIGURE 13.13. Hysterectomy clamps. (Courtesy of Zinnati Surgical Instruments, Inc., Chatsworth, CA.)

Mayo scissors are used when dividing tough tissue, such as the rectus fascia, parametrial tissue, or vaginal cuff. Metzenbaum scissors are more delicate than the heavier Mayo scissors and are used for cutting thinner tissue, such as peritoneum and adhesions. Metzenbaum scissors are frequently used for retroperitoneal dissection or for developing tissue planes in adhered or distorted tissue. Iris scissors are small scissors used for delicate dissection. Originally designed for ophthalmic surgery, they are used in gynecology for precise vulvar and vaginal surgery, such as fistula repair or colporrhaphy.

Suture scissors are used only to cut suture and never tissue. Suture scissors are general-purpose scissors with blunt ends to avoid the possibility that the tips will injure structures distal to the suture.

**Tissue Forceps**

Tissue or thumb forceps consist of two strips of metal joined at one end (Fig. 13.11). The opposable ends of the forceps are used to grasp and hold tissue during dissection, suturing, or cutting. These ends are of varying shapes and configuration, depending on the purpose for which the forceps are intended. The most common alteration to the ends is the addition of teeth. Smooth forceps without teeth are used when handling friable or delicate tissue. DeBakey forceps have long fine smooth tips that provide precise control of small or delicate tissue deep in the wound. They are commonly used in vascular surgery or retroperitoneal node dissection. Toothed forceps bite into tissue, providing a firm grip with minimal pressure. The teeth can vary from one to many and be fine or large. Adson forceps are equipped with fine teeth and are commonly used to approximate skin for staple or suture placement. Ring-tipped and Russian forceps increase the grasping force without using teeth by increasing the surface area of the grasping tips. These forceps are used when a secure hold is needed on structures that would be traumatized by toothed forceps. Bonney tissue forceps are heavy-toothed forceps with serrations along the shaft for maximum gripping power. They are used when sewing fascia.

**Clamps**

Grasping forceps, commonly referred to as clamps, are designed to grasp and apply traction to tissues (Fig. 13.12). All have finger rings and a locking mechanism. Babcock clamps have no teeth and are atraumatic. These clamps can grasp and hold delicate tissues such as fallopian tube or bowel without causing damage. Allis clamps have serrated edges with short teeth. This clamp has much more grasping power than the Babcock clamp. Kocher/Oschner clamps have transverse ridges...
along the shaft and interlocking teeth at the tip. Because of their design, tissue within the clamp is unlikely to slip. These clamps are frequently used to grasp heavy tissue such as fascia and occasionally as hysterectomy clamps. Ring forceps can be used like ring-tipped tissue forceps, but more commonly are used to hold folded sponges. In this fashion, they can be used to retract tissue, sponge fluid or blood, or apply solutions to the skin in preparation for surgery. Renal stone forceps were designed to remove stones from the renal pelvis but are commonly used by the gynecologic surgeon to explore the uterine cavity for polyps or retained tissue. When used in this capacity, they are inserted, opened, rotated 180 degrees, closed, and withdrawn.

Heaney, Heaney-Ballentine, and Masterson clamps are the commonly used clamps for clamping the parametrial and paracervical tissue during hysterectomy (Fig. 13.13). Hysterectomy clamps are heavy crushing clamps with ridged shafts. The classic clamps (Heaney, Heaney-Ballentine) also have toothed tips. The more recent Masterson clamp lacks a toothed tip and was designed to generate the least amount of crushing force.

Retractors

Retractors are used to hold tissue out of the operative field to improve exposure during surgical procedures (Fig. 13.14). Retractors are either held by an assistant (manual retractors) or use counterpressure from other tissue (self-retaining retractors) to hold themselves in place. Self-retaining retractors frequently are used to hold the sides of the incision apart during gynecologic surgery. Gynecologists seem to favor the O’Connor-O’Sullivan retractor when performing pelvic surgery. General surgeons, on the other hand, prefer the Balfour retractor. The O’Connor-O’Sullivan is a circular retractor with four blades, two permanently attached lateral retractors to retract the sidewalls, and a removable upper and lower blade to retract the bowel and bladder, respectively. This retractor is available with large or small lateral blades, whereas the removable blades come in several sizes. The Balfour retractor also has two lateral blades but only one additional retractor blade. This blade normally is employed as an upper blade with a manual retractor used for bladder retraction if needed. However, if the bowel is carefully packed away with laparotomy packs, the third blade can be used as a bladder retractor. All blades of the Balfour retractor are removable and available in different sizes.

The Bookwalter retractor is the most versatile of retractors, providing excellent exposure to the operative field. It consists of a circular metal ring to which a wide variety of retractors can be attached at any point. Its best use is during radical pelvic surgery or when operating on massively obese patients. In extremely obese patients, it may necessary to attach the Bookwalter retractor to the operating table. Manual retractors allow maximum flexibility in providing exposure (Fig. 13.15). They can be used alone or as a supplement to self-retaining retractors. Common manual retractors include the Heaney, Deaver, and Richardson retractors. Specialized retractors include the Briesky-Navratil (used during sacropinous vault suspension), Army-Navy, and Parker retractors (used for skin and subcutaneous tissue).

Dilators

Dilators are metal or plastic cylinders used to dilate the cervical os to sufficient size to admit other surgical instruments (Fig. 13.16). Dilators may have tapered (Hank and Pratt) or rounded (Hegar) tips. Dilators with tapered tips require less force to perform dilatation than dilators with rounded tips. The sizes are measured either by diameter or by circumference. The unit of measurement for diameter is millimeters, whereas the unit of measurement for circumference is in French calibration. The relationship of the two measurements can be calculated by the formula for the circumference of a circle where the diameter times pi (3.14) equals the circumference. For comparison purposes, approximately 3 French equals 1 mm of diameter.

CONCLUSION

This chapter has attempted to present an introduction to the mechanisms of wound healing, wound closure, suture material, and instrumentation. It is hoped that this chapter will be a useful resource not only for those embarking on a surgical career but also for experienced surgeons as well.
Principles of Anatomy and Perioperative Considerations

BEST SURGICAL PRACTICES

- Secondary wound closure should ideally be performed on Day 1.
- Proper surgical technique is one of the most critical factors in preventing wound dehiscence.
- Abdominal wall fascia should be loosely closed with suture bites of 1 to 1.5 cm.
- The use of mass closure techniques using long-delayed or permanent suture to close fascia is recommended to reduce fascial dehiscence.
- The use of catgut sutures has been limited in many countries because of increasing concerns over the possibility of theoretical infection with transmissible spongiform encephalopathies (TSE), such as "mad cow" disease.
- Suture knots produced by tying a loop of suture to a single strand are less secure than those tied using a strand to strand. This is particularly critical when using monofilament suture.

Bibliography

SECTION III ■ PRINCIPLES OF GYNECOLOGIC SURGICAL TECHNIQUES AND MANAGEMENT OF ENDOSCOPY
CHAPTER 14 ■ INCISIONS FOR GYNECOLOGIC SURGERY

JAMES J. BURKE II AND DONALD G. GALLUP

DEFINITIONS

Arcuate line—The demarcation above which the posterior lamella of the internal oblique aponeurosis fuses with the aponeurosis of the transversalis muscle and passes posterior to the rectus muscles. Below this line, the aponeurosis of the internal oblique passes anterior to the rectus muscles.

Cherney incision—A transverse abdominal incision in which the rectus muscles are transected at their insertion on the pubic symphysis. The fascia may or may not be dissected free from the rectus muscles. Entry into the peritoneum may be vertical or transverse.

Dehiscence—Disruption of a surgical wound, either superficial or deep. Superficial dehiscence is separation of the skin and subcutaneous tissue because of seroma, hematoma, or abscess formation. Fascial dehiscence describes the separation of the fascia without extrusion of the bowel.

Evisceration—Disruption of the fascia with extrusion of the bowel through the wound.

Gridiron incision—A muscle splitting, oblique incision, useful for a transperitoneal or extraperitoneal approach to pelvic organs, similar to a McBurney’s incision.

Herna—A late complication of wound disruption. A fascial disruption occurs with protrusion of the peritoneum, bowel, and omentum. The skin and subcutaneous tissue are intact.

Langer lines—The natural, anatomic tissue lines on the abdominal skin.

Linea alba—Where the aponeurosis of the internal and external oblique muscles insert, anterior to the rectus musculature.

Maylard incision—A transverse abdominal incision in which the rectus muscles are transected after ligation of the inferior epigastric vessels. The fascia is not dissected free of the rectus muscles. The peritoneum is usually entered in a transverse fashion.

Panniculectomy—Surgical removal of the pannus, excess skin, and subcutaneous fat, which hangs like an apron from the abdomen. Removal facillitates gynecological surgery.

Pfannenstiel incision—A commonly used transverse abdominal incision in which the rectus muscles are not cut and the fascia is dissected superiorly and inferiorly along the rectus muscles. The peritoneum is usually entered vertically.

Schuchardt incision—an incision made in the vagina along the sulcus of the vagina from the lateral fornix to the introitus and through the perineum. This incision can increase room in the vagina so as to aid in difficult vaginal surgeries.

Smead-Jones closure—An interrupted closure of the anterior abdominal wall using a far-far, near-near approach. The closure includes all of the abdominal wall structures on the far-far portion and only the fascia on the near-near portion.

One of the last marks of any abdominal surgery, and most noticeable to the patient, is the scar made by the incision. In selecting an incision, the gynecologist must take into consideration the underlying pathology prompting the surgery, the suspicion of malignancy, the absence or presence of upper abdominal disease, and the underlying comorbid state of the patient. Although there are many types of incisions for gynecological surgery, selection of any incision must be highly individualized. However, selection of an incision should not be dictated by patient choice to preserve cosmesis if it may compromise the surgical approach. Conversely, unduly large or poorly positioned incisions may increase the likelihood of infection, herniation, or dehiscence, as well as unsightly cosmesis. During the surgical consenting process, the patient should be counseled on the location of the incision, the rationale for the particular incision, and any possible complication that may arise from the planned incision. In gynecologic oncology patients, the need for urinary diversion, colostomy, or an extraperitoneal approach to node-bearing areas will dictate the type of incision to be made. This chapter presents the classic incisions used by gynecologists to perform most gynecologic surgery. In addition, incisions used for gynecologic oncology will be shown. Finally, discussion and management of common complications associated with abdominal incisions will be presented.

ANATOMY OF THE ANTERIOR ABDOMINAL WALL

To avoid injury to vessels and nerves and to close any incision with minimal chance of dehiscence, abdominal wall anatomy should be thoroughly understood. The abdominal wall protects the visceral organs and vasculature within the abdominal cavity. Cephalad, the anterior abdominal wall extends to the costal margins and the xiphoid process. The costal cartilages of the seventh, eighth, ninth, and tenth ribs form a portion of the cephalad boundary. Lateral boundaries include the iliac crests; inferiorly, the abdominal wall is delineated by the inguinal ligaments, the pubic crests, and the superior border of the symphysis pubis. The principal anatomic structures of the abdominal wall include the overlying skin, subcutaneous tissue, muscles, fascia, and the nerves and vascular supply to these structures. Many factors—such as age, muscle mass and tone, obesity, intraabdominal pathology, previous pregnancies, and posture—can result in variation in the contour of the abdominal wall. These variations in contour affect abdominal wall topography and may present problems in the correct choice and placement of incisions.
Skin and Lymphatics

The skin contains small vessels, lymphatics, and nerves. A minimal loss of skin sensation can result from any abdominal incision. Numbness below a transverse incision frequently occurs. As stated in the discussion on nerve supply, laterally extended transverse abdominal incisions can result in numbness of the skin on the anterior thigh.

The lymphatic drainage of the upper abdominal wall passes directly to the axillary lymph nodes. The lymphatic drainage of the lower abdomen passes to the inguinal nodes and then to the iliac chain. Some lymphatics around the umbilicus drain toward the liver through the falciform ligament. When an incision is placed transversely in the lower abdomen, lymphatic drainage of the abdominal wall above the incision site is interrupted. Some tissue swelling may develop temporarily until collateral lymphatic drainage can be established. Patients should be counseled about this possible swelling before undergoing surgery.

In 1861, Langer, working with cadavers, described cleavage lines of the skin that pull the skin edges apart when cut across. These have become known as Langer lines (Fig. 14.1). These lines usually run horizontally across the abdomen. A vertical incision in the skin of the abdomen cuts perpendicular to Langer lines, whereas a horizontal incision cuts parallel to them. Thus, transverse incisions heal with a relatively fine scar, and vertical incisions can heal with a broad scar, particularly in the lower abdomen.

Muscles and Fascia

The abdominal muscles assist in respiration, defecation, urination, coughing, and childbirth by increasing intraabdominal pressure. They work synergistically with the muscles of the back to flex, extend, and rotate the trunk and pelvis. There are two groups of muscles that form the musculature of the anterior abdominal wall. The flat muscles include the external oblique, the internal oblique, and the transversalis. Their fibers basically run diagonally or transversely. The second group, composed of the rectus muscles and the paired pyramidalis muscles, have fibers that run vertically (Fig. 14.3). The recti, with their thin investing fascia, are muscles of locomotion and posture. The paired pyramidalis muscles arise from the crest of the pubic symphysis and insert into the pubic symphysis. Preservation of the pyramidalis muscles is not essential when making incisions. The integrity of the anterior abdominal wall is not associated with this second group of muscles.

A cross section of the lower abdominal wall shows that the fascia of the abdominal muscles envelop the anterior and posterior surfaces of the rectus muscles and anchor the external oblique, the internal oblique, and the transversalis muscles to the vertical (rectus) muscles (Fig. 14.3). There is excellent fascial support anteriorly and posteriorly to the rectus muscles above the arcuate (semicircular) line. In this location, the fascial aponeurosis of the external oblique and the split fascial aponeurosis of the internal oblique fuse together anterior to the rectus muscle and insert in the midline (linea alba). Above the arcuate line, the posterior lamella of the internal oblique muscle fuses with the posterior lamella of the transversalis muscle, passes posterior to the rectus muscle, and inserts in the midline. The lower half of the lower abdominal wall is weakened below the arcuate line, at a level about equal to the anterior superior iliac spine, where the posterior division of the rectus sheath disappears in this location, the divided lamella of the internal oblique muscle combines and passes anterior to the rectus muscle. From this lower portion of the lower abdominal wall to the pubic rami, only the attenuated transversalis fascia and the peritoneum lie adjacent to the posterior surface of the muscle. It is in this weakened section of the lower abdomen that most incisional hernias occur after pelvic surgery through lower midline incisions. In the lower abdomen, the force required to approximate edges of a vertical incision is 30 times greater than the force required to approximate edges of a transverse incision.

The external oblique muscle and its aponeurosis form the most anterior layer of the flat muscles. The external oblique muscle originates from the lower eight ribs. Superiorly, the fibers of this muscle run transversely; inferiorly, they assume an oblique downward course. A portion of the muscle gives rise to a broad fibrous aponeurosis, which courses medially, anterior to the rectus muscle. The next posterior fanlike muscle is the internal oblique, which originates primarily from the iliac crest,
the thoracolumbar fascia, and the inguinal ligament. The midportion of the muscle runs an upward oblique course and gives rise to the aponeurosis of the internal oblique. As noted, at the lateral border of the rectus musculature, the aponeurosis splits and forms a sheath around the rectus muscle, rejoining medial to the rectus to help form the linea alba. The third flat muscle, the transverse abdominis, arises from the lower six costal cartilages, thoracolumbar fascia, and internal lip of the iliac crest. It has a truly transverse course. Above the midway point between the umbilicus and pubis, the aponeurosis of this muscle passes behind the rectus muscle and contributes to the posterior rectus sheath. Below this point, the aponeurosis passes anterior to the rectus muscle, contributing to the anterior rectus sheath. Medial to the rectus muscle, the fascia of all three flat muscles insert to form the linea alba.

The major functions of the flat muscles are to assist with respirations and to assist in increasing intraabdominal pressure. Each time these muscles contract, they pull at the linea alba. Because the linea alba represents the insertion of six major abdominal muscles (three on each side), cutting it, as with lower midline incisions, actually interrupts the major portion of the insertion of these six muscles. Thus, contractions of these muscles in the postoperative period can result in considerable tension on a suture line in the linea alba and can cause considerable discomfort.

The rectus abdominis muscle arises from the pubic crest. It courses superiorly and inserts into the xiphoid process with the upper attachments being three times as broad as its pubic insertion. It has three or four fibrous insertions. One is at the level of the umbilicus; two are usually halfway between the umbilicus and the insertions, superiorly and inferiorly. Of note, the fibrous insertions are tightly adherent to the anterior rectus sheath. These limit the retraction of the muscle when it is cut. Thus, when performing a transverse-muscle cutting incision, it is not necessary to reapproximate the rectus muscle. The pyramidalis, a triangular muscle, usually lies anterior to the rectus and arises from the anterior portion of the symphysis, inserting into the inferior portion of the linea alba. The midportion of this muscle usually has an avascular raphe, which can easily be incised for adequate exposure of the Retzius space.

### Blood Supply

The abundant blood supply to the anterior abdominal wall comes from several sources. The main arterial supply consists...
FIGURE 14.3. Cross section of lower abdominal wall. A: The anterior fascial sheath of the rectus muscle from external oblique muscle (1) and split aponeurosis of internal oblique muscle (2). The posterior sheath is formed by aponeurosis of transversalis muscle (3) and split aponeurosis of internal oblique muscle. B: Lower portion of abdominal wall below arcuate line (linea semicircularis) with absence of a posterior fascial sheath of the rectus muscle and all of the fascial aponeuroses (1–3) forming the anterior rectus sheath.

of the superior epigastric, musculophrenic, deep circumflex iliac, and inferior epigastric vessels. The medial abdominal wall receives blood from the epigastric arteries, whereas the lateral wall is supplied by the musculophrenic and deep circumflex iliac arteries. The lateral wall is also supplied by the lower intercostal and lumbar arteries (T8 to T12 and L1). This freely anastomosing vascular system provides one continuous arterial and venous channel on both sides of the anterior abdominal wall, extending from the subclavian artery and vein (cephalad) to the external iliac vessels (caudad) (Fig. 14.4). Because of the rich anastomosis, vascular deficiency is usually not a complication of abdominal wall surgery. The linea alba is relatively bloodless. The limited vascular supply in this area of fascial fusion can impair wound healing when lower midline incisions are used. Thus, a secure closure is mandatory to avoid incisional hernias or eviscerations.

Conversely, the epigastric vessels are subject to injury, particularly when a muscle-splitting incision is used. Also, the deep circumflex or musculophrenic vessels can be injured when an extraperitoneal approach is chosen.

The superior epigastric artery is a continuation of the internal thoracic (mammary) artery. It enters the sheath of the rectus from behind the seventh costal cartilage and descends posterior to the rectus. It has multiple branches in the substance of the rectus muscle and anastomoses to the inferior epigastric artery. In the upper abdomen, cephalad to the umbilicus, the main branch of the artery tends to lie posterior to the midportion of the rectus muscle (Fig. 14.5). The inferior epigastric artery arises from the external iliac artery near the midinguinal point. It continues in a cephalad course along the posterior lateral portion of the rectus muscle and has an anastomosis with the superior epigastric arteries. The lower a transverse incision is made, the more lateral the inferior epigastric arteries are encountered. Bleeding from branches of the inferior epigastric vessels beneath the rectus muscle can dissect cephalad or caudad along the entire length of the posterior sheath. Below the arcuate line, bleeding can dissect laterally and inferiorly along the retroperitoneal planes and spaces, resulting in extensive hematomas of the abdominal wall and pelvis. Such bleeding can produce confusing acute abdominal signs in the postoperative patient, and large quantities of blood may be lost in these loose tissues and spaces.

The musculophrenic artery, arising from the internal thoracic, courses along the costal margin, behind the cartilages. It has an anastomosis with the deep circumflex artery, which originates from the external iliac at about the same level as the inferior epigastric artery. The deep circumflex courses behind the inguinal ligament and along the iliac crest, eventually piercing the transversus muscle and digitating between that muscle and the internal oblique. Before its anastomosis with the musculophrenic, it can be relatively large. Care must be taken when these muscles are incised laterally.

The venous drainage of the abdominal wall accompanies the arteries. The veins of the abdominal wall may be dilated in patients with obstruction of blood flow through the liver and porta hepatis.

Innervation

The nerve supply to the anterior abdominal wall is easily damaged by some incisions. The anterior abdominal wall is supplied by the thoracolumbar nerves, the iliohypogastric nerves, and the ilioinguinal nerves. The thoracolumbar nerves, which are the seventh to eleventh intercostal nerves, leave the intercostal spaces and travel caudad and anterior between the

FIGURE 14.4. The major arterial blood supply of the anterior abdominal wall consists of four major vessels. Two lateral and two medial contribute to the rich anastomosis. (From Gallup DG. Opening and closing the abdomen and wound healing. In: Gershenson D, Curry S, DeCherney A, eds. Operative gynecology. 1st ed. Philadelphia: WB Saunders, 1993:127, with permission.)
transversus and internal oblique. They supply these muscles and the external oblique. They enter the sheath of the rectus, and their branches supply the rectus and the overlying skin. Most of the nerves are supplied by several trunks. Any one nerve in the anterior abdominal wall contains fibers from the last two to three intercostal nerves. When an incision is made lateral to the midline, a transverse type is least likely to cause injury to nerves. In the upper abdomen, an obliquely caudad and laterally directed incision is least likely to cause significant nerve injury. In the lower part of the abdomen, an obliquely directed cephalad and laterally directed incision is relatively nerve sparing.

A vertical incision that passes lateral to the rectus muscle or through the muscle itself can denervate medially lying tissue. Depending on the length of the incision, atony or atrophy of the muscle can occur. A midline incision in the linea alba or a transverse incision (even through the rectus muscle), however, does not interfere with motor innervation of the abdominal musculature.

A minimal loss of skin sensation can result from abdominal incisions and is unavoidable in most cases. The iliohypogastric and ilioinguinal nerves are sensory in function (Fig. 14.6). Injury to the former, when wide transverse incisions are used, can result in sensation changes in the skin over the mons, whereas injury to the latter can result in sensation changes to the labia majora. A widely placed transverse incision can result in numbness of the skin over the upper anterior thigh. Both nerves are chiefly derived from the first lumbar nerve root. Although they lie for a distance between the internal oblique and the transversus, they do not enter the rectus sheath. They do not supply the external oblique or the rectus muscle. Both nerves supply the lower fibers of the internal oblique and transversus. If damage occurs to these nerves at the level of the anterosuperior iliac spine, these muscle fibers are denervated. A weakening
Incisions for Gynecologic Surgery

of the normal canal-controlling mechanism can occur, predisposing the patient to an inguinal hernia.

PHYSIOLOGY OF WOUND HEALING

Wound complications are a psychological and economic problem for the patient and include infections, dehiscence, and evisceration, as well as late-occurring problems such as incisional hernias and wound sinus formation. Factors negatively affecting proper wound healing include diabetes, malnutrition, prior irradiation or chemotherapy, older patient age, alcoholism, preoperative shaving the evening before the operation (instead of clipping of hair), longer duration of preoperative hospitalization, longer duration of the operation, use of Penrose-type drains brought out through the incision, ascites, malignancy, immunosuppression (including long-term corticosteroid therapy), and obesity. In addition, factors affecting wound disruption that usually occur in the absence of infection include choice of suture material, closure technique, occurrence of excessive coughing caused by pulmonary disease, retching and vomiting, and intestinal obstruction.

The four phases of wound healing are inflammation, migration, proliferation, and maturation. Breaks in the normal cycle of wound healing can occur anywhere, depending on preexisting conditions. Increases in fibroblasts during the proliferation phase, which occurs from day 5 through day 20, provide most of the strength to the wound. By day 21, most wounds have regained almost 30% of their original tensile strength. Any wound contamination or the presence of foreign bodies can cause chronic inflammation, wound sinuses, delayed incisional herniae, or the early postoperative problems of infection and dehiscence.

The risks of wound infections are directly related to the classification of wounds (Table 14.1). Obviously, few surgeons would primarily close a dirty wound. Many of the abdominal procedures performed by gynecologists include a hysterectomy.

Whenever the vagina is entered, the procedure is then classified as a clean-contaminated procedure with attendant risk.

**SUTURES**

Suture choice is basically a surgeon’s prerogative, but the characteristics of suture material intended for fascial closure should be well known to the surgeon. Additionally, suture choice should be based on the patient’s condition, the type of incision, and the strength and reaction of the suture (Table 14.2). In general, the ideal suture material should have the following characteristics: knot security, inertness, adequate tensile strength, flexibility, ease in handling, smooth passage through tissue, nonallergenicity, resistance to infection, and absorbability at a predictable rate. Neither plain catgut nor chromic catgut maintains tensile strength during the critical time of wound healing. They should not be used for fascial closure of the abdominal wall, irrespective of the type of incision used. Estimation of tensile strength of chromic suture after 14 days is 34%, whereas plain gut has none.

In general, sutures are classified as nonabsorbable if they maintain tensile strength for more than 60 days. In the permanent suture group, monofilament sutures yield less inflammation than that of polyfilament sutures. Wire has been the traditional suture used by surgeons for decades in high-risk patients, particularly when infection was an associated operative finding. However, wire is difficult to tie and breaks easily if bent sharply. If placed too closely to the incisional edges, it may cut through tissues. In some patients, wire can cause a prickling sensation. Also, wire ends may penetrate the surgeon’s gloves, exposing the surgeon to body fluid–borne pathogens. Furthermore, in animal models, both monofilament nylon and monofilament polypropylene sutures have elicited less infection in contaminated tissue and may be more durable than wire. Both cotton and silk are highly tissue-reactive sutures. Although silk and cotton are considered nonabsorbable sutures, silk loses all of its tensile strength after 1 year, and cotton loses half of its tensile strength after 1 year. If a permanent suture is chosen for closure, one of the monofilament polypropylene sutures or monofilament nylon should be used.

During the past two decades, synthetic absorbable sutures have been added to the surgeon’s armamentarium. Polyglycolic acid and polyglactin have been extensively studied. They maintain an estimated 55% of their original tensile strength at 14 days but lose all their tensile strength by 30 days. A newer polyglycolic acid suture, Dexon 2, appears to have better knot security. Many surgeons use one of these for various types of transverse incision closures. In 1984, Fagniez and colleagues reported few cases of fascial dehiscence in a large series of patients who had midline incisions closed with polyglycolic acid sutures.

Polyglyconate (Maxon) and polydioxanone (PDS) represent a new class of monofilament absorbable sutures, sometimes referred to as a delayed-absorbable suture. In animal studies, both of these sutures were observed to have a much less inflammatory response than that of polyglactin sutures. In addition, these investigators estimated that Maxon and PDS retain about 90% of their tensile strength by postoperative day 14 and retain 50% by postoperative day 30. In one study of degradation patterns of Maxon and PDS in rabbit fascia, PDS was noted to be superior. Rodeheaver and associates found no significant difference in knot-breaking strength in these two sutures, but Maxon appeared to have less stiffness in handling. Another study in rabbits also revealed the tensile strength superiority of Maxon and PDS compared with polyglycolic acid and polyglactin. In this study, Maxon was thought to have the best knot security. These investigators also observed that the most

Scale on 1, least; 4, most.
consistent knot security was achieved when six square knots were used. Alternatively, two surgeon's knots and two square knots can be used. Our clinical impression is that there is little difference in suture handling and knot security when Maxon and PDS II are compared. When wound healing is anticipated to take longer than 2 weeks, particularly for fascial closure of midline incisions, one of these two delayed-absorbable sutures should be highly considered. In addition, usage of one of these sutures should be considered in the presence of infection or contamination.

Finally, knot security will depend on suture size and the tissue needing approximation. Although sliding knots, also known as nonidentical sliding knots, can be safely used for pelvic viscera, sutures used to close abdominal wall fascia should be tied with square knots. Sometimes it is convenient to tie a loop-to-strand knot as a way of terminating a continuous tape to close the skin. No drains were used, and only one and oral antibiotics, transverse incisions, copious lavage, and culi measured 6 to 11 cm in thickness. They used systemic antibiotics, including surgeon experience, the population operated on, and PDS II are compared. A neoplastic layer may diminish tension from the approximated skin with a fine (4-0) running polyglycolic acid suture in the subcutaneous, subcutaneous sutures should be avoided because the subcutaneous spaces. When a bacteria-containing organ is opened (the unprepped bowel or abscessed gynecological organs) and delayed closure is not used, copious saline irrigation of all layers for closure should be instituted. In addition, a monofilament delayed or nonabsorbable suture should be used in the closure. Systemic antibiotics can help control wound infections when pelvic infection is encountered. To be of benefit, they should be administered at least 30 minutes before the skin incision and readministered if the operation is prolonged. Currently, first- and second-generation cephalosporins are the most popular antibiotics used in the prophylactic setting.

ABDOMINAL INCISIONS

In general, abdominal incisions used for most gynecologic procedures can be divided into transverse or vertical incisions. For extraperitoneal incisions and access to organs not associated with the female genital tract, modifications of oblique incisions are sometimes used. Because of the ease and rapid entry, the abdomen was originally routinely opened by a longitudinal incision in the linea alba. One of the first successful abdominal operations was performed by McDowell in 1809. In the early days of abdominal surgery, transverse incisions were generally avoided because they were more time-consuming. Also, an ungrounded fear was that transection of the rectus muscle would leave a defect because of retraction of the muscle. As previously stated in the section on anatomy, the adherence of the rectus to the anterior rectus fascia by several transverse inscriptions prevents retraction. In the late 1880s and early 1900s, several transverse incisions were developed, such as the Küster, Pfannenstiel, Maylard, and Chernet incisions. Most of the transverse incisions used for pelvic surgery are identified by the name of the surgeon who first described them, whereas few vertical abdominal incisions have no such eponyms.

Transverse Incisions

Transverse incisions for pelvic surgery are attractive because they produce the best cosmetic results. Additionally, low transverse incisions are as much as 30 times stronger than midline incisions, are less painful, and result in less interference with postoperative respirations. Wound dehiscence is allegedly more common with vertical incisions. The older literature suggests that wound evisceration was three to five times more common and herma occurrence was two to three times more common when vertical incisions were used compared to transverse incisions. Many earlier studies reported an increased incidence of eviscerations with midline incisions that could be associated with inappropriate closures. More recent studies, however, have shown no difference in the risk of wound dehiscence or even a slight advantage for midline incisions. A large study, completed at Hutzel Hospital in Detroit by Hendrix and colleagues, found that there was no difference in fascial dehiscence between transverse (Pfannenstiel) and vertical incisions. Transverse incisions have certain associated disadvantages. They are relatively more time-consuming and result in hemorrhagic. Occasionally, nerves are divided, and division of multiple layers of fascia and muscle can result in formation of potential spaces with subsequent hematoma or seroma.
through subcutaneous fat, down to the aponeurosis of the ex-verse skin incision begins below the level of the anterior su-
neous layers, and may be made at any level suitable to the surgeon (Fig. 14.7A). It is usually 10 to 15 cm long and extends through
mally is compromised with most low transverse incisions.
entrenal oblique muscle and the anterior sheath of the recti in the
fascial incision is about 25% longer than a midline incision from
terial reverse incision that is slightly curved (concavity upward)
ligation. Occasionally, the surgeon who uses a Pfannenstiel incision finds the incision inadequate for exposure for hemostasis or not large enough to expose areas of associated abnormal conditions. Under these circumstances, the safe approach is not to transect the rectus muscles halfway but to perform a Cherney incision. Partial incision of the rectus muscle can lead to injury to the inferior epigastric vessels. Also, if conversion to a Maylard is attempted after a previous Pfannenstiel, the anterior rectus sheath will have already been widely separated from the rectus muscles. The ends of the muscle are likely to retract and will not reunite when the edges of the aponeuroses are later reapproximated. In this situation, it may be necessary to reapproximate the rectus muscle ends with horizontal mattress sutures.

even if the peritoneum is opened, the space of Retzius can be

formation. Ability to explore the upper-abdominal cavity ade-
quately is compromised with most low transverse incisions.

Pfannenstiel Incision

Most surgeons would agree that the Pfannenstiel incision pro-
vides the best wound security of all gynecologic incisions. The
cosmetic results are excellent, but exposure is limited. Thus, it
should not be used for patients with known gynecologic malig-
nancies. It should not be used when pelvic exposure is needed in
operating on patients with nonmalignant conditions, such as
severe endometriosis or large leiomyomas with distortion of the
lower uterine segment, or when reoperating on a patient for hemorrhage.
The original, true Pfannenstiel incision is described as a
transverse incision that is slightly curved (concavity upward)
and may be made at any level suitable to the surgeon (Fig. 14.7A). It is usually 10 to 15 cm long and extends through the skin and subcutaneous fat to the level of the rectus fascia. The rectus fascia is incised transversely on either side of the linea alba, which is cut separately, joining the two lateral incisions but leaving the rectus fascia intact across the midline (Fig. 14.7B). The rectus sheath is separated from the under-
lining muscle by inserting the fingers on either side of the cut
edge of the sheath and pulling the fascia in opposite directions,
with one hand toward the head and the other hand toward the
feet. This maneuver frees the fascia from the anterior surface of the rectus muscle as far as desired between the symphysis and
the umbilicus (Fig. 14.7C). The rectus muscles are then sepa-
rated in the midline, and the peritoneum is opened vertically
(Fig. 14.7D). This procedure avoids the necessity of dissect-
ing the subcutaneous fat away from the anterior rectus fascia,
as is done in the K"ustner incision. It separates the perforating
nerves and small blood vessels that enter the fascia from the un-
derlying muscles and nourishes the fascia, although it possibly
weakens the incision.

If the Pfannenstiel incision is extended laterally beyond the
edge of the rectus muscles and into the substance of the exter-
nal and internal oblique muscles, injury to the iliohypogastric
or ilioinguinal nerves can occur, with resulting neuroma forma-
tion. Ability to explore the upper-abdominal cavity ade-
quately is compromised with most low transverse incisions.

K"ustner Incision

Some surgeons advocate a K"ustner incision, incorrectly referred to as a modified Pfannenstiel incision. The slightly curved trans-
verse skin incision begins below the level of the anterior su-
perior iliac spine and extends just below the pubic hairline,
through subcutaneous fat, down to the aponeurosis of the ex-ternal oblique muscle and the anterior sheath of the recti in the
same manner as all other transverse incisions (Fig. 14.8A). The
superficial branches of the inferior epigastric artery and vein
may be encountered in the subcutaneous fat at the lateral mar-
gin of the incision. When encountered, they can be ligated or
sealed with Bovie cautery. The fascia is cleaned superiorly and
inferiorly until a sufficient area is exposed from the region of the
umbilicus to the symphysis to permit an adequate vertical inci-
sion in the linea alba. Excessive separation of the fat from the
fascia in the lateral margins of the incision is unnecessary and

can provide sites for small postoperative herniations separa-
tion of the rectus muscles and entrance into the peritoneum are
performed in the same manner in the ordinary midline incision
(Fig. 14.3B). Because of the importance of obtaining adequate
hemostasis in the subcutaneous fat of the skin flaps, this inci-
sion is definitely more time-consuming than the low midline
incision or the Pfannenstiel incision. It offers little or no ad-
vantage, and its extensibility is severely limited. If this incision
is used, strong consideration of subcutaneous, closed-suction
drainage should be given.

Cherney Incision

The Cherney differs from the muscle-dividing Maylard incision
by the location of transection of the recti. In both incisions, the
skin and fascia are divided transversely as with a Pfannen-
stiel, but Cherney advocated freeing the rectus muscles at their
tendinous insertion into the symphysis pubis. The recti are then
retracted cephalad to improve exposure. The transverse Cher-
ney incision is about 25% longer than a midline incision from
the umbilicus to the symphysis.

The Cherney incision provides excellent access to the space
of Retzius for urinary incontinence procedures. It provides ex-
cellent exposure of the pelvic side wall when needed, for ex-
ample, in patients who require hypogastric artery ligation. Occasionally, the surgeon who uses a Pfannenstiel incision finds the incision inadequate for exposure for hemostasis or not large enough to expose areas of associated abnormal conditions. Under these circumstances, the safe approach is not to transect the rectus muscles halfway but to perform a Cherney incision. Partial incision of the rectus muscle can lead to injury to the inferior epsi-
gastic vessels. Also, if conversion to a Maylard is attempted
after a previous Pfannenstiel, the anterior rectus sheath will
have already been widely separated from the rectus muscles.

The Cherney incision provides excellent access to the space
of Retzius for urinary incontinence procedures. It provides ex-
cellent exposure of the pelvic side wall when needed, for ex-
ample, in patients who require hypogastric artery ligation. Occasionally, the surgeon who uses a Pfannenstiel incision finds the incision inadequate for exposure for hemostasis or not large enough to expose areas of associated abnormal conditions. Under these circumstances, the safe approach is not to transect the rectus muscles halfway but to perform a Cherney incision. Partial incision of the rectus muscle can lead to injury to the inferior epigastric vessels. Also, if conversion to a Maylard is attempted after a previous Pfannenstiel, the anterior rectus sheath will have already been widely separated from the rectus muscles. The ends of the muscle are likely to retract and will not reunite when the edges of the aponeuroses are later reapproximated. In this situation, it may be necessary to reapproximate the rectus muscle ends with horizontal mattress sutures.

Even if the peritoneum is opened, the space of Retzius can be
bluntly dissected (Fig. 14.9). The inferior epigastric vessels, which course more laterally in the caudad portion of the ab-
dominal wall, are identified. The pyramidal muscles are sharply
dissected. The Ebrous tendinous rectus muscles are then dis-
sected sharply from their insertion into the symphysis pubis
(Fig. 14.10). Bleeding is negligible in this area, and the infe-
rior epigastric vessels do not need to be ligated. The peritoneal
incision can be extended laterally about 2 cm cephalad to the
bladder while the vessels are visualized.

As stated earlier, transverse incisions, particularly the Cher-
ney and the later-described Maylard, can result in nerve injury.
The femoral nerve is particularly at risk when a self-retaining
retractor with deep lateral blades is used in these widely ex-
tended incisions. If a self-retaining retractor is used with these
incisions, the lateral blades should be only deep enough to
fit under the edges of the incision. They should not rest on the
poas muscle.
FIGURE 14.7. A: The skin incision for a Pfannenstiel incision is elliptical just above the symphysis pubis. B: The skin, subcutaneous fat, and fascia of the abdominal wall are incised transversely. C: The fascia is separated from the rectus muscle superiorly, inferiorly, and laterally. Small perforating vessels require ligation or coagulation. D: The rectus muscles are separated, and the peritoneum is incised in the midline.
Incisions for Gynecologic Surgery

In closing a Cherney incision, we prefer to close the peritoneum separately with a running polyglycolic acid suture. Drainage of the subfascial space may be necessary. The ends of the rectus tendons are united to the inferior portion of the lower flap of the rectus sheath with five or six interrupted delayed-absorbable or permanent sutures in horizontal mattress configuration (Fig. 14.11). To avoid osteomyelitis, the rectus muscles should not be sutured to the periosteum of the symphysis pubis. Fascial closure is then accomplished with a running continuous suture of delayed-absorbable suture, as in the Pfannenstiel. Although the lines of tension favor transverse incisions as opposed to vertical incisions, running sutures should be placed at least 1.5 cm from the fascial edge and 1.5 cm from one another. The remainder of the closure is similar to the Pfannenstiel closure, depending on the surgeon’s preference.

Maylard Incision
The Maylard incision is a true transverse muscle-cutting incision in which all layers of the lower abdominal wall are incised transversely. This incision was originally described by Ernest Maylard in 1907. The incision provides excellent pelvic exposure and is used by many surgeons for radical pelvic surgery, including radical hysterectomy with pelvic lymph node dissection and pelvic extirpation. Although we prefer midline incisions for patients with suspicious adnexal masses, young patients with adnexal masses that are question-able for malignancy by radiographic and serological studies may be candidates for this cosmetic incision. Patients must be informed that if malignancy is found, the transverse incision will take the form of a “hockey stick” (i.e., a J-shaped incision; see Incisions for Extraperitoneal Approaches), or a separate upper-abdominal incision will be used to evaluate the upper-abdominal cavity and retroperitoneal paraaortic nodes.

The Maylard-Bardenheuer incision has been modified in several aspects since its original description. Before the skin incision is made, a series of three to four perpendicular markings with a sterile marking pen are made across the planned line of the incision. These markings help in later approximation of the skin edges. The transverse skin incision is made about 3 to 8 cm above the symphysis, depending on the indications for surgery and patient age and weight. The skin incision should never be made in a deep skin crease or beneath a large panniculus. The fascia is incised transversely, and the aponeurosis is not detached from the underlying muscle.

After a transverse fascial incision lateral to the borders of the rectus muscles, the inferior epigastric vessels, lying on the posterior lateral border of each muscle, are identified. (Some surgeons suggest preservation of these vessels even when the rectus muscles are transected.) The vessels are ligated before incising the rectus muscles to avoid tearing of the vessels, vessel retraction, and hematoma formation (Fig. 14.12). The fingers of the surgeon tease the overlying rectus muscle from the peritoneum, and the muscles are sectioned between the fingers by using a Bovie cautery.

FIGURE 14.10. The finger of the operator is placed posterior to the rectus muscle, and with gentle traction, the muscle is pulled cephalad. The rectus muscle can then be dissected from its insertion at the symphysis by the Bovie device. The peritoneal incision can then be extended laterally, avoiding the inferior epigastric vessels, which are positioned laterally. (From Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. Surgical atlas of gynecologic oncology. Philadelphia: WB Saunders, 1994:43, with permission.)

For better approximation of the muscles during closure, we prefer to suture the underlying muscle to the overlying fascia before entering the peritoneum. A 2-0 delayed-absorbable “U” suture is used, and the knots are placed anterior to the fascia. The peritoneum is incised transversely.

Closure of the fascia is similar to the running technique for other transverse incisions. The muscles do not need to be reaproximated with individual sutures (exception noted above), although some surgeons prefer to close the parietal peritoneum with a running polyglycolic suture. A subfascial drain is indicated if hemostasis is not absolute (Fig. 14.13).

Caution should be exercised in using the Maylard incision in patients with impaired circulation to the leg secondary to obstruction of the common iliac arteries or terminal aorta. In this situation, blood flow from the inferior epigastric artery may provide the only additional collateral circulation to the
Incisions for Gynecologic Surgery

Deep Epigastric Vessels

FIGURE 14.12. Maylard incision. The rectus muscles are incised with a knife or a Bovie device. The hand of the surgeon is withdrawn as the muscle is cut. The inferior epigastric vessels were previously isolated, sectioned, and ligated. (From Gallup DG. Opening and closing the abdomen. In: Phelan JP, Clark SL, eds. Cesarean delivery. New York: Chapman & Hall, 1988:449, with permission.)

lower extremity. Ligation of this artery could result in lower-extremity ischemia and a real vascular surgical emergency. In the gynecologic patient with clinical evidence of impaired circulation in the lower extremity, a midline incision should be used.

Vertical Incisions

Generally, vertical incisions afford excellent exposure. They can be easily extended and provide rapid entry to the abdominal cavity. Whether midline or paramedian, the resulting scar may be wide.

Midline (Median) Incision

As stated in the section on anatomy, the midline incision is the least hemorrhagic incision, as well as the incision that affords rapid entry into the abdominal/pelvic cavity. Exposure is excellent, and minimal nerve damage occurs. However, dehiscence and hernias are said to be more common, particularly in the area inferior to the arcuate line. Abdominal wound disruption is one of the most serious postoperative problems associated with gynecologic surgery. The “burst abdomen,” or evisceration, seen more frequently in general surgery patients, occurs with a frequency of 0.3% to 0.7% in gynecologic patients and is associated with a mortality of 10% to 35%. The type of incision is only one factor associated with evisceration, and wound infection is present in more than half the cases. Use of chronic cataract for fascial closure is associated with a higher incidence of dehiscence compared with that for any other class of suture. Mechanical factors—such as wound hematomas, paroxysmal coughing associated with chronic lung disease, and gastrointestinal problems (retching, vomiting, ileus)—can lead to evisceration. Newer closure techniques have been shown to have lower wound infection, dehiscence, and hernia rates and are discussed later in the chapter.

The midline incision is the most easily mastered gynecologic incision because the fascial area is relatively bloodless and the rectus muscles are usually separated in parous women. If the patient has a prior midline incision, the surgeon should incise the peritoneum more cephalad to the earlier incision to avoid injury to possibly adherent bowel. In patients undergoing radical pelvic surgery or surgery for deep-seated, adherent pelvic masses, we prefer to develop the space of Retzius to allow extension of the incision between the pyramidal muscles, providing better exposure in the deep pelvis. In nulliparous women, the midline separation between the rectus muscles may not be obvious. In such cases, the pyramidalis muscles are useful landmarks in directing the surgeon to the midline. Because this incision can easily be extended, the midline incision is the most versatile of all incisions used by gynecologists. Hemostasis from incision of more anterior layers should always be complete before the peritoneum is entered (usually done with the scalpel) (Fig. 14.14). Once the abdomen is

FIGURE 14.13. The peritoneum has been closed with 2-0 polyglycolic acid sutures. A closed drainage system is used if hemostasis is not absolute. A running delayed-absorbable suture is used, placing the bites about 1.5 cm from the fascial edge. (From Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. Surgical atlas of gynecologic oncology. Philadelphia: WB Saunders, 1994:43, with permission.)
Paramedian Incision

Paramedian incisions have been advocated over midline incisions because of alleged greater strength. In a prospective study, Guillou and coworkers found no significant difference in respiratory complications, wound infection, and dehiscence when comparing midline, medial paramedian, and lateral paramedian incisions. None of the patients with lateral paramedian incisions developed an incisional hernia. The incidence of hernia in midline and medial paramedian incisions was the same. In a randomized prospective study, however, Cox and colleagues found 22 incisional hernias in patients with midline incisions compared with two hernias in the patients who had paramedian incisions. Like the midline or median incision, the paramedian incision has excellent extensibility and exposure, particularly on the side of the pelvis where the incision is made. For example, a left paramedian incision can be useful when operating for disease that involves the sigmoid colon and/or the left pelvic sidewall.

Although advantageous in some situations, paramedian incisions have many potential problems, including increased infection rates, increased intraoperative bleeding, increased operating time, and the possibility of nerve damage with resultant atrophy to the rectus muscle. Long paramedian incisions can increase pain with respiration during the immediate postoperative period. If a paramedian incision is placed parallel to a previous midline incision, or vice versa, the blood supply between the two incisions can be inadequate, resulting in tissue slough, delayed healing, and/or incisional hernia formation.

Closure of Vertical Incisions

Although closure of transverse incisions (discussed previously) raises little controversy because of the inherent relative strength of the incision, the closure of vertical incisions is controversial. Three general comments about closure can be made:

1. Paramedian incisions, because of their location, may require layered closure. However, we tend to use a mass running closure technique as an expedient, yet safe, technique for closure of midline and lateral paramedian incisions. In closing midline incisions, some surgeons prefer a layered closure (Fig. 14.15). However, two metaanalyses (Weiland et al., and Hodgson et al.) have shown that mass closures are superior to layered closures with respect to postoperative incisional herniae, wound dehiscence, suture sinuses, infection, and wound pain. If a layered closure is used, sutures should always be loosely tied because the major cause of wound evisceration is too many sutures placed too closely together, placed too close to the fascial edge, and tied too tightly (remember, “approximate; not strangulate”). Often, at reoperation for evisceration, the sutures and knots are intact, but the suture has simply torn through the fascia. To avoid wound disruptions in high-risk patients, several investigators have advocated a Smead-Jones closure technique (Fig. 14.16). This is a far-far, near-near mass closure technique. The first (far-far) bite includes both the fascia and peritoneum on each side, and only the anterior fascia is included in the near-near bite. The widely spaced initial pass takes the tension off the healing incision, and the carefully placed near-near bites approximate the fascial edges to allow good healing without intervening fat or muscle. A No. 1 nylon or No. 1 polypropylene suture is used, with the key to the success of this closure being widely spaced far-far bites (at least 1.5 to 2 cm from the fascial edges). The main disadvantage to the Smead-Jones closure is that it is time-consuming.

2. With the advent of modern suture materials and knowledge about suturing techniques, retention sutures are rarely needed, except in some cases of evisceration.

3. With midline incisions, rectus muscles should not be sutured together unless there is sufficient diastasis to cause symptoms. In closing midline incisions, some surgeons prefer a layered closure (Fig. 14.15). However, two metaanalyses (Weiland et al., and Hodgson et al.) have shown that mass closures are superior to layered closures with respect to postoperative incisional herniae, wound dehiscence, suture sinuses, infection, and wound pain. If a layered closure is used, sutures should always be loosely tied because the major cause of wound evisceration is too many sutures placed too closely together, placed too close
FIGURE 14.16. Smead-Jones layered closure. This is a far-far, near-near suturing technique, with the anterior fascia being included in the near-near bite. A No. 1 nylon or No. 1 polypropylene suture (or some other delayed-absorbable suture) is used, with the key to the success of this closure being widely spaced far-far bites (at least 1.5 to 2 cm from the fascial edges). This closure technique may be performed in an interrupted fashion or as running suture. (From Morrow CP, Curtin JP. Incisions and wound healing. In: Gynecologic cancer surgery. Churchill Livingstone, 1996:152, with permission.)

FIGURE 14.17. Closure of a midline incision using a No. 2 polypropylene, running mass closure. The anterior fascia, muscle, posterior fascia, and peritoneum are included in the bites (inset), which are taken 1.5 to 2 cm from the fascial edge and about 1 cm apart. With permanent polypropylene suture, a hemoclip can be used on the short end to avoid suture unraveling. (From Gallup DG. Opening and closing the abdomen. In: Phelan JP, Clark SL, eds. Cesarean delivery. New York: Chapman & Hall, 1988:449, with permission.)

demonstrating no fascial dehiscence in 210 patients. However, one patient in their series later developed an incisional hernia.

Several studies using running mass closure of the abdomen have been published and are listed in Table 14.3. These studies show a fascial dehiscence rate of 0.4% with this closure technique. The patient with the fascial dehiscence reported by Sutton and Morgan eviscerated after the closure suture was transected by a Kevorkian curette during wound debridement. In a randomized prospective study, Stone and colleagues found no difference in dehiscence rates between interrupted and mass closures.

Gallup and colleagues closed the midline incisions in their study with a continuous No. 2 polypropylene suture, placing the bites 1.5 to 2 cm from the fascial edge and including all anterior abdominal wall layers (the peritoneum, if easily located, the fascial layers, and the intervening muscle) (Fig. 14.17). One suture should be started from each end of the incision, tying the ends in the middle and securing the suture with three square knots (six throws). In the original series, a small hemoclip was placed above each knot to prevent unraveling. These caveats must be kept in mind with this closure technique: (a) a double-strand suture should never be tied to a single strand, and (b) the sutures should not be pulled too tightly, as this distributes tension unequally over the incision and negates the major advantage of this closure. Not all investigators include the peritoneum in the closure, but they still report excellent results. As shown by Ellis and Heddle in 1977, closure of the peritoneum as a separate layer appears to play no significant role in wound healing when midline incisions are used.

One problem with the use of large-bore, permanent suture for mass closure is occasional, late-occurring wound sinus

Incisions for Gynecologic Surgery

263

Once the uterus and other organs are removed, the pelvic peritoneum is not reapproximated. However, the vaginal cuff is closed. Fascia may be closed with a Smead-Jones or running subcutaneous suture, or a continuous subcutaneous tissue suture may be used, if the patient is at low risk for infection. A running subcutaneous tissue suture is preferable for patients at high risk of infection. Any incision for obese patients, it should be made lower on the abdomen to preserve the cosmetic appearance of the abdominal wall.

Incisions for Obese Patients

Obesity, especially when the condition is morbid (>130% of ideal body weight or body mass index >30 kg/m²), presents problems with incision placement and closure. Obesity is a recognized high-risk factor for wound infections and complications. Pitkin observed a 4% wound complication rate in nonobese women undergoing abdominal hysterectomy compared with a 29% rate in obese patients. Krebs and Helmink reported a wound infection rate of 24% in massively obese pa-

The McBurney incision is an excellent choice for an uncomplicated appendectomy and can be used for the extraperitoneal drainage of an abscess from pelvic inflammatory disease. In pelvic inflammatory disease, when drainage becomes necessary for the treatment of infected pelvic abscesses, antibiotics should be administered and peritoneum incised until pus is seen. The peritoneum is generally incised transversely in the lower abdomen. In treating a large tuboovarian abscess where an incision is also possible by approaching the abscess laterally as an alternative to the McBurney incision. The incision in the lower abdomen is usually extended transversely to the anterosuperior iliac spine. This permits entrance into the site of infection without soiling the peritoneal cavity.

The gridiron incision can be used in the left lower quadrant to drain an abscess on the left side of the pelvis as well as to perform sigmoid colostomy. Closure is depicted in Figure 14.18D–E and is best made with a delayed-absorbable suture.

Rockey-Davis Incision

An alternative to the McBurney incision is the Rockey-Davis (or Elliot) incision. It is a transverse incision placed at the junction of the middle and lower thirds of a line extending from the anterosuperior iliac spine to the umbilicus. Medially, the incision extends to the border of the rectus muscle. The peritoneum is incised transversely. This incision has provided satisfactory exposure to pathology in either lower-abdominal quadrant. A similar incision made lower on the abdomen preserves the cosmetic appearance of the abdominal wall.

Oblique Incisions

Oblique incisions can be used for a transperitoneal or an extraperitoneal approach.

Gridiron (Muscle-Splitting) Incision of McBurney

The McBurney incision is an excellent choice for an uncomplicated appendectomy and can be used for the extraperitoneal drainage of an abscess from pelvic inflammatory disease. In pelvic inflammatory disease, when drainage becomes necessary for the treatment of infected pelvic abscesses, antibiotics should be administered and peritoneum incised until pus is seen. The peritoneum is generally incised transversely in the lower abdomen. In treating a large tuboovarian abscess where an incision is also possible by approaching the abscess laterally as an alternative to the McBurney incision. The incision in the lower abdomen is usually extended transversely to the anterosuperior iliac spine. This permits entrance into the site of infection without soiling the peritoneal cavity.

The gridiron incision is made obliquely downward and inward over the McBurney point (Fig. 14.18A). The location of the incision can be varied when the incision is performed for appendec-
tomy during pregnancy or when it is used for abscess drainage, as mentioned above. The incision in the skin can be made at a lower level to preserve the cosmetic appearance of the abdomi-
nal wall. The incision is carried through the skin and subcu-
taneous fat to the external oblique muscle. The fibers of the muscle are separated in the direction in which they run (Fig. 14.18B). The internal oblique and the transverse abdominis are separated in the line of their fibers (Fig. 14.18C). At this point, the internal oblique and the transversus abdominis muscles in the same direction and are closely fused. Retractors are avoided, if possible. Instead, the peritoneum should be gently reflected away from the abdominal wall inferiorly and the abscess ex-
tended for extraperitoneal drainage. Thickened indurated tissue may make this step difficult. If the parietal peritoneum is adherent to the peritoneal surface of the abscess, drainage still may be possible without transgressing free space in the peritoneal cavity. The surgeon should avoid con-
taminating the peritoneal cavity with pus, if possible.

The gridiron incision can be used in the lower left quadrant to drain an abscess on the left side of the pelvis as well as to perform sigmoid colostomy. Closure is depicted in Figure 14.18D–E and is best made with a delayed-absorbable suture.

Rockey-Davis Incision

An alternative to the McBurney incision is the Rockey-Davis (or Elliot) incision. It is a transverse incision placed at the junction of the middle and lower thirds of a line extending from the anterosuperior iliac spine to the umbilicus. Medially, the incision extends to the border of the rectus muscle. The peritoneum is incised transversely. This incision has provided satisfactory exposure to pathology in either lower-abdominal quadrant. A similar incision made lower on the abdomen preserves the cosmetic appearance of the abdominal wall.

Incisions for Obese Patients

Obesity, especially when the condition is morbid (>130% of ideal body weight or body mass index >30 kg/m²), presents problems with incision placement and closure. Obesity is a recognized high-risk factor for wound infections and complications. Pitkin observed a 4% wound complication rate in nonobese women undergoing abdominal hysterectomy compared with a 29% rate in obese patients. mass closure (our preference). Subcutaneous sutures are not used, but a Jackson-Pratt or Blake drain is placed anterior to the fascia, after irrigating the tissues with normal saline. This drain is removed in 72 hours or when the output is less than 50 mL per 24 hours. The skin is closed with staples, which are left in place for 2 weeks. Unless small bowel surgery has been done, a nasogastric tube is rarely needed. Gallup’s relatively low wound infection rate in obese patients supports this type of operative management.

Panniculectomy and Abdominoplasty

An alternate surgical approach in the massively obese patient is to remove the large panniculus before the intended pelvic surgery. As observed by Kelly in 1910, wound complications can be avoided and cosmesis can be achieved by this procedure. Exposure to the pelvic organs is certainly improved. In 1978, Pratt and Irons reported on 126 panniculectomies, and 83 of these were performed to facilitate exposure to the surgical field. The average hospital stay was only 14 days, but 34.5% of the patients had some degree of morbidity. In the series by Voss and colleagues, 5 of 76 (6.6%) patients undergoing panniculectomy and hysterectomy developed pulmonary embolism. In another series, investigators encountered excessive blood loss and acknowledged the need for transfusion in combined surgery. More recently, several series have noted the relative safety of combining abdominoplasty with other surgical
procedures. Hopkins and colleagues performed a retrospective review of patients who underwent panniculectomy at the time of gynecological surgery. They identified 78 patients (average weight 278 lb) on whom the procedure was performed. Their infection rate was a laudable 1.3%, with an equally impressive average blood loss of 71 mL. Four of the patients had minimal incisional separations.

As more sophisticated monitoring, better antibiotics, better suture material and techniques, and a safer blood supply have become more available, selective use of combined gynecologic procedures and plastic surgical removal of the panniculus is increasing. In a study of patients who had a mean weight of 261 lb, Morrow et al. found no operative mortality and a mean hospital stay of 8.2 days. Only 11% of the patients required transfusion. The investigators in this series emphasized that the panniculectomy should be performed initially to improve exposure. Although removal of a large panniculus results in better exposure, patient selection for this potentially morbid procedure should be carefully considered. Also, the patient must be counseled and must be strongly motivated to lose weight and change her nutritional habits. If the patient is not committed to these lifestyle changes, it seems impractical to perform an extensive abdominoplasty procedure and incur the associated morbidity.

If the surgical procedure is not urgent, an alternative would be to defer the procedure until the patient has achieved 40% to 50% of the planned weight loss. Patients who have large diastasis recti in association with the panniculus are also candidates for this procedure, at which time plication of the rectus fascia should be performed, either directly or using a "vest-over-pants" layered technique. In many instances, the rectus abdominoplasty is as much a cosmetic and therapeutic benefit to the patient as it is the panniculectomy. When both anatomic conditions exist, the panniculectomy alone does not give a satisfactory surgical result.

Of the various operative techniques available for panniculectomy and abdominoplasty, the elliptical transverse incision, originally described by Kelly, has proved to be the procedure of choice. Two modifications of the transverse panniculectomy can be useful. The most common procedure includes an elliptical "watermelon" incision (Fig. 14.20A), extending from the lateral aspect of the lumbar regions to about 3 to 4 cm above the umbilicus. If the patient requests the preservation of the umbilicus, it can be excised and transplanted to the upper pedicle of skin. However, as shown by Cousin and colleagues, this transplantation can lead to increased wound complications. Inferiorly, the transverse incision follows the con cave skinfold that separates the overhanging panniculus from the suprapubic skin. The underlying fat is excised deeply in a slightly wedged manner, with the deep portion of the fat extending outward and slightly beyond the skin margin to avoid necrosis of the skin edge. Meticulous attention must be given to absolute hemostasis (a time-consuming procedure) to avoid postoperative hematoma formation and infection. The excessive use of cautery, which produces a favorable environment for bacterial growth in devitalized tissue, should be avoided.

The lateral angles of the incision may require separate "V" incisions to avoid the unsightly folds of redundant fat (Fig. 14.20B). When these V-shaped wedges are closed, the angle of the incision is converted into a Y-shaped configuration, which eliminates the excessive skin in the lateral aspects of the abdominal wall. After the removal of the large panniculus, the abdomen can be opened either transversely or vertically. A vertical incision has been advocated to improve exposure. If an abdominoplasty is needed to approximate widely separated rectus muscles, a midline incision is necessary. In this way, a tight closure of the rectus fascia or a vest-over-pants repair, as shown in Figure 14.20D–E, gives additional strength to the abdominal wall. If the rectus fascia is of poor quality and does not provide adequate support to the abdominal wall, a mesh graft can be inserted at the completion of the procedure, either anterior or posterior to the rectus muscle (discussed below). If the fascia of the rectus sheath can be plicated in the midline, wide plication and anchoring of the medial margins of the rectus muscle can be used to close the diastasis, resulting in a firm abdominal wall.

A second type of transverse panniculectomy is a "W" technique, initially described by Regnault in 1973 and shown in Figure 14.20C. The incision is outlined before the operative procedure in the form of a "W" over the symphysis pubis, inside the hairline. The incision is started in the center of the mons pubis and extended laterally and downward on each side to the...
Panniculectomy incisions.

The skin is closed with staples or 3-0 polypropylene interrupted sutures, which are left in place for at least 2 weeks. Rather than being removed all at once, alternate staples can be removed over a period of several days and replaced with adhesive reinforced surgical tape (e.g., Steri-Strips). A firm elastic-based tape dressing (e.g., Elastoplast) is applied under tension over the abdominal wall in a crisscross manner, beginning at the rib cage and extending to the thighs (Fig. 14.20F). This abdominal support relieves tension on the suture line and also prevents seroma and hematoma formation beneath the skin flaps. Another technique is to use an abdominal binder (or multiple binders placed end to end) to support the anterior abdominal wall and prevent seroma and hematoma formation.

**INCISIONS FOR EXTRAPERITONEAL APPROACHES**

Although controversial as a routine surgical procedure, the value of a staging laparotomy to assess paraaortic lymph nodes in patients with advanced stage (IIIb to IV) cervical cancer has been studied extensively over the past two decades. As the stage of disease increases, the incidence of positive paraaortic nodes is progressively higher and has prompted organizations such as the Gynecologic Oncology Group to require paraaortic node sampling before placing patients with advanced cervical cancer on some phase III studies. Serious bowel complications have been observed in cervical cancer patients who have had operative evaluation through a transperitoneal approach followed by radiotherapy. When extraperitoneal approaches to evaluate paraaortic lymph nodes are compared with transperitoneal approaches before radiation therapy, more serious, later occurring small bowel problems are associated with the latter approach (Wharton et al., 1977). To avoid these complications, an extraperitoneal approach has been advocated by means of bilateral superior groin incisions, a unilateral J-shaped incision, or an upper-abdominal incision.

We use the J-shaped incision or the “sunrise” incision for staging. If bulky pelvic nodes are evident or paraaortic nodes contain metastases, these can be removed without entering the peritoneum and may improve patient response to therapy (Downey et al., 1999). Irradiation with concurrent chemotherapycan then be safely used, starting almost immediately.

**J-Shaped Incision**

A modification of the extraperitoneal inguinal incision (a modified Gibson incision) was described in the gynecologic...
Incisions for Gynecologic Surgery

FIGURE 14.21. J-shaped incision on the right is shown in relation to deeper structures, the ureter, iliac vessels, and great vessels. It is initiated about 3 cm cephalad to the umbilicus and is carried inferiorly parallel to the round ligament. (From Gallup DG, Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. Surgical atlas of gynecologic oncology. Philadelphia: WB Saunders, 1994:43, with permission.)

literature by Berman and colleagues in 1977. These investigators prefer to make the skin incision on the left, because the left paraaortic lymphatic channels are lateral and posterior to the aorta. They believe that it is technically more feasible to dissect the precaval nodes from a left-sided incision if a single incision is to be used for extraperitoneal paraaortic node sampling. We prefer to make the incision on the right, as discussed later.

Access is gained by a vertical incision, starting just cephalad to the umbilicus and 3 cm medial to the right iliac crest. Caudad to the crest, the incision is carried medially, about 3 cm cephalad and parallel to the inguinal ligament (Fig. 14.21). The fascial layers are incised separately (Fig. 14.22). Exposure of the extraperitoneal space is achieved by rolling the peritoneum medially and cephalad (Fig. 14.23). The round ligament and inferior epigastric vessels can be ligated and transected to improve exposure. The paraaortic area is exposed by blunt dissection, and node sampling is performed by removing the precaval fat pad over the vena cava. With a Deaver retractor on the medial and cephalad portion of the incision, paraaortic nodes can be sampled to the level of the inferior mesenteric artery, directly anterior and lateral to the aorta.

In the left-sided approach, left paraaortic node dissection is more easily accomplished. Berman and colleagues described lifting the peritoneum from the underlying vena cava to resect the precaval fat pad. They cautioned that gentle traction must be used when dissecting the precaval nodes to avoid injury to the inferior mesenteric vessels and also suggested that the table should be tilted toward the patient’s right to facilitate dissection.

The inferior vena cava lies relatively posterior to the aorta, and we have experienced technical difficulties in removing precaval nodes through a left-sided approach. In a later updated report from the same institution, Ballon and associates observed that 2 of 95 patients had avulsion of the inferior mesenteric artery (repaired without sequela). In addition to the relative difficulty in sampling right-sided nodes, the lower portion of a J-shaped incision lies in future radiation fields in some patients.

Sunrise Incision

Because there is a delay in initiation of irradiation by some radiation oncologists when a midline incision is used for staging, Gallup and colleagues have subsequently used a suprapubic incision to remove paraaortic nodes extraperitoneally. In this small reported series, the mean number of paraaortic nodes removed was 12.2, and the mean operating time was 111 minutes. All but 2 of 20 patients underwent external-beam irradiation within 2 weeks of the operative procedure (Fig. 14.24).

The sunrise skin incision is initiated in a transverse manner about 4 to 6 cm cephalad to the umbilicus (Fig. 14.25). It is carried laterally in a downward fashion to the level of the iliac
FIGURE 14.22. The previously incised external oblique fascia is shown retracted with small clamps. The internal oblique muscle and transversus abdominis are then sectioned. The fingers of the operator push the peritoneum medial and posterior while these two muscles are sharply incised. The Bovie device is used to transect these muscles, with the fingers of the operator protecting the underlying peritoneum. (From Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. Surgical atlas of gynecologic oncology. Philadelphia: WB Saunders, 1994:43, with permission.)

FIGURE 14.23. With the round ligament sectioned, the peritoneum is blindly dissected by the hand of the operator. The psoas muscle is palpated, as is the external iliac artery lying medial to the psoas. The peritoneum is gently swept from lateral and caudal to medial and cephalad. This maneuver easily exposes the psoas muscle and the pelvic vessels. The ureter remains on the medial left of the retracted peritoneum. (From Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. Surgical atlas of gynecologic oncology. Philadelphia: WB Saunders, 1994:43, with permission.)
FIGURE 14.24. The sunrise incision made 3 days before this illustration shows Steri-Strips approximating the skin. The radiation field in this postoperative patient has been outlined for early irradiation after a staging procedure for carcinoma of the cervix. (From Gallup DG. Opening and closing the abdomen and wound healing. In: Gershenson D, Curry S, DeCherney A, eds. Operative gynecology. 1st ed. Philadelphia: WB Saunders, 1993:127, with permission.)

FIGURE 14.25. For an extraperitoneal approach to paraaortic nodes, we prefer to use the sunrise incision. In the center, this incision is about 6 cm above the umbilicus. The incision is carried laterally and downward to the level of the iliac crests. In the event of palpable bulky disease in the lower common iliac or pelvic nodes, the incision can be extended caudad to remove the nodes. (From Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. Surgical atlas of gynecologic oncology. Philadelphia: WB Saunders, 1994:43, with permission.)

crests. Preoperatively, the site of the supraumbilical incision can be estimated and varied by placing a radiopaque object at the level of the umbilicus during intravenous contrast computed tomography (CT) to estimate the level of the bifurcation of the aorta. In this patient, a unilateral incision, usually performed on the right side, can be used, and adequate exposure to both sides of the aorta can be obtained. In the event of bulky disease in the lower common iliac or pelvic nodes, the incision can be extended in a caudad fashion to remove these nodes. The advantage of pelvic node debulking in cervical cancer patients, who were later irradiated, has been reported by Howey and associates.

Once the skin and subcutaneous tissue are incised, the fascia is also incised transversely. After the rectus muscles are dissected free from their attachments to the anterior fascia, they are transected with a Bovie device. In relatively obese patients, the left rectus is also transected for adequate exposure to the left paraaortic nodes. Because the deep epigastric vessels lie posterior to, and in the center of, the rectus muscle at this level, the vessels do not need to be isolated separately. Any bleeding can be controlled with ligation or cautery. With the rectus transected, the transversus abdominis muscle is located on the right and is incised with scissors or cautery. The peritoneum is retracted medially and cephalad by the hand of the surgeon. The incision into the transversus is extended more inferiorly and laterally to complete the transection of this muscle without entering the peritoneum. The fingers of the surgeon stretch the wound to ensure adequate exposure.

The surgeon’s hand is inserted deep into the incision until the psoas and external iliac vessels are palpated. The peritoneum is bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the great vessels are exposed. This maneuver is similar to that illustrated in Fig. 14.23, except the peritoneum is swept more cephalad. If the peritoneum is entered during any of these maneuvers, it should be closed immediately. A self-retaining retractor can be inserted to retract the right ureter and ovarian vessels to avoid injury. The precaval nodes, located within the fat pad over the vena cava, are then resected in the usual manner by using vascular clips and scissors and a “clip-cut” technique.
In thin patients, the paraaortic nodes lateral and anterior to the aorta can be removed through a right abdominal approach. If exposure is limited, however, the left rectus muscle can be transected and the peritoneum mobilized from the left side as previously described.

After closure of the fascia, the wound is irrigated with copious amounts of saline. Some investigators prefer to then spray the wound with a combined broad-spectrum antibiotic spray. Vertical interrupted mattress sutures of No. 3 nylon or No. 3 monofilament polypropylene are placed 2 to 3 cm apart. They are loosely tied over dilute povidone-iodine dressing gauze.

If exposure is limited, however, the left rectus muscle can be transected and the peritoneum mobilized from the left side as previously described. If both spaces are opened, the drains are placed bilaterally in the extraperitoneal spaces, with the fascia and skin closed in the usual manner.

### DELAYED PRIMARY CLOSURE AND SECONDARY CLOSURE

The value of delayed primary wound closure in managing possible contaminated wounds has been recognized by military surgeons for many years. In 1968, Grosfeld and Solit reported that patients with perforating appendicitis had a reduction in wound infection rates from 34.1% to 2.3% when delayed closure was used. Similarly, in a high-risk group of patients—which included patients with obesity, cancer, possible contamination from above-and-below procedures, infection, and bowel content contamination—Brown and colleagues found a marked reduction in wound infection rates when delayed primary closure was used compared with immediate closure in matched patients. The infection rate for the former group was 2.1%; for the latter, 23.3%. Possible candidates for such a closure include patients with supplicative appendicitis, ruptured tuboovarian abscess, extensive bowel injury in the unprepared bowel, or diverticulitis with contamination. Delayed closure can also be of value in select patients who have gross incisions associated with cutting and cautery techniques.

After closure of the fascia, the wound is irrigated with copious amounts of saline. Some investigators prefer to then spray the wound with a combined broad-spectrum antibiotic spray. Vertical interrupted mattress sutures of No. 3 nylon or No. 3 monofilament polypropylene are placed 2 to 3 cm apart. They are loosely tied over dilute povidone-iodine dressing gauze. The dressing sponges are changed two to three times a day with a wet-to-dry technique, using sterile saline or 0.1% Dakin’s solution (sodium hypochlorite). Some surgeons use dressings, consisting of rolled gauze on the lateral borders of the incision, to support these sutures. In 4 to 5 days, depending on the appearance of granulation tissue in the subcutaneous tissues, the previously placed sutures are tied to approximate the skin edges. Tincture of benzoin is placed at the lateral edges of the closed incision, and Steri-Strips are used to approximate uneven skin edges.

Alternatively, the skin edges of the incision can be closed with widely spaced staples, “wisking” the intervening spaces with saline-soaked gauze (e.g., Na-gauze or Kerlix strips). Once adequate granulation tissue is present, the skin edges can be reaproximated with nonabsorbable monofilament sutures and local lidocaine at the patient’s bedside before discharge from the hospital.

### COMPLETE WOUND DEHISCENCE AND EVISCERATION

Technically, wound dehiscence means separation of all layers of the abdominal incision, but wound dehiscence has been
The bowel and omentum should be inspected and thoroughly moved, and aerobic and anaerobic cultures should be obtained.

Electrolyte studies should be obtained.

Necrotic tissue clots and suture material should be re-securing it with an abdominal binder. Broad-spectrum antibiotics should be initiated, and baseline blood counts and serum electrolyte studies to avoid abdominal distention, and broad-spectrum antibiotics should be continued and modified according to culture results.

Incisions for Gynecologic Surgery

Eviscerations usually occur from day 5 to 14 after operation, with a mean of about 8 days. One of the early signs of complete dehiscence and impending evisceration is the seepage of serosanguineous pink discharge from an apparently intact wound. It can be present for several days before evisceration occurs. Although occult hematomas are usually the cause of such discharge, these wounds need to be examined carefully by probing with a cotton-tipped swab to assess the integrity of the fascial closure. Frequently, the patient is conscious of something giving way, “tearing” or “popping” immediately before the burst abdomen becomes clinically apparent.

With few exceptions, complete dehiscence or eviscerations should be closed as soon as they are recognized. In case of evisceration, when a delay of several hours is anticipated because of a recent meal, the bowel can be replaced by using sterile gloves, gently packing it in place with lap pads soaked in saline, and through silver wire and preferably No. 2 polypropylene sutures. All layers are incorporated.

Secondary closure of an evisceration with through-and-through silver wire and preferably No. 2 polypropylene sutures. B: All layers are incorporated.

Cleaned with several liters of warm normal saline. If the fascial margins can be located and are not ragged, a Smead-Jones closure (Fig. 14.16) with large-bore polypropylene or nylon can be used. The subcutaneous tissue and skin are packed open for later delayed closure or VAC placement.

If the wound edges are ragged or the patient’s condition is poor, a through-and-through retention suture of No. 2 nylon or polypropylene is used. The sutures are placed at least 2.5 to 3 cm from the skin edges and are passed through all layers. To allow for edema, they are placed 2 cm apart (Fig. 14.26). To prevent inclusion of the underlying intestine in a suture, all sutures are held up before the first one is tied. Skin edges un-opposed between the through-and-through sutures can be approximated with interrupted 3.0 polypropylene. The through-and-through sutures should be left in place for 3 weeks. A nasogastric tube should be used in the immediate postoperative period to avoid abdominal distention, and broad-spectrum antibiotics should be continued and modified according to culture results.

INCISIONAL HERNIA

Incomplete healing of an operative wound will result in an incisional hernia. In this situation, the peritoneum remains intact,
and the fascial margins and adjacent muscles separate, leaving a defect beneath the subcutaneous tissue into which the bowel may herniate. Causes of herniation are similar to those of evisceration; however, the skin, subcutaneous tissue, and peritoneum remain intact. Most cases of ventral hernia follow an incisional infection, weakening the supporting tissues. Increased intraabdominal pressure from coughing and vomiting, along with necrosis of the fascial margins, permits the sutures to pull through the edge of the fascia. These changes result in separation of the wound edges and failure of fibroblastic bridging of the fascia. This complication occurs more frequently in lower-abdominal incisions because of the anatomic deficit of the posterior fascial sheet beneath the rectus in the area inferior to the semicircular line. Ventral hernias occur after low midline incisions in about 0.5% to 1% of all gynecologic operations, with the incidence rising to about 10% after a wound infection. Similarly, reclosure after dehiscence increases the chance of herniation formation to about 2.5%.

Although the initial fascial defect may be small, the size of the resultant hernia can assume varying proportions and involve the entire length of the lower-abdominal wall. The size of the hernia depends on the mobility of the bowel and omen tum and the final aperture size of the ventral defect. A large amount of small bowel and omentum can escape from a small fascial defect into an easily expandable subcutaneous space. The smaller the fascial defect through which small bowel can herniate, the greater the frequency of incarceration, obstruction, and infarction. Patients with ventral hernias often report lower-abdominal discomfort, and with large ventral hernias, the abdominal wall is distended to varying degrees (Fig. 14.27). Patients with large hernias may note bowel peristalsis beneath the skin and report that the bulge becomes smaller when they are in a recumbent position. The hernia is more noticeable during coughing and straining and can increase in size over time because of enlargement of the hernial ring or incorporation of additional segments of bowel into the hernial sac. Rarely, a ventral hernia produces acute symptoms of visceral torsion, incarceration, and infarction. Repair of the hernia is preferably done on an elective basis.

**Surgical Management of Small Hernias**

The principles of ventral hernia repair include (a) dissection of the hernia sac from the subcutaneous fat, rectus fascia, and peritoneal margin; (b) excision of the redundant hernia (peritoneal) sac; and (c) closure of the abdominal wound, using a layer-for-layer closure, an overlap repair of the rectus fascia, or the placement of a synthetic mesh prosthesis. The low midline incisional scar is excised, and the underlying subcutaneous fat is mobilized free from the adjacent hernia sac. Sharp dissection is used to separate the skin and underlying fat widely from the margins of the hernia sac (Fig. 14.28A). The surgeon should defer opening the sac until the boundaries of the hernia have been delineated and dissected, because this aids in identifying the various tissue planes. To identify the margins of the fascial ring, it is advisable to open the sac and separate any underlying bowel from the peritoneal surface of the sac (Fig. 14.28B). Loops of small bowel and adherent omentum frequently obscure the true identity of the sac, and many pockets of the peritoneal lining are formed by fibrous bands that anchor the bowel to the peritoneum. After releasing the omentum and bowel, with particular attention given to hemostasis, it is important to determine whether the hernia defect can be adequately closed with the adjacent fascia before excising the line of the sac. If adequate fascial tissue remains after the dissection, either a layer-for-layer or an overlap fascial closure should be done. If inadequate fascia is available to close, the defect must be bridged with a synthetic mesh. However, most incisional hernias can be closed without the use of a mesh support. When there has been failure of an initial hernia repair, when the hernia defect is so large that the edges cannot be adequately approximated, or when the tissues of the abdominal wall are attenuated, the use of synthetic mesh is strongly advised.

The layer-for-layer closure is accomplished after closure of the peritoneum as the initial layer. The fascial margins of the anterior rectus sheath are then sutured with nonabsorbable or delayed absorbable suture (Fig. 14.28C). Interrupted far-near, near-far pulley sutures (modified Smead-Jones) that include the inner margin of the abdominal musculature are placed to avoid subsequent pull-through of the suture from the edge of the incision. These sutures serve as internal stay sutures and increase the tensile strength of the wound while healing takes place. When there is adequate fascial margin of good strength, a vest-over-pants closure gives extra support to the defect and produces a double-layer closure of the fascia (Fig. 14.28D). The surgeon should separate the peritoneum and posterior rectus sheath from the hernia margins to permit an overlap of the anterior fascia. The peritoneum is closed separately with a continuous suture of No. 2-0 delayed-absorbable suture of polyglactin material. The anterior rectus sheath of the hernia margins is separated widely on each side of the wound. Horizontal mattress sutures of a permanent suture (such as polypropylene) are placed 3 to 4 cm distant from the fascial edge and pass through the free margin of the opposite fascia before returning to the distal portion of the anterior fascia. The sutures are held until all sutures have been placed. When the sutures are tied, the free fascial margin is drawn firmly beneath the opposite fascial layer, producing a double support to the hernia closure. The
**FIGURE 14.28.** Repair of ventral hernia. A: Wide dissection of subcutaneous fat from the lateral boundaries of the hernia. B: The hernial sac is opened, and adherent bowel and omentum are released from the peritoneal surface. C: Layer-by-layer closure of midline ventral hernia. Redundant hernial sac has been excised, and the fascial margins are sutured by far-near, near-far technique. A crown stitch at the lower pole anchors the apex of the defect to the lateral fascial margins. When possible, the peritoneum is closed as a separate layer. D: The vest-over-pants technique of midline hernia repair. The peritoneum is separated from hernia and closed. The anterior rectus fascia is dissected widely, and horizontal mattress sutures are placed distant from fascial edge and passed through the opposite fascial margin. When the sutures are tied, the fascial margins are drawn firmly beneath the opposite layer, producing a double-fascial layer closure of hernia. E: Completion of a vest-over-pants closure of midline ventral hernia, showing suture of the free margin of the fascial flap to the underlying fascial surface. Perforated plastic closed-suction drainage tubes are sutured to the fascia to permit adequate drainage.
Closure of large ventral hernia by using synthetic mesh. A: Attenuated margins of hernial sac have been freed and excised. The rectus muscles are widely separated from the underlying margins of the hernia, which include fused peritoneum and posterior fascia. The rectus margins are outlined (dashed line). B: A synthetic mesh is placed between the rectus muscle and the closed layer of peritoneum and posterior rectus sheath. Replacement of sutures through the rectus muscle and anchoring of mesh to the posterior sheath can be accomplished without entering the peritoneal cavity (inset). C: Closure of rectus muscles or fascia over mesh prosthesis by using a far-near, near-far suture. The margins of the mesh show the width of the permanent hernial support.
In the fascial partition method, relaxing incisions are made through the external oblique (EO) and transverse abdominis (TA) muscles. These relaxing incisions are made lateral to the rectus musculature, from the level of the lowest rib to the inguinal ligament. Further dissection is carried as far as possible (Fig. 14.31B). Once adequately mobilized, the peritoneum and fascia are closed in a Smead-Jones fashion (Fig. 14.31A). The sliding myofascial flap uses relaxing incisions in the external oblique fascia only (Fig. 14.31A). These relaxing incisions are made lateral to the rectus musculature, from the level of the lowest rib to the inguinal ligament. Further dissection is completed with a combination of blunt and sharp dissection and carried as far as possible (Fig. 14.31B). Once adequately mobilized, the peritoneum and fascia are closed in a Smead-Jones fashion (Fig. 14.31C).

Should the subcutaneous tissues be “wet,” a closed-suction drainage system may be placed longitudinally on either side of the fascial incision and the subcutaneous fat and skin closed separately. Suction is applied to the drainage tubes to give negative pressure beneath the skin and prevent elevation of the skin flaps by serum or blood. The drains may be removed by day 3 but must be left in place until there has been complete cessation of incisional drainage.

Postoperatively, the patient is ambulated on the day after surgery, without prolonged bed rest. The abdominal incision should be protected from excessive strain (e.g., coughing) by use of an elastic abdominal binder. If the bowel becomes distended, the use of nasogastric tube decompression should be considered (but is rarely needed). Prophylactic antibiotics are used perioperatively to prevent secondary infection in the operative site and are particularly useful in patients in whom mesh has been used for closure of a large hernia defect. Alternatively, many incisional hernias are being repaired by general surgeons using a laparoscopic approach rather than reincision.
Adequate exposure is just as important with vaginal surgery as it is with abdominal surgery. When exposure is not adequate with abdominal operations, the incision is extended, or some other measure is used to improve exposure. Certain measures also can improve exposure with vaginal operations. A tight vaginal introitus may restrict exposure of the upper vagina but can be enlarged at the beginning of the operation by making a midline or mediolateral episiotomy incision. A mediolateral incision can be made on one or both sides of the vaginal introitus. If a midline episiotomy is made and closed transversely, the vaginal introitus can be made larger than before, if that is deemed advisable. These incisions can be closed with 2-0 or 3-0 delayed-absorbable suture.

Sometimes the entire vagina is small in caliber because of virginity or nulliparity, atrophic shrunken vaginal mucosa, previous colporrhaphy, or previous irradiation or disease. The vaginal vault may be fixed in a relatively high position, with relatively little descensus. Because adequate exposure through the vagina may be impossible, some operations may require an abdominal approach. On the other hand, required exposure may be obtained by making a Schuchardt incision. The entire vagina can be enlarged with this incision, achieving remarkable improvement in exposure of the upper vagina. Therefore, a patient whose problem might otherwise have necessitated an abdominal approach can have the advantage of a perfectly satisfactory vaginal operation if a Schuchardt incision is made.

According to Speert (1958), Langenbeck made a deep relaxing incision into the perineal body in attempting vaginal hysterectomy for uterine cancer in 1828. Similar incisions were used by Oldhaussen in 1881 and Duhrssen in 1891. Karl Schuchardt described his incision in 1893:

\[\text{to make more accessible from below a uterus whose mobility is limited. . . . With the patient in the lithotomy position and her buttocks elevated, a large, essentially sagittal incision is made, somewhat convex externally, beginning between the middle and posterior third of the labium majus, . . . extending posterior toward the sacrum, and stopping two fingerbreaths [sic] from the anus. The wound is deepened only in the fatty tissue of the ischiorectal fossa, leaving the funnel of the levator ani muscle, the rectum behind it, and the sacral ligaments intact. Internally, the sidewall of the vagina is opened into the ischiorectal fossa and the vagina divided in its lateral aspect by a long incision extending up to the cervix. There thus results a surprisingly free view of all the structures under consideration.}\]

The incision is ordinarily made on the patient’s left side by a right-handed operator (Fig. 14.32). A left-handed operator may find it technically easier to make the incision on the patient’s right side. Bilateral incisions have been advocated in extreme cases. The side on which the incision is made may be dictated by the location of the pathology to be removed. Injection of the tissues to be incised with sterile saline solution can be helpful, especially beneath the vaginal mucosa in the line of the incision. The assistant pulls upward to the left with the index finger placed as deep as possible in the vagina just to the left of the urethra. The operator makes countertraction.
AB

FIGURE 14.32. A. The Schuchardt incision begins at the 4-o’clock position in the vaginal introitus and extends into the buttock and up the posterolateral wall of the vagina to the cervix. B. The ischiorectal fossa fat is exposed. The puborectalis muscle is divided. The left paravesical and pararectal spaces can be exposed through the incision.

by placing two fingers in the vagina and pulling downward to the right. This pull and counterpull in opposite directions stretches the left vaginal wall. The incision is made with the electrosurgical unit beginning at the 4-o’clock position at the introitus and extending downward in the skin of the buttck to the level of the anus. The incision is then carried upward through the vaginal mucosa into the upper third of the vagina. As the incision is deepened, the fingers of the operator’s left hand are used to displace the rectum medially to protect it from injury. The ischiorectal fossa fat is visible below the puborectalis muscle, which is incised with the electrosurgical knife (Fig. 14.32). If necessary, the left paravesical space can be developed. For the best possible exposure, the apex of the vaginal incision should intersect any incision made around the cervix, achieving hemostasis by coagulation or ligation.

At the end of the operation, the Schuchardt incision is closed with 2-0 and 3-0 delayed-absorbable sutures, attempting to reapproximate the puborectalis muscle edges and to obliterate the dead space in the ischiorectal fossa. Drainage of these incisions is usually not necessary.

The Schuchardt incision most often is used for extensive vaginal hysterectomy for early invasive cervical cancer. We also have used it when performing extensive dissections to remove endometriosis in the vaginal vault, to gain better exposure for difficult vaginal hysterectomy or vesicovaginal fistula repair, to repair injuries to the lower ureter, to remove organized hematomas just above the puborectalis muscle, to drain lymphoceles vaginally, or to remove benign cystic teratomas in the lower presacral area behind the rectum. It can convert a technically difficult, complicated, and dangerous vaginal operation into one that is simple, easy, and safe. It is difficult to understand why perineotomy incisions are so quickly performed for obstetric operations and so reluctantly for gynecologic operations.

BEST SURGICAL PRACTICES

During counseling for surgery, location of the incision, rationale, and any potential complications must be presented to the patient.

Fascial closures (of midline and some transverse incisions) should be accomplished with delayed absorbable monofilament suture. Plain catgut or chromic catgut should never be used for fascial closures.

Closed drainage systems (i.e., Jackson-Pratt or Blake) should be used when drains are considered. Passive drains, such as Penrose drains, should not be used.

To prevent surgical site infections, hair removal should be done by clipping and not by shaving.

Monofilament sutures should be tied with either three square knots (six throws) or one surgeon’s knot and two square knots (four throws).

For superficial dehiscence, consider delayed closure or vacuum-assisted device closure over secondary-intention closure with wet to dry dressing changes for improved patient healing. Delayed closure in the office may be less expensive and more convenient for the patient compared to VAC.

CHAPTER 15 ■ PRINCIPLES OF ELECTROSURGERY AS APPLIED TO GYNECOLOGY

RICHARD M. SODERSTROM AND ANDREW L. BRILL

DEFINITIONS

Active electrode monitoring—Technique of placing a sleeve around the electrode to detect stray energy and to carry the induced energy to ground. Stray energy generally occurs from breaks in insulation or capacitive coupling.

Ammeter—Device that measures the amount of current flowing through a conductor at a specific moment.

Amper—Quantity of electrons that move through a conductor over time (coulombs per second).

Bipolar—Type of electrode or electrical delivery system in which the active and passive electrodes are of similar sizes and, thus, similar current densities. The bipolar generators are usually calibrated against a 100-V load of resistance.

BLEND—Term used when the electrical current is interrupted between 20% and 50% of the time.

Capacitance or capacitive coupling—Ability of two conductors to transmit or receive electrical flow while separated by an insulator; one conductor carries the active current and induces a separate current in the nearby conductor. In general, it occurs in monopolar circuits consisting of two metal plates or tubes separated by air or another insulator. It does not occur during bipolar electrosurgery.

COAG—Term used to describe an interrupted electrical current. In some generators, the period of interruption of current flow can be adjusted from 10% to 50%. At the same power settings, the voltage of the waveform is always higher than it is with CUT waveforms.

Coulomb—Measure of a quantity of electrons.

Current (power) density—Surface area of an electrode in contact with tissue during electrical flow. The smaller the spot of contact, the greater is the heat effect for the same amount of time, increasing by the square root of the area of contact.

Current rate (amperes)—Flow rate of a quantity (coulombs) of electrons.

Direct coupling—Occurs when two conductive materials in the same circuit touch during electrical activation or are close enough that arcing can occur. A break in the insulation of an electrode that allows sparking to tissue is an example of direct coupling.

Edge density—Affinity of electrons to concentrate at the edges of flat or irregularly shaped electrodes as they exit the electrode. This feature enhances the cutting ability of blade-shaped electrodes.

Electricity—Movement of electrons between two oppositely charged poles, positive and negative.

Electrocautery—Transfer of energy by heat, such as a hot wire. Electrons do not move into the affected tissue; only heat is transferred.

Electrosurgery—Transfer of energy from an electrosurgical generator to tissue by means of energy packets (electrons).

Energy (joules)—Quantity of work produced over time. Energy (joules) equals work (watts) multiplied by time (seconds).

Faradic effect—Electrical stimulation of muscle responding to a frequency of electrical current that is less than 100,000 cycles per second.

Fulguration—Intentional application of sparks to tissue surface to coagulate surface bleeding. The COAG waveform is preferable.

Heat (thermal energy)—Produced as electrons move from the low resistance of an electrosurgical probe to the high resistance of tissue. This energy may boil (vaporize) or denature (coagulate) tissue, depending on the extent and rapidity with which heat is generated.

Hybrid laparoscopic trocar sleeve—Conductive trocar sleeve used in laparoscopy that is covered by an outer non-conductive locking sleeve.

Impedance (ohms)—Resistance to flow of electrons through a conductor. Although resistance refers to direct current through a uniform wire, such as copper, it is generally substituted for impedance. Impedance is correctly applied with changes in voltage (alternating or fluctuating), frequency (modulating or demodulating), or tissue type (lipid membranes, soft tissue, fibrous tissue, fat, muscle, bone, or artificial appliances). It can measure the combination of tissue resistance and capacitance. Impedance in human tissue is generally 100 to 1,000 V in the fallopian tube, it is 400 to 500 V.

Isolation ground circuitry—Safety feature that uses transformers not in contact with the parent generator so that the induced electrical flow “floats” its own separate circuit. If a break in the floating circuit occurs, all energy within that circuit stops and does not seek ground.

Kilohertz (kHz)—Measure representing 1,000 cycles of radio waves per second.
**Principles of Electrosurgery as Applied to Gynecology**

**Monopolar**—Type of electrode or electrical system in which the active electrode is small (high current density) and the passive electrode is large (low current density). Most monopolar generators are calibrated against a 500-V load of 2 million cycles per second in electrosurgery.

**Open circuit**—State in which a generator is activated before the active electrode touches tissue. This promotes higher voltage, especially in the COAG mode, than activating the generator after touching the tissue. Open circuitry is used to start fulguration.

**Patient return electrode (grounding pad)**—Large conductive pad (low current density) placed on the patient to complete an electric circuit.

**Return-electrode monitoring**—Dual-padded patient return-electrode system designed to monitor irregular separation of the ground pad.

**Sparking (arcing, fulguration)**—Result of electrical flow through gas (air, argon).

**Vaporizing**—Raising the cellular temperature rapidly above 100°C, which causes cell rupture, releasing steam.

**Watts (work)**—Amount of work produced by electron flow (current). Work (watts) equals force (volts) multiplied by current rate (amperes).

**Waveform**—Oscillating characteristic of an alternating electrical current from positive to negative.

**Waveform frequency**—Number of oscillations of an alternating electrical current, usually between 350,000 and 4 million cycles per second in electrosurgery.

Usually, little attention is paid to the applied principles of electrical physics when surgeons receive their formal training. Most training programs consider electrosurgery a skill acquired by the student through hands-on exposure, and the average faculty knowledge in the biophysical principles of electrosurgery is awarded through a “grandfather” process of credentialing. As a result, many myths about the risks of electrosurgery have been perpetrated during the past decades. Furthermore, the absence of fundamental knowledge handicaps the potential to transform science into art. The modern electrosurgical generator (ESU) is a finely tuned solid-state instrument that offers the student through hands-on exposure, and the average faculty knowledge in the biophysical principles of electrosurgery.

**Electrical Physics**

**Voltage (volts)**—Force (pressure) driving current.

**Electric current**—Number of oscillations of an alternating electrical current.

**Watts (work)**—Amount of work produced by electron flow (current). Work (watts) equals force (volts) multiplied by current rate (amperes).

**Electric power**—Result of electrical flow. Electric power equals work (watts) divided by time (seconds).

**Electric energy**—Amount of work produced by electron flow (current). Energy (joules) equals force (volts) multiplied by work (watts) multiplied by time (seconds).

**Basic Electrical Definitions**

**Electrons** are particles of energy that, when pushed (or passed) through human tissue perform work, thereby causing heat and incision. Voltage is the pressure force required to push electrons. The standard unit of measure of this electrical pressure is 1 V. Thus, in drawing an analogy of electricity to water, an electron is to a molecule of water what voltage is to water pressure.

**Water** is the volume of electrons is measured in coulombs. In the early 1970s, electrosurgery was the main energy source used during laparoscopy, and it was used with great efficacy, even though most procedures were typically sterilization and simple adhesiolysis. Anecdotal reports of bowel injuries presumed to be secondary to “sparking” of monopolar energy prompted several investigators to develop bipolar instrumentation, as they asserted these tools would reduce the bowel injuries caused by the monopolar technique. By 1980, bipolar electrosurgery had become a standard part of the surgical armamentarium of most laparoscopic surgeons. In parallel, laser instrumentation specifically designed for endoscopic procedures became available, and postgraduate education in their application became commonplace, temporarily relegating electrosurgery as a backup method. Despite the early promises of laser surgery, surgical injuries formerly attributed to monopolar electrosurgery have persisted; no study to date has demonstrated a reduction in laparoscopic complications, especially bowel injuries, in step with changes from bipolar electrosurgery to laser technology.

Near the end of the 1980s, general surgeons recognized the advantages of laparoscopic surgery, especially for cholecystectomy, and quickly became frustrated by several limitations of contemporary lasers, returning to electrosurgical generators for comparatively more versatility and power. The manufacturers responded quickly with the production of solid-state generators specifically designed for endoscopic use. Each energy source capable of destroying tissue can, in specific circumstances, lead to a surgical complication that may be unique to that energy source. But a watt is a watt, and when the output of energy of any source is matched for power density, power output in wattage, and for the same amount of time (joules), the same tissue injury occurs. Although many hazards attendant to an energy source such as electrosurgery can be reduced and managed, not all can be eliminated. Surgeons are expected to be familiar with their surgical tools and appreciate the variables inherent in each technology.

Electrocautery is not electrosurgery; it is a term frequently misused when physicians actually mean electrosurgery. Electrocautery involves use of a direct electrical current to heat a metal conductor with a high resistance, which makes the metal physically hot. Tissue is then directly heated or cauterized by touching the hot metal object to tissue. In contemporary surgery, few instruments employ the principles of electrocautery, because it affords no precise control over thermal effects. Electrosurgery involves manipulating electrons through living tissue by using a high-frequency alternating current with enough current concentration (current density) to create heat within a tissue cell to destroy tissue. Electrosurgical generators are machines that produce an alternating current of electricity at a frequency that does not stimulate muscle activity (500,000 to 3 million cycles per second). Whereas direct current flows in one direction only, alternating current flows to and fro, first increasing to a maximum in one direction and then increasing to a maximum in the other direction. This sinusoidal waveform can be interrupted or varied, which create different surgical effects.

The output waveform of alternating current has a negative and a positive excursion, or peak. As it passes through each cell, the electrolytic polarity is agitated, creating cellular heat (Fig. 15.1). Thus, as opposed to direct heating by electrocautery, thermal effects of electrosurgery are a secondary thermodynamic phenomenon. The measurement from zero polarity to positive or negative polarity is called the peak voltage of the waveform (the relation is the same for peak current). The measurement from plus peak to negative peak, which is twice peak voltage, is called peak-to-peak voltage. For historical reasons alone, a pure CUT current is a simple sinusoidal (undamped, uninterrupted, or nonmodulated) waveform that is produced by continuous output (Fig. 15.2), whereas a waveform produced by highly interrupted (modulated or damped) output is called COAG current (Fig. 15.3).

When there is a continuous current or waveform, the peak voltage need not be as high as with the COAG waveform to create the same wattage (i.e., power is conserved regardless of the degree of current interruption). However, when a coagulation effect must be enhanced, the interrupted COAG waveform is preferable and is created by pushing higher energy bursts of electrons through the tissue. The cooling effect of the current off time between bursts facilitates the coagulation effect. For an instant, with the interrupted waveform, a comparatively higher peak voltage than the uninterrupted waveform is present within the electrical circuit. Most electrosurgical generators also provide BLEND current, which does not result from combined CUT and COAG waveforms, as is commonly thought. Rather, the BLEND current is a waveform that is interrupted at variable intervals, delivering variable degrees of coagulating and cutting properties (Fig. 15.4). The degree to which the BLEND mode cuts or coagulates depends on the relative time interval that the current is on or off. Thus, one of the tissue effects of electrosurgery depends on the various modes of delivering electric current (Fig. 15.5).
MONOPOLAR ELECTROSURGERY

As electrons, pushed with a given voltage, are concentrated in one specific location, heat within the tissue increases rapidly. This concentration is defined as current density. The traditional diathermy generator, an example of equipment using this principle, is familiar to many physicians. Electrons are passed through the body by applying two large metal conductors or plates, of equal size, on opposite sides of the tissue to be heated. The electrons are pushed through the plate called the active electrode and then received on the other plate, the return (neutral) electrode or ground plate, as they pass through a myriad of circuits through the interposed tissues. Once the electrons enter the body (conductor), they are dispersed through the tissue toward the pathways of least resistance to the return electrode. Because current is dispersed over the entire surface area of both plates (low current density), any generated heat is of low intensity and below the burn threshold. However, if either plate is significantly reduced in size, current density (and thus heat) is correspondingly increased and a burn may then occur (Fig. 15.6).

Thus, an active electrode that concentrates current of high current density creates a burn where current enters the body; similarly, a burn will occur if this current is conducted out the body via a return electrode of small contact area (high current density). Like water, electrons flow through the path of least resistance. If tissue resistance is high but the corresponding voltage pressure is low, the current may cease to flow or may search out alternate pathways with lower resistance. When the voltage is increased, the electrons have more “push” to find an alternate pathway, such as through a vital structure where the current is concentrated, or they might seek out an alternate return electrode, like a cardiac monitor electrode. Therefore, the surgeon should use the lowest voltage necessary to accomplish a given task and must ensure that the dispersive electrode is in good contact with the patient and broad enough to reduce current density far below the level of tissue burning. Contemporay electrosurgical generators with isolated ground circuitry systems and/or return-electrode sentinel systems preclude alternate pathways and are preferable when an ineffective or incomplete return path is present.

ELECTROSURGICAL GENERATORS

Significant differences exist among electrosurgical generators. In general, instrumentation set by a number dial is calibrated to peak voltage rather than power output, as is typically found in generators that have a digital liquid-crystal display window showing the output in watts. To determine the wattage output with dial-a-number generators, the operator must refer to an output graph found in the manufacturer’s manual; some generators have these output curves imprinted on the top of
284 Principles of Gynecologic Surgical Techniques and Management of Endoscopy

FIGURE 15.5. A pure cutting/desiccation (CUT), interrupted electrical current (COAG), and BLEND set at 50 W. As the generator is switched from one waveform to another, the voltage must change to match the designated power output. The voltage increases from CUT to BLEND to COAG.

the generator box (Fig. 15.7). The power output set by the manufacturer is the power available at the start of the electrosurgical process; however, this power output decreases as tissue impedance progressively increases during the heating of cellular fluids. Hence, the power output measurement of each generator is calibrated against a fixed resistance. For monopolar use, most generators are calibrated against a 500-V load; for bipolar use, the load is usually set at 100 V (Fig. 15.8).

Each electrosurgical generator has its own power output characteristics; the proper settings can be found with attention to the manual and with experience.

For general surgical use, most generators can produce a maximum of 8,000 V in the COAG mode. An 8,000-V pressure can push electrons 3 mm through room air under certain atmospheric conditions, which means that arcing to distant tissue is improbable; most of the time, electrosurgical generators are used in the 1,000- to 3,000-V range. The waveform frequency is set above 350,000 cycles per second to prevent muscle stimulation. At frequencies below 100,000 cycles per second, tetanic muscle contraction can occur, which is known as the faradic effect and is undesirable. The higher the frequency of the generator output, the more “leakage” of current occurs, which can enhance the induction of current on nearby conductors by capacitance, potentially harmful during certain endoscopic procedures.

Most contemporary generators offer an isolated ground circuitry system to reduce the risk of monopolar energy seeking an alternative pathway to ground; older-model generators are known as ground-referenced generators. With an isolated or “floating” ground system, the electricity delivered to the patient and returned to the generator is created by an induction of current in transformers that are insulated or isolated from the frame of the generator. When a break in the circuit occurs, the electrons do not seek ground, and thus, no current flows. This also reduces the risk of an aberrant burn to the surgeon, unless the surgeon is leaning against the patient, thus becoming part of the isolated circuit.

Return-electrode safety systems use disposable return electrodes (called ground pads), which are usually composed of two conductive pads placed side by side. Built-in monitors, through low-impedance feedback to the generators, measure pad-to-skin contact stability and power-density contact by measuring the balance of contact between the two adjacent pads. If there is an imbalance or poor contact to the patient leading to higher current density, an alarm sounds, and the generator output is automatically terminated. The return electrode should be oriented so that each pad is at equal distance from the operating site and in close proximity and the largest edge faces the operative site.

The basic principles of safety during electrosurgery include the following:

1. Avoid arcing electrosurgical energy to a hemostat during coaptive coagulation: Always touch the hemostat first, and then initiate energy. Place electrode pencils in their safety holster when not in use.
2. Use a monitored return-electrode system (frequently referred to as a REM system). Place return electrode pads with the longest edge close to the operative site on a non-dependent, clean, dry, shaved area, avoiding bony prominence and scar tissue. Use the right-sized pad for the patient, but never cut a pad to size.
3. Select the lowest voltage that will create the desired effect. Activate CUT for all desiccation procedures; use COAG for fulguration procedures.
4. Activate the electrode in short bursts (over 3 seconds).
5. Use the manufacturer’s recommended connection cables. Never use metal towel clips to attach cables to drapes, as leakage current in the form of capacitance can cause a skin burn.
6. Inspect instrument insulation before each use.
7. If the patient has a pacemaker, get advice from the pacemaker representative before using monopolar energy. Consider using bipolar electrosurgery.

8. If the usual power settings are inadequate, do not increase the power until the circuit is checked, especially the contact of the return electrode.

**BIPOLAR ELECTROSURGERY**

As mentioned earlier, in monopolar electrosurgery, a ground plate or return (dispersive) electrode carries the flowing electrons back to the generator after they have passed through the patient. The electrons are first focused by the active or efferent electrode to a point of high current density generating temperatures sufficient to burn tissue, and then dispersed over the larger surface area of the return electrode, where any thermal effects are well below the threshold for burning.

The bipolar system incorporates an active (efferent) electrode and a return (afferent) electrode into a two-poled instrument, such as forceps or scissors. This eliminates the need for a ground plate, allowing the instrument to produce a high current density at each pole of the forceps (Fig. 15.9). This permits a discrete amount of desiccation that is confined primarily to the shape and size of the forceps in contact with the tissue, and eliminates the chance of stray or alternate pathways.

Although these advantages over monopolar electrosurgery seem obvious, several restrictions unique to bipolar electrosurgery need to be appreciated. First, the load of impedance (tissue resistance) used to calibrate power output is usually several times lower than that with monopolar modes in contemporary generators. In a generator that has an output-selection knob measuring volts rather than watts, the bipolar output of energy is many watts less than the same setting in the monopolar side of the generator. In generators that read power output in watts, the impedance load is three to five times less than the load used to calibrate monopolar output, so the tissue effect may be much less than the same output reading for monopolar. Therefore, in most situations, bipolar applications are limited to a discrete area held between the forceps or scissor poles, with a restricted power output but with high power density. For sterilization procedures, the manufacturer’s advice should be followed because each instrument can differ in design and ability to desiccate completely. With bipolar electrosurgery, only a CUT or continuous waveform should be used.

**BIOPHYSICAL BEHAVIOR OF ELECTROSURGERY**

Electrosurgery may be used to cut (vaporize), or to coagulate deeply (desiccate) or superficially (fulgurate). These terms are frequently interchanged but stand for specific electrosurgical end points that should be familiar to the surgeon. As mentioned earlier, at the end of an electrode, the tissue effect depends on the shape and size of the electrode, the frequency and degree of current modulation, the peak voltage, and the current coupled against output impedance. The tissue may be cut in a smooth deliberate fashion without arcing, or it can be burned and charred by carbonization.
Electrocoagulation may be performed in many different forms, from slow delicate contact coagulation (desiccation) to the charring effects of the spray coagulation mode (fulguration), at times leading to carbonization. The temperature differences can vary from 45°C to more than 500°C.

The essential characteristic of CUT waveforms is that they are continuous sine waves—that is, if the voltage output of the generator is plotted over time, a pure CUT waveform is a continuous sine wave alternating from positive to negative at the operating frequency of the generator, 500 to 3,000 kHz. The COAG waveform consists of short bursts of high-voltage radiofrequency sine waves. With the sine wave frequency of 500 kHz, the COAG bursts occur 31,250 times per second. The important feature of the COAG waveform is the pause between each burst. First, suppose that a COAG waveform had the same peak voltage as the CUT waveform. The average power delivered (heat per second) would be less because the COAG is turned off most of the time (Fig. 15.10). Then suppose that the COAG waveform had the same average voltage as the CUT waveform and thus could deliver the same heat per second. Because the COAG is turned off most of the time, it can only produce the same average voltage as the CUT by having large peak voltages and currents during the periods when the generator is on (Fig. 15.11).

A high-voltage COAG waveform can spark to tissue without significant cutting effect because the heat is more widely dispersed by the long sparks and because the heating effect is intermittent. The temperature of the water in the cells does not get high enough to flash into steam. In this way, it is possible to fulgurate long after the water is driven out of the tissue and to actually char it to carbon.

Coagulation is a general term that includes both desiccation and fulguration. Fulguration can be contrasted with desiccation in several ways. First, sparking to tissue with fulguration always produces necrosis anywhere sparks land. This is not surprising, because each cycle of voltage produces a new spark, and each spark has an extremely high current density. In desiccation, the current is no more concentrated than the area of contact between the electrode and the tissue (Fig. 15.12). As a result, desiccation may or may not produce necrosis, depending on the current density. For an equal level of current flow, fulguration is always more efficient at producing surface necrosis; however, the depth of tissue injury is superficial compared with that of contact desiccation. With fulguration, the sparks jump from one spot to another in a random fashion, and the energy is “sprayed” rather than concentrated (Fig. 15.13).

In general, fulguration requires only one fifth the average current flow of desiccation. For example, if a ball electrode is pressed against moist tissue, the electrode begins in the desiccation mode, regardless of the waveform (Fig. 15.12). The initial tissue resistance is low, and the resulting current is high, typically 0.5 to 0.8 A (average). As the tissue dries out, resistance rises until the electrical contact is broken. Because moist tissue is no longer touching the electrode, sparks jump to the nearest areas of moist tissue in the fulguration mode, as long as the voltage is high enough to make a spark. Eventually, the resistance of desiccated tissue stops the flow of electrons, self-limiting the depth of coagulation.

Electrosurgical electrodes can be sculpted to perform certain tasks. A needle electrode, a knife, a wire loop, or even a scissors can be shaped and sized to a specific duty. When the
Figure 15.11. When the power settings are equal between pure cutting/desiccation (CUT) and interrupted electrical current (COAG), the peak voltage of COAG is about three times higher than that of CUT. RMS, root mean square.

Waveform variables are added, cutters can be made to coagulate, and coagulators can be made to cut. The faster an electrode passes over or through tissue, the less is the coagulation effect, leading to more cutting. If the power setting and the electrode size remain constant, more desiccation of the adjacent tissue occurs the slower the electrode is passed through the tissue (Fig. 15.14). The more broad the electrode is, the less cutting and more coagulation effect there are (Fig. 15.15). If the electrode is touched to the tissue before keying the generator, desiccation occurs, but with more lateral charring in the COAG mode than in the CUT mode. There is a point at which the desiccation effect is limited in depth by the impedance to flow at a fixed power setting. Interwoven into these acts are the output intensity and output impedance characteristics of the different electrosurgical generators. If a constant voltage can be maintained at a given power setting, which is variable as tissue resistance changes, lateral thermal damage is controlled, giving the surgeon a predetermined surgical effect. By using “smart” generator technology that integrates feedback from the output electrode, newer generators output a constant voltage to control the depth of coagulation independent of the cutting rate.

Incisions

High electrical current that is delivered with a fine electrode of small surface area yields a high power density, which generates intense intracellular heat, causing the intracellular water to boil and thereby literally exploding or vaporizing the cell. Steam vapor occupies six times the volume of liquid water. The vaporization of the cell dissipates heat, a cooling effect that reduces thermal damage to adjacent tissue. This cooling effect, however, allows for little heat transfer to deeper tissue, resulting in minimal or no coagulation effects when electrosurgery is used at the CUT mode. To further enhance the vaporizing effects of the CUT waveform, the electrode should be activated just before touching the tissue (Fig. 15.15). The low-voltage sparks, by their high power density, produce a plume of steam and carbon particles between the electrode and the impacted tissue through which the current is rapidly conducted. This highly focused electrical energy yields the maximum power density, resulting in the most efficient cutting effects and the least thermal damage. Therefore, to incise tissue, CUT current should be used with a small or thin electrode that is activated just before making contact with the target tissue. The electrode “glides” on a layer of steam as the sparks do the cutting.

Because speed of passage and electrode size and shape determine the heat effect on tissue to be incised and the degree of lateral thermal spread, the amount of desired thermal effect decides what electrode to use and how fast the incision should be made. In addition, the chosen waveform can play a role. To compound the decision, the natural resistance of the tissue (e.g., fat has high impedance) to be incised should be considered. In cutting or vaporization, the voltage must exceed about 200 peak V to ionize the air between the electrode and tissue for sparking. Although most choose a scalpel to incise the skin, a knife or needle electrode can mimic the incision if the surgeon...
applies the principle of speed of passage and waveform. With either electrode, the speed of passage is coupled with a CUT waveform. Because a needle electrode has the highest power density, if the speed of passage is swift and the waveform is set at pure CUT, no visible desiccation of tissue occurs, but like a knife, the skin bleeds with minimal coagulation effect. A slow deliberate sweep of the electrode causes some desiccation effect, and the skin may blister and heal poorly. For that reason, only the experienced electrosurgeon should cut the skin with an active electrode.

As an example, abdominal fat, which has a high intrinsic impedance, can be readily cut using a blade electrode with a COAG waveform because of the high current density at the edge of that electrode. Small bleeders at the edge of the incision are simultaneously fulgurated. As larger vessels are exposed, such as the superficial epigastrics, the blade can then be rotated 90 degrees to desiccate these structures before incision, using its broad surface and lower current density. Thus, manipulating a particular electrode with a certain waveform can produce a spectrum of desired thermal end points.

The most common desiccation maneuver used in surgery is the coaptation of blood vessels. Coaptive coagulation involves clamping a bleeding vessel with a conductive clamp and applying a current to coagulate and promote a collagen weld of the vessel. To prevent overdesiccation of surrounding tissue, the low-voltage, uninterrupted waveform (CUT) should be applied. It is important that the generator not be activated until the electrode is in contact with tissue. With monopolar energy, deep desiccation of the tissue in the grasp of the instrument, such as a hemostat, is uniform throughout the thickness of the tissue; with bipolar energy, the output characteristics are such that the surface is heated first, leaving the center of the tissue mass to be heated last. For this reason, many recent models of bipolar electrosurgical generators are preset in the CUT mode and have a current flow meter (ammeter) to ensure that desiccation is complete. If the tissue is too thick, the bipolar current may cease to flow before deep desiccation is complete; thus, if the tissue coagulated is cut, it may bleed briskly.

CUT techniques can be used to amputate large tissue pedicles with either monopolar or bipolar modes provided that the amount of energy is sufficient. The monopolar snare-electrode, common to intracolonic surgery, can be used to amputate an ovarian pedicle with ease and with minimal lateral spread if the power setting is kept low. In addition, time must be allowed to first desiccate the tissue to be cut. Then, by increasing the pressure to tighten the snare, the cutting effect of the waveform and the wire loop transect the tissue with ease. The COAG waveform should not be used because, as previously mentioned, the voltage is increased threefold and the generator runs at less than 10% efficiency.

If the surgeon keys the generator when an electrode is not in touch with tissue, open circuitry occurs. Because the electrons cannot move to ground, there is a pressure buildup of voltage output by the generator. An analogy would be holding a finger over the end of a garden hose with the faucet valve completely open. When the finger is released from the end of the hose,
for a moment the water pressure buildup projects the water well beyond the point of projection when the current flows continuously under steady pressure.

In general, open circuitry should not be used except to initiate a fulguration of tissue or to start an incision. A common accident that occurs during routine surgery is when the surgeon keys the generator before touching a hemostat for coaptation of a blood vessel. Because of the high voltage created by open circuitry, especially in the COAG mode, the voltage drives the energy through the surgical glove of the person holding the hemostat. Before this was understood, the glove was usually blamed as being defective.

**FULGURATION TECHNIQUES**

The fulguration or COAG waveform is frequently used at the wrong time and for the wrong reasons. The generator manufacturers introduced terms that at the outset seemed to simplify the output waveform choices available to surgeons. For the most part, however, the assigned labels COAG and CUT have confused the surgeon about the science of their purposes. If the surgeon coapt tissue with a grasping electrode, either waveform begins to desiccate tissue. If, however, the tissue shrinks away from the electrode contact point, sparking (fulguration) occurs, creating surface char that acts as an insulator, preventing deeper desiccation.

If an electrode is held off the surface of the tissue and the generator is activated, sparking to tissue occurs, sending each spark in a random fashion to char the surface only because the char acts as an insulator. Surface charring is desirable to stop surface oozing, such as muscle bleeding of a venous nature. Because blood is saline rich, a bloody field is hard to coagulate because of ready conduction and diffusion of current density. Irrigating with a nonelectrolyte solution or removing the blood from the bleeders by using suction improves the task. For arterial vessels larger than 1 to 2 mm, fulguration is usually not effective, and desiccation, staples, or ligatures are usually required.

Because the tissue effect of fulguration is due to the high power density of each spark, the effect of a single spark is probably the same, independent of voltage (at least within the voltage range of current generators). Thus, during fulguration techniques, the higher output settings can be used with more efficiency, reducing the chance of touching the electrode to the tissue, which might cause an undesirable desiccation effect. It is this feature of fulguration that encouraged the development of the argon beam coagulator.

**ARGON BEAM COAGULATOR**

The argon beam coagulator is a monopolar electrode device that is housed inside a cannula through which argon gas is delivered at 12 L per minute for open laparotomy and 4 L per minute for laparoscopy (Fig. 15.17). The ionization properties of argon gas flowing over the electrode enhance the distance the spark can travel to complete the circuit to the tissue surface. Because the electrons prefer to stay in the stream of argon gas rather than pass through room air or carbon dioxide (CO₂), each having a higher resistance to electron flow, the collimation or parallel alignment of the sparks leaves a more uniform surface coagulation effect. These properties create a bright blush hue to the sparks, which makes them easy to see and aim at the bleeding surface. The gas, expelled under pressure, blows the pooled blood away from the surface bleeders, making coagulation more discrete and efficient. Flooding the field with glycine while fulgurating the tissue adds another dimension to efficient surface coagulation (see below). To create the planned fulguration effect, the wand must move like a paintbrush to prevent deep tissue damage.

**ELECTROSURGERY DURING PREGNANCY**

No data indicate that using electrosurgical techniques in a pregnant patient has any untoward effect on the fetus at any stage of development. Owing to the dispersion effect, the fetus, bathed in electrolyte-rich amniotic fluid, is protected from any concentration of electrical current. Just as the output frequency of all electrosurgical generators is above the faradic effect (the level that stimulates muscle contraction) for adult electrosurgery, the same is true for the fetus.
During a cesarean section, the only concern is the accidental touching of an activated electrode to the fetus, which causes tissue heating. This does not mean that the usual technique of making an incision in the uterus would preclude using an electrosurgical incision, but rather that a “backstop” under the incision line, between the amniotic membrane and the mus- cule wall, should be in place. Although using a nonconductive material, such as a plastic suction tip, may seem wise, a metal ribbon retractor also can be used because it has a large surface area serving to diffuse the current density. Caution should be exercised when using the gloved finger of the surgeon as a back- stop because if open circuitry is used, the voltage may create a hole in the glove.

NONELECTROLYTE IRRIGATION FLUIDS

As with operative hysteroscopy and cystoscopy, nonelectrolyte fluids, such as glycerol and sorbitol, can be used during other surgical procedures to facilitate electrical energy to desiccate or fulgurate tissue. Blood does not mix well with these fluid ication, total energy delivery is dramatically less than conven- tional bipolar systems. Consequently, sticking and charring to coagulation, tissue effects. Tonal feedback from a dedicated generator con- firms complete desiccation of the tissue bundle, after which the tissue heating. This does not mean that the usual technique of making an incision in the uterus would preclude using an electrosurgical incision, but rather that a “backstop” under the incision line, between the amniotic membrane and the mus- cule wall, should be in place. Although using a nonconductive material, such as a plastic suction tip, may seem wise, a metal ribbon retractor also can be used because it has a large surface area serving to diffuse the current density. Caution should be exercised when using the gloved finger of the surgeon as a back- stop because if open circuitry is used, the voltage may create a hole in the glove.

Capacitance is the induction of electrical current between two conductors, each insulated from one another, can induce an electrical current from one to the other (Fig. 15.18), which can then be released or discharged. The amount of this induced transfer of energy is influenced by the length of the conductors (the longer the distance, the more effect), the distance between the conductors (the shorter the distance, the more effect), the character of the waveform (COAG waveform increases the effect), and the frequency of the waveform (the higher the frequency of the generator, the more the capacitance effect). The operating laparoscope becomes a capacitor when monopolar energy with a high-voltage interrupted current is transmitted through a long insulated electrode, especially if the electrosurgical generator emits high-frequency cycles. Because the operating channel is eccentrically located in the shell of the laparoscope, thus in close proximity, the induced current in the shell can be 50% to 80% of that current flowing through the active electrode into the laparoscope shell (Fig. 15.19).

If a metal trocar sleeve is used to transport the operating laparoscope into the abdomen, the induced current is quickly transferred through the metal sleeve, through the patient from the umbilicus, and finally to the return electrode. Because the current (power) density is broad (low) where the trocar sheath contacts the abdominal wall, no harmful heating occurs. If the trocar sheath is nonconductive (e.g., fiberglass) or radiolucent, or if a plastic securing collar is used (with either a metal or nonconductive trocar sleeve), the current remains isolated, and the laparoscope cannot deliver the induced energy via the umbilicus to the return electrode. In this scenario, if a vital structure, such as bowel, touches the laparoscope or cannula (especially when blood vessels surrounded by fat (e.g., mesenteric vessels) are coagulated with a bipolar instrument using a COAG waveform; here, cutting a presumptively desiccated vessel may lead to bleeding from a still patent lumen. When using an uninterrupted waveform, an in-line ammeter can be a valuable accessory, particularly for tubal sterilization, to ensure that all of the tissue between the forceps has been coagulated before transection.

As with laser surgery, during operative laparoscopy, smoke accumulation can occur, especially when fulguration techniques are used; for the most part, desiccation techniques create steam. Smoke can be reduced or eliminated by irrigating the field to be coagulated with glycine or sorbitol rather than with saline or lactated Ringer solution because the energy is not dispersed within the solution, as it is with electrolyte-rich fluids; in a liquid media, smoke does not develop.

In the early 1980s, it was thought that the occasional bowel perforation after a laparoscopy was the result of sparking or arcing to the bowel when electrodes were used. Because the physics of fulguration do not allow an arc to be maintained in one spot, it is now understood that at the worst, only a surface charring of the bowel could occur. To burn a hole in the bowel, the electrode must touch the bowel during the delivery of electroenergy and remain in contact with the bowel wall long enough to coagulate deep into the bowel wall. For this reason, it is best to disconnect electrodes from the generator when they are not needed for energy delivery. To prevent accidentally touching the bowel with an active electrode, the surgeon should withdraw the laparoscope from the operating field to maximize the panoramic view before keying the generator.

**CAPACITANCE IN MONOPOLAR ELECTROSURGERY**

Capacitance is a physical property of monopolar energy whereby two conductors in close proximity, each insulated from one another, can induce an electrical current from one to the other (Fig. 15.18), which can then be released or discharged. The amount of this induced transfer of energy is influenced by the length of the conductors (the longer the distance, the more effect), the distance between the conductors (the shorter the distance, the more effect), the character of the waveform (COAG waveform increases the effect), and the frequency of the waveform (the higher the frequency of the generator, the more the capacitance effect). The operating laparoscope becomes a capacitor when monopolar energy with a high-voltage interrupted current is transmitted through a long insulated electrode, especially if the electrosurgical generator emits high-frequency cycles. Because the operating channel is eccentrically located in the shell of the laparoscope, thus in close proximity, the induced current in the shell can be 50% to 80% of that current flowing through the active electrode into the laparoscope shell (Fig. 15.19).

If a metal trocar sleeve is used to transport the operating laparoscope into the abdomen, the induced current is quickly transferred through the metal sleeve, through the patient from the umbilicus, and finally to the return electrode. Because the current (power) density is broad (low) where the trocar sheath contacts the abdominal wall, no harmful heating occurs. If the trocar sheath is nonconductive (e.g., fiberglass) or radiolucent, or if a plastic securing collar is used (with either a metal or nonconductive trocar sleeve), the current remains isolated, and the laparoscope cannot deliver the induced energy via the umbilicus to the return electrode. In this scenario, if a vital structure, such as bowel, touches the laparoscope or cannula (especially

![Figure 15.18: Capacitance is the induction of electrical current between two conductors separated by insulation; one conductor carries the active current and induces, by high-frequency radio waves, a separate current in the nearby conductor.](image-url)

![Figure 15.19: Part of the formula that increases the capacitance effect as endoscopic surgery is the length (L) of the capacitor plus the diameter of the electrode (a), divided by the distance of separation or insulation (b).](image-url)
FIGURE 15.20. The Encision (formerly known as Electroshield™) device eliminates the threat of an inadvertent capacitance injury during laparoscopy by returning the capacitance-induced current back to the generator. If an insulation breakdown occurs, it alerts the surgeon.

a small portion of its surface) while energy is being activated, the energy induced into the laparoscope can burn the organ; typically, this may occur outside of the view of the laparoscopist. This same problem can occur when a secondary trocar sleeve is made of metal and uses a plastic securing collar (hybrid laparoscopic trocar sleeve) if that sleeve is used to transport a monopolar electrode. In this situation, the metal trocar sleeve becomes an active electrode by the capacitance effect. The best way to reduce this risk is to use all-metal trocar sleeves and metal securing collars; the next best way is to use all-plastic sleeves and collars. Never mix plastic with metal.

Unintended electrical injuries also can result from direct coupling or insulation failure. Direct coupling occurs when the active electrode touches other metal instruments within the abdomen, transferring the energy to the second instrument, which can injure tissue with which it comes in contact. For example, the active electrode touches the laparoscope, which then touches a small surface area and burns bowel or other organs. The only way to avoid injuries from direct coupling is never to activate the electrode until the operative field is in full panoramic view.

A device has been manufactured that eliminates the risk of capacitance regardless of the type of trocar sleeve used (Encision, Inc., Boulder, CO) (Fig. 15.20). The device is a cannula that shrugs the electrode shaft and shunts all capacitance-coupled current directly to the return plate of the generator, thereby avoiding transmission to biologic tissue. In addition, if there is a break in the insulation of the active electrode, which could promote direct coupling of the primary current to other metal instruments or adjacent tissue, this device alerts the surgeon with an audible alarm. Insulation failures occur when the insulation shield of the electrode is compromised from high voltage, abuse, poor handling, or mechanical accidents. The defect in the insulation, often too small to be recognized, can divert the full current from the generator to unintended tissue proximal to the end of the electrode. Sometimes the defect is on the part of the electrode that is within the trocar sleeve.

NUANCES OF ELECTROSURGERY TECHNIQUES

Before taking any electrosurgical action to control bleeding, accurately determine the source of bleeding and its proximity to vital anatomy. Identify the bleeders by combining mechanical tamponade with active hydrolavage. If the bowel, bladder, or ureter is in close proximity to the bleeder, mobilize that structure sufficiently before applying energy.

Because the output voltage of COAG current is very high, contact coagulation is generally limited to superficial layers because of the accelerated build-up of tissue resistance from rapid desiccation and carbonization. Conversely, electrode contact using the lower-voltage CUT current heats tissue more gradually, leading to deeper and more reliable penetration.

Coaptive sealing of the uterine and ovarian vessels using any type of monopolar current may be ineffective if the blood flow remains uninterrupted. Unless a vessel is sufficiently squeezed before electricity is applied, current density is dramatically reduced by conduction in blood, as any heat is dissipated by convection. Bipolar cautery is recommended for these longer pedicles.

Preferentially use BLEND or COAG current for a wider zone of hemostasis during incision of vascular tissues and to facilitate dissection of tissues with greater impedance, such as fatty or desiccated pedicles and adhesions. On the other hand, it is more prudent to use the lower-voltage CUT current via the edge of an electrode whenever lateral thermal spread may pose extra liability to adjacent tissues.
If bleeding in the vicinity of the bowel, bladder, or ureter cannot be controlled with pressure alone, carefully direct short bursts of noncontact COAG current with a broad-surface electrode to attain hemostasis with the least-possible amount of electrosurgical penetration. Still, vesical bleeding is best controlled by mechanical means, using the patency of pressure or suture ligature.

Although the flow of current is restricted to the tissue between the poles during bipolar electrosurgery, this does not eliminate the risk of thermal injury to tissue that is distant from the site of directed hemostasis. As current is applied between the poles, the intervening tissue gradually descimates until it becomes thoroughly dehydrated. Desiccation is complete when the tissue whitens and visible steam emission stops. If the application of current continues, the heat spreads well beyond the electrical limits of the instrument. Unwanted thermal damage can be minimized by terminating the flow of current at the end of the visible vapor phase, applying current in a pulsatile fashion to permit tissue cooling, and securing pedicles by a stepwise process that alternates between partial desiccation and incremental cutting. Because the rate of temperature generation is a direct function of the volume of tissue being desiccated, thermal spread can also be reduced by using the sides or tips of a slightly open forceps to press or lift, rather than coagulate for hemostasis.

As with contact monopolar coagulation, tissue between the electrodes of a bipolar instrument may become adherent during desiccation. Repeated attempts to shake the tissue free may lead to traumatic avulsion of a key vascular pedicle. A stuck vascular pedicle can usually be unglued by energizing the opened device while immersed in a conductive irrigant, such as saline. Once the solution is boiled by the high current density between the electrodes, the mechanical action of bubbling is usually sufficient to atraumatically free the pedicle.

**ELECTROPHYSICS APPLIED TO OPERATIVE HYSTEROSCOPY**

With endometrial ablation, the resectoscope cutting loop and a roller electrode or coagulating loop are used. Some surgeons shave the endometrial lining with the cutting loop electrode; others desiccate the endometrial lining with the roller ball or bar. A few surgeons shave first and then "paint" the shaved myometrium with the roller electrode or coagulation loop. Unfortunately, studies on the tissue effects of different techniques, electrodes, and waveforms are few in number. Even the pressure applied to the endometrial surface changes the current (power) density; the more the pressure, the broader is the contact surface of the electrode, creating a decreased current density. Because the speed of passage of the electrode unique to each surgeon is another variable, only the outcome statistics can be evaluated with any reasonable scrutiny. Some surgeons exclusively use a COAG waveform at 30 W; others have reported success using a CUT waveform at 100 W.

Typically, endomyometrial resection is accomplished using a pure uninterrupted CUT waveform while dragging the wire loop in a slow deliberate motion to a depth of 4 mm through the tissue, providing some coagulation effect in addition to the cutting. By using the CUT waveform, bubble formation on the anterior surface of the endometrial cavity is less than that in the coagulation mode. The same waveform with a light contact of the coagulation loop electrode set at 100 W is used during the painting phase. Unlike the roller-ball or roller-bar electrode, which can trap dead tissue in its axle and increase the impedance of electron flow, the coagulation loop electrode avoids that impedance. By not rolling, the surface of the electrode in contact with tissue stays clean, much like an eraser cleans itself. If the roller electrode is a bar or barrel, either slow the rolling motion or increase the power output because of lower current density. At the end of the ablation process, some surgeons switch to a COAG waveform at 75 W. With the increased peak voltage of this waveform, skipped areas are sought out by the electrons under higher pressure, ensuring complete surface coagulation.

Monopolar resectoscopic surgery is uniquely associated with accidental burns to the vagina and perineum. Because the inner and outer sheaths of the resectoscope are separated by air, which is an insulator, current can be induced into the outer sheath by capacitive coupling. Insulation breaches can divert the direct current from the proximal electrode to the outer sheath. Episodes of relatively high current density on touching small areas of genital tissue with the outer sheath can be sufficient to burn tissue. From investigations using in vitro anatomical surrogates, these injuries occur from defects in electrosurgical penetration, especially when interrupted COAG current is used and the cervix is overdilated and in contact with less than 2 cm of the outer sheath of the resectoscope. Resectoscopic monopolar electrode injury and subsequent current diversion can be promulgated by the high electrical force created by open circuit activation as well as prolonged activation along already desiccated tissue.

**BIPOLAR HYSTEROSCOPIC SURGERY**

Deprising entirely from monopolar electrosurgery, a new family of instrumentation has been recently introduced that uses bona fide bipolar technology to attain the desired electrosurgical effect. The primary advantage of bipolar electrosurgery stems from the isolation of the electrical circuit between a set of closely separated active electrodes. Nevertheless, performance is like a monopolar device, providing tissue vaporization and desiccation while retaining all of the inherent safety features of bipolar electrosurgery. The VersaPoint™ system (Gynecare/Ethicon, Somerville, NJ) consists of a dedicated bipolar electrosurgical generator and a variety of specialized hysteroscopic and resectoscopic bipolar electrodes for different tissue end points, including 1.6-mm flexible coaxial electrodes with variable tip geometry and vaporizing and cutting loop electrodes for resectoscopic surgery. A key feature of the system is its ability to adjust automatically to a default power setting for each type of electrode, which can then be adjusted by the surgeon. The patient contact end of each electrode consists of two poles separated by a ceramic insulator, referred to as the return and active tip. The active tip electrode is fabricated in a range of configurations and sizes to produce tissue effects ranging from tissue vaporization to desiccation. To function, both electrodes have to be simultaneously immersed in isotonic saline. The VERSA-POINT generator varies the output power in response to local impedance changes at the active electrode. A high-impedance vapor pocket is created that surrounds and insulates the active electrode from completing its circuit through the normal saline until tissue contact is made. Once contact occurs, current flows through the tissue, and by seeking the path of least resistance,
returns through the saline to the proximal return electrode and finally back to the generator.

**BIPOLAR ENDOMETRIAL ABLATION**

The NovaSure Global Endometrial Ablation System consists of a single-use, three-dimensional bipolar device and radiofrequency generator that enables a controlled endometrial ablation in an average of 90 seconds without the need of a hysteroscope or hysteroscopic skills (Fig. 15.21). The device is inserted transcervically into the uterine cavity; the sheath is retracted by deploying a fan-shaped bipolar electrode that conforms to the uterine cavity. Unlike the balloon concept of other devices designed for endometrial ablation, vacuum is used to ensure good electrode tissue contact. This also allows removal of blood, endometrial debris, and steam, eliminating any uncontrollable steam ablation effect. Any type of “pretreatment” of the endometrium is not necessary. The electrode consists of a conformable bipolar metallized porous fabric mounted on an expandable frame. An integral component of the handheld endometrial device is an intrauterine measuring device to evaluate uterine cavity width. Once the length is evaluated by sounding, the values are keyed into the generator, which automatically calculates the needed output power to ensure a confluent area of ablation within the uterine cavity.

A perforation detection system is an integral part of the NovaSure System. Delivered at a slow flow rate and pressure, CO₂ pressure is monitored within the uterine cavity, with the generator sensing a maintained pressure over a known period of time. Once the proper pressure is maintained, confirming good uterine wall integrity, the generator proceeds with the ablation in an automatic or semiautomatic mode.

Using a constant power output generator, the maximum power delivered is 180 W. The depth of ablation is controlled by

![Deep Ablation](image1)

![Shallow Ablation](image2)

**FIGURE 15.21.** The NovaSure Global Endometrial Ablation System is a bipolar device for endometrial ablation using a metallized mesh electrode, vacuum for firm tissue contact, and a controlled generator designed to create a shallower depth of desiccation at the cornual area and lower uterine segment, with a deeper ablation in the uterine midbody.
monitoring tissue impedance during the procedure. A shorter center-to-center distance between electrodes provides a shallower depth of desiccation at the cornual area and lower uterine segment, and a deeper ablation in the uterine midbody. Once the tissue impedance reaches 50 ohms, or after 2 minutes, the NovaSure Global Endometrial Ablation System terminates the process.

### APPLIED PHYSICS IN LOOP ELECTRODE EXCISION PROCEDURES

For almost half a century, circular and other shaped wire electrodes have been available for use as biopsy tools in dermatology and gynecology. In gynecology, these loops were used for cervical and hot-cuve biopsies. After such biopsies, anecdotal case histories of severe scarring led gynecologists to choose nonelectrical methods of cervical biopsy by the 1950s. Although the rate was not established, infertility after hot-cuve cervical biopsy occurred because of cervical stenosis.

Today, a renewed interest in electrosurgical wire loop biopsy has surfaced in the form of loop electrode excision procedure (LEEP), also referred to as large loop excision of transformation zone (LLETZ). As an outpatient procedure, LEEP or LLETZ surgery offers a one-time approach to a pesky problem plus an adequate and complete biopsy specimen. Made popular by British and French gynecologists, this excisional approach to cervical dysplasia gives a histologic confirmation of the treatment of the entire lesion, unlike the limited sampling of the lesion by colposcopic-directed biopsy followed by cryosurgery or laser ablation.

The long-term results after cervical healing are not available. No publication has evaluated different electrode loops matched with different electrosurgical generators, exploring their thermal effects on the tissue left behind the remaining viable cervix. Performing LEEP procedures is a complete exercise in the applied principles of electrosurgery. The following features of LEEP procedures should be appreciated:

**Electrode size:** The thinner the wire, the higher the power density, giving a better cutting effect. Electrode wires thicker than 0.20 mm in diameter can cause deep coagulation, up to a 10-mm depth, depending on speed of excision and waveform.

**Waveform:** There is an increasing depth of coagulation as the waveform is blended from a pure damped waveform to a 50:50 ratio of undamped-to-damped waveform.

**Power density:** In addition to the diameter or gauge of the wire used, the size and depth of the biopsy must be considered. As the electrode loop sinks deeper into the cervical tissue, the power density, as measured by the length and total surface area of wire loop penetrating the cervical tissue, decreases rapidly, losing the cutting effect created by a high power density. To compensate for this change, the operator must increase the power output from the generator during the incision process or increase the speed of the electrode incision process. If the power output is adequate (usually at 60 W) but the loop is passed through the tissue at a slow pace, deep coagulation of the cervix may occur. When possible, it is preferable to use a generator with a low-output impedance because this keeps the energy fluctuations created by different tissue densities to a minimum. Several generators that are especially helpful in LEEP procedures have been designed. They control the flow of energy through a low-impedance feedback by controlling voltage; the effect is much like a speed-control device in an automobile. If a constant voltage can be maintained at a given power setting that changes as tissue resistance changes, lateral thermal damage is controlled, giving the surgeon a predetermined surgical effect. Using constant voltage controls the depth of coagulation independent of the cutting rate.

**Speed of incision:** The more rapid the passage of the wire through the cervical tissue, the cleaner the incision, with less thermal artifact in the excised specimen. Conversely, the slower the passage, the more thermal damage to the adjacent tissue, resulting in better coagulation of the cone bed but more tissue necrosis and postoperative scarring. The loop wire should be rigid, if a loop that bends or flexes reduces the speed of incision, leading to deep coagulation even when a pure cutting waveform is used. It appears that tungsten wire, because of its rigid characteristics (especially at higher temperatures), is preferred over stainless-steel wire, unless the yoke of the loop electrode handle can be shaped so that the stainless-steel wire remains rigid.

Because the vaginal fluids are rich in electrolytes, the vagina and cervix should be rinsed with a nonelectrolytic fluid before biopsy; the acetic acid solution used during colposcopy is adequate. The generator should be keyed or activated before the electrode touches the tissue, and the energy should be delivered in a continuous mode until the biopsy is complete. If the operator turns the energy off during the excisional biopsy, deep coagulation will occur when the generator is restarted, and the power may be insufficient to cut the tissue.

Care should be taken to not touch the metal speculum with the active electrode. Because the surface area of the metal speculum (in contact with the patient) is large, the current density is too low to cause a burn, but the effective high-frequency energy delivered through the speculum is altered to a much lower frequency, which may stimulate involuntary muscle contractions of the patient. This is not painful, but it is startling and disconcerting to both patient and operator. Thus, the use of an insulated metal speculum is preferable.

It is better to cut and excise with minimal coagulation during the biopsy process and then use fulguration, not desiccation, to control spot bleeding. Use a large ball electrode held close to, yet off of, the bleeding site, and switch to a damped (coagulation) waveform with high-voltage output. If the operative field is obscured with electrolyte-rich blood, reduce the amount of blood by blotting with a dry swab or with suction during the fulguration process. As an alternative, slow irrigation with a nonelectrolytic solution (e.g., sterile or distilled water) also allows effective spot fulguration with the ball electrode.

Again, with LEEP or LLETZ procedures, it is best to choose a rigid loop electrode with a steady pace of transfer through the tissue to be excised. Choose an uninterrupted waveform with minimal, if any, higher-voltage characteristics. A pure CUT waveform delivered through an electrode, transecting the tissue at a slower rate, creates some coagulation effect. The latter may be preferable to a partially interrupted waveform (BLEND) passed through a loop electrode that may “stall” because of inadequate power as it tries to pass through the cervical tissue.

### COMPLICATIONS DURING ELECTROSURGERY

The most common complication during electrosurgery is a return-electrode burn that is due to improper application of
Electrosurgery provides the surgeon with a wide range of options: type of current, power level, monopolar or bipolar systems, mode of application, and types and sizes of electrodes. With proper equipment and a basic understanding of the electrosurgical principles, the reproductive surgeon can use electrosurgery to manipulate electrons to sufficient concentration (current density) in living tissue. The electrosurgical generator produces sinusoidal waveforms, variants of current, and voltage as either a continuous (undamped) output called CUT, a moderately interrupted (damped) output called BLEND, or a highly interrupted (damped) output called COAG. In most circumstances, the CUT waveform should be used to cut and desiccate tissue, reserving the COAG waveform for surface fulguration to control small open bleeders and for superficial coagulation.

The electrode. Because these burns account for two thirds of electrocautery accidents, each manufacturer provides specific recommendations for skin preparation and site application. Alternate site burns, such as to cardiac monitor leads, usually result from improper grounding, use of too much power, and high-voltage application.

Interspersed complications during laparotomy are rare. Following the principles of electrosurgery should prevent such occurrences. For laparoscopy, claims of sparking to adjacent organs causing burns or perforation can be refuted if one understands the principle of fulguration. Because human tissue cannot maintain an arc as metal can, the tissue effect is one of surface charring without the consequences of deep penetration. An exception is the use of the argon beam coagulator, which if held in one spot can cause deeper penetration than that of the random scatter of high-voltage fulguration. Although capacitance, described above, can lead to a serious injury when monopolar electrosurgery is used, the variables that must be present are such that the incidence is uncommon. Although monopolar electrosurgery can be used safely, the surgeon must have a thorough grasp of electrosurgical principles. Bipolar energy, with its reduced power output, can give a false sense of security. If one studies the energy physics of each tool, the adage “a watt is a watt is a watt” rings true.

With operative hysteroscopy, uterine perforation with the active electrode is the most common electrosurgical complication. Using proper technique with the admittance of never activating the electrode during a forward motion will largely eliminate perforation injuries. Understanding the tissue effect of different-shaped electrodes, coupled with the principle of using the lowest power necessary to perform the task, will also reduce complications.

**SUMMARY**

Electrosurgery provides the surgeon with a wide range of options: type of current, power level, monopolar or bipolar systems, mode of application, and types and sizes of electrodes. With proper equipment and a basic understanding of the electrosurgical principles, the reproductive surgeon can use electrosurgery in many useful ways. Faulty or improper equipment or a lack of understanding by the surgeon can result in poor surgical outcome and unnecessary complications. Just as physicians are expected to understand and prescribe drugs in a precise and logical manner, so should they have a working knowledge of the energy sources they choose to use in surgery.

**BEST SURGICAL PRACTICES**

- Electrosurgery creates a desired tissue effect by delivering high-frequency alternating current with different electrodes that manipulate electrons to sufficient concentration (current density) in living tissue.
- The electrosurgical generator produces sinusoidal waveforms, variants of current, and voltage as either a continuous (undamped) output called CUT, a moderately interrupted (damped) output called BLEND, or a highly interrupted (damped) output called COAG. In most circumstances, the CUT waveform should be used to cut and desiccate tissue, reserving the COAG waveform for surface fulguration to control small open bleeders and for superficial coagulation.
- Whereas each waveform is associated with specific tissue effects, these behaviors can be altered by the shape and size of the electrode via the manipulation of current density. All of these tissue effects are also influenced by the electrode velocity through the tissue. Prudent electrosurgical techniques integrate these variables, depending on the desired result.
- The lower-voltage CUT waveform should be used to incise tissue and for coaptive sealing of larger blood vessels. The higher voltage of the COAG current produces rapid tissue desiccation and carbonization, resulting in increased tissue resistance limiting coagulation to superficial small vessels. The BLEND current may provide a satisfactory combination for cutting through fatty tissues, such as the subcutaneous tissue or omentum.
- Coaptive sealing of the uterine and ovarian vessels using any type of monopolar current may be ineffective if the blood flow remains uninterrupted. Unless a vessel is sufficiently squeezed before electricity is applied, current density is dramatically reduced by conduction in blood, as any heat is dissipated by convection. Bipolar cautery is recommended for these larger pedicles.
- Fundamental principles to reduce risk during electrosurgery include:
  - When coaptively desiccating tissue with a hemostat, always touch the hemostat first, and then initiate the energy.
  - Place electrode pencils in their safety holster when not in use.
  - With monopolar systems, use a monitored return-electrode system (frequently referred to as a REM system). Place return electrodes close to the operative site on a clean, dry, shaved area, avoiding bony prominence and scar tissue.
  - Activate CUT for all desiccation-coagulation procedures; use COAG for fulguration procedures.
  - Activate the electrode in short bursts (about 3 sec). Use the manufacturer’s recommended connection cables. Inspect instrument insulation before each use. If the usual power settings seem inadequate, do not increase the power until the circuit is checked, especially the return electrode.
  - Select the lowest voltage that will create the desired effect. Consider using bipolar methods. Bipolar systems deliver current as an uninterrupted CUT waveform calibrated against a lower resistance than monopolar systems. As such, it is wise to use a current flow meter to confirm complete desiccation of tissue, especially during tubal sterilization. In some tissues, the thermal effect will be limited such that monopolar application will be preferable.
  - The degree of thermal necrosis on tissue that is electrically incised is dependent on the velocity of passage as well as electrode size and shape and the electrosurgical waveform.
  - As one electrode is changed to another, the surgeon should adjust the generator output to match the task at hand.
  - The most common complication during electrosurgery is return-electrode burns, owing to improper application of the electrode. Prophylactic measures include proper skin preparation and site application. Alternate site burns, such as to cardiac leads, usually result from improper grounding, use of too much power, and high-voltage applications.
- **Nuances of Electrosurgery Techniques**
  - Before taking any electrosurgical action to control bleeding, accurately determine the source of bleeding and its proximity to vital anatomy. Identify the bleeders by combining mechanical tamponade with active hydrodissection. If the bowel, bladder, or ureter is in close proximity to the
Because the output voltage of COAG current is very high, contact coagulation is generally limited to superficial layers. That is because of the accelerated build-up of tissue resistance from rapid desiccation and carbonization. Conversely, electrode contact using the lower-voltage CUT current heats tissue more gradually, leading to deeper and more reliable penetration.

- Preferentially use BLEND or COAG current for a wider zone of hemostasis during incision of vascular tissues and to facilitate dissection of tissues with greater impedance, such as fatty or desiccated pedicles and adhesions. On the other hand, it is more prudent to use the lower-voltage CUT current via the edge of an electrode whenever lateral thermal spread may pose extra liability to adjacent tissues.

- If bleeding in the vicinity of the bowel, bladder, or ureter cannot be controlled with pressure alone, carefully direct short bursts of noncontact COAG current with a broad-surface electrode to attain hemostasis with the least-possible amount of electrosurgical penetration. Still, visceral bleeding is best controlled by mechanical means, using the patience of pressure or suture ligation.

- Although the flow of current is restricted to the tissue between the poles during bipolar electrosurgery, this does not eliminate the risk of thermal injury to tissue that is distant from the site of directed hemostasis. As current is applied between the poles, the intervening tissue gradually desiccates until it becomes thoroughly dehydrated. Desiccation is complete when the tissue whitens and visible steam emission stops. If the application of current continues, the heat spreads well beyond the electrical limits of the instrument. Unwanted thermal damage can be minimized by terminating the flow of current at the end of the visible vapor phase, applying current in a pulsatile fashion to permit tissue cooling, and securing pedicles by a step-wise process that alternates between partial desiccation and incremental cutting. Because the rate of temperature generation is a direct function of the volume of tissue being desiccated, thermal spread can also be reduced by using the sides or tips of a slightly open forceps to press or lift, rather than coapt for hemostasis.

- As with contact monopolar coagulation, tissue between the electrodes of a bipolar instrument may become adherent during desiccation. Repeated attempts to shake the tissue free may lead to traumatic avulsion of a key vascular pedicle. A stuck vascular pedicle can usually be unglued by energizing the opened device while immersed in a conductive irrigant, such as saline. Once the solution is boiled by the high current density between the electrodes, the mechanical action of bubbling is usually sufficient toatraumatically free the pedicle.

---

**Bibliography**

The carbon dioxide (CO\textsubscript{2}) laser generating energy at a wavelength of 690 nanometers (nm). It was stimulated to emit the first working laser, which consisted of a ruby crystal having a fied microwaves by stimulated emission of radiation. In 1958, coworkers produced a device called a maser, which amplification by an external energy source, such as electricity or light, which stimulates the active lasing medium. The active medium is designed so that light of a specific wavelength will resonate between the closed ends of the cavity, much as sound will resonate in a properly constructed chamber. The active medium is stimulated, or “pumped,” by an external energy source, such as electricity or light, which stimulates the active lasing medium to higher energy levels. As decay back to resting energy levels occurs, photons of energy are released into the optical cavity. Electrons that are still in excited higher orbital energy levels can also be stimulated by bombardment with these newly re-leased photons so that they undergo identical decay and emit an identical photon. This is called stimulated emission, because one photon has stimulated the production of another photon.

The optical cavity of the laser tube is closed at each end by a mirror. One of these mirrors is totally reflective, but the other is semitransparent. Although photon direction in the tube is random, a certain number of photons will be emitted in the axis of the optical cavity. The others are focused by the mirrors so that most are resonating or bouncing back and forth along the axis of the cavity. Some of these photons emerge through the semitransparent mirror and are emitted from the laser as the monochromatic parallel coherent laser beam. Coherent means that the waves are all in phase or perfectly aligned. The laser thus creates a light that travels in a tight beam over long distances.

Laser power is measured in terms of watts, and laser energy is expressed in terms of joules. One joule equals 1 W of power applied for 1 second. Lasers are named for the active medium contained in their optical cavities. Many different lasers have been constructed for diverse uses. In gynecologic surgery, the CO₂ and YAG lasers are the most commonly used. Despite many efforts, fiber-optic delivery systems have never been satisfactorily adapted to CO₂ laser energy. However, other lasers produce wavelengths that are conducted along quartz fibers. The use of the fiber is of great advantage in endoscopic surgery because it can be passed down the channel of an operative telescope, suction irrigator probe, or other hollow channel within the instrument.

Power Density and Transverse Electromagnetic Mode

When laser energy passes from the laser, the photons are coherent and parallel and theoretically could travel in space in this form to infinity. This changes when laser light is focused through a lens or directed into a quartz fiber. CO₂ laser energy is usually focused by a lens to a relatively small spot: the focal point of that lens. Focal spot size varies directly with the focal length of the lens. In surgical usage, however, additional lenses or mechanical devices allow the surgeon to change the spot-size diameter with ease. For any given power setting of the CO₂ laser, the concentration or density of the power is greater as the spot size becomes smaller, and conversely, as the spot size (tissue impact area) is enlarged, the power density decreases. By focusing or defocusing the laser energy, it is used as a cutting or coagulating tool. The concentration of laser energy at its focal point is referred to as its power density (PD) and is expressed as watts per square centimeter. A simplified formula for power density is watts per square mm calculated by the formula PD = power in watts × 100/area of spot size in mm squared. Because the calculation of power density is relatively complicated, most surgeons prefer to note the power setting on the laser and the effective spot size used for surgery. Obviously, the biologic effect and type of surgical injury are varied by changing spot size.

Although the photons of laser light are parallel, laser energy is not completely uniform throughout the cross-sectional diameter of the beam (Fig. 16.1). The term transverse electromagnetic mode (TEM) refers to the energy distribution of the cross-sectional diameter. For example, in most CO₂ surgical lasers, the energy distribution is greatest at the center of the beam and decreases toward the periphery. If one graphs the energy distribution of the cross-sectional beam diameter of the CO₂ laser, the resultant curve is bell-shaped. This Gaussian distribution does not hold true in fiber-optic lasers, YAG, potassium-titanyl-phosphate (KTP), and argon, in which energy distribution tends to be more uniform. However, when energy from these lasers enters a quartz fiber, conduction alters parallelism, and beam divergence of approximately 15 degrees occurs at the fiber tip. Thus, laser energy emerging from a fiber-optic conductor is not coherent, and the greatest concentration...
of this energy exists at the fiber–air or tissue interface where the spot size is smallest—that is, the same diameter as the conductor.

**Time Dependence of Lasers**

The effect of lasers on tissue is dependent on the duration that the tissue is exposed to laser energy. In continuous wave (CW) mode delivery, the laser oscillates constantly and delivers non-varying power to the tissue. A pulsed laser can deliver energy in the form of a single pulse or a train of pulses. The duration of a pulse is typically less than 0.25 second. Pulsing the laser to the tissue for a short duration is useful to control the delivery and power of the beam. Significantly higher power density can cut tissue with minimal coagulation necrosis at the margins. A Q-switching laser is a laser that reduces its pulse time and significantly increases its peak power. In this mode, laser radiation is released in a short burst of laser light with high peak power. When the shutter of the optical cavity is rapidly opened, the laser energy is discharged in an extremely short period of time ($10^{-6}$ to $10^{-9}$ seconds). Laser energy of $10^5$ watts can be obtained using this mode. A Q-switched laser pulse is used when it is critical to minimize adjacent tissue effects, for example, in laser surgery to the eye. Pulsing lasers at extremely high peak power (e.g., 500–2500 pulses/second) permit cutting tissue with lower water content.

**MEDICAL LASERS AND TISSUE INTERACTION**

**CO2 Laser**

Laser energy interacts with tissue causing biologic, photochemical, or thermal reactions. The laser energy is absorbed, scattered, or affected by the thermal conductivity and local circulation of the tissue. The primary tissue effect of the surgical lasers used in gynecology is thermal. The beam profile for any given power setting can be altered by changing the spot size diameter (Fig. 16.2). Soft tissue is about 80% water by volume. CO2 laser is highly absorbed by water, limiting its penetration to the surface of the tissue, where it can be monitored visually. Deep penetration of this laser energy into tissue is minimal as long as intracellular and extracellular water remains to be vaporized. When heat is delivered by the laser beam, the tissue’s temperature is elevated. The area of laser impact has a shape reflecting the laser beam’s intensity profile. When tissue temperature is elevated to 57°C, irreversible damage to the cell’s proteins occurs, and the cell dies. Between 57°C and 100°C, there will be tissue death without vaporization. Above 100°C, vaporization occurs, with conversion of the fluid content of tissue to vapor and the other cellular components being converted to smoke. This product is referred to as the laser plume. When the plume is evacuated, it debrides the area and effectively removes the tissue. Additional tissue damage results from lateral conduction of heat away from the laser impact site. The amount of damage caused by heat conduction is directly proportional to the amount of time spent in lasing.

There are three zones of laser tissue damage that may be defined: (i) the area vaporized, (ii) the area of tissue death that results from the heated tissue short of vaporization, and (iii) the area of tissue damage caused by conduction of the heat away from the lased site (Fig. 16.3). Knowledge of beam geometry also plays a role in achieving a specific laser surgical effect. For example, a sharply focused laser beam with power settings of 15 to 25 W and a spot diameter of 0.2 mm produces a high power density up to 50,000 to 80,000 W/cm². This laser beam configuration produces narrow tissue vaporization comparable to an incision made by a scalpel (Fig. 16.4). Defocusing the beam enlarges the spot, and using the same settings, power density is reduced to 500 to 1,000 W/cm². This technique is used to treat a thin surface rapidly. The proper power setting and spot diameter combine to determine effect on the tissue. The surgeon can view the process through an operative microscope with little fear of deep thermal damage. This margin of safety has contributed to the popularity of CO2 laser surgery.

There are several advantages of CO2 laser over a knife and electrosurgical instruments. Laser surgery is performed with no contact to the tissue. No bacteria is transferred from the surgical instrument to the tissue. The laser beam sterilizes the operative field as it vaporizes it. Because it removes tissue with vaporization and evacuation, the suctioned plume allows the tissue base to heal without a devitalized tissue covering. Postoperative pain is reduced because nerve endings are sealed by the

![FIGURE 16.2. Beam profile variations. For any given power setting, beam profile (the shape of the Gaussian curve) can be altered by changing spot size diameter. The small spot size results in a steep curve, which is used for cutting. Larger spot sizes produce flatter curves suitable for vaporization. Tissue damage and crater shape mirror the energy distribution.](image)
FIGURE 16.3. Beam profile and tissue damage. Laser wounds produce three zones of tissue damage: the vaporization crater, the area of tissue necrosis caused by heating tissue to temperatures between 57°C and 100°C, and the area of damage resulting from heat conduction. Higher power settings produce more rapid vaporization of tissue and lessen secondary thermal damage.

APPLICATION OF LASER GYNECOLOGY

Coagulating lasers can be used in patients with bleeding disorders. The laser can be delivered for easy access to confined areas with a clear field of view.

Helium Neon

The helium neon laser (HeNe) is a gas laser with a wavelength of 633 nm in the red portion of the visible spectrum. It is a low-powered laser with output ranging from 1 to 100 mW. It is used in many common tools, including bar-code scanners. The most popular HeNe lasers produce red light. Other colored helium neon lasers include green with a wavelength of 543 nm, yellow at 594 nm, and orange at 612 nm.

Helium neon laser is used as an “aiming beam” for lasers that have nonvisible wavelengths, such as carbon dioxide. When HeNe laser is aligned with the nonvisible laser, it defines the laser’s impact site for the surgeon. This alignment of these two laser beams is checked before treatment begins.

Neodymium YAG

YAG laser energy is able to penetrate tissue to a much greater depth. Unlike CO₂ laser, the neodymium-doped yttrium aluminum garnet (Nd:YAG) laser is poorly absorbed by water. The YAG is often used in a liquid medium. Because it penetrates water so well, the YAG is not a good laser for vaporization. It is an effective coagulator, however, as it passes deeper into tissue before absorption occurs.

YAG energy scatters in tissue, so thermal damage is greater than with CO₂ laser. It is absorbed with a power density that is maximum below the tissue surface. This limits the ability to visually monitor the YAG laser’s depth of penetration and stresses the importance of the surgeon to understand the physics of each laser. YAG laser can be transmitted through quartz fibers and fluids. The depth of penetration provides excellent hemostasis. Goldrath and colleagues in 1981 recognized this and used Nd:YAG laser for the first hysteroscopic endometrial ablations. This laser is also used for removal of hair and vascular lesions in a Q-switched delivery.

Argon, KTP-YAG

The argon laser produces a blue-green light that has two distinct bands at 488 nm and 515 nm, whereas KTP-YAG is located at 532 nm on the electromagnetic spectrum. These are referred to as colored lasers because they are in the visible spectrum. These lasers can be transmitted through water or quartz fibers of 200 to 600 micron diameter. Hemoglobin and other deeply colored pigments absorb their wavelengths and are responsible for their use in vascular and pigmented lesions. Penetration into skin, typically 1 to 2 mm, is affected by the concentration of skin pigments. Argon, KTP-YAG lasers produce a moderate scatter 100 times that of CO₂ laser. This results in an excellent hemostasis. Because of the scatter, they have minimal cutting ability. The depth of tissue injury is roughly correlated with the laser power settings.
The KTP-532 laser derives its name from the potassium (K), titanyl (T), and phosphate (P) crystal used to double the frequency and halve the wavelength of the YAG laser. The 532-nm wavelength is emerald green. Its tissue effects are very similar to those produced by the argon laser. The KTP-532 is used to vaporize or to coagulate, and energy emerging from the end of the fiber can be used to cut tissue. Their greatest application has been in endoscopic surgery, because the delivery systems for their energy can be passed down the operative channel of an endoscope.

**Holmium YAG**

This laser’s wavelength is 2,100 nm. It is used in urology to disintegrate renal stones and ablate obstructing tissue within the prostate. It can be delivered through both large and small fibers. The smaller fiber of 200 microns gives access through flexible ureteroscopes to reach the lower pole of the kidney. It is pulsed at 350 to 700 microseconds at repeating intervals of 5 to 20 Hz to disintegrate the stones. The Ho:YAG laser’s depth of penetration in tissue is 0.4 mm. Like CO₂ laser, this laser is absorbed at the superficial layers of tissue. Vaporization speed, coagulation depth, and hemostasis can be precisely controlled. These properties can be particularly useful in gynecologic endoscopy. Laser treatment can be delivered through small channels to areas of difficult access. Of equal interest is its ability to limit the lateral spread of the thermal energy. The risk of injury to bowel, ureters, blood vessels, and nerves because of any lateral thermal spread is reduced.

**Dye Lasers**

Argon-pumped rhodamine-B dye lasers are tuned to produce a specific wavelength of light. They are delivered to cells that have been sensitized with hematoporphyrin derivatives (HPDs). Certain HPD drugs concentrate in malignant tissue and are activated by specific laser wavelengths. This results in a cytotoxic effect on the tumor. The release of singlet oxygen results in the death of the cancer cells. The U.S. Food and Drug Administration has approved specific HPDs for use in cancer therapy, and it is currently in use in oncologic centers.

**Aesthetic surgery**

Aesthetic surgery for women is the newest use of lasers by some gynecologic surgeons. The applications include hair removal, vein treatment, and epithelial resurfacing. Some of the lasers used are listed in Table 16.2.

| TABLE 16.2 |
| LASER USED IN AESTHETIC SURGERY |
| Carbon dioxide 1,064 nm |
| Erbium–YAG 2,940 nm |
| Diode 810 nm 100 msec long pulse 595 |
| Alexandrite 755 nm Q-switched for blue, black green tattoo removal |
| Ruby long pulse 694 nm Q-switched |
| Nd:YAG 1,064 nm long pulse, Q-switched, frequency doubled 532 nm for red or orange ink tattoo removal |

**DELIVERY SYSTEMS**

The laser beam must be delivered from its source to the tissue. Carbon dioxide laser, the first laser used in gynecology, is delivered to tissue through air in an articulated arm composed of hollow tubes and a series of internal mirrors. The mirrors are precisely aligned to keep the laser beam directed along the path of the arm. At the distal end a lens made of a special compound focuses the laser beam.

**Micromanipulator**

Gynecologists became interested in laser surgery after they observed its use in treating vocal cord papillomas in children. CO₂ laser was directed to the vocal cord tumor under magnification of an operating microscope. The delivery unit used to aim and control the laser beam is called a micromanipulator. This system allows the surgeon to precisely deliver the laser to the tissue. It was attached to the microscope for easy access by the surgeon. The beam was reflected to the tissue by a mirror controlled by a joystick. After observing the effective use with this instrumentation on children’s vocal cord papillomas, surgeons adapted the system to gynecology. They substituted a colposcope for the operating microscope and used it to treat the cervix and vulva (Fig. 16.5). Micromanipulators can be fitted with focusing lenses similar to a zoom lens of a camera. This allows the spot to be varied in size without changing the optical focus for the surgeon.
Application of Laser Gynecology

**FIGURE 16.6.** Cervical vaporization defect.
After the cervix has been vaporized to the approximate depth, an additional 3 mm of endocervical canal is vaporized to avoid endocervical prolapse and to ensure that the new squamocolumnar junction is just inside of the external os.

**Laser Hand Piece**
As CO₂ laser became popular in the 1980s, other delivery systems were developed, including the freehand mode. This system is composed of a focusing lens contained within a metal tube that is held in the hand. The lens typically has a short focal length, capable of producing a very small 0.2-mm spot size. With this narrow beam, the laser is used as a cutting instrument. By pulling the hand piece away from the tissue, the surgeon creates a larger spot size used for vaporizing tissue. Cutting and coagulating external genital surgery became its principal application (Fig. 16.6).

**ENDOSCOPY**
The next advancement was the use of lasers in laparoscopy. CO₂ laser was delivered through large channels in a single puncture operative laparoscope. The large channels were necessary to transmit the beam and avoid reflections from the channel walls. Rigid wave guides were introduced that could also be used through ancillary 3 mm or larger channels.

**FIBER OPTICS**
As fiber lasers including Nd:YAG and KTP became available, they were also delivered through small channels. Fiber delivery is less cumbersome and produces less plume and more hemostasis. It requires smaller channels. The aiming beam is easily seen. This mode of delivery is especially useful in hysteroscopy because fiber lasers could be used through fluid distending media. Neodymium and holmium YAG are delivered through optical quartz fibers 100 to 600 microns in diameter. At the tip of the fiber, the beam diverges, so power density is greatest just off the tip of the fiber. The beam also can also be defocused by moving the tip of the fiber farther away from the target tissue.

**LASER SURGERY OF THE LOWER REPRODUCTIVE TRACT**
The first use of lasers in gynecology was to treat cervical intraepithelial neoplasia (CIN) and visible condylomata of the lower reproductive tract. The precise cutting and ablative properties of CO₂ laser prompted an interest in this surgery. It was successfully used in the 1980s, and CO₂ laser was enthusiastically received by many gynecologists. Colposcopy provided an accurate means of identifying the location and size of the lesions, and CO₂ laser provided unparalleled precision to treat these conditions. Micromanipulator delivery is most popular, although another alternative is using the laser hand piece while visualizing the surgical field through a colposcope.

CIN, later also referred to as squamous intraepithelial lesions (SILs), has been treated successfully by either in situ destruction or excision. In 1968, Paluske and Townsend reported
a series in which cryosurgery was used to destroy CIN. From the beginning, however, the use of destructive procedures that did not produce a palpable specimen evoked strong criticism, fearing that lack of a complete pathologic examination of the target tissue could result in a missed diagnosis of invasion. In the late 1960s, Cartier in Paris developed a cutting loop electrode with a 2 mm tip that, when properly used, produced only a very small amount of thermal damage in the excised specimen. A larger wire loop was designed for excisional cervical surgery in the United States. Its use, known as a loop electrode excision procedure (LEEP) or a large loop excision of transformation zone (LLETZ), provided a tissue specimen as an alternative to ablation procedures.

### Laser Surgery of the Cervix

Although CIN has been described as a noninvasive surface phenomenon, it is well known that the process involves the endocervical crypts. The work of Te Linde, Danforth, Flumen, Burghardt, and others pointed out that the endocervical crypts were involved in CIN, but it was Anderson and Hartley in 1950 who really emphasized the therapeutic implications; namely, adequate depth of destruction or excision is required to achieve satisfactory results. Anderson and Hartley measured the depth of crypt involvement and found that 99% of CIN extends no further than 4 mm from the surface into the cervical crypt. A logical assumption can then be made. If an area of intraepithelial neoplasia on the cervix was either excised or vaporized to a depth greater than 4 mm, virtually all of the neoplastic process would be treated. This concept of depth-of-crypt involvement is extremely important to the surgeon, for it dictates a measurable depth of destruction to be achieved by vaporization of the transformation zone if a surgical specimen is not to be removed by conization (Fig. 16.6).

It follows that if the lesion of intraepithelial neoplasia is visualized in its entirety (i.e., if the borders of the lesion are clearly seen on the cervix, and the lesion does not extend up into the canal), then it can be biopsied and correctly diagnosed as intraepithelial neoplasia. This assumption provides the justification for all nonexcisional, ablative procedures used to destroy cervical intraepithelial disease. Laser ablation—by virtue of its ability to be delivered under colposcopic magnification and applied according to a patient’s specific, unique anatomy—is a valuable tool.

### Vaporization Conization

Conization has been defined as an operation that removes a volume of tissue from the central longitudinal axis of the cervix; this includes the external os and a certain length of endocervical canal. The actual shape of the volume of tissue removed should be determined by the distribution of the lesion and not by some preconceived geometric shape. Conization, then, is a generic term, and does not necessarily imply that a perfect cone-shaped defect has been produced in the cervix. Cones can be asymmetric and are short, long, thin, cylindrical, or any other shape that accomplishes the intended goal of complete removal of the lesion and the tissue at risk. A number of techniques have been used to perform conization operations. In laser surgery, the end result is the same. If the CIN lesion cannot be entirely visualized or a neoplasm cannot be properly diagnosed for any reason, the CIN should not be treated by an ablative procedure. The requirements for vaporization conization are listed in Table 16.3.

Vaporization conization using CO2 laser through the colposcope can be performed in the office, the clinic, or the operating room. It has the advantage of being able to vaporize intraepithelial disease occurring on unusually shaped cervices as may be seen in fetal diethylstilbestrol (DES)-exposed patients (patients with cervical-vaginal anomalies or very narrow vaginas). Using the colposcope, the laser surgeon need only be able to see the lesion to treat it. This method continues to produce a most satisfactory result. General anesthesia is usually not required for cervical vaporization if the patient has been carefully reassured about the laser surgery and the nature of her disease. Preoperative medication may include antiprostaglandins; this reduces the cramping that accompanies the laser ablation. Local anesthesia is the most preferred by colposcopists. I use intracervical lidocaine 1%, injection directly into the cervix at 12, 4, and 7 o’clock. Patients who request sedation or general anesthesia are treated on an outpatient basis.

The alignment of the CO2 laser beam and the visible aiming beam is tested on a tongue blade before its use on the patient. The area is placed in a dorsal lithotomy position, and a bivalve speculum is inserted into the vagina. A suction line with a laser filter is attached to the speculum. This is necessary to maintain a clear view of the operative site. Paper drapes and flammable material are avoided because of the risk of fire. Wet towels are placed at the margins of the operative field. No special prep is necessary. The cervix is cleaned with a 4% acetic acid solution, and the lesion to be treated is identified. The margin of the transformation zone is outlined by a series of vaporization craters, using short bursts of laser energy (Fig. 16.7). The entire transformation zone is included in the area to be vaporized. The dots are connected so that the area to be treated is completely outlined. A spot size of 2 mm is used for the vaporization operation. An experienced laser surgeon may use a higher power setting and be able to direct the laser more rapidly, shortening the operative time. Lower power settings mean greater ease of vaporization and very accurate observation of the depth of the defect. The vaporization is carried to 7 mm (Fig. 16.8). The depth can be measured with a calibrated measuring device. Often, the cervix and the area of the external os are not flush, and an accurate measurement of depth of vaporization may be difficult. For this reason, it seems more accurate to divide the cervix into sections and then destroy the tissue section by section. In this way, part of the normal cervical anatomy is preserved throughout the operation, and even though the topography of the cervix may change, the exact depth of destruction can always be measured for each section. The margin peripheral to the transformation zone is treated for a distance of 2 to 5 mm.

Cervical stenosis can occur following ablative treatment. In a series of cervical stenosis patients reported by Valle and colleagues, Marlow successfully treated cervical stenosis with CO2 and YAG lasers. Lasers have also been used to successfully treat stenosis in other organs. Laser surgery is preferred because of the minimal damage to adjacent tissue. Urologists...
treat narrowing of the prostatic urethra with holmium YAG laser. Oncologists treat obstructive stenosis of the esophagus with photodynamic therapy.

Bleeding is usually not encountered during vaporization procedures; however, if bleeding does occur, a wet cotton-tipped applicator is used to tamponade the vessel. The power density is then lowered by defocusing the beam or by slightly reducing the power, and the bleeding point is coagulated by using a rapid circular motion to surround the vessel. If bleeding is not controlled with this technique, other forms of hemostasis should be considered.

**Excision Laser Conization of the Cervix**

The goals of excisional conization are to produce a conization biopsy specimen that is adequate for pathologic examination and, if possible, excise all disease. The indications for laser excisional conization are the same as for cold-knife conization:

1. The lesion extends into the canal and cannot be entirely seen.
2. The entire transformation zone cannot be visualized.
3. Abnormal cytology is noted in the absence of a positive colposcopy.
4. There is positive endocervical curettage.
5. Invasive cancer cannot be ruled out by biopsy.

The average excisional conization penetrates the cervical struma more deeply than the vaporization conization, and the patient may experience more discomfort, as well as more bleeding, with this procedure. Although excisional conization can be satisfactorily performed with local anesthesia, I do not hesitate to perform this procedure on an outpatient basis under general anesthesia. The surgeon determines the size of the cone to fit the patient and lesion. A weighted speculum is placed in the vagina, and the anterior lip of the cervix is grasped with an atraumatic tenaculum. The cervix is painted with 4% acetic acid, and the patient is recolposcoped. The borders of the lesion are carefully noted. Following a tongue blade test of the beam, I use CO₂ laser settings of 25 to 50 W and the smallest spot size of 0.5 to 1 mm. Smoke evacuation is carried out with a filtered suction. Gentle traction with a laser conization hook allows the surgeon to tailor the cone shape to the distribution of the lesion or transformation zone. A water-soaked small cotton applicator can be inserted into the canal as a backstop to prevent deeper incision in the upper canal.

Excisional conization of the cervix by LEEP has provided an alternative procedure to laser with shorter operating time and reduced instrumentation expenses.

**Laser Combination Procedures**

One application of CO₂ laser is the combination cone. The central lesion in the cervix is removed by LEEP or knife conization. This is followed by laser vaporization of intraepithelial disease extending to the vagina. Large areas of intraepithelial neoplasia and multifocal lesions that involve much of the cervix and then extend into the vagina or even involve the vulva can be treated by this combination laser procedure. Peripheral portions of the lesion should be previously biopsied and proven to be benign. Thus, the indications for both excisional and vaporization have been met, and a conservative procedure has been performed. Combination procedures are the most conservative procedures possible because the operation is microsurgical and tailored to destroy the smallest amount of tissue.

**Postoperative Instructions**

Patients undergoing laser surgery to the cervix usually require very little postoperative care. The patient is seen in
postoperative follow-up in 2 to 4 weeks. Cotton is avoided for at least 4 weeks. Temperature elevations above 38°C and bleeding heavier than her normal menses are reported. About 15% of these patients will have some small amount of vaginal bleeding. Excessive bleeding is encountered in only about 2% of the patients. The patient is allowed to return to work within 48 hours. The very definite advantages associated with laser are listed in Table 16.4.

Results of Laser Surgery of the Cervix

Baggish and Dorsey reported a series of more than 4,000 cases of CIN treated by laser with an overall success rate between 96% and 97%. In those patients monitored by colposcopy, cytology, and biopsy for 1 year or more, vaporization procedures and excision conization procedures seem to produce about the same cure rate. In addition, cure rates do not vary when degree of CIN is taken into consideration. Persad and colleagues reported 1,126 patients with CIN treated over 13 years by laser with no evidence of recurrence or persistence in 92%. The median follow-up was 60 months. Other authors, such as Burke and colleagues, Reid (1987), and Wright, report success rates between 91% and 98%.

Laser Surgery of the Vulva

Unlike the cervix, the vulva is often the site of multifocal disease. There is no doubt that the concepts of accurate identification of disease and proper depth of destruction must also be applied to the therapy of vulvar intraepithelial neoplasia (VIN). Vulvar laser surgery should be done with the aid of the colposcope, and I usually prefer to use the micromanipulator. It is also imperative that the surgeon performing laser surgery on the vulva or the vagina has a working knowledge of vulvovaginal histology and of the variations in thickness of normal and abnormal neoplastic vulvar/vaginal epithelium.

Vulvar skin is composed of two layers, epidermis and dermis (Fig. 16.9). The margin between epidermis and dermis is an irregular one because of the rete ridges. Between the rete ridges are projections of dermis known as dermal papillae. The dermis can be divided into two layers: the superficial papillary layer and the deeper reticular layer. There are also skin appendages, such as pilosebaceous follicles, sebaceous glands, and apocrine glands, which project deep into the dermis. VIN, as well as human papillomavirus (HPV), may involve skin appendages and epidermis. Although the thickness of the epidermis may be a fraction of a millimeter, the dermis may measure 7 to 8 mm in thickness, and skin appendages may penetrate the full thickness. It is the goal of the laser surgeon to remove the involved epidermis and a portion of the skin appendage that may also be involved in the disease process.

When the epidermis is removed by the plastic surgeon’s knife in obtaining a split-thickness graft, or when the epidermis is removed by the laser surgeon during a vaporization procedure for intraepithelial neoplasia, the donor site or the vaporization site heals without replacement by a skin graft because the remaining skin appendages located in the dermis have not been completely destroyed. Each skin appendage serves as a source of squamous epithelium, so that when reepithelialization takes place, the process proceeds from the skin appendages. On the other hand, if the entire thickness of the dermis is taken and the skin appendages are completely destroyed, the operative site must be grafted or closed. It is important for the surgeon to review vulvar biopsies to judge the extent, if any, of disease into the skin appendages.

Unlike cervical vaporization, the depth of vaporization on the vulva cannot be measured. The expert laser microsurgeon is able to recognize the depth of ablation and can remove epidermis so accurately that the papillary dermis is not entirely destroyed. The papillary dermis can be identified at colposcopic magnifications. Reid (1991) has suggested that four surgical planes can be recognized. The first surgical plane represents the epidermis down to the basement membrane. The second surgical plane is described as extending into the papillary layer of the dermis so that the laser surgeon removes both the epidermis and the papillary dermis. The third surgical plane reaches well into the reticular dermis and uncovers the coarse collagen bundles that can be seen through the colposcope as grayish white fibers. The fourth surgical plane involves complete removal of the skin right down to the underlying subdermal fat. If this level is reached, healing must take place from the periphery, or a graft must be supplied.

### Condylomata Accuminata

The human papillomavirus involves the epidermis and may also involve the superficial portions of skin appendages. One of the common mistakes of the novice surgeon is to go too deeply into the dermis in an attempt to destroy condylomata. Although only the warty lesion itself plus the surrounding epidermal margin need to be destroyed, a power density that is sufficient to
accomplish this maneuver without creating excessive carbonization at the impact site must be used. Power densities below 600 W/cm² cause excessive carbonization and, although the carbonized surface of the vulva will raise laser-impact site temperatures to more than 600 °C. The power densities that I like to use are between 600 and 1,500 W/cm², and a 2- to 3-mm focal spot size with a power setting of 15 to 30 W will accomplish this. Each condyloma should be identified and the laser beam directed at this target. Laser vaporizes the condyloma directly with the beam. The char and debris are wiped away, and the proper surgical level is colposcopically identified. Vaporization is taken to the papillary dermis (second surgical plane). Cold normal saline is used to cool the vulvar skin, because cooling helps reduce the heat diffusion and, therefore, the resultant tissue injury lateral to the laser impact site.

Vulvar Intraepithelial Neoplasia

It is impossible to colposcopically differentiate between some forms of HPV lesions that occur on the vulva and significant VIN. Therefore, it is extremely important to obtain a biopsy specimen of the vulva in as many areas as necessary to correctly identify the pathology before laser surgery. Local or general anesthesia may be used for vulvar laser surgery. In the case of multiple lesions or very large areas of involvement, general anesthesia is more practical (Fig. 16.9). Despite extensive vulvar laser surgery, patients usually are allowed to return home on the day of the operation.

When laser surgery is used, the vulva is recolposcopied, and 4% acetic acid is applied to demonstrate areas and borders of neoplastic or viral involvement. The larger areas are outlined in the manner described for CIN. If a lesion is large, it may be divided into smaller areas for lasing, because this provides a more accurate approach. As soon as the laser beam is passed over the surface of the tissue, all landmarks disappear. Proper identification and marking of the limits of the disease by the laser is a highly necessary step in treatment. A spot size of 2 to 3 mm and a power setting of 15 to 30 W may be used, depending on the surgeon's skill in manipulating the beam and spot size. Although destruction must be carried to the third surgical plane (i.e., the reticular dermis), the first step in vulvar laser surgery always involves identifying the papillary dermis. When the tiny micropapules of this layer are seen, the laser surgeon again ablates through this most superficial dermis, wiping away char and identifying the underlying reticular dermis. Often intermittent pulses of laser energy can improve surgical control of the laser beam. Instead of reducing the power of the beam, it is possible to use the mechanical timer on the laser console to reduce exposure by delivering one-tenth-second to one-twentieth-second bursts of laser energy. This technique allows the surgeon time to react to the microsurgical review of the tissue and more easily control the rate of energy delivery, thus too-deep penetration, char, and residual thermal damage are also reduced to a minimum.

Postoperative Care

If the lasing has been extensive, a Foley catheter may be required to avoid the immediate discomfort caused by urinary salts on the denuded vulvar surface. Catheters can be placed either through the urethra or suprapubically. Suprapubic drainage avoids the deposit of urinary salts on the wound, reducing pain and possible infection.

Consequently, an antibacterial cream or ointment, such as sulfadine cream or bacitracin ointment, is applied to the laser treated tissue to protect the raw surface from agglutination and to help prevent superficial infection. The patient must be given instructions to keep the vulvar folds separated, and the application of this medication helps with this respect. An ice pack is placed on the vulva when the patient leaves the operating room. Sitz baths begin the first day after laser surgery and are continued two times a day until the patient is no longer uncomfortable and the vulvar area is well on its way to epithelialization. The patient is seen in a week to ensure there is no agglutination of vulvar folds.

Results of Vulvar Laser Surgery

The results of laser surgery on the vulva have been quite satisfactory, and there are some definite advantages to using the CO₂ laser for this disease as opposed to using conventional skinning vulvectomy. These again include accurate ablation of relatively large areas and a more controlled depth of removal because of colposcopically identifiable tissue planes (Fig. 16.10). Rapid healing usually occurs because of relatively little residual thermal damage. In Dorsey's series of more than 100 patients with intraepithelial neoplasia, 1-year cure rates have been more than 90%. Other lower reproductive tract laser surgeons report similar figures. One of the greatest benefits of vulvar laser surgery is that normal vulvar anatomy, particularly the labia minora and clitorus, is maintained (Fig. 16.11). This may not be possible when skinning vulvectomy is performed.

Vaginal intraepithelial neoplasia (VAIN) and associated HPV infections are among the most difficult lower reproductive tract intraepithelial neoplasias to treat for a number of reasons:

1. The vagina has a large surface area, which is difficult to visualize colposcopically.
2. There are many rugae and folds in the vagina.
3. The angle of the vaginal axis makes it difficult to treat by perpendicular beam impact.
4. The vaginal fornices are difficult to stabilize because they may vary in color from a pale grayish white to the intense whiteness produced by hyperkeratosis. Often the lesions are multifocal and the borders are usually distinct, although the lesions may be somewhat serpiginous. VAIN may appear as an iodine-free zone. In the postmenopausal patient, it is helpful to treat the patient with topical estrogen for 2 weeks before examination for optimal accuracy of the iodine test.

The laser microsurgery is particularly aggressive in obtaining adequate biopsy specimens for VAIN. If the patient has had a hysterectomy, the lateral fornix may contain a dimple that must be everted for adequate visualization and biopsy. A laser hook or skin hook can be used to evert this area and stabilize the tissue so that appropriate biopsy can be obtained. The surgeon should be certain of the noninvasive nature of the disease before vaporization is performed.

Technique for Laser Vaporization Of Vain

The squamous epithelium of the mucous membrane of the vagina rests on a basement membrane. Below this is the lamina propria of the vagina, and this layer corresponds to the dermis of the vulvar skin. Below the lamina propria is a layer of muscle,
loose connective tissue, and fat. When the vaginal epithelium is destroyed, there must be visual identification of the underlying lamina propria because, as in the case of the vulva, it is impossible to accurately measure the depth of destruction in this very irregular area. Because the vaginal squamous epithelium is only a fraction of a millimeter thick and there are no skin appendages in the vagina, ablation is a superficial operation. Exposing the vaginal epithelium by manipulating the speculum for diagnosis and laser treatment is painful for most patients. The surgeon often cocks the speculum to one side and shoots through the open sides to manipulate the target into a position that is perpendicular to the laser beam. The vaginal rugae must also be ironed out to ensure even laser energy application. All of this is most uncomfortable. For this reason, most patients with VAIN require general anesthesia on an outpatient basis.

The micromanipulator is preferred for laser VAIN treatment because it eliminates bulky and unnecessary instrumentation from the vagina. A spot size of 2 mm and power settings of 15 to 30 W are used. Large areas are subdivided so that more accurate ablation can be performed. The laser beam is rapidly passed over the area, and the epidermis is lifted away from the underlying lamina propria. A wet sponge or cotton swab is used to wipe away char and coagulated epithelium. Often the surgeon will find that the tops of rugae have been removed, but the troughs or valleys in between still contain viable dysplastic epithelium. With proper use of the speculum and other instruments, this problem is easily overcome. Adequate margins of 5 mm or more are used.

**Postoperative Care for Vaginal Laser Surgery**

Much of the discomfort encountered in postoperative vaginal laser surgery stems from laser wounds in the vaginal introitus. Because VAIN and VIN are so often multifocal diseases, many of these patients will have had extensive laser surgery of the entire lower reproductive tract. In addition to sitz baths and protective vulvar creams, we also use daily vaginal applications of either estrogen or sulfa cream or of some other bacteriostatic preparation. With extensive laser treatment, vaginal walls can touch each other. The patient should also be examined at intervals to make sure that vaginal coaptation is not occurring. Vaginal healing usually takes place from the periphery of the wound because of the lack of skin appendages in vaginal mucosa. If the laser surgeon has been thorough and the denuded area is large, healing is often delayed, and granulation tissue may result. This granulation tissue can be removed and the wound then treated with silver nitrate.
FIGURE 16.11. Laser surgery to vulva for multifocal VIN. Treatment is tailored to intraepithelial lesion’s distribution. Normal clitoral and perianal tissue is preserved.

Results of Laser Vaporization of VIN
Dorsey reported more than 80 patients treated with CO2 laser for VIN with a recurrence rates for multifocal HPV-associated VIN of 30% within the first year. Patients with unicentric VIN had a better than 90% chance of cure with one laser surgery. Townsend and colleagues have reported very satisfactory cure rates in the laser therapy of this disease.

Indications for Laser Surgery and HPV Infection
Although 1-year cure rates produced by laser surgery for lower reproductive tract intraepithelial neoplasia have been very satisfactory, particularly in cervical cases, the persistence or recurrence of wart virus lesions has been discouraging to patients and physicians alike. Our inability to cure HPV manifestations has led many laser surgeons to question the indications for laser surgery for this disease. Most agree that intraepithelial neoplasia should be treated; however, disagreement concerning the advisability or necessity of therapy for minor HPV infection prevails. For example, patients who have evidence of HPV infection on a cytologic smear or who have a whitish change in the vaginal introitus after application of acetic acid are dubious candidates for laser surgery. Because recurrence or persistence of subclinical HPV is so common, a more logical approach is to monitor these patients carefully but not subject them all to surgery unless significant change occurs.

Anal Intraepithelial Neoplasia
Because of the high frequency of multifocal disease, colposcopic examination is not complete without inspection of the perianal tissue and the anal canal. The same techniques that were described earlier are used for the diagnosis and treatment of intraepithelial neoplasia and HPV in this region. An anoscope is used to inspect the anal canal. The surgeon should be careful to avoid lasing hemorrhoids with CO2 laser because of its poor hemostasis with large vessels. A theoretic hazard of laser surgery in this region is the ignition or possible explosion of methane gas from the bowel. Some surgeons insert a wet gauze sponge in the rectum to keep stool out of the field. I have never experienced this complication.

INTRAABDOMINAL LASER SURGERY
Intraabdominal laser surgery has provided a significant and useful new tool for surgery in gynecology. It is unique and offers an alternative to the knife and electrosurgical instruments. Its use in the abdomen began in the late 1970s, and by the first part of the 1980s, there were substantial number of reports from both Europe and the United States dealing primarily using CO2 laser. Numerous reports attested to the efficacy of laser in both reproductive and reconstructive surgery (Table 16.5).

The advantages of laser surgery in the abdomen include precision, limited adjacent tissue damage, rapid healing, minimal scarring, and the ability to treat areas of difficult access from a remote site. An example of the minimal trauma of laser on tissue is the research work of Bern, who demonstrated the ability to remove intracellular chromosomal material with the carbon dioxide laser without destroying the cell. Extensive studies of laser energy in basic science preceded its use in

is in the micromanipulator, so no instrument need be in
the field. The angle with which the laser beam can be delivered,
however, is limited to the viewing angle of the microscope. The
advantages and disadvantages of the microscopic delivery are
listed in Table 16.7. Free hand delivery offers an alternative
without this limitation (Table 16.8).

Today the major interest in gynecologic surgery has shifted
to the endoscopic delivery of the laser beam.

GYNECOLOGIC LASER LAPAROSCOPY

Laparoscopy was introduced in the late 1960s with unipolar
electrical instruments for tubal sterilization. During the 1970s,
Semm described the techniques of laparoscopic vessel ligation
and tissue suturing, and in 1978, Bruhat used the CO₂ laser
with an operative laparoscope to treat ectopic pregnancy. The

ability to cut and vaporize tissue, and to control bleeding as
well, provided gynecologic laser surgeons with the tools nec-
essary to do complicated surgical procedures. Laser alone may
not result in hemostasis with large vessels. Conventional meth-
ods for achieving hemostasis must also be mastered by the laser
laparoskop (Table 16.9). These include ligation of vascular
pedicls and electrical surgical coagulation. The laser is a sur-
gical tool and should not be considered a complete system
of laparoscopy by itself. It should be viewed as an instrument
that forms a part of our laparoscopic armamentarium.

The CO₂ laser can be connected to an operative laparo-
scope through a laser coupler that transmits the beam through
a focusing lens and then down a special channel in the lapa-
scope. Interchangeable lenses provide focal lengths commen-
surate with the length of the laparoscope. Focal spot sizes pro-
duced by these systems are usually a bit less than a millimeter
in diameter. The CO₂ laser is an excellent laser for laparoscopic
usage because it cuts quickly, produces very little thermal dam-
age, and can be used for vaporization, coagulation, or exci-
sion. It is very safe in the hands of a knowledgeable surgeon
because of its almost complete absorption at the surface of
the tissue containing water. The mirrors in the CO₂ laser arm
must be very carefully aligned. The fiber-optic laser’s energy
through flexible small quartz fibers simplifies its use in endo-
scopic surgery. The deeper penetration of these wavelengths,
however, must always be kept in mind.

The blue or green aiming beams of these lasers are more
easily seen against the reddish background of the abdominal
organs than is the helium-neon beam. The quartz laser fibers
will pass through an 18-gauge or smaller needle, so hand pieces
designed for suction and irrigation also may have a central
channel that accommodates the fiber. This enables the surgeon
to use suction, irrigation, and laser energy through one hand
piece, and these hand pieces fit easily through a 3-mm trocar
sheath. The disadvantages of fiber-optic lasers are that they do
not cut quite as well as CO₂ lasers and are less safe because of
their penetration of both tissue and water. The safe and effective use of the laser in laparoscopy has
been demonstrated by Daniell and Brown, Daniell and Her-
ber, Feste, Martin, Kelly and Roberts, Baggish, Dorsey, and
Nezhat and colleagues. Laser laparoscopy has translated into
shorter hospital stays, reduced costs, and less scarring. The
disadvantages of laser laparoscopy include the expense of the
equipment, outdated of instrumentation, and requirement for
special training and maintenance.

YAG laser energy was first used through the laparoscope
in 1982. Some laser surgeons consider the delivery of YAG
energy by bare fiber too dangerous for use in the abdominal
cavity because of the deep penetration of the YAG beam and
danger of injury to organs below the surface.

Technique

Under general inhalation anesthesia, the patient is placed in a modified lithotomy position so that the thigh is almost level with the patient’s abdomen. This enables the surgeon to direct the laparoscope cephalad. This maneuver may be important not only for exploration but also for operating at the pelvic brim. If the hip is flexed and the thighs are elevated, the scope and perhaps the accessory instrumentation cannot be manipulated freely because they will be in contact with the patient’s thighs. After preparation and draping, an intratracheal manipulator device is placed into the uterus for two purposes: to elevate or maneuver the uterus during surgery without having to use intraabdominal instruments for this task and to perform chromoperturbation when necessary. If adhesions are suspected to the laparoscopy trocar insertion site, I prefer to use a technique demonstrated by Professor Palmer of Paris. Using his technique, the insertion site is selected in the midclavicular line, two finger widths below the left costal margin. The insufflation needle is attached to syringe half filled with normal saline. After inserting the needle through the abdominal wall, an aspiration is performed to rule out vessel or bowel perforation. If the aspiration is negative, the normal saline is injected and should have minimal resistance. Resistance indicates that the needle tip is not within the abdominal cavity. If this test is negative, the gas insufflation is initiated. A low opening pressure confirms correct needle placement within an open space in the peritoneum. Next, the laparoscopic trocar is inserted at the needle site. Additional trocars are inserted under direct vision.

Irrespective of the type of laser used, a superior suction-irrigation device that does not obstruct is needed. The new rapid-fill automatic insufflators are highly desirable because they can be set to maintain a constant intraabdominal pressure and will deliver a flow of CO₂ and simultaneously record intraabdominal pressure. A high-intensity light source is also of great importance. A video camera is attached to the laparoscope, and the operative endoscopy is performed while the surgeon views the video monitor (Fig. 16.12). The advantage of video usage is that the entire operating room becomes a team. The assistant is always aware of the progress of the operation, and the surgeon is able to stand erect while inspecting all parts of the abdominal cavity.

Most of our advanced operative laparoscopic procedures require three trocars. The laparoscope is most commonly inserted in the umbilicus margin. Ancillary trocars are placed according to the pathology found, the procedure planned, and the surgeon’s preferences. They are inserted under direct vision to avoid abdominal wall and deep pelvic vessel injury. The anterior pelvis should be inspected before the trocar insertion to identify the bladder margin if possible and avoid injury to this organ. Transillumination of the anterior abdominal wall helps to identify large vessels and rectus muscle margins.

I prefer to use 5-mm trocars and a 30-degree laparoscope for diagnostic use. The 30-degree laparoscope allows the surgeon to see the undersurface of the abdominal wall better. For operative laparoscopy, trocars of larger diameters are selected depending on the intended use such as the need for specimen pouches. Laparoscopic needle holders and curved needles can be passed without difficulty through larger sleeves.

After the trocars and instruments have been inserted, the laser source is attached to the laparoscope or ancillary instrument. Calibration of the laser is tested. I prefer 10 W for 0.1-second settings for this. Beam alignment, aiming beam, spot size, power setting, and continuous or pulsed delivery is tested on a tongue blade. Section, filtration of the plume, and irrigation systems are prepared.

Power setting and timing mode for the surgery to be performed is selected. Pulsed delivery is used where precise tissue effect is important. If the aiming beam is difficult to see within the pelvis, decreasing the laparoscopic light may be helpful. The operative site is inspected and a suction device positioned in close proximity to maintain visibility if significant plume is anticipated. Adequate backstops for the laser beam are checked in CO₂ is used. Care is taken not to laser tissue if it is covered with a layer of water because this will result in the fluid boiling and unnecessary thermal damage.

Carbon Dioxide Adhesiolysis

Laparoscopy has greatly increased our capacity to identify postoperative and postinflammatory pelvic adhesions. Endometriosis is the third common cause of adhesions. Laparoscopy is used to diagnose endometriosis at early stages before the development of dense adhesions. Advanced endometriosis is associated with vascular adhesions that can be treated with lasers. Omentum adhesions to the anterior abdominal wall are handled rapidly and efficiently with laser through an operative laparoscope alone without insertion of other trocars. Bowel adhesions prove a more difficult problem. A pulsed laser can be used if a backstop can be manipulated between loops of bowel, or if the loop of bowel can be held gently apart so the laser energy is directly applied to the adhesion without fear of bowel damage. Laser adhesiolysis must consider vital structures such as bowel, ureters, and major blood vessels that may be attached or in close proximity. Filmy adhesions can be vaporized and divided with low power density and pulsed for precise control. With appropriate technique, the adhesion can be vaporized without damage to underlying structures such as tube, ovary, or bowel. Thick adhesions between delicate structures such as tube and ovary may be lased with intermediate power density and spot size.

The proper power density must be selected for each laser procedure. In general, power densities used in intraabdominal laparoscopy are relatively low. Because CO₂ laser energy continues to travel once it cuts through the target tissue, the surgeon must select an appropriate backstop (Fig. 16.13). Various rods are available to use as both dissecting tools and laser...
Laparoscopy laser lysis of adhesions. The laser beam is delivered within the hollow ancillary probe to the pelvic adhesion. The distal end probe acts as a backstop and limits the laser vaporization to the pelvic adhesion. The instrument’s use must consider multiple other variables such as the patient’s anatomy.

Without a backstop, glass, Pyrex, and quartz rods should be avoided because they may shatter under the intense heat of the laser. Water that is pooled or injected retroperitoneal serves as an excellent backstop for CO2 laser. Titanium with dulled surfaces or blackened rods can also be used. Constant irrigation with body-temperature physiologic solutions washes away any char that may accumulate.

Although CO2 laser is superb for coagulating small bleeders, vessels larger than 0.5 mm in diameter may be difficult to coagulate. If it is not immediately apparent that the laser is achieving hemostasis without significant damage to tissue, conventional methods of hemostasis such as electrosurgical coagulation or suturing, should be used. A filtered evacuation system to remove the laser plume is needed to maintain a clear field of view.

Surgery using laser energy has been compared with mechanical and electrosurgical devices. Evaluation of a single instrument’s use must consider multiple other variables such as the patient’s anatomy, individual surgeon’s skill, absence of long-term follow-up, and the use of concomitant multiple adjuvant therapies. This makes evidence-based comparisons difficult if not impossible.

Laser Surgery of the Fallopian Tube

Laparoscopic tuboplasty using electrosurgical instruments was reported in 1980 by Gomel and others with successful outcomes. The ability to diagnose and treat tubal obstruction during the same procedure was attractive and spurred interest in laparoscopic tuboplasty. The shortened recovery period and the potential shortened time to conception was also attractive. Steptoe and Edwards successfully introduced in vitro fertilization in 1978 with the term cesarean delivery of Louise Brown, who weighed 5 pounds, 12 ounces. For the 20% of couples with tubal obstruction, the expansion of assisted reproductive technology (ART) has significantly reduced the number of tubal surgeries done for fertility. There remains a group of patients who for some reason may benefit from laparoscopic surgery on the tube. Examples include patients with pain associated with tubal disease and patients who chose not to use ART. They can select laser tubal surgery with its unique capabilities. The success of this procedure is related to the preoperative integrity of the tube. The technique involves using an atraumatic grasping tool to stabilize and expose the tube. Any obstruction site including the fimbria is identified. The central site of distal obstruction can be identified by observing the vascular distribution. The tube is gently distended by intrauterine injection of dilute indigo-carmine solution. The use of a backstop is not necessary. As the laser incises the distal tube, the fimbria is immediately identified as the dye appears. Three or four radial incisions are made in the closed tube with a small spot-size laser beam so that satisfactory eversion of mucosa can be accomplished without suturing. The defocused laser beam is applied to the outside of the fimbria. Heat and the resultant contraction of desiccated tissue cause the eversion of the fimbria. Flowering of the tube is accomplished using a spot size of 3 to 5 mm and a low power setting of 2 to 3 W of CO2 laser. This technique was first described by Bruhat and is referred to as Bruhat’s procedure.

Laser Myomectomy

The indications for a laparoscopic myomectomy are the same as the indications for myomectomy in general. Significant size, rapid growth, selected cases of infertility or pressure symptoms, and heavy bleeding have all been acceptable indications for surgical intervention. Pedunculated leiomyomas can be easily removed at laparoscopy, but intramural myomas that are deeply imbedded in the myometrium may pose a real challenge.

Laparoscopic myomectomy is a controversial procedure because of the need to perform careful uterine reconstruction if the patient desires future childbearing. This operation should not be attempted by any laparoscopist who is not familiar with advanced laparoscopic suturing techniques or ability to close the myometrium in layers. An injection of a dilute solution of vasopressin is made to the margins of the leiomyoma and the surrounding myometrium. Lower abdominal accessory trocars are used according to the size and location of the fibroids. Incisions to remove the fibroids are made away from the ovaries and tubes if possible to reduce postoperative adhesions to these structures. Lateral forceps are used to grasp the myometrium, and this is gently stripped away from the underlying myoma, much in the way that an orange is peeled. Laser is used to coagulate vessels on the surface of the leiomyoma and, as the base is approached, to coagulate and cut vessels in that area. If excessive bleeding is encountered, bipolar coagulation or endoscopic suturing will usually control the bleeding. Constant traction is placed on the leiomyoma as it is being removed through a small line trocar. A small myoma corkscrew instrument can be used through this trocar to stabilize and exert the necessary traction. Larger intrauterine leiomyomas 6 to 8 cm in size may require morcellation using a morcellator or minilaparotomy. The specimen can also be removed through colpotomy by minilaparotomy.

Myomectomy must be carefully performed, and hemostasis must be complete at the end of the procedure. The possibility of excessive blood loss during this operation is always present, and both patient and surgeon must be prepared for immediate laparotomy (Fig. 16.14). Carbon dioxide, KTP, argon, and YAG lasers have all been used for myomectomy. Closure of the myometrial defect is accomplished using continuous layers of absorbable sutures. An
Open free-hand laser myomectomy. Retractor surfaces are covered with wet towels to prevent reflection of the laser beam.

Laser Surgery for Endometriosis

Laparoscopy provides a diagnostic and therapeutic surgical procedure for endometriosis. Continued monitoring and management also uses laparoscopy. Small implants of mild to moderate endometriosis can be effectively vaporized, coagulated, or excised with either the CO2 or the fiber-optic laser. Even small endometrial implants are surrounded by subclinical endometriosis, so a margin of vaporization or coagulation may be needed around the endometrial implant. Dense adhesions associated with advanced endometriosis can also be treated, including those located over the ovary. Cases of severe endometriosis involving the ovary in most cases is avoided because it is rarely needed except for those cases of severe endometriosis involving the ovary at the end of the surgery.

Application of Laser Gynecology

Ovarian Cystectomy

Resection of an ovarian cyst at laparoscopy is controversial. Some surgeons are concerned that spillage of an undiagnosed malignant ovarian tumor can result in the spread of the cancer. On the other hand, gynecologic oncologists are increasingly using laparoscopy in the evaluation and treatment of pelvic cancers. Although rare, most ovarian malignancies are not discovered when they are at an early stage. On the other hand, practicing gynecologists are commonly presented with ovarian cysts for treatment. The vast majority of young women with persisting cystic adnexal masses will not have ovarian cancer. If a concern for possible ovarian cancer develops, laparoscopy provides access for histologic diagnosis. The cystic masses should always be first evaluated by noninvasive means, such as pelvic ultrasound, magnetic resonance imaging, or computed tomography. Appropriate ovarian tumor markers are also available. Symptomatic parovarian cysts can be drained easily with laser. No direct contact with the cyst is necessary unless the surgeon desires to create an enlarged window or obtain tissue for histology. Unilocular, symptomatic, persisting ovarian cysts with benign imaging profile and thin walls are best suited for laparoscopy. The surgeon can encounter cysts whose contents, if spilled, can stimulate adverse peritoneal response. This group of cysts include mucinous cystadenomas and dermoids. A means for copious irrigation with a physiologic solution should be available. To avoid recurrence, ovarian endometriomas should be excised rather than vaporized. Saturating the ovary in most cases is avoided because it is rarely needed and it can result in adhesions to the ovary. Danell published a small series of patients with polycystic ovaries unresponsive to hormone treatment that were able to achieve ovulation following laser surgery to the subcapsular cysts.

Uterosacral Ligament Surgery

Pain stimuli originating from the cervix are transmitted through the uterosacral ligaments to the sacral sympathetic plexus by way of nerve roots S2, S3, and S4. This plexus is concentrated within the uterosacral ligament at its attachment to the back of the cervix. Severance of the uterosacral was first reported by Doyle in 1963. He reported relief of dysmenorrhea in 86% of 235 patients. Feist reported relief of dysmenorrhea in 78% of the women who underwent CO2 laser division of the uterosacral ligaments and who were monitored for 5 years. Lichten in 1987, in a well-controlled series, reported a success rate of more than 80% in patients followed for more than a year. Dorsey reported 60 patients undergoing uterosacral ligament division for either primary dysmenorrhea or

Dysmenorrhea associated with endometriosis. Significant pain relief occurred in 70% of the women monitored over the course of the year. The uterosacral ligament can sometimes be confused with the ureter, so the latter structure must always be positively identified. The ureter is identified at the bifurcation of the common iliac artery and traced into the pelvis to a point at which it disappears in the cardinal ligament. At the same time that the uterosacral ligament is identified, the division is planned close to its insertion into the uterus. Uterosacral ligaments vary tremendously in size and structure. The division should begin at the posterior cervical wall. Lateral to the uterosacral ligament lies a branch of the uterine artery as well as the ureter, so one should stay medial. Power settings of 20 W may be used on the CO₂ laser; on fiber-optic lasers, 10 to 15 W will suffice (Fig. 16.4).

**Tubal Pregnancy**

Laparoscopic laser surgery for tubal pregnancy was reported by Bruhat in 1978. Ampullary ectopic pregnancies are usually intramural rather than intraluminal, and this is the perfect setting for a laser incision. A dilute solution of vasopressin can be delivered percutaneously to the tube, and the laser is used for the linear salpingostomy. Hemostasis is achieved by any of the lasers, however, bipolar coagulation may be necessary for very active bleeding. Usually the pregnancy is extruded from the tube as the incision is made. Gentle traction with an atrumatic forceps or with an irrigation stream is helpful. It is not necessary or desirable to curette the tube in an effort to remove the contents. It is always necessary to monitor any conservatively treated tubal pregnancy with postoperative human chorionic gonadotropin (hCG) titers to rule out persistent trophoblastic disease.

Partial salpingectomy is sometimes necessary. This may be particularly true for isthmic tubal pregnancies. Pregnancies in this region of the tube are usually intraluminal, and although they are not encountered as frequently as ampullary pregnancies, segmental rupture may occur earlier, and recanalization of the tube is infrequent. For this reason, excision of the segment may be desirable. This can be performed by coagulation on either side of the ectopic pregnancy and then excision with laser or laparoscopic scissors. Bipolar coagulation may be necessary because of the bleeding despite the use of vasopressin. The ability to diagnose ectopic pregnancy early with sensitive hCG tests and sonograms has decreased the incidence of ruptured ectopic pregnancies. This has also resulted in an increase use of nonsurgical treatment of early unruptured ectopic pregnancy. Salpingectomy is used when the tube is destroyed or when future pregnancy is not desired.

It is essential to follow any conservatively treated tubal pregnancy with postoperative hCG titers to rule out persistent trophoblastic disease.
Salpingo-Oophorectomy and Laparoscopically Assisted Hysterectomy

These procedures are now well known to most laparoscopic surgeons, and we have found the laser to be of assistance in their performance. These operations involve securing large vascular pedicles or dividing adhesions, ablating endometrial implants, and performing other tasks related to removal of the specimen.

- Dividing large pedicles that have either been coagulated with bipolar forceps or suture ligated
- Accomplishing division of adhesions, ablating endometrial implants, and performing other tasks related to removal of the specimen
- Dividing the peritoneum over the bladder, mobilizing the bladder off of the cervix finding uterosacral ligaments, and entering the vagina from above all of these specifically in laparoscopically assisted hysterectomy

Laser through the operative laparoscope allows for rapid and safe performance of these steps without the need for constantly introducing or removing instruments through the trocar sleeves.

HYSTEROSCOPIC LASER SURGERY

Nd:YAG Laser

The first endometrial ablation series by Goldstrath and colleagues in 1981 used fiberoptic YAG laser for the energy source. Because of its ability to penetrate tissue, the YAG represents an ideal laser for endometrial ablation. Myometrium is normally about 2 to 3 cm in thickness except at the corna, where it may be significantly less. Endometrial thickness can usually be measured in terms of a few millimeters. Because YAG laser energy delivered by the unclad laser fiber penetrates about 4 mm, the YAG can be used to effectively coagulate the endometrium and the inner layers of the myometrium. The risk of damage to tissues outside the myometrium is minimal.

The YAG laser is a very effective coagulating tool, and where properly used for endometrial ablation, it gave good results. Fiber laser ablation has the advantage of being able to be delivered through small caliber hysteroscopes. The width of laser beam from the fiber, however, is narrow: less than 1 mm in diameter. The treatment of the entire uterine chamber with YAG resulted in a prolonged operative time.

All patients who are candidates for endometrial ablation should have an examination of the endometrium to rule out malignancy or premalignant lesions. Atrypal adenomatous hyperplasia should not be ablated. Patients can be given medication to suppress the endometrium. Note that one of the advantages of hysteroscopic laser surgery is that normal saline distending medium avoids the dangers associated with vascular absorption of ionomic solutions used in electrosurgery. Controlled close-loop distending systems improve visualization, even in the presence of active bleeding. An effort is made to destroy all endometrium in the uterine cavity. Care is taken in proximity to the internal os of the fallopian tubes, considering the thinning of the wall at that point and the deep penetration of the YAG laser. Division of the lower endometrial cavity, the laser treatment is extended to the internal cervical os. Laser ablation of the endocervix is avoided to reduce the risk of stenosis, hematomatia, and postoperative bleeding.

Garry and associates have reported a series of more than 600 endometrial ablations accomplished with laser without complications and with an overall success rate of more than 80%.

Continuous-flow resectoscopes with rollerball, loop, or electrosurgical tips are faster and easier to use than the fiber-optic laser. Global endometrial ablation techniques have replaced the fiber lasers for most with a few selected indications. However, the original endometrial ablation techniques are used as the gold standard for effectiveness comparisons.

Other hysteroscopic surgeries that have used laser include metroplasty, division of uterine septa, destruction of uterine synchiea, and excision of submucous leiomyomas. Small caliber hysteroscopes can be used with fiber laser because of their small operative channels, an advantage when the uterine cavity or cervical canal is very narrow.

Laser Metroplasty

Any of the fiber-optic lasers can be used for division or removal of uterine septa and synchiea. It should be emphasized that when septa are divided, concomitant laparoscopy should be performed to ensure that perforation does not occur.

Pedunculated myomas may be removed by laser division of the pedicle. Deeper submucous myomas are more easily handled by resectoscopic surgery.

LASER SAFETY

It is important that surgeons, nurses, and all those associated with laser surgery have an understanding of the potential health and safety hazards associated with the use of medical laser systems and the precautions needed to use them safely. Laser injury and potential hazards can be considered related to the organ systems at risk. The eye is considered to be the organ most vulnerable to damage by laser. The eye collects and concentrates light energy on the retina. It has a natural protective mechanism in the lid and tearing reflexes. However, many lasers are extremely intense and are delivered so rapidly that injury can occur. Lasers in the visible and near infrared bands will be transmitted through the eye to the retina. With sufficient intensity, they can cause visual loss. Laser light cannot damage a tissue unless the light energy can reach and be absorbed in that tissue. Injury to the cornea and lens may occur with lasers in specific spectral bands in the ultraviolet and infrared spectrum. The laser energy necessary to injure the cornea is much greater that that required to injure the retina. Protective measures for eye protection include spectacles, goggles, or coverall goggles to filter out the specific laser wavelength while transmitting visible light. Colposcopes and operative lenses of laparoscopes shield the laser surgeon’s eyes from CO2 laser injury when delivered through these systems. The fiber-optic lasers that penetrate water and clear glass also penetrate the eye. In endoscopic surgery, special glasses or filters specific for the laser are used for protection. The optical filter is coupled to the eyepiece of the telescope and can be activated when the surgeon steps on the foot switch. As a general rule, eye protectors are required for work with class 4 lasers. Any surgical lasers with an average power exceeding 0.5 W are class 4. Most surgical lasers are class 4.
Skin is considerably less vulnerable to laser injury than the eye. Skin injury can also occur from ignition of flammable material by the laser beam. Laser hazards to operating room personnel and patient includes accidental exposure from misdirection of the laser beam. The risk of this happening can be reduced by using the “standby” mode when not actually operating. Surgeons are not highly susceptible to laser injury. However, when using handheld laser delivery systems, one should remember that the surgeon’s hand is the closest to the laser target and subject to reflection from adjacent surgical instruments. Fortunately, most reflected beams are highly divergent because the beam is normally focused. The zone of potential hazard by reflection is referred to as a nominal hazard zone (NHZ). Service personnel may encounter laser beams that are unfocused and concentrated. Electrical hazards of laser equipment are similar to other types of electrical or electronic equipment. There is no unique electrical safety problem associated with laser use. Biomedical engineer and technicians should have no difficulty providing guidance for the control of any electrical hazards from laser equipment.

Vaporization of tissue produces smoke with potential health hazards. Careful evacuation and filtration of the laser plume will reduce any hazard of laser smoke inhalation. The evacuation of the plume is most effective if the tip of the beam is within 2 cm of the tissue being treated. It is important to remove smoke from the closed abdominal cavity during laparoscopic surgery. This allows the surgeon to see clearly as well as removing it from inhalation by the operating room personnel. Special high-efficiency masks provide additional respiratory protection. Warning or indicator signs are required by ANSI Z136.1–1990 for class 4 laser treatment controlled areas.

I have used laser surgery in gynecology for more than 32 years. Over this period, many applications of laser have been recognized and defined, as outlined in this chapter. Numerous skilled surgeons throughout the world have contributed to its literature. Lasers are unique and useful tools in the hands of trained surgeons. They are not a magic wand that can be used to accomplish all surgical tasks. The introduction of lasers to gynecologic surgery occurred at a time when laser use in the military, aerospace, and everyday life was highly publicized. This focus of attention was responsible, in part, for laser’s introduction to gynecology. The initial popularity of laser surgery in turn stimulated the development of more sophisticated electro-surgical instruments. This has resulted in the improvement of the tools using electro-surgical energy. The techniques for laser surgery performed by experienced gynecologists are presented in this chapter. The long-term benefits and future use of lasers in gynecology will require carefully designed and randomized studies. 

**BEST SURGICAL PRACTICES**

- Understand the physics and tissue effects of the laser you are using.
- Implement precautions needed for laser safety.
- Set the time the laser is exposed to tissue for the optimum effect.
- Biopsy tissue before coagulation or vaporization if intraepithelial stage is in doubt.
- Select appropriate backstops if laser beam can continue through the tissue being treated.

CHAPTER 17 ■ DIAGNOSTIC AND OPERATIVE LAPAROSCOPY
HOWARD T. SHARP, SEAN L. FRANCIS, AND ANA ALVAREZ MURPHY

DEFINITIONS

Aqua dissection—The use of fluid, most often sterile water or saline, under force, to separate one anatomical plane from another. The laparoscopic motorized irrigation is an excellent tool for performing aqua dissection.

Chromopertubation—A procedure in which a colored dye is passed through the fallopian tubes to confirm that they are patent.

Colpotomy—A surgical incision in the vagina. The -otomy part of the word is from the Greek word tome, meaning cutting.

High definition—A term initially introduced in the 1930s to define the then-new technology that replaced the experimental systems that ranged from 15 lines to about 220 lines of resolution. High-definition television (HDTV) is now defined as resolution 1,080 or 720 lines. HD is broadcast digitally and consequently produces a more vivid and realistic picture.

Morcellate—To divide into small portions.

Reposable—A trocar/sleeve kit in which disposable trocars are used with reusable sleeves in an effort to reduce the cost of disposable products while ensuring sharp, undamaged instruments more commonly found in the disposable kits.

Veres needle—A spring-loaded needle designed to allow entry into body cavities without trauma to underlying organs during laparoscopy.

Laparoscopic surgical advances have accelerated remarkably over the past decades. What was initially a primitive tool for diagnostic purposes and simple procedures such as tubal sterilization has evolved into a more coordinated system for the repair or removal of diseased abdominal and pelvic organs. As operative laparoscopy has become more complex and technology has continued to advance, new challenges and complications have been recognized. The proper use of equipment and techniques can greatly add to patient safety and satisfaction. To this end, the purpose of the chapter is to review contemporary equipment, commonly used surgical techniques, and strategies to avoid and manage complications associated with laparoscopic surgery.

HISTORY

The first description of endoscopy is attributed to Phillip Bozzini in 1805, as he attempted to view the urethral mucosa with a simple tube and candlelight. Hysteroscopy was the first gynecologic endoscopic procedure performed when Panfletoni used a cystoscope to identify uterine polyps in 1869.

Laparoscopy was first performed by Jacobaeus of Sweden in 1910, wherein a Nitze cystoscope, composed of a candle and a hollow tube, was used to illuminate the peritoneal cavity. Kalk of Germany was instrumental in developing laparoscopy into a diagnostic and surgical procedure in the early 1930s. By the end of the 1930s, laparoscopy was being used in the diagnosis of ectopic pregnancy and the performance of tubal sterilization. Raoul Palmer of France reported the use of gaseous distention with lithotomy Trendelenburg positioning in 1947. The use of “cold light” and fiberoptics were landmark innovations credited to Fourestier, Glado, Valmiere, and Kampany and Hopkins, respectively. Monopolar electrocautery for tubal sterilization was popularized in the 1960s. Semm of Germany reported advanced-operative laparoscopic procedures such as salpingectomy, myomec tomoy, oophorectomy, ovarian cystectomy, and salpingectomy in the 1970s. These pioneers of endoscopic surgery and many others have laid the crucial groundwork that has enabled modern gynecologic surgeons to perform advanced-operative laparoscopy on a routine basis, with a variety of energy systems under increasingly ergonomic and efficient conditions.

INDICATIONS FOR LAPAROSCOPY

Diagnostic Laparoscopy
Laparoscopy can provide valuable clinical information in a number of circumstances. It can aid in the evaluation of patients with acute pelvic and abdominal pain, including ovarian torsion, ovarian cyst rupture, ectopic pregnancy, appendicitis, and pelvic inflammatory disease. In the evaluation of less emergent conditions, such as chronic pelvic pain and infertility, it is useful to identify pelvic adhesions, endometriosis, hernias, uterine fibroids, and adnexal masses. Before performing diagnostic laparoscopy, a thorough history, detailed physical examination, and appropriate imaging studies should be completed.

Operative Laparoscopy
Most surgeries traditionally performed by the abdominal or vaginal approach can now be performed laparoscopically. Studies are still needed to better define which advanced procedures are most appropriate to perform laparoscopically from an economic and safety vantage point. Operator experience is a critical factor that must be considered. Commonly performed laparoscopic procedures include adhesiolysis, treatment of endometriosis, tubal sterilization, ovarian cystectomy, oophorectomy, salpingectomy, salpingostomy, and hysterectomy.
advanced procedures include repair of pelvic organ prolapse, tubal reanastomosis, myomectomy, radical hysterectomy, and lymphadenectomy.

**EQUIPMENT**

Contemporary laparoscopy equipment consists of an imaging system comprising a telescope (laparoscope) and video camera system, an insufflation or abdominal wall lift system, and specialized surgical instruments. Digitization and robotics are areas that continue to evolve.

**Imaging Systems**

Imaging systems consist of a laparoscope, light source, fiber-optic cord, camera unit, and monitors. High-definition digital cameras are now available that are compatible with the increased resolution capabilities of high-definition flat screen monitors. Most imaging systems are also equipped with a printer, video recorder, or DVD recorder for documentation.

The laparoscope in its basic form is a telescope. Laparoscopes range from 1.8 mm to 12 mm in diameter, with a distal end (objective) available in varying viewing angles (Fig. 17.1). The 0-degree deflection-angle telescope is most commonly used and provides a straightforward view, whereas a 30-degree fore-oblique lens allows for visualization in a large frontal view but must be continuously directed to maintain field orientation. Operative laparoscopes are equipped with a central channel that allows laser, electrosurgical, or mechanical instruments to be introduced into the abdomen. Light is introduced through the laparoscope with a fiberoptic cable powered by a light source. It is important that the light source have sufficient power to deliver adequate light through the fiber-optic cable. Ideally, high-intensity light sources that use xenon or halogen are used. Though a significant amount of original light is lost from the original hot light source, the fiber-optic cable is able to transmit enough heat to burn paper drapes as well as patient’s skin; therefore, caution should be used to avoid inadvertent contact with drapes or the patient.

**Insufflation and Abdominal Lifting Systems**

Insufflation systems allow gas to fill the abdominopelvic cavity to optimize visualization. Insufflators are designed to deliver gas at low rates during initial Veres needle insertion, but are also able to provide high flow rates when gas is lost to maintain a relatively constant set intraabdominal pressure during surgery. Insufflation may be achieved with a Veres needle or the Hassan trocar, filtered tubing, an insufflator, and gas tanks. Insufflation tubing with a 0.3-micron filter is recommended to prevent intraperitoneal contamination with bacteria, microparticles, and debris from the insufflator and gas tank. A Veres needle is often used to create a pneumoperitoneum, although other methods, such as direct trocar insertion and open laparoscopy, will be discussed. The Veres needle is available in reusable or disposable models containing a springloaded tip that retracts as it pierces the abdominal wall, allowing a blunt tip to engage on entry to the peri toneal cavity (Fig. 17.2). This is designed to avoid damaging bowel or other intraabdominal organs. Though filtered room air has been used, carbon
dioxide is most commonly used today. Carbon dioxide has the advantage of being rapidly absorbed by blood. However, it is converted to carbonic acid on moist peritoneal surfaces, which can cause pain. For this reason, nitrous oxide or helium are preferred by some, especially in cases using local anesthesia or conscious sedation. Some have advocated the use of heated or hydrated gas to prevent hypothermia during laparoscopy. Insufflators that contain a heating unit have little or no effect on temperature by the time the gas has traveled 50 to 100 cm in tubing. In longer surgeries, prevention of hypothermia is better achieved by using a heated body surface blanket or the Insuflow device (Lexicon), which delivers heated and hydrated gas. Gasless laparoscopy can also be performed with the use of a mechanical lifting arm that attaches to a fanlike retractor along the peritoneal surface of the abdominal wall, obviating the need for gas distension. Some favor this approach in patients with cardiopulmonary risk factors.

**Surgical Instrumentation**

Trocars and sleeves are used to pierce the abdominal wall for placement of the laparoscope and surgical instruments (Fig. 17.3). Trocar sleeves range from 2 to 15 mm in diameter and are available as reusable, disposable, and reposable systems. Disposable systems consist of completely disposable trocars and sleeves. They offer the advantage of consistent sharpness but are more expensive. Reusable trocars offer the advantage of being the most cost-effective, but they must be maintained for sharpness. Reposable systems are composed of a disposable bladed or nonbladed trocar with a reusable sleeve. All are acceptable for use. Most sleeves contain a Luer-lock port that attaches to insufflation tubing. Trocar tips may be pyramidal, conical (reusable), bladed, blunt tipped, or have optical access (disposable). Conical and blunt-tipped trocars have the advantage of making smaller fascial defects but require greater force to place. Optical access trocars such as Optiview (Ethicon) and Visiport (U.S. Surgical) enable the surgeon to visualize the layers of the abdominal wall during placement. Expandable trocar sheaths are available that are initially placed through the abdominal wall with a Veres needle and then expanded to accept a 5- to 12-mm port (Step port, InnerDyne). These offer the advantage of creating smaller abdominal wall defects and thereby reducing the risk of hernia formation and injury to the inferior epigastric vessels.

Ancillary instruments may be placed through secondary trocar sleeves to aid in diagnostic and operative laparoscopy (Figs. 17.4 and 17.5). These include blunt probes; a variety of graspers, including toothed and atraumatic graspers; scissors; needle drivers; knot pushers; biopsy forceps; suction-irrigators; energy delivery tools; specimen retrieval bags; and tissue morcellators. A uterine manipulator may be used to improve access to the uterus, fallopian tubes, ovaries, and the posterior and anterior cul-de-sacs. These are available in reusable and disposable models. Some manipulators are inserted in a fixed position and allow limited uterine mobility, whereas others are hinged and allow the uterus to be moved anteriorly, posteriorly, and laterally. Many of these also offer the ability to perform chromotubation for evaluation of fallopian tube patency.
More advanced manipulators, such as the KOH Colpotomizer (CooperSurgical) (Fig. 17.6), provide a stainless-steel cup that engulfs the cervix, allowing the surgeon to cut against it when resecting the uterus and cervix from the vagina during a laparoscopic hysterectomy. The same device also provides a balloon that is inflated to prevent the pneumoperitoneum from escaping through the vagina once the incision has been made on the vaginal cuff. Through this instrument can significantly facilitate the hysterectomy, it is more expensive than other manipulators, and the time required to insert it can potentially contribute to the overall anesthesia time.

Energy and Hemostasis

The application of energy systems to laparoscopy has expanded laparoscopic surgeons’ ability to perform complex surgeries with the capability to rapidly divide tissues and maintain hemostasis. This technology has also introduced a new set of complications, such as unrecognized bowel burns from inadvertent direct and capacitative coupling. In an effort to reduce risks associated with monopolar electrosurgical devices, several options are available. One is the use of endomechanical energy; a second is the use of bipolar electrosurgery, lasers, or ultrasonic energy; and a third is the gaining of a better understanding of electrosurgical principles. Though our understanding of laparoscopically applied electrophysics has improved, gynecologic surgeons often have no formal electrosurgical training or credentialing in contrast to the once-common laser safety courses. Electrosurgery and laser principles are explained in Chapters 15 and 16.

Endomechanical Energy

Endomechanical energy can be used for tissue division and hemostasis in a number of ways, including suturing, stapling, and the application of vascular clips.

Suture. The simplest laparoscopic ligature to apply is the pre-tied loop, available as a slip knot on a push rod that is used to push a suture loop around a tissue pedicle for hemostasis (Fig. 17.7). The Roeder loop, which was modified by Kurt Semm for laparoscopic use, can also be tied in the operating room using standard suture. Laparoscopic suturing can be performed using stock suture, ideally 36 to 48 inches in length (Fig. 17.8). Needle drivers are used to drive needles through tissue, and knots may be tied outside the laparoscopic port (extracorporeal knot) or within the body (intracorporeal knot). Extracorporeal knots are usually performed as sliding square knots, pushed through the trocar sleeve to the tissue by multiple passes of a knot pusher, which serves as the surgeon’s finger (Fig. 17.9). Intracorporeal knots are tied within the abdomen by looping the suture material around the laparoscopic needle holders using the same technique as an “instrument tie” (Fig. 17.10). Laparoscopic suturing requires considerable practice to confidently load the needle onto the needle driver and place sutures accurately. To this end, the Endostitch (U.S. Surgical) was developed, wherein the needle is preloaded and the suture is passed through tissue up to 2 cm thick by closing a handle and a toggle switch (Fig. 17.7). The endostitch is a 10-mm instrument with jaws measuring 4 mm wide and 2 cm long. Other automated products are also available, including the Suture Assistant (Ethicon Endosurgery) (Fig. 17.7) and the Lapra-ty (Ethicon Endosurgery). In an effort to accommodate surgeons desiring to use the laparoscopic needle driver and suture, companies such as Cook produce self-righting needle drivers, which are intended to automatically fix the needle at a perpendicular or oblique position to the needle driver. Such devices facilitate suturing laparoscopically.

Staplers. The endo-GIA, originally designed for gastrointestinal anastomosis, is used in gynecologic laparoscopy as a stapling device for securing and dividing tissue. When the jaws of the instrument are closed over tissue and as the grip is fired, six staggered rows of staples, 3 cm in length and 1 cm in width, are placed. A knife blade simultaneously divides the tissue, leaving three rows of staples on each side of the incision.

Vascular Clips. Endoscopic vascular clips may be used to achieve hemostasis for bleeding vessels or pedicles (Fig. 17.7). These offer the advantage of being used near vital structures,
FIGURE 17.8. Extracorporeal knot tying with slip knot. A: With both suture ends outside the body, the suture is cut below the needle. A single throw is made. B: With the free end of the suture, three revolutions are made around both suture strands. C: The tail of the suture is inserted through the lowest loop. D: The tail is pulled to tighten the knot, the suture is cut above the knot, and the slip knot is pushed with a closed-nose knot pusher to the desired position. (Modified from Murphy AA. Operative laparoscopy. Fertil Steril 1987;47:1.)

FIGURE 17.10. Intracorporeal knot tying. A: The needle is passed through the tissue. B: A surgeon's knot is made with the instruments and pulled tight.
Monopolar and bipolar electrosurgical instruments are frequently used to perform tubal sterilization and to obtain hemostasis. Monopolar instruments use current that flows from an active electrode, through tissue, having a cutting or coagulating effect. Current travels through the patient, exiting from an active electrode, through tissue, having a cutting or coagulating effect, and returning through a return electrode within the same instrument directly back to the electrosurgical unit. There is no need for a return electrode plate (usually placed on the patient’s thigh) to the electrosurgical unit. Needlepoint electrodes, hook electrodes (Fig. 17.5), and most endoscopic scissors (Fig. 17.4) are examples of monopolar electrosurgical instruments. Bipolar instruments, such as the Kleppinger forceps (Fig. 17.4) and the newer impedance-controlled bipolar systems, use current that flows from an active electrode, through tissue having a cutting or coagulating effect, and returning through a return electrode within the same instrument directly back to the electrosurgical unit. There is no need for a return electrode plate on the patient (see Chapter 15).

Electrosurgical instruments use “household current” that is transformed into radiofrequency current. The waveform of radiofrequency current can be altered. If the waveform is not altered (undamped), it is considered continuous. This is also referred to as cutting mode or cutting waveform. Cutting waveform uses low voltage compared with damped current. Cutting current causes cells to vaporize at their boiling point (100 °C) without elevating tissue temperatures to high levels, thus minimizing lateral thermal spread. With waveform modification, current can be interrupted (damped) to varying degrees (Fig. 17.12). These modifications refer to blend 1 (80% on, 20% off), blend 2 (60% on, 40% off), blend 3 (50% on, 50% off), and coagulation (6% on, 94% off). As a result of current interruption (coagulation), bursts of energy with higher voltage (5,000 V) and therefore lower current, given a constant wattage (watts = voltage × current), will occur. This results in denaturation and charring (fulguration) to cause hemostasis with minimal cutting. Understanding the concepts of cutting and coagulation is clinically relevant when bleeding is encountered. For example, when there is a bleeding vessel or pedicle, it is best to desiccate the vessel by applying pressure to the vessel or tissue pedicle with a tissue grasper and cutting current. This causes fibrous bonding of the dehydrated cells of the endothelium without significant lateral thermal spread. It also decreases the risk of thermal bowel injury from capacitive coupling (see Chapter 15) as lower voltage is used. Conversely, when the coagulation waveform is used in this scenario, instead of causing bonding inside the vessel, superficial lateral thermal spread is more likely to occur along the tissue surface, resulting in eschar formation and subsequent bleeding.

Current density refers to the amount of current flow per cross-sectional area in the direction of current flow described in amps per meters squared. This concept has several direct applications to the use of electrosurgical energy in laparoscopy. This principle is used to safely return current from the patient to the electrosurgical unit (ESU). Because current density is described in terms of current per meters squared, applying energy to a small area of bleeding or to a bleeding tissue pedicle will result in an intended thermal effect, inversely related to the electrode size. For example, the use of a needlepoint electrode will have high-current density compared with a much larger spatula tip, resulting in greater energy applied to a small surface in the former. The current density principle is used to allow current to exit the body without causing injury, as it exits through the relatively large surface area of the return electrode, usually placed on the patient’s thigh. This does not cause an exit

**FIGURE 17.12.** Coagulating and cutting waveforms.

where the use of other forms of energy may otherwise result in lateral thermal damage.

**Laser Energy**

The term laser is an acronym for light amplification by spontaneous emission of radiation. Surgical lasers available for gynecologic use include CO₂, argon, potassium-titanyl-phosphate (KTP), and neodymium:yttrium-aluminum-garnet (Nd-YAG). These have the ability to vaporize, cut, and, to varying degrees, coagulate tissue (see Chapter 16). Laser energy is an acronym for ultrasonic energy. The Harmonic Scalpel (Ethicon Endosurgery) uses vibration at the rate of 55,000 cycles per second as an energy source to break hydrogen bonds in tissue, resulting in cutting or coagulation of vessels. The Harmonic Scalpel is available as a 5-mm rounded “scalpel” with a blunt or hooked edge or as a 5- to 10-mm “sheat” or Harmonic Ace (Fig. 17.11), which can be used to grasp tissue. This modality results in minimal lateral thermal spread of energy, and there is no risk of electrical injury.

**Electrosurgery**

Electrosurgical instruments use “household current” that is transformed into radiofrequency current. The waveform of radiofrequency current can be altered. If the waveform is not altered (undamped), it is considered continuous. This is also referred to as cutting mode or cutting waveform. Cutting waveform uses low voltage compared with damped current. Cutting current causes cells to vaporize at their boiling point (100 °C) without elevating tissue temperatures to high levels, thus minimizing lateral thermal spread. With waveform modification, current can be interrupted (damped) to varying degrees (Fig. 17.12). These modifications refer to blend 1 (80% on, 20% off), blend 2 (60% on, 40% off), blend 3 (50% on, 50% off), and coagulation (6% on, 94% off). As a result of current interruption (coagulation), bursts of energy with higher voltage (5,000 V) and therefore lower current, given a constant wattage (watts = voltage × current), will occur. This results in denaturation and charring (fulguration) to cause hemostasis with minimal cutting. Understanding the concepts of cutting and coagulation is clinically relevant when bleeding is encountered. For example, when there is a bleeding vessel or pedicle, it is best to desiccate the vessel by applying pressure to the vessel or tissue pedicle with a tissue grasper and cutting current. This causes fibrous bonding of the dehydrated cells of the endothelium without significant lateral thermal spread. It also decreases the risk of thermal bowel injury from capacitive coupling (see Chapter 15) as lower voltage is used. Conversely, when the coagulation waveform is used in this scenario, instead of causing bonding inside the vessel, superficial lateral thermal spread is more likely to occur along the tissue surface, resulting in eschar formation and subsequent bleeding.

Current density refers to the amount of current flow per cross-sectional area in the direction of current flow described in amps per meters squared. This concept has several direct applications to the use of electrosurgical energy in laparoscopy. This principle is used to safely return current from the patient to the electrosurgical unit (ESU). Because current density is described in terms of current per meters squared, applying energy to a small area of bleeding or to a bleeding tissue pedicle will result in an intended thermal effect, inversely related to the electrode size. For example, the use of a needlepoint electrode will have high-current density compared with a much larger spatula tip, resulting in greater energy applied to a small surface in the former. The current density principle is used to allow current to exit the body without causing injury, as it exits through the relatively large surface area of the return electrode, usually placed on the patient’s thigh. This does not cause an exit...
site burn because of low current density. Exit site burns have typically occurred when part of the return electrode has peeled away from the patient, resulting in a smaller area of surface contact, thus creating high current density at the exit site.

Bipolar instruments have undergone significant transformation in recent years. Simple bipolar systems, such as the ESU with a Kleppinger forceps, have evolved to devices that provide bipolar energy that senses tissue impedance to perform controlled energy delivery. These devices, such as Enseal (Surgical), Plasma Kinetic dissection forceps (Cyrus Medical), and Ligasure (Valleylab), use pressure and pulsed current to seal vessels with minimal lateral thermal spread. These devices can seal vessels up to 7 mm in diameter.

**Robotics**

In 1994, the first U.S. Food and Drug Administration-approved robotic surgical device called AESOP (Automatic Endoscopic System for Optimal Positioning, Computer Motion, Inc.) was introduced. With this system, the surgeon can control the orientation of the laparoscope through voice commands. The da Vinci Robotic Surgical System (Intuitive Surgical) and Zeus Robotic Surgical System (Computer Motion) allow the surgeon to operate from a remote station with hand controls that can provide increased dexterity and minimize fatigue, tremors, or incidental hand movement. These systems are being used in surgical centers but have not gained universal adoption because of technical training and cost limitations. The optimal application for these devices is continuing to be defined.

**POSITIONING THE PATIENT FOR LAPAROSCOPIC SURGERY**

The patient should be placed on the operating table in the low lithotomy position with the buttocks at or slightly over the table's edge to allow placement and use of an intravenous manipulator and to have access to the perineum if needed during surgery. The patient's thighs should be bent and elevated above the plane of the abdominal wall, it is difficult to gain access to the upper abdomen and pelvic brim without bumping into the legs because of the fulcrum effect of instruments placed into lower ports. Stirrups should have ample padding to support the lower leg without creating pressure points. Particular attention should be given to preventing injury to the perineal nerve, which is especially vulnerable to compression injury. It is preferable to use a stirrup that can be elevated without undraping the patient so that a high lithotomy position can be used for intraabdominal pressure can be viewed. Insufflation tubing, light cords, electrosurgical cords, and suction-irrigation tubing should be out of the patient's path with suction tubing if necessary. Knowledgeable operating room personnel are likewise critical to the laparoscopic mission. The scrub technician usually stands caudad to the surgical assistant. A circulating technician assists in troubleshooting equipment and obtaining supplies and equipment.

**ENTERING THE ABDOMINAL CAVITY**

The abdominal cavity may be initially entered at the umbilicus or alternative sites by Veres needle, open laparoscopy, or direct trocar insertion.

**Umbilical Site Veres Needle Technique**

When the umbilical site and Veres needle technique is used, the Veres needle is first placed into the abdominal cavity to establish a pneumoperitoneum, and a trocar is subsequently placed into the pneumoperitoneum. A metaanalysis of methods used to establish pneumoperitoneum compared open access (Hasson-type) with closed access (needle/trocar), and two types of closed access techniques (direct trocar versus needle/trocar). It was noted that deaths were only reported in the needle/trocar group. However, because of the rarity of death as an outcome, the statistical risk could not be compared meaningfully. The metaanalysis was underpowered to adequately compare the two closed techniques. Therefore, the question of which technique for initial port placement is safest has not been definitively answered to date.

A scalpel is used to make a small skin incision in accordance with the size of the trocar to be placed at the umbilicus. The umbilicus should be elevated and the scalpel held parallel to the long axis of the patient to avoid incidentally lacerating the great vessels, which lie in close proximity to the umbilicus. Having the anesthesiologist decompress the stomach with a nasogastric tube will decrease the risk of inserting the Veres needle or trocar into an overdistended stomach. The patient's abdomen should be relaxed by neuromuscular blockade if general anesthesia is being used to allow adequate elevation for Veres needle and trocar insertion. The patient should be lying in a flat or neutral position on the operating table because the use of Trendelenburg positioning may cause the trajectory of the Veres needle or trocar to be closer to the great vessels rather than the pelvic cavity. In the thin patient, the Veres needle or trocar may be inserted ventrally (90 degrees to the long axis of the patient); as long as the abdominal wall has been elevated adequately (Fig. 17.14). Placing the Veres needle close to the base of the umbilicus takes advantage of the thin natural confluence of tissue planes at the umbilicus. Separate clicks can be heard or felt as the needle traverses the rectus fascia and then peritoneum.
Correct placement of the Veres needle into the abdominal cavity can be assessed by several techniques. The hanging drop technique is used by placing a small amount of sterile saline in the top of the Veres needle to verify a negative intraabdominal pressure as it descends into the abdominal cavity. Alternatively, the syringe barrel test can be performed by watching the column of saline descend the barrel of a syringe attached to the Veres needle. Aspiration of a syringe attached to the Veres needle can test for blood or gastrointestinal contents. Low-flow insufflation should be performed at a flow rate of approximately 1 L/min until further signs of intraabdominal needle placement are confirmed, such as low intraabdominal pressure (<10 mm Hg) or loss of dullness to percussion over the right upper quadrant. If the “intraabdominal” pressure reading is higher than 10 mm Hg, the probability of extraperitoneal insufflation is high, and the approach should be reassessed. A prospective, observational study of four tests to ascertain Veres needle placement compared the double click test, the hanging drop test, the aspiration test, and the initial five insufflation pressures in 345 women. High insufflation pressures were the most sensitive for preperitoneal insufflation. High-flow insufflation may be used in the presence of reassuring signs of correct needle placement. During insufflation, intraabdominal pressures should not exceed 20 to 25 mm Hg to avoid interfering with diaphragmatic excursion and central venous return from caval compression. After an adequate pneumoperitoneum has been established, ranging from 1 to 5 liters depending on body habitus, a trocar is inserted at the umbilicus, paying attention to the angle of insertion based on body habitus, as discussed. Once the trocar is placed, the bladed or central portion is removed, and the laparoscope is placed through the trocar sleeve to ensure correct placement before attaching the insufflation tubing to the trocar sleeve.

Alternates to Umbilical Entry

When Veres needle insufflation is not successful, or in patients who are at risk for adhesions near the umbilicus, placing the Veres needle at a site other than the umbilicus is usually successful. Two commonly used sites are Palmer’s point and the left ninth intercostal space. Palmer’s point is located 3 cm from the midline and 3 cm below the left rib cage. The needle is directed 15 degrees cephalad after the skin has been stretched caudally. If the ninth intercostal space is used, the Veres needle should be placed between the ninth and tenth rib, grazing the top of the tenth rib. This grazing minimizes the risk of damaging the intercostal neurovascular bundle. The rib cage provides a natural elevation of a space devoid of bowel regardless of patient weight. There is a remote chance of pneumothorax with this technique. Before performing either of these techniques, palpation for splenomegaly should be performed. After Veres needle placement, a 5-mm trocar is usually placed at Palmer’s point.

Open Laparoscopy

Hasson described the technique of open laparoscopy in 1971 as a way of avoiding blind trocar placement. A small incision is made at the umbilicus. Allis clamps are used to grasp the fascia, which is incised, and the peritoneum is entered directly. A Hasson-type cannula is used that can be anchored to sutures in the rectus fascia. In a review of more than 5,000 cases over nearly three decades, this technique has been shown to be associated with a low complication rate.

Direct Trocar Insertion

Direct trocar placement has also been described by placing the trocar through the umbilicus initially, rather than using the Veres needle.

SECONDARY TROCAR PLACEMENT

One or two secondary ports are usually adequate for most laparoscopic procedures. More complicated surgeries may require up to five. These may be placed lateral to the inferior epigastric artery or in the midline above the bladder. The size and number of trocars will depend on the procedure and equipment to be used. A 2- to 5-mm trocar is usually used for diagnostic laparoscopy to maneuver pelvic organs for adequate visualization. Most instruments for tissue manipulation will fit through a 3-mm port. Some energy delivery systems and tissue retrieval systems require the use of larger ports (8 to 15 mm). Anticipating the need for larger ports can lead to significant cost savings when disposable trocars are used.
The placement of lateral trocars can be associated with injury to the inferior epigastric artery. Before lateral trocar placement, this vessel can usually be seen along the anterior abdominal wall as it branches off the external iliac artery. Insertion of a spinal needle through the anterior abdominal wall at the intended site of trocar insertion can help find a safe trajectory away from the inferior epigastric artery. If the vessel cannot be seen, a safe location can usually be found by measuring 3 cm superior to the pubic symphysis and 8 cm lateral. Secondary trocars should be inserted in a controlled fashion, under direct vision. Placement of suprapubic secondary trocars should be placed well above the bladder. Two finger breadths measured above the pubic symphysis has been standard terminology for midline trocar placement. Because of the significant differences in finger widths among surgeons, and considering the increased risk of bladder injury using the suprapubic location, it is also worth placing a spinal needle through the anterior abdominal wall in the midline to ensure that the port is well above the bladder. If the patient has had a prior laparotomy, the bladder may be tethered superiorly, and it may be necessary to place the trocar higher.

Tissue Removal

Small tissue fragments, such as peritoneal biopsy specimens, may be removed through 5-mm trocar sleeves. Large, dense specimens, such as leiomyoma fragments, require larger ports (10 to 15 mm). Fluid-filled specimens, such as ovarian cysts, may be placed in a plastic specimen removal bag (Fig. 17.15). Fluid is drained while in the bag to avoid spillage (Endocatch, U.S. Surgical Corp., Endopouch, Ethicon Inc.). Posterior colpotomy can also be performed for specimen removal. Colpotomy may be performed vaginally, as one would when performing vaginal hysterectomy or laparoscopically. Laparoscopic colpotomy is performed by first inserting a lubricated sponge stick into the posterior vaginal fornix for cul-de-sac elevation. An incision is then made between the uterosacral ligaments into the posterior vaginal fornix, using the sponge stick as a backstop. Laser, unipolar scissors, or the Harmonic Scalpel may be used as an energy source. An endoscopic specimen bag may be removed through the colpotomy incision. A wet lap pad may be placed vaginally to allow optimal pneumoperitoneum for laparoscopic closure of the colpotomy, or the colpotomy may be closed vaginally. Alternatively, morcellation may be performed with a handheld morcellator or an electromechanical morcellator (Fig. 17.16). For safety reasons, it is important that the tip of the morcellator be in view at all times. Keeping the cutting tip elevated and parallel with the abdominal wall adds to visualization and decreases the risk of inadvertently injuring bowel and other vital structures, as severe injuries have been reported, including injury to the pancreas. The specimen should be drawn up into the morcellator rather than pushing the morcellator into the specimen.

Diagnostic Laparoscopy

A systematic approach to diagnostic laparoscopy, like checklists for pilots, can help ensure thoroughness in what is regarded as a routine surgery. After insertion of the laparoscope, the abdomen should be carefully examined, particularly the area in the trajectory of the Veres needle or trocar, to ensure that inadvertent bowel or vascular damage was not caused.
Pelvic adhesions have been associated with infertility and chronic pelvic pain. It should be noted that chronic pelvic pain is often a complex condition, and in the absence of gastrointestinal obstructive symptoms, adhesiolysis is usually not curative of pain. To better understand the nature of symptomatic adhesion, pain mapping under conscious sedation may be a useful technique. In performing adhesiolysis, optimal results depend on the use of microsurgical technique, gentle tissue handling, and meticulous hemostasis with minimal tissue fulguration. Adhesiolysis can be performed by a number of techniques, including blunt and sharp dissection, electrodissection, aquadissection, and laser dissection.

**Aquadissection** can be used to free adhesions from the pelvic sidewall to avoid injury to ureter or the great vessels. It is also a useful technique in removing endometriotic nodules. With this technique, the peritoneum is grasped, and an incision is made large enough to place the tip of a powered suction-irrigation device. Irrigation is used to force fluid under the peritoneum, causing it to balloon out from deeper tissues. The adhesion or peritoneum can then be dissected free.

**Laser dissection** has been used in laparoscopy with great success as a result of minimal lateral thermal spread compared with most forms of electrosurgery. However, it should be noted that this form of energy is indeed still an energy source and obtains hemostasis through lateral thermal spread. The small spot size of laser makes this a useful tool for precision adhesiolysis. The CO₂ laser has a depth of penetration to 0.1 mm and is excellent for cutting. With the adhesion on tension, the CO₂ laser is introduced through the operating channel of the laparoscope or through a secondary port.

Ureter

FIGURE 17.17. Pelvic sidewall dissection. The peritoneum has been incised so that the retroperitoneal structures can be visualized.

The Harmonic Scalpel is used with a technique similar to both bipolar dissection (laparoscopic coagulating shears and Harmonic ACE) and monopolar dissection (scalpel tip), depending on which tip is used. This technique does not use electrosurgery. These have the advantage of limited lateral thermal spread, similar to the newer bipolar electrosurgical instruments.

Sidewall and Retroperitoneal Space Dissection

It is often necessary to identify the course of ureter and iliac vessel in cases of pelvic sidewall adhesions or endometriosis. If the ureter is able to be identified at the pelvic brim but then is obscured by adhesions, endometriosis, or an ovarian mass along its caudal course, the peritoneum overlying the sidewall can be grasped and opened with scissors (Fig. 17.17). A Maryland dissector can be used to gently spread the peritoneum to view the ureter. If the anatomy is distorted, it may be necessary to start the dissection at the pelvic brim or by opening the round ligament. If the round ligament is to be opened, it should be divided with an energy source as lateral as possible, and a blunt grasper can be used to dissect the retroperitoneal space, watching for the ureter on the medial leaf of the broad ligament and avoiding the iliac vessels. Developing the pararectal space can help to define anatomic landmarks to avoid inadvertent vascular or ureteral injury. Once the ureter and uterine artery are located, adhesions can be lysed with an energy system of the surgeon’s choice.

Posterior Cul-de-sac Dissection

When endometriosis or pelvic adhesions partially or completely obliterate the posterior cul-de-sac and are associated with pelvic pain or infertility, a surgical approach is usually indicated. Cul-de-sac obliteration secondary to endometriosis often involves deep fibrotic endometriosis that may involve the rectum, rectovaginal septum, or uterosacral ligaments. Dissection of the posterior cul-de-sac may be necessary and can be performed laparoscopically by skilled surgeons. The goal is to lyse adhesions, excise large or deep endometriotic lesions, and resect or vaporize small superficial lesions.

The patient should undergo a bowel prep before surgery. A uterine manipulator is used to antever the uterus, and a rectal probe is placed in the rectum to delineate and retract the rectum posteriorly. A sponge stick placed in the vagina can further delineate the rectum from the vagina (Fig. 17.18). The anterior rectum is carefully dissected from the posterior aspect of the uterus or vagina with scissors, laser, harmonic scalpel, or tissue-controlled bipolar energy system. The use of monopolar and traditional bipolar energy can result in significant thermal injury to the rectum. Aquadissection may also be useful. Dissection should continue until the loose areolar tissue of the rectovaginal space is reached. If a ureter is near the site of dissection, the position of the ureter should be confirmed before any dissection takes place. The fibrotic endometriosis can then be excised from the posterior vagina or uterosacral ligaments. If endometriosis extends to the vaginal mucosa, this is excised, and the posterior vagina is closed vaginally or laparoscopically. Palpation of the endometriotic nodule before and after removal is helpful to ensure complete excision.

Uterus anteverted
Sponge stick in posterior fornix

FIGURE 17.18. Dissection of the posterior cul-de-sac. Instruments in the uterus, posterior fornix of the vagina, and rectum help define the anatomy.
Oophorectomy and Salpingo-oophorectomy

Several techniques for laparoscopic oophorectomy or salpingo-oophorectomy have been described. One procedure involves the placement of three loop ligatures around the ovary and adnexa. Before placement of the loops, the structures must be free of adhesions. Incisions in the mesosalpinx are sometimes necessary to facilitate placement. The ovary or adnexa is cut distal to the three loops. Small bleeding points can be coagulated on the stump, but care must be taken not to coagulate the sutures.

Alternatively, the peritoneum is opened, and the ureter is identified (Fig. 17.19A,B). Lactated Ringer solution or saline can be injected into the retroperitoneal space to push the ureter away from the site of coagulation and increase the margin of safety. The uteroovarian ligament is coagulated or sealed with bipolar energy or ultrasonic energy and transected, and the infundibulopelvic ligament is then coagulated or sealed and transected. Pedicles are examined for hemostasis, and the ovary is removed by one of the described methods of tissue removal. If the fallopian tube is to be removed with the ovary, the proximal fallopian tube and uteroovarian ligament are coagulated or sealed before transection (Fig. 17.20A–C). After transection of the infundibulopelvic ligament, the mesosalpinx is coagulated or sealed and cut in the same manner that is used for salpingectomy. Laparoscopic stapling devices can also be used on the pedicles, but care must be used to avoid the ureter.

LAPAROSCOPIC MYOMECTOMY

Laparoscopic myomectomy is a heterogeneous procedure that can range from a simple procedure to one of the more difficult laparoscopic surgeries requiring expert laparoscopic suturing skills. For example, large pedunculated fibroids (8–10 cm) can be detached in a few minutes. Large intramural fibroids may take several hours to remove and repair in the hands of expert laparoscopic surgeons. Two case-control studies comparing open with laparoscopic myomectomy have both demonstrated significantly longer mean operating room time and shorter hospital stays with the laparoscopic group. The use of a preoperative gonadotropin-releasing hormone (GnRH) agonist may be considered in patients who are anemic. A prospective randomized study using leuprolide acetate in patients undergoing laparoscopic myomectomy also demonstrated significantly lower blood loss and operative times in the treatment group. The authors of this study noted increased operative time in the subset of markedly hypoechoic fibroids because of increased fibroid softness. Other studies have shown longer operative times and a higher conversion to laparotomy rate associated with the use of GnRH agonists in laparoscopic myomectomy because of difficult cleavage planes.

Pedunculated myomas can be resected by coagulating and transecting the base (Fig. 17.21). Morcellation can be performed with a hand morcellator or an electric morcellator, or alternatively, a posterior colpotomy may be performed to tissue extraction. It is best to avoid losing myoma pieces that become detached, as there have been reports of specimens becoming infected or continuing to grow at the trocar incision site and elsewhere in the pelvic cavity. However, loss of tissue is not necessarily an indication for laparotomy, as a case series of 12 retained specimens, three of which were myomas, resulted in no sequelae with 2-year follow-up. In the case of pedunculated myomas, the defect is not typically sutured.

Intramural and subserosal fibroids require an incision to be made with scissors, laser, needle electrode, or Harmonic Scalpel. Before incising the uterine serosa, it is possible to inject hemostatic agents into the serosa and myoma. A dilute vasopressin solution or bupivacaine plus epinephrine may be injected transabdominally into the myometrium through a spinal needle. A randomized placebo-controlled trial demonstrated significantly lower blood loss, total operative and
enucleation time, and degree of surgical difficulty associated with bupivacaine plus epinephrine compared with saline. When the whorled white appearance of the myoma is seen, the edges of the uterine serosa are held open with atraumatic graspers, and a corkscrew retractor is screwed into the myoma. Using upward traction with the corkscrew retractor, the myoma is peeled away from the uterine corpus (Fig. 17.22). Hemostasis is achieved with electrosurgery or Harmonic Scalpel. The defect is sutured closed in two or three layers, depending on the depth of the defect, using a delayed absorbable suture as described previously. Another option is to perform uterine closure through a minilaparotomy if the fundus or area to be sutured is able to be delivered through a small incision. Uterine rupture has been reported in patients undergoing laparoscopic myomectomy, and pregnancy should be monitored with the same caution given to patients who have undergone abdominal myomectomy. It is not known whether laparoscopic repairs are equivalent to repair by laparotomy.

LAPAROSCOPY USING LOCAL ANESTHESIA OR CONSCIOUS SEDATION

Laparoscopy can be performed under conscious sedation in the operating room or in a nonhospital environment, such as physician’s office, using conscious sedation or local anesthesia without the assistance of an anesthesiologist. Microlaparoscopy is often used with 2- or 3-mm instrumentation. Local anesthesia and conscious sedation has long been used to perform tubal ligation. The use of microlaparoscopic instrumentation has assisted in performing laparoscopy under conscious sedation in the office setting for pain mapping in chronic pelvic pain patients. Pain mapping may be useful in patients with chronic pelvic pain of uncertain etiology, as this enables the patient to participate in the evaluation of the pelvis while searching...
for a painful focus and to decipher between incidental versus painful adhesions and endometriosis. If conscious sedation is to be performed in the office without the presence of an anesthesiologist, it is important to follow state guidelines for conscious sedation. The American College of Surgeons has developed guidelines that have been endorsed by the American College of Obstetricians and Gynecologists that detail requirements for resuscitation and an optimally safe environment.

Laparoscopy under conscious sedation is usually performed combining local anesthesia and intravenous sedation. Proper patient selection is important, as patients must be able to withstand lifting the abdomen at the umbilicus for trocar insertion and tolerate local infiltration at the umbilicus. The umbilicus is infiltrated at the skin and then down through the fascia with a 25-gauge needle while elevating the umbilicus, using approximately 10 mL of 1% lidocaine or 0.25% bupivacaine. If conscious sedation is used, short-acting narcotics, such as remifentanil, are ideal if pain mapping is to be performed such that the patient is awake and able to respond to intraperitoneal stimuli. If tubal sterilization is to be performed, an anxiolytic drug such as midazolam is useful.

**COMPLICATIONS**

**Nerve Injury**

Most nerve injuries occurring during laparoscopic surgery are neurapraxia or nerve contusion and will usually resolve within 6 weeks. Neurotmesis, or complete division of the nerve, is the most severe form of nerve injury, often resulting in permanent disability. Proper preoperative and intraoperative patient positioning—as well as a knowledge of known risk factors associated with mononeuropathies—is an important part of providing a safe environment for laparoscopic surgery. Femoral neuropathy occurring during laparoscopy can be associated with excessive hip flexion or abduction, or long operating times. When lithotomy positioning is used in patients undergoing vaginal or laparoscopic surgery, the thigh should be flexed no greater than 90 degrees and abducted no greater than 45 degrees. If a patient’s position is changed intraoperatively from low lithotomy to high lithotomy, these relationships should be maintained. Obturator neuropathy is most commonly associated with direct injury during radical pelvic surgery or lymphadenectomy, but it can also occur as a result of excessive hip flexion. The mechanism whereby excessive hip flexion can cause obturator nerve injury is anatomic. As the obturator nerve leaves the obturator foramen, it lies directly against bone and can become acutely angulated and deformed if the hips are excessively flexed, particularly during prolonged surgery. The obturator neurovascular bundle is also vulnerable during...
laporoscopic retropubic dissection, particularly during the paravesical repair of lateral defects of the anterior vaginal wall. Surgeons who operate in these spaces should be well versed in the anatomy of the obturator nerve. The ilioinguinal and iliohypogastric nerves can be injured from lateral trocar use with subsequent suture ligation and fibrinocoagulation. Care should be taken to avoid extreme lateral trocar placement; however, there is no absolute consensus as to the maximum lateral trocar placement, and injury can not always be avoided. Sciatic neuropathy during laparoscopic surgery can be a result of tension caused by nerve stretching. Injury to the sciatic nerve has been reported in procedures lasting as short as 35 minutes in free-hanging limbs. The peroneal division of the sciatic nerve is under the least amount of tension when the knee and hip are flexed, as the nerve is fixed at the sacrosciatic notch and the fibular head. Tension along the nerve is increased with hip flexion when the knee joint becomes straightened or externally rotated. Patients at increased risk of sustaining sciatic nerve injury are long-legged, obese, or short in stature. In hanging-type stirrups, long-legged or obese patients have a tendency for external hip rotation, and shorter patients have less flexion at the knee. In such cases, stirrups that support the ankle and calf may be more appropriate.

**Vascular Injuries**

Of all the injuries associated with laparoscopy, vascular injuries are the most acutely life threatening, particularly in the case of injury to the aorta, vena cava, or iliac vessels. Injury can occur during Veres needle placement, trocar insertion, or during tissue dissection. Injury to the great vessels requires immediate laparotomy, manual compression, repair, and usually transfusion. Injury to smaller vessels can usually be rendered hemostatic with the use of bipolar electrosurgery, hemostatic clips, or laparoscopic suturing techniques. Injury to the inferior epigastric arteries can occur during placement of the lateral trocar. The inferior epigastric artery can usually be seen before lateral trocar placement as it branches off the external iliac artery running cephalad along the abdominal wall peritoneum. If it is injured, a bipolar forceps can be placed through the contralateral port in an attempt to coagulate. Alternatively, several endoscopic fascial closure devices are now available that allow a suture to be passed through the fascia and peritoneum that can result in vascular occlusion. Hemostasis can usually be immediately achieved by placing a 30-cc Foley catheter through the trocar site with the aid of an 8-inch clamp and inflating the balloon for tamponade. This injury can also be managed by enlarging the trocar site by a few centimeters to visualize, clamp, and ligate the bleeding vessel.

**Gastrointestinal Injury**

Gastrointestinal injury is the most lethal injury associated with laparoscopy, with a mortality rate reported as high as 3.6%. Injury may occur from Veres needle placement, trocar insertion, adhesiolysis, tissue dissection, devascularization injury, or thermal injury. As a general rule, Veres needle injury needs no repair as long as the puncture is not associated with bleeding or a subsequent rent from additional tissue manipulation. In the case of colonic puncture without tearing, nonoperative management with antibiotics, copious irrigation, and suction has been suggested. Transluminal bowel injuries are usually managed with an interrupted layer of 3-0 interrupted silk suture placed perpendicular to the long axis of the intestine to avoid stricture formation. This is usually performed by laparotomy or by minilaparotomy at the umbilical site, where the injured bowel loop is pulled through to the skin surface and repaired. Laparoscopic repair has also been reported as effective by surgeons with advanced gastrointestinal surgical skills. If the laceration to the small bowel exceeds one half of the luminal diameter, segmental resection is recommended.

Trocar injury to the colon is reported to occur with a frequency of approximately 1 per 1,000 cases. Undetected injury to the large intestine can be associated with significant morbidity compared with injury to the small intestine and stomach because of the high concentration of coliform bacteria in the large intestine. Therefore, if injury to the colon is suspected, the area should be inspected carefully using atraumatic bowel graspers, or laparotomy may be performed. The management of large intestinal injuries depends on size, site, and length of time from injury to diagnosis. In general, once the diagnosis of colonic injury is made, broad-spectrum antibiotics should be administered, and consultation should be sought with a surgeon who has experience with bowel injury. In the case of a small rent with minimal soilage, the defect can be closed in two layers with copious irrigation. When a larger injury has occurred and the bowel has not been prepared with a mechanical or antibiotic regimen, or when the injury involves the intestinal mesentery, a diverting colostomy is usually necessary. In the case of delayed (postoperative) diagnosis, a diverting colostomy should be performed. If injury to the rectosigmoid colon is suspected, filling the posterior cul-de-sac with normal saline and performing proctosigmoidoscopy, or injecting air into the rectum through a catheter-tipped bulb syringe and looking laparoscopically for bubbles, may aid in detection (flat tire test).

Thermal injuries are histologically different from traumatic injuries and therefore must be treated differently. Thermal bowel injuries can be differentiated histologically from traumatic injury by the presence of thermal necrosis and the absence of capillary ingrowth and white cell infiltrate in the former. Because of this coagulation necrosis, thermal injuries require wide resection even though the bowel may still have a
normal appearance adjacent to the injury, as it may take days for the extent of the injury to become apparent.

**Trocar Site Hernia**

In a retrospective review of more than 3,500 laparoscopies in 199 hospitals in France, trocar site hernias were reported to be 0.17%. The fascia should be closed in trocar sites that are 10 mm and larger. Although there are case reports of hernia occurring at 5-mm trocar sites, closing 5-mm trocar sites usually requires enlarging the skin incision or using laparoscopic fascial closure devices, which may not be warranted in this rare possibility. Closing the fascia may not entirely prevent hernia formation. A survey of more than 3,200 gynecologists noted that 18% of hernias occurred despite fascial closure and appeared to be related to the number of laparoscopies performed rather than the length of the surgeon's career. Trocar site hernias can present as occult or incarcerated hernias. A defect is usually palpable over the trocar site incision with Valsalva, or a mass can be seen. If the patient presents with signs of bowel obstruction, the bowel must be inspected carefully, and if there is evidence of necrosis or vascular compromise, the bowel should be resected.

**Urinary Tract Injury**

Bladder injury during laparoscopy is estimated to occur 1 in 300 cases. Higher injury rates have been reported with laparoscopic hysterectomy and bladder neck suspension. Risk factors for bladder injury include a distended bladder during suprapubic trocar insertion; previous surgery causing distortion to bladder anatomy, causing it to be pulled cephalad with the parietal peritoneum; and endometriosis obliterating the anterior cul-de-sac. Inserting a Foley catheter into the bladder before trocar placement and using lateral trocar sites will lessen the risk of bladder injury. In cases when a midline, suprapubic trocar is used, and the superior aspect of the bladder cannot be deciphered, filling the bladder with 300 mL of water or saline through a Foley catheter will define the bladder margins. Intraoperative signs of bladder injury include clear fluid in the operative field, visible bladder laceration, and gas distention of the Foley bag. To adequately make the diagnosis, the bladder wall can be inspected directly, or methylene blue or indigo carmine, diluted with 200 to 300 mL of sterile normal saline, may be instilled retrograde through the Foley catheter. Intentional cystotomy or cystoscopy may be performed for inspection in the case of doubt and to inspect the extent of the injury to ensure that there is no ureretic involvement. Recommendations for repair of bladder injuries have been reviewed in a consensus statement of the International Society of Urology (Société Internationale d’Urologie). In the acute setting, bladder injuries can be treated with catheter drainage alone if the injury is small, uncomplicated, and isolated. A cystogram should be performed on the 10th day of drainage, and more than 85% of bladder injuries will be healed. A surgical repair should be performed if the Foley catheter is unable to provide adequate drainage because of blood clots or persistent extravasation, or if there is concomitant injury to the urethra or ureter. Cystotomy closure should be performed using a watertight, multilayered repair with absorbable suture. Laparoscopic repair should be performed in the case of a small injury with adequate surgical expertise and adequate exposure, as long as the ureters and bladder neck are not compromised.

According to a nationwide Finnish record linkage study, although the overall complication rates for laparoscopy are decreasing, the rate of ureteral injury has remained steady at 1%, with the greatest risk associated with laparoscopic hysterectomy. A review of the world literature through 2003 concluded that laparoscopically assisted vaginal hysterectomy was the most frequently performed surgery associated with ureteral injury. The usual time to diagnosis in postoperative patients with ureteral injury is typically between 2 and 7 days but has been reported as late as 33 days after surgery. Patients often present with symptoms of abdominal pain, fever, hematuria, flank pain, or peritonitis. Leukocytosis is a common finding. Management of ureteral injury should be undertaken in collaboration with a surgeon trained in ureteral injury repair. In the majority of cases, percutaneous or cystoscopic stenting techniques can be used. Laparotomy is usually performed for end-to-end anastomosis or reimplantation of the ureter into the bladder, but in experienced hands, repair may be performed laparoscopically. The literature is growing in favor of intraoperative diagnostic cystoscopy after complex vaginal, laparoscopic, and abdominal pelvic surgery in an effort to avoid delayed diagnosis of injuries to the urinary tract. It appears that cases in which the diagnosis is delayed are most likely to result in the greatest morbidity and legal repercussions.

**CONCLUSION**

Laparoscopy has become a mainstay of gynecologic surgery. Laparoscopic technology continues to evolve, requiring continuing education and research. The main benefits of laparoscopic surgery have been shorter hospitalization, improved cosmesis, and, in some cases, improved safety and cost. Evidence-based surgical studies are difficult to perform but will be required to fully understand the role of each laparoscopic procedure in terms of long-term outcomes and cost.

**BEST SURGICAL PRACTICES**

- A good laparoscopic surgeon should know his or her limitations and not hesitate to call for help.
- Conversion to laparotomy is not considered failure.
- Careful selection of patients is the first key to success in any surgery.
- Preparation is essential in laparoscopic surgery and may include a “pilots checklist” and/or “dress rehearsal” to avoid being caught with too few or wrong-size trocar ports.
- “Shortcuts” modifying a surgical procedure in an effort to facilitate one’s laparoscopic abilities “change” the procedure. Once the surgical technique has been changed, success rates obtained from literature or prior experience can not be attributed to the new procedure.
- Careful positioning of the patient can help avoid nerve injuries.
- Traction-countertraction and exposure are important in open and laparoscopic surgery. To maximize these, an additional trocar port is often helpful.
- Consider intraoperative cystoscopy with indigo carmine in complex pelvic surgery.
- Understand your energy source—e.g., monopolar, harmonic.
Bibliography

CHAPTER 18 ■ OPERATIVE HYSTEROSCOPY

MICHAEL S. BAGGISH

DEFINITIONS

Hysteroscopy—Direct visual inspection of the cervical canal and uterine cavity through a rigid, flexible, or contact hysteroscope.

Index of refraction—The bending of light caused by the ratio of its velocity in room air to its velocity within an optical fiber.

Resectoscope—A specialized electrosurgical endoscope that consists of an inner and outer sheath equipped with a 30° telescope. The inner sheath has a common channel for the telescope fluid medium and electrode.

Uterine synechiae—Adhesions that form between the anterior and posterior walls of the uterus as a result of trauma or infection in a milieu of estrogen deprivation.

INTRODUCTION

Hysteroscopy has become a standard part of the gynecologic surgeon's armamentarium and is now routinely taught as part of residency training curriculums and postgraduate seminars. As gynecologists have grown better acquainted with the benefits and techniques of operative hysteroscopy, and as hysteroscopy increasingly has become the method of choice for treatment of intrauterine pathology, the number of complications has also risen. Most of these complications are caused by operator error and inexperience.

Hysteroscopic procedures were first described by Panteleoni in 1869, but the technique did not excite substantial interest within the specialty until the late 1970s. There has been concern that hysteroscopy performed as a routine office procedure to diagnose the causes of abnormal uterine bleeding might spread undiagnosed endometrial carcinoma transtubally. The most vocal opponents of hysteroscopy have continued to perform dilatation and curettage (D&C) rather than hysteroscopy to diagnose the causes of abnormal uterine bleeding. The preceding are not taught within the specialty until the late 1970s. There has been concern that hysteroscopy performed as a routine office procedure to diagnose the causes of abnormal uterine bleeding might spread undiagnosed endometrial carcinoma transtubally. The most vocal opponents of hysteroscopy have continued to perform dilatation and curettage (D&C) rather than hysteroscopy to diagnose the causes of abnormal uterine bleeding.

The advantages of hysteroscopy as an accurate diagnostic technique are that it not only allows direct visual observation and accurate localization of pathology but also provides a means to sample the site most likely to yield positive results. During the 1980s, 1990s, and early 2000s, gynecology has shifted heavily toward endoscopy as a specialty.

The philosophy of least-invasive surgery is driven by the positive outcomes of shortened hospital stays and diminished recovery times and by good performance in a competitive free-market environment. Operative hysteroscopy has, in many instances, superseded even laparoscopy in meeting these strategic criteria. Hysteroscopy generally is a low-risk technique that uses the endocervical canal, the natural passageway of the body, to gain entry into the intrauterine environment. Refinements of optical and fiber-optic light instrumentation and of operative accessories allows high-resolution and excellent visual documentation by hysteroscopy, and tremendous advances still are being made. Nonhysteroscopic techniques to treat intrauterine septa and adhesions are obsolete. Ablation or resection of the endometrium is considered an acceptable alternative to hysterectomy for the management of abnormal uterine bleeding.

Submucous myomata no longer require hysterectomy because they can be satisfactorily managed conservatively by operative hysteroscopy. Cornual and interstitial tubal obstruction also are now managed hysteroscopically. Office-based, low-skilled techniques for rapidly managing abnormal uterine bleeding by means of thermal catheters are now a reality. Hysteroscopy in the 21st century has finally found its proper niche, and every gynecologist is required to learn the skills of hysteroscopy, just as every urologist surely must be an accomplished cystoscopist.

Learning how to perform an adequate hysteroscopy and then becoming competent to do hysteroscopic surgery are practice, skill-related techniques. Older methods of acquiring endoscopic skills focused on course attendance, preceptorship, and practice. During the late 1990s and continuing to the present time, simulators have been developed to facilitate hand-eye coordination exercises. Several of the computer-based models with advanced interactive graphics provide sophisticated models for the student to shave myomata, ablate endometrium, and pass cannulas into tubal ostia (Fig. 18.1A). However, the most basic skill levels a hysteroscopist must attain are the ability to insert the scope safely into the uterine cavity followed by satisfactory distension of the cavity to obtain clear visualization of that cavity. The preceding are not taught by simulation and must be learned in vivo. Without this skill set, hysteroscopy cannot be successfully performed.

INSTRUMENTATION

Telescopes

The 4-mm telescope (lens) gives the sharpest, clearest image in addition to a small outside diameter (Fig. 18.1B). The most desirable optics provide a large field that subdends an angle of approximately 105° degrees (Fig. 18.1C). However, 3-mm diameter telescopes, which have greatly improved optics, provide comparable views. These contemporary 3-mm diameter telescopes coupled to endoscopic video systems with zoom lenses are highly satisfactory for office hysteroscopy, as well as for operative hysteroscopy. Telescopes are usually available with a 0-degree straight-on or a 30-degree fore-oblique view.
Operative Hysteroscopy

(Fig. 18.1D). The major advantage of the 0-degree lens is that it allows the operator to see operative devices as a relatively distant panorama, whereas this view is lost when 30-degree lens is used. The telescope has three parts: the eyepiece, the barrel, and the objective lens (Fig. 18.1E). Surrounding the optics are numerous small-diameter incoherent fiber-optic bundles that provide intense cold illumination to the operative field. Although a few manufacturers provide focusing telescopes that permit contact hysteroscopy, the standard telescope has fixed optics. The contact hysteroscope is a highly specialized device used largely in research settings. Although magnifying hysteroscopes reached a peak of popularity in the 1980s, their full practical value has not been realized.

Light Generators

The quality and power of light delivered to the telescope depend on the wattage and characteristics of the remote light generator and the type and structural integrity of the connecting fiber-optic light cable. Three general types of light generators are available: tungsten, metal halide, and xenon. The simplest and cheapest generator is the tungsten generator, which produces an orange-yellow light; the xenon white light is a powerful generator that provides the best shower for video imaging (Fig. 18.2A). The xenon light generator is well worth the additional cost because of its superior color and intensity (Fig. 18.2B–D). Fiber-optic light cables must be intact to convey the optimal light from the generator to the telescope. Broken fibers can be easily identified by viewing the stretched-out cable against a dark background and looking for light emitting through the sides of the cable. The liquid cable conducts light effectively

Diagnostic and Operative Sheaths

A diagnostic sheath is required to deliver the distending medium into the uterine cavity. The telescope fits into the sheath and is secured by means of a watertight seal that locks into place. The sheath is 4 to 5 mm in diameter, depending on the outer diameter of the telescope, with a 3-mm clearance between the inner wall and the telescope, through which either carbon dioxide or liquid distending medium is transmitted (Fig. 18.1C). Medium instillation into the sheath is controlled by means of an external stopcock. Even the 5-mm instrument allows easy access through the narrow endocervical canal past the point of maximal constriction (i.e., the internal os). Therefore, diagnostic hysteroscopy usually can be performed without cervical canal dilatation. If the hysteroscope is inserted into the canal under direct vision (as it should be), and if the axis of the cervical and uterine canal are carefully followed until the corpus is reached, there should be no risk of perforation. Imprecise or loose coupling between the telescope and sheath will result in leakage of the medium at that interface.

Operative sheaths have a larger diameter than do diagnostic sheaths (Fig. 18.3A–C). They range in size from 7 to 10 mm and average 8 mm in diameter. The operative sheath allows space for instillation of the medium, for the 3- to 4-mm telescope, and for the insertion of operating devices. The operating channel is sealed with a rubber nipple or gasket to prevent leakage of the distending medium. The standard operating sheath consists of a single common cavity shared by the medium, telescope, and

![FIGURE 18.1. A: Computerized simulation permits the gynecologist to interact by manipulating a resectoscope and resecting a virtual submucous myoma. (From Baggish MS, Velle RF, Gaedel H. Hysteroscopy: visual perspectives of uterine anatomy, physiology and pathology. Philadelphia: Lippincott, Williams & Wilkins, 2007, with permission.) B: Three 4-mm (outer and diameter) telescopes are shown here. Top is a 30-degree, middle is a 70-degree, and below is a 0-degree telescope. (From Baggish MS, Velle RF, Gaedel H. Hysteroscopy: visual perspectives of uterine anatomy, physiology, and pathology. Philadelphia: Lippincott, Williams & Wilkins, 2007, with permission.) C: Telescopes must couple to a 3-mm sheath to be practically functional. The distention liquid or gaseous medium gains access to the uterine cavity via the sheath.](image-url)
operating tools. The major disadvantages of this type of sheath are that the uterine cavity cannot be flushed with the distending medium, and the operative tools cannot be accurately placed and manipulated within the cavity (Fig. 18.4A). Hysteroscopes with isolated channels overcome the problems inherent to the common cavity sheath (Fig. 18.4B). The dual operating channels permit flushing of the cavity and precise placement of operating accessories. The most recently introduced isolated-channel sheath consists of a double-flushing sheath (Fig. 18.4C) that permits media instillation by way of the inner sheath and media return by way of the perforated outer sheath. The constant flow of the fluid medium in and out of the cavity creates a
very clear operative field. The single isolated operating channel has a diameter sufficiently large (3 mm) to permit an entirely new generation of larger, sturdier operating tools to be used (Fig. 18.4D). The new sheath combines the advantages of the resectoscope with the facility of the operating hysteroscope.

The resectoscope is a specialized electrosurgical (monopolar or bipolar) endoscope that consists of an inner sheath and outer sheath (Fig. 18.3A). The outer sheath is for fluid return as described above. The inner sheath has a common channel for the telescope, fluid medium, and electrode (Fig. 18.3B). The double-armed electrode is fitted to a trigger device that pushes the electrode out beyond the sheath and then pulls it back within the sheath (Fig. 18.5C). The operating tools consist of three basic electrodes: a ball, barrel, and cutting loop (Fig. 18.3D–G). Most resectoscopes are equipped with a 30-degree telescope. The lens is angled toward the electrode to
permit a clear view of the near operative field. Vision of the electrode is lost when the electrode is fully extended outward. Most operating sheaths measure 8 mm or more outer diameter. Dilatation is usually required for insertion. Contemporary small diameter resectoscope uses a 3-mm telescope and a 7 to 7.5-mm sheath.

**ACCESSORY INSTRUMENTS**

During the late 1990s, many new accessory devices appeared on the market. The standard accessories are the 7F (i.e., 2.3 mm) alligator grasping forceps, biopsy forceps, and scissors. The small size of these fragile semirigid instruments is a disadvantage, and excessive torque at the junction of the shaft and handle frequently leads to breakage. However, flexible devices are less likely to fracture and are equally as facile compared with the semirigid variety. Development of the large isolated-channel sheath has made the use of totally flexible 3-mm operating instruments feasible. The scissors and graspers are substantially heavier and almost indestructible (Fig. 18.6A–C).

A variety of monopolar and bipolar electrodes are also now available for operative hysteroscopy. Monopolar balls, needles, shaving loops (3 mm), and ridged (vaporizing) loops can be inserted through the large operating channel (Fig. 18.7A,B). Bipolar needles for myolysis, as well as bipolar ball and cutting loop electrodes, have been manufactured (Fig. 18.7C), together with bipolar scissors and needles.

The hysteroscopic sheath has an advantage over the resectoscopic sheath, allowing insertion of an aspirating cannula (2.3 or 3 mm), which permits the operator to selectively clear the field of bubbles and debris that cannot be removed by the way of the return second sheath (Fig. 18.8). Nevertheless, the resectoscope is generally easier to use for the average gynecologist.

A complete bipolar system marketed under the trade name of Versapoint (Gynecare, Ethicon, Somerville, NJ) permits cutting and ablation via operative hysteroscopes or via a dedicated bipolar resectoscope. The mechanism for the bipolar current flow through the electrode is illustrated in Figure 18.9A. The electrodes measure 5F diameter (i.e., 2 mm) and therefore can be accommodated by standard and isolated hysteroscopic channels (Fig. 18.9B). The biggest advantage of this bipolar technology is the same that exists for the neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser; that is, saline may be used as the distending medium for the operative hysteroscopy. This obviates the risk of hyponatremia (see sections on media and complications).
FIGURE 18.4. A: A single-channel operating sheath consists of a single cavity that the telescope, distending medium, and operating instruments share. O.C., operating channel. B: A dual-channel operating sheath is constructed with (1) isolated channels for a telescope, (2 and 3) two operating devices, and (4) distending medium. C: The terminal portion of the second generation isolated-channel hysteroscope shows the channel for the 4-mm optic (top) and a 3-mm operating channel for a variety of large accessory instruments (bottom). The two channels at either side are the fluid intake channels. D: The double sheath mechanism of the isolated-channel hysteroscope. The perforations in the outer sheath are for fluid return. The uterus is continuously flushed. (A and B: From Baggish MS, Barbot J, Valle RF. Diagnostic and operative hysteroscopy. Chicago: Mosby-Year Book, 1989, with permission; C and D: From Bryan Corporation, Woburn, MA, with permission.)
The Flexible Hysteroscope

The 4.8-mm diameter fiber-optic hysteroscope consists of three sections: a soft flexible front section, a rigid rotating middle section, and a semirigid rear section. In 1990, Lin and colleagues reported their experiences with this instrument in 153 procedures, including transcervical tubocornual recanalization, chorionic villus sampling, and retrieval of lost intrauterine devices (IUDs). The flexible hysteroscope has particular advantage in its ease of aligning the catheter for tubal canalization. Several manufacturers now produce fiber-optic (flexible hysteroscopes) (Fig. 18.10).

DISTENDING MEDIA

Under normal circumstances, the uterine cavity is a potential space, and the anterior and posterior walls are in close apposition. To achieve a panoramic view within the uterus, the walls must be forcibly separated. The thick muscle of the uterine wall requires a minimum pressure of 40 mm Hg to distend the cavity sufficiently to see with a hysteroscope. The endometrium is so richly endowed with blood vessels that touching it with the sheath of the hysteroscope invariably produces bleeding. The walls of the uterus must be held more widely apart during operative hysteroscopy. Although a variety of distending media can be used to attain the desired degree of distention, it usually requires pressures approximating 70 mm Hg, which at the same time propel the medium through the oviducts into the peritoneal cavity. Overdistilation of the cervix with a loosely applied hysteroscopic sheath results in leakage of the medium, suboptimal pressure, and poor expansion of the uterine cavity. In contrast, a tight application of the sheath maintains the medium within the cavity, keeps intrauterine pressure above mean arterial pressure, and maintains a clear operative field.

Media may be conveniently divided into gaseous or liquid. The latter may be further subdivided into high-viscosity and low-viscosity fluids.
E: The ball or barrel electrode is the instrument most utilized for endometrial ablation. F: The button electrode is specifically employed for point coagulation. G: The angulated needle electrode is favored for fine cutting, e.g., adhesions or pedunculated myomas.

A: Direct vision intrauterine biopsies may be performed utilizing this flexible, fine forceps. B: Crocodile jawed forceps are ideal for grabbing and retaining devices or tissue within the uterine cavity. C: Scissors have a variety of intrauterine applications, including cutting adhesions and uterine septa.
### FIGURE 18.7

A: This straight cutting needle (insulated with Teflon) protrudes from the terminal portion of the sheath of a flushing operating hysteroscopy. This device can cut septa, adhesions, myomas, and polyps. B: The button electrode may be inserted through the operating channel and used for coagulation indications but never for cutting. C: A 3-mm bipolar needle that can be inserted into a submucous myoma for myolysis. (From Unimed, Largo, FL, with permission.)

### GASEOUS MEDIA

#### Carbon Dioxide

Carbon dioxide ($CO_2$) is a colorless gas that is highly soluble when mixed with blood. It can be used to safely distend the uterus when instilled with a proper insufflation apparatus, as described by Lindemann. This distension medium is ideal for office hysteroscopy. The hysteroscopic insufflator delivers $CO_2$ into the uterus at a flow rate measured in cubic centimeters per minute, in contrast to the laparoscopic insufflator, in which $CO_2$ flows in at the rate of liters per minute. The laparoscopic insufflator is both unsuitable and unsafe for hysteroscopic insufflation. The rate of flow of $CO_2$ into the uterus should never exceed 100 mL per minute, and pressure should be adjusted below 150 mm Hg (Fig. 18.11). Before $CO_2$ is infused, the hysteroscopic tubing and the hysteroscope must be purged of air. Additionally, the Trendelenburg position should be avoided. When $CO_2$ flow is excessive, bubbles appear and obscure the field. Bleeding and $CO_2$ gas are incompatible; the gas and blood mix, producing an obscuring bubbling foam. $CO_2$ tends to flatten the endometrium, and this artifact can obscure pathology. When $CO_2$ is improperly instilled, emboli form and can produce severe derangements in cardiovascular physiology. The best feature in favor of $CO_2$ is its neatness. It does not foul instruments, it does not mess up the office or operating room, and it allows entry evaluation of the endocervical canal. $CO_2$ is therefore an excellent diagnostic medium, perhaps the best, according to Siegler and Kemmann. However, the liquid media are superior in most aspects for operative hysteroscopy. $CO_2$ cannot be used to flush the cavity of debris, and if the pressure drops sufficiently to allow the walls of the uterus to coapt, bleeding will ensue, making this medium less than advantageous.

#### LIQUID MEDIA

##### High Viscosity

Hyskon (32% dextran 70 in dextrose) is a colorless, viscous solution that is an excellent medium for both diagnostic and operative hysteroscopy (Fig. 18.12A). Baggish and colleagues (1992)
published data on blood levels of Hyskon attained during a variety of operative procedures. Hyskon blood levels were not directly correlated with either the volume of instilled medium or the operative time. The blood levels did correlate with the degree of uterine damage created. The mean intratubercular pressure measured during Hyskon infusion was 76 mm Hg. Ruiz and Neuwirth monitored Hyskon reactions in nearly 2,000 hysteroscopies and reported a rate of pulmonary edema of 0.11% and anaphylactoid reaction of 0.05%. Although no significant correlation between volume and reaction was demonstrated, the investigators cautioned that when more than 500 mL of Hyskon were instilled, the incidence of pulmonary edema increased to 1.4%. They recommended that 500 mL represent the upper limits for Hyskon infused during a single case. Hyskon is a safe medium and has properties that other media do not share. A major advantage of Hyskon is its immiscibility with blood, which permits excellent visualization, even during active bleeding, and permits the surgeon to pinpoint the site of bleeding.

Because Hyskon is so viscid, it is difficult to instill during diagnostic hysteroscopy when the 5-mm sheath with the 1-mm clearance between the lens and sheath is used. Up to 650 mm Hg pressure may be required to push it through the sheath-lens interface. With the addition of a simple hand pump (Cook OB/GYN, Spencer, IN), a 60-mL syringe of Hyskon is easy to instill and is ideal for diagnostic office hysteroscopy (Fig. 18.12B,C). Most diagnostic hysteroscopies can be satisfactorily completed with less than 100 mL of Hyskon, whereas most operative procedures usually require 200 to 500 mL of Hyskon (Fig. 18.12B). Interestingly, Hyskon interaction with heat induced by Na-YAG laser at about the 100°C level appears to complement the thermal action of the laser.

A disadvantage of Hyskon is that dried residue tends to harden and clog hysteroscopic sheath channels. This clogging is easily prevented by immediately flushing the scope and sheath with hot water after completion of the surgery.

As we have mentioned, two types of Hyskon reactions have been reported. The rare idiosyncratic anaphylactoid reaction should be managed like any acute allergic reaction. The second reaction is caused by excessive vascular uptake of dextran, which allows a more general manifestation of its physiologic actions, including fibrinolytic action, stearic exclusion,
CO₂ must be infused by a special insufflator that measures flow rate (not to exceed 100 mL per minute) and uterine pressure (not to exceed 150 mm Hg).

A: The author’s favorite medium for viewing the uterine cavity in the clearest fashion is 32% dextran 70, Hyskon. The medium is nonmiscible with blood. B: A simple Hyskon Pump (Cook OB/GYN). This syringe driver allows Hyskon to be administered through even a diagnostic sheath with ease. C: Hyskon is pumped through the 60-mL syringe to the hysteroscopic sheath by means of special tubing that fast locks into the syringe on one end and onto the intake channel of the sheath on the other end.
alteration of platelet adhesiveness, and interference with von Willebrand’s factor (factor VIIIIR). The end result is a blinding, diastatic. The osmotic activity of dextran is such that for each gram of Hyskon instilled into the vascular space, 20 mL of interstitial water will be pulled into the circulation; 100 mL of Hyskon (32% dextran) will expand the plasma volume by 32 g × 20 mL or a total of 640 mL.

As the volume of instilled vascular Hyskon increases, a critical level is reached, and pulmonary edema occurs. Finally, dextran 70 (Hyskon) is a mixture of macromolecules ranging from 25 to 125 kd. Although the lower-weight molecules are rapidly excreted, the larger molecules can interfere with glomerular filtration and will remain in the bloodstream for 4 to 6 weeks, as detailed in the report by Mishler. Seven case reports of Hyskon-related pulmonary edema were published between 1985 and 1990. The pathogenesis of the Hyskon reaction has been incorrectly described as an example of noncardiogenic pulmonary edema, and this incorrect description has unfortunately been propagated from report to report. No evidence whatsoever supports this hypothesis. The Hyskon-induced pulmonary edema reaction is fully understood, and its actions are cardiogenic, as described earlier. Hyskon can be used universally with electro-surgical devices, lasers, and conventional equipment.

**Low Viscosity**

Several general statements regarding low viscosity fluid safety may be considered here. Low-viscosity fluids must be continuously flushed through the uterine cavity if a clear view is to be maintained. A standard diagnostic sheath does not make up for the deficit to maintain uterine distension. A standard operating table, permitting the fluid to infuse by gravity feed. A newer technology for instilling low-viscosity fluid is by rotary pump. The newest pumps weigh the fluid in real time and give the surgeon a constant readout of flow rate and total volume of fluid infused (Fig. 18.13A).

**Normal Saline, Ringer Lactate**

Normal (physiologic) saline (0.9% sodium chloride) is perhaps the safest of any hysteroscopic media. The worst results of excessive vascular absorption are fluid overload and pulmonary edema, which are managed by diuresis and support. The medium is readily available in 3-L sterile bags that can be mounted on an intravenous pole or given via an infusion pump. Cary and colleagues (1992) reported excellent safety results and precise maintenance of uterine pressure by using a pump delivery system, which was combined with one of the operating channels of the dual-channel operating sheath to provide an outflow tract and thus a constant flow rate through the uterine cavity (Fig. 18.13B–D). Unfortunately, because saline is an efficient conductor of electrons, it does not permit a current density that is high enough for tissue action when using a monopolary system. Saline is therefore not suitable for monopolar electro-surgery, although it is effective when the Nd-YAG laser, the KTP/532 laser, bipo-lar electrodes, and mechanical devices such as scissors are the hysteroscopic accessories of choice. In contrast with the Hyskon medium, saline leaks easily out of the uterus. Constant infusion and high flow rates are required to maintain distension. This medium also mixes easily with blood, which further necessitates constant flow of the medium through the operative field for flushing. The large volumes of fluid required make this medium less than ideal for office use.

The best drapes for the operating room is the urologic pock (tucked under the buttocks) with a plastic reservoir pocket into which the outflow fluid may be collected and quantitated to determine the fluid deficit (i.e., the difference between instilled fluid and returned fluid). The surgeon should be given a running account by a nurse or surgical assistant of the volume of fluid instilled (i.e., liters of fluid hung on intravenous pole minus volume of return fluid). Whenever any significant fluid deficit is calculated, the procedure should be discontinued and scheduled for completion at a later date. For purposes of this chapter, a significant overload of isotonic sodium chloride could be quantitated to 1.5 to 2 L.

**Glycine 1.5% and Sorbitol 3%**

Glycine (1.5%) and sorbitol (3%) solutions were first used in urologic surgery, principally for male patients. They were adopted later by gynecologists for use with monopolary electro-surgical devices (e.g., the resectoscope). Both glycine and sorbitol are used for hysteroscopic distension, but both have significant disadvantages inherent to their composition. Clearly, better and safer alternatives exist for uterine distension. Both solutions are hypoosmolar (sorbitol, 178 mOsm/L; glycine, 200 mOsm/L). When delivered by a high-pressure infusion pump, glycine has been reported to cause disturbances in oxygenation and coagulation. However, the principal hazards of these media relate to their vascular absorption and the creation of an acute hyponatremic, hypo-osmolar state. A fluid deficit equal to or greater than 500 mL should alert the surgeon to the likelihood of hyponatremia and hyposomolality. Two reports have presented data concerning significant complications secondary to hyponatremia. In one series of four women, two died (50% mortality); in the other, one of four women died (25% mortality). Absorption of hypo-osmolar solutions produces a gradient between the circulating blood and the brain cells. The brain cells respond by pumping cation out to give the surgeon a constant readout of flow rate and total volume of fluid infused (Fig. 18.13A).

D: This apparatus is very similar to the technology shown in Figure 13C but permits the usage of multiple bags of fluid.
diminish the positive infusion of water into the brain. Unfortunately, the cation pumping mechanism of the brain is deficient in women, secondary probably to the actions of progesterone, and women are at significantly greater risk for the development of life-threatening cerebral edema when a hyposmolar state exists. When sorbitol or glycine are used as uterine distension media, we refer the reader to the papers of Arieff and Ayus and those of Baggish for a detailed discussion of the treatment of acute severe hyponatremia.

Minimally, preoperative, intraoperative, and 4-hour postoperative serum sodium determinations should be requested on a stat basis. A fact that all hysteroscopists should bear in mind is the consistent overfilling of the medium bags by the manufacturer. Typically, the bags have 150 mL more fluid than indicated.

5% Mannitol and 2.2% Glycine
Mannitol (5%) and glycine (2.2%) are safer than the former two solutions because they may be used with electrosurgical devices and are approximately isoosmolar. Mannitol has an osmolality of 285 mOsm and is an osmotic diuretic (Fig. 18.14A,B). In optical characteristics are equivalent to glycine and sorbitol; however, it is an infinitely safer medium. In a study of 181 hysteroscopic examinations using isotonic 2.2% glycine, although there was a mean decrease in sodium of 9 mmol/L in patients absorbing 1,000 mL, the serum osmolality remained normal with no significant adverse sequelae.

As already noted above, regardless of the medium used, the exact volume of fluid infused (taking into account bag overfilling) must be accurately measured and recorded. In a similar fashion, the operating room nurse must empty collection canisters to accurately measure the medium return volume; less compulsion about these measurements is unacceptable.

**DIAGNOSTIC HYSTEROSCOPY TECHNIQUES**

Diagnostic hysteroscopy can be performed in an office setting under local anesthesia. The injection of lidocaine 1%, 10 to 15 mL, directly into the cervix produces excellent anesthesia for this easy operation, and discomfort for the patient can be diminished by meperidine (Darvon), 600 to 800 mg, administered 30 minutes before the procedure. Patients who require cardiac prophylaxis (e.g., prolapsed mitral valve) should be covered by appropriate antibiotics. Patients should be given suitable information for informed consent.

Accurate knowledge of the position of the uterus is critical to facilitate the examination. The best view of the uterus is obtained during the proliferative phase of the menstrual cycle. The patient is placed in the dorsal lithotomy position. The perineum and vagina are gently swabbed with povidone-iodine or another suitable antiseptic solution. A Sims retractor is placed in the posterior vagina and retracted downward (Fig. 18.15A). The edge of the cervix comes into view and is grasped with a single toothed tenaculum (Fig. 18.15B). A suitable telescope is selected and checked by the operator for clarity of the eyepiece and objective lens. If necessary, the lens is cleansed with a soft saline-soaked or water-soaked sponge. The light generator is switched on, and the fiber-optic cable is attached to the telescope. The telescope is inserted into the diagnostic sheath, and the selected medium is flushed through the sheath to expel any air within the sheath (Fig. 18.16A,B). At Good Samaritan Hospital in Cincinnati, 60 mL of Hyskon, delivered by a Cook OB/GYN handheld pump, is routinely used for office hysteroscopy. Typically, one full syringe of this medium is ample for completion of a diagnostic examination of the uterus. The flow of Hyskon starts as the hysteroscope is engaged into the external os of the cervix.

If CO2 is the selected medium, the flow rate is adjusted to deliver 30 mL per minute. The hysteroscope is engaged into the external cervical os. As the endoscope is advanced, the gas separates the walls of the endocervix, allowing an excellent view of the endocervical folds and crypts. The internal os is seen above as the endoscope is manipulated along the axis of the canal and through the os under direct vision. Flow is adjusted to a rate 60 mL per minute when the isthmus is entered (Fig. 18.17A,B).

Routine dilatation of the cervix should be avoided because even careful and gentle insertion of cervical dilators will traumatize the endocervix and endometrium. Typically, the
endocervical canal shows longitudinal folds, papillae, and clefts. The vascular pattern of the normal endocervix reveals branching treelike vessels. These are especially well observed with a focusing hysteroscope. The internal os appears as a narrow constriction at the top of the endocervical canal. The isthmus is a cylindrical extension above the os. The corpus is a capacious cavity above the isthmus. The central point of müllerian duct fusion is seen projecting down from the fundus. The cornua occupy either side of this fused area. The tubal ostia are visible at the upper extremities of the fundal cornua and show great variation in their appearance and angle of entry into the uterine cavity. The uterine mucosa (endometrium) is smooth and pink-white in color during the proliferative phase. The gland openings appear as white-ringed elevations surrounded with netlike vessels. During the secretory phase of the cycle, the endometrium is lush and velvety; it protrudes into the cavity irregularly and can be easily mistaken for small polyps. The hue of secretory endometrium is

FIGURE 18.16. A: The diagnostic lens (telescope) and its 5-mm outer diameter diagnostic sheath are excellent instruments for office or surgicenter outpatient hysteroscopy. B: Close-up showing 0-degree 4-mm telescope engaging into the diagnostic sheath.
Operative Hysteroscopy

FIGURE 18.17. A: This view is taken within the distended cervix looking upward into the dark corpus. B: The hysteroscope's objective lens is just above the internal os. The panoramic cavity is seen. The recesses to the right and left are the cornu.

magenta. The interior of the cavity, particularly when liquid media are used, first appears cloudy, with fine debris floating in the medium.

When CO2 is the distending medium, the endometrium is artificially flattened. Although the cornua are easily recognized, the tubal ostia may not be seen during the latter phase of the menstrual cycle. The thickness of the endometrium can be easily appreciated by placing pressure on the telescope and pushing on the posterior wall of the uterus. This maneuver creates a groove in the endometrium.

OPERATIVE HYSTEROSCOPY TECHNIQUES

The telescope is inserted into the operative or resectoscope sheath. If the operative sheath is used, a proper nipple is selected and attached to the opening of the operating channel (Fig. 18.18A,B). The sheath is flushed with the distending medium, and light cable is attached. Careful dilatation with Pratt dilators should be performed until the operative sheath negotiates a tight passage through the cervix. With the medium flowing, the hysteroscope can be inserted into the uterine cavity under direct vision or coupled to the television camera. The uterine cavity is scanned, and the operator mentally notes landmarks (e.g., the tubal ostia, depth of the cornua, the location and attachments of the lesion, the proximity of the internal cervical os). The flow of the debris with the liquid medium will also help the operator locate the tubal ostia. If there is difficulty viewing the cavity clearly, the hysteroscope has probably been inserted too deeply, and the telescope has come in contact with the uterine wall. When the view is blocked, the most prudent first maneuver is to pull the instrument back with the medium flowing into the uterus.

After a clear view is obtained, the operating device (e.g., electrode or scissors) is inserted into the cavity and advanced to make contact with the endometrium for relative calibration and spatial orientation within the cavity. The knowledgeable and skilled endoscopist at this point inserts an aspirating cannula to further clear the cavity of debris. The cavity can

FIGURE 18.18. A: The telescope is secured by means of a water-tight pin and screw mechanism. A gray nipple gasket covers entry into the operating channel. B: Close-up of operating sheath. A flexible instrument has been inserted via the gray nipple into the operating channel. The two stopcocks are for (1) infusion of the distending medium and (2) return and jettison of circulating fluid. Note all stopcocks are opened.
also be further distended with a constant flow sheath by clos- ing off the return valve stopcock. The valve is then opened, and the cavity is flushed clear. No operative procedure can even be performed unless an absolutely unobstructed view is obtained. In certain cases, it is advantageous to perform a simul- taneous laparoscopy to permit an assistant to view the serosal sur- face of the uterus to provide some additional insurance against inadvertent perforation. Laparoscopy is recommended during the cutting of septa, during lysis of uterine adhesions, and dur- ing excisions for large submucous myomata.

Most experienced hysteroscopic surgeons use the endo- scopic microchip camera coupled directly to the telescope. The current state of the art technology employs digital cameras and digital recorders. Performance of hysteroscopic surgery by video monitoring has the following advantages (Fig. 18.19):

1. Some camera lenses permit sufficient magnification of the operative field for the image to fill the entire video monitor screen.
2. The video camera eliminates one source of operator fa- tigue by allowing the endoscopist to sit upright rather than hunched over.
3. An image projected clearly on the video screen helps resi- dents, nurses, and students maintain interest throughout the procedure; enables them to learn more about the technique; and allows them to render better assistance than is possible with conventional procedures.
4. The risk of an eye injury and the need for protective eyewear are obviated.

Endoscopic video camera lenses range in focal length from 25 to 38 mm. A 28- to 30-mm lens provides satisfactory magnifi- cation. The operator should first view the cavity by direct vision and should then attach the camera to the eyepiece of the lens. The view with the coupled camera provides magnifi- cation comparable to that obtained during microsurgery. If a video recorder is available, a permanent record of the proce- dure can be captured on tape. A xenon light generator provides the best illumination for video techniques, although less expen- sive light sources may be satisfactory when coupled to newer cameras, which are highly light sensitive.

Laser and Electrosurgical Devices

The Nd-YAG laser, which works by thermal energy, is the pre- ferred laser for hysteroscopic surgery. Electrosurgical devices exert their tissue actions in a similar fashion: Light energy from lasers is transformed to thermal energy by electron flow (Fig. 18.20A). Lasers and electrosurgical devices both produce coagulation at 60°C to 70°C and vaporization at 100°C (Table 18.1), and both require sufficient power density to exert the desired action. Similar tissue actions can be produced by rais- ing the power density or by keeping the power constant and increasing the tissue exposure time. A 1-mm laser fiber deliv- ering 40 watts of power to tissue will create a power density of 3,000 W/cm². A 3-mm ball electrode will need to generate 300 W of power to create a similar power density (Fig. 18.20B).

The Nd-YAG laser beam can be transmitted equally well with any distending medium, whereas monopolar electrosur- gical devices operate most effectively in an electrolyte-free medium.

Uterine perforation by either a laser fiber or an electrode is much more serious than perforation by scissors or another mechanical device because the thermal energy can inflict great damage to surrounding structures (e.g., bowel or bladder). The injury may not attain its maximum damage until 2 or 3 days after surgery. Therefore, either laparoscopy or laparotomy is indicated in such cases to determine the extent of injury.

Regardless of whether a laser, resectoscope, or handheld electrode is used, depth of tissue action is extremely important; transmural injury is possible at high-power densities or with prolonged exposure. One must keep in mind that the thickness of the distended uterine wall (0.5 to 1 cm) is considerably less than that of the nondistended uterine wall (1.5 to 2 cm) (Fig. 18.21A,B).

Backscatter then lifts the surface of the endometrium off as the tissue is ablated. B: Electrosurgery coagulation of the endometrium with a ball electrode. As the time increases, the temperatures in the vicinity of the electrode are raised to 100° C or vaporization temperature. A vapor barrier is formed and current ceases to flow unless high voltage penetrates the insulating barrier. (From ERBE, Tubingen, Germany, with permission.)

SPECIFIC PROCEDURES IN HYSTEROSCOPIC SURGERY

Septate Uterus
Modern hysteroscopy has rendered the correction of septate uterus relatively simple and straightforward by the transcervical route, as documented by DeCherney and associates (1986) and by March and Israel (1987). Uterine septa are a treatable factor contributing to pregnancy wastage usually secondary to premature labor and late second-trimester abortion. The diagnosis of a uterine septum is usually made at hysterosalpingography or during a diagnostic hysteroscopy.

Unfortunately, neither of the studies mentioned above differentiates between septate and bicornuate uteri. A diagnostic laparoscopy is most helpful for an accurate differential diagnosis. A laparoscopic view of a septate uterus will reveal a wide but otherwise normal fundus, whereas the bicornuate uterus typically appears heart shaped. Alborzi and associates (2003) in a small study reported that sono-hysterosalpingography is sufficiently accurate to differentiate bicornuate from septate uterus, thereby eliminating the need for diagnostic laparoscopy. A bicornuate uterus, if pregnancy wastage is demonstrated, should be treated by a Jones or Strassman procedure. A septate uterus should be treated hysteroscopically. The standard technique, reported by March and colleagues (1978), is to cut the septum with scissors under direct hysteroscopic view.

a According to Bender and Schramm, 1968.

Cararach and colleagues compared hysteroscopic incision of septate uteri during a 5-year period (81 women) using a scissors or resectoscope approach and found only marginal benefit in favor of the former. Choe and Baggish used the Nd-YAG laser fiber to transect septa in 14 women. Of 13 patients who conceived, 10 delivered a live-born, term infant (87%), compared with a preoperative term pregnancy rate of 11%. Clearly the Nd-YAG laser, resectoscope, or needle electrodes are more appropriate for the broad and usually vascular septum. Four recent studies evaluated reproductive outcomes following hysteroscopic metroplasty (Litta et al., 2004; Pabuccu and Gomel, 2004; Saygili-Yilmaz et al., 2003; Patton and Novy, 2004). The percentage of pregnancies reaching term following metroplasty ranged from 50% to 83%.

Uterine rupture during pregnancy and more specifically in labor has been reported after hysteroscopic metroplasty without uterine perforation. It would be prudent to inform the patient who will undergo metroplasty of the subsequent risk so that she is knowledgeable and can inform her obstetrician should she become pregnant.

**Hysteroscopic Technique**

The uterine septum is viewed from the level of the internal cervical os. The endoscope is moved into each chamber of the divided uterine cavity, and the locations of the tubal ostia are noted. The hysteroscope is again withdrawn to a level just above the internal os. The appropriate operating instrument is inserted through the sheath, and the septum is cut from below and upward, as described by March (Fig. 18.22). As the fundus is approached, the operator depends on a signal without uterine perforation.
from the assistant to indicate when the quality of the hysteroscopic light demonstrates transmission through the intact uterine wall. A dialog between the hysteroscopist and laparoscopist prevents perforation. A new technique permits the operator to scan the uterus ultrasonographically to determine whether the myometrium has been entered and to monitor the amount of space existing between the operating device and the serosal surface of the uterus. It is not necessary to excise the septum completely; incising the septum is quite adequate. Transection eliminates the septum and unites the uterus into a single cavity. We take the opportunity here to stress an important technical point. The surgeon should be aware of the common tendency of the cutting instrument to drift posteriorly and should clip the septum squarely in the middle. When the drift goes unnoticed, the operating instrument invariably cuts into the myometrium and causes pulsatile bleeding. Similarily, correcting the septum too perfectly at the level of the fundus will result in deep penetration into the myometrium and subsequent hemorrhage (Fig. 18.23A–C). If a multichannel hysteroscope is used, a 3-mm ball electrode may be used to coagulate the bleeding vessel. The double-needle bipolar electrode is a safe alternative method for electrocoagulation.

If bleeding does ensue, a Foley catheter with a 10-mL balloon is inserted into the endometrial cavity at the terminus of the operation and inflated to 5 to 6 mL. The pressure exerted by the bag on the uterine walls is sufficient to control the bleeding promptly. The bag is deflated 6 to 12 hours postoperatively and is removed if no further bleeding ensues. Overinflation of a catheter bag can lead to uterine rupture; therefore, one should add increments of water, 1 to 2 mL at a time, to the catheter bag until bleeding ceases. Patients are usually advised to take 2.5 mg of estrogen daily by mouth for 30 days after surgery. Antibiotics are not routinely administered.

Uterine Synchiea

Adhesions form between the anterior and posterior walls of the uterus as a result of trauma or infection in a milieu of estrogen deprivation. Classically, this problem follows an abortion or postpartum hemorrhage, for which a vigorous curettage has been performed to control the bleeding, as reported by March and associates. Friedler and associates report the incidence of adhesions after one abortion to be 16.3%. This figure rises to 32% after three or more abortions. The severity of adhesions also typically rises as the number of abortions increase. Guida and associates reported a significant reduction in the formation of adhesions following sundry hysteroscopic operations via the postoperative instillation of hyaluronic acid.
Acid gel. Microscopic sections obtained from the curettage invariably reveal fragments of myometrium interspersed with inflamed decidua and glands. Historically, the patient does not resume menstruation; however, a minority of patients continue to menstruate normally. Because the patient is subsequently infertile or amenorrheic, a hysterosogram is performed. The radiograph reveals filling defects that vary from minimal to severe (i.e., virtually obliterating the endometrial cavity). Past treatment of uterine synechiae consisted of blind curettage; the results were predictably poor. With the advent of operative panoramic hysteroscopy, treatment progressed to identification of adhesions and sharp incision of the adhesions with scissors (Fig. 18.24A–C).

Adhesiolysis surgery is probably the most difficult of hysteroscopic operations. Because numerous vascular channels are opened up, the risk of intravascular absorption of the medium is high. Rock and colleagues reported a technique of laparoscopically injecting the uterus with leukomethylene blue dye to help identify the junction at which the anterior and posterior walls were adhered. Capella-Alloue and associates reported 31 cases of severe adhesions that underwent hysteroscopic lysis ranging over 1 to 4 operations. The number of subsequent pregnancies after treatment was 43%, and the live birth rate was 32%. A report from Belgium (2004) of 46 women with Ashermann disease, of whom one third had severe adhesions, described live births as greater than 40%.

FIGURE 18.24. A: Extensive adhesions between the anterior and posterior wall with a layered pattern. Hysteroscopic scissors are employed to cut them under direct vision. B: Thick vascularized adhesions are cut using the bipolar Thermachoice electrode. C Upper left: Extensive diaphragm-like adhesions cover the cavity of the uterus (a). The arrow points to an opening in the adhesions. Lower left: Close-up view of adhesions shown above. Note the blood vessels within the adhesions. Lower right: Following the incisions into the adhesions shown on the left, another layer was encountered (upper right). The latter was cut, exposing the main uterine cavity (c).
Hysteroscopic Technique

A thorough diagnostic hysteroscopy is performed to assess the degree of adhesion formation and deformity of the cavity. Small openings in the curtain of adhesions in which there are flow patterns of tiny blood fragments and tissue debris are helpful and should be sought out, as are any normal anatomic landmarks. Photographs, videotapes, and detailed drawings are helpful reminders in planning the strategy for cutting these adhesions.

Simultaneous laparoscopy is prudent measure to prevent perforation of the uterus. Flexible or semirigid scissors, the resectoscope, Versapoint, and the Nd-YAG laser are the operating instruments of choice, although some operators use the monopolar needle electrode at 40 to 50 W of cutting power, blend 1 or 2. The laser is initially set to deliver 30 to 50 W of power. The medium is instilled into the cavity by way of an operating sheath. Continuous maintenance of distention is one key to success. Filmy and central adhesions should be cut first, always following the fluid flow. Marginal and dense adhesions should be tackled last, always cutting from below and moving upward. A second key to success is to maintain the hysteroscope in midchannel relative to the uterine walls. The cavity can usually be restored to reasonably normal architecture. Bleeding is not uncommon during this operation, particularly when cutting marginal adhesions, because the border between adhesion and myometrium is blurred. Hyskon provides an advantage here.

The patient should be placed on conjugated estrogens, 2.5 mg daily, during postoperative recovery. Placement of an IUD within the cavity to keep the walls from adhering is clearly not based on scientific fact but has been used for so many years that it is standard postoperative measure.

Cannulation of Fallopian Tube

Novy and associates described a technique for passing a special catheter into the tubal ostium and through the obstructed interstitial portion of the tube. The procedure was successful in 92% of the cases. Dumesic and Dhillon reported a tubal cannulation procedure in which they used a flexible guiding insert to facilitate passage of the cornual cannulation catheter. These techniques are useful for treating interstitial obstruction secondary to cellular debris and tubal spasm. The obvious advantage of this cannulation technique is its usefulness in treating cases that might otherwise require tubocornual anastomosis. Pregnancy rates range from 25% to 54% in 6 months.

Hysteroscopic Technique

A 5.5F Teflon cannula with a metal obturator (Cook OB/GYN) is introduced through the operating channel of the hysteroscopic sheath. The obturator is removed. A 3F catheter with an birds eye cannula is introduced into the 5.5F cannula by way of a Y-adapter on the end of the cannula, engaged into the tubal ostium, and gently advanced into the tube. When the cornual portion of the tube is negotiated or when resistance is encountered, the guide wire is withdrawn, and leukomethylene blue or indigo carmine dye injected through the 3F catheter. Simultaneous laparoscopy allows on to see the dye exit the fimbriated end of the tube and confirm patency. Alternatively, one can place a radiologic plate beneath the patient and inject opaque dye (Fig. 18.23).

Endometrial Polyps

Functional and nonfunctional polyps produce intermenstrual bleeding, as reported by Barbot. Functional polyps tend to be smaller than nonfunctional polyps. If a hystogram is performed, then a focal filling defect will be seen. Diagnosis is directly and readily made by hysteroscopy. Polyps protrude into the endometrial cavity. A functioning polyp has a lining identical to the surrounding endometrium. The nonfunctioning polyp presents as a white protuberance covered with branching surface vessels; thick-walled vessels are usually seen within the depths of the polyps. Polyps are relatively easy to diagnose and similarly to treat.
hysteroscopy and biopsy should be performed on any woman receiving tamoxifen and reporting uterine bleeding. Garatti and colleagues compared the accuracy of blind sampling of the endometrium versus hysteroscopically directed biopsies in postmenopausal women receiving tamoxifen for breast cancer. The authors reported that sensitivity and negative predictive value of 100% with each technique. However, the specificity (80% vs. 68%) and positive predictive value (69% vs. 43%) were better for hysteroscopic versus blind sampling.

Ceci and associates confirmed that tamoxifen exerted a strong estrogenic action on the endometrium, which increased with time. Georghe and colleagues compared blind removal of uterine polyps (curettage and polyp forceps) with hysteroscopy. Polyps were diagnosed in 43% of cases by curettage. Out of 45 cases in which polyp forceps removed the polyp remnants or complete polyps remained in 31 cases. The authors concluded that hysteroscopically controlled polyp extraction was superior to blind techniques.

**Hysteroscopic Technique**

A multichannel operating hysteroscope is inserted into the uterine cavity, and a retractable electric snare loop is inserted through the 3-mm channel of the operating sheath. The polyp is encircled by the loop such that the loop encompasses the polyp base as it is tightened. The polyp is cut off at the base with 30 to 50 W. Alternatively, a polyp may be cut at its base with a needle electrode or laser fiber. The polyp may also be shaved by means of the resectoscope (Fig. 18.26).

![FIGURE 18.26. A functioning polyp on the right cornual wall of the uterus is resected by means of a resectoscopic loop electrode. Note that the technique is the same as the one employed for shaving a submucous myoma. (By permission: Baggish MS, Valle RF, Guedj H. Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology. 3rd ed. Lippincott Williams & Wilkins, 2007.)](image)

### Myomata Uteri

Submucous myomas characteristically appear as white spherical masses covered with a network of fragile thin-walled vessels when viewed by hysteroscopy. Myomas typically are sessile or pedunculated. A hysterosgram shows a filling defect that interferes with implantation of the fertilized ovum and become a contributing factor to subfertility.

In the past, a diagnosis of submucous myoma was usually followed by a recommendation for hysterectomy. Today, hysteroscopic surgery offers a therapeutic alternative to that radical approach. Various regimens of drug therapy (e.g., danazol [Danocrine] and gonadotropin-releasing hormone [GnRH] analogs such as leuprolide acetate [Lupron] or goserelin acetate [Zoladex]) have been recommended as supplementary preoperative medical therapy. The general plan is to treat symptomatic patients for 2 to 3 months preoperatively to reduce the size and vascularity of the lesion during surgery. All patients should be given detailed information concerning the need for typing and holding of blood and the possibility of hysterectomy if intractable bleeding occurs.

Valle (1990) reported data on 59 cases of abnormal bleeding, dysmenorrhea, and infertility that were diagnosed as submucous myomas. Hysteroscopic elimination or markedly decreased bleeding in 52 of these cases. Baggish and Sze treated 71 patients with symptomatic myomas and four patients with incidental submucous myomas. The treatment methods used with the multichannel hysteroscope were Nd-YAG laser (n = 41), monopolar loop (n = 6), monopolar needle (n = 6), bipolar needles (n = 10), and electrocautery or scissors and laser (n = 12). As with Valle’s series, results were excellent; 65 of 75 (87%) returned to normal menses postoperatively. Barbot and Parent (personal communication, 1994) performed hysteroscopic myomectomies in 825 women, of whom 83% were relieved of abnormal bleeding and suffered no recurrence. Litta et al described a technique of not only resecting the submucous component but continuing hysteroscopic resectoscopic cutting into the myometrium to remove more myoma tissue. We do not resect into the myometrium because the risks of severe hemorrhage, perforation, and subsequent dehiscence are increased.

Emmanuel and colleagues reported 285 women who underwent hysteroscopic resection of submucous myomas. The median follow-up was approximately 4 years (1–104 months), and 83.5% of the operated patients required no further surgery.

Clark and associates treated 37 women using the bipolar Versapoint electrode via ablation or excision. Improvement of bleeding symptoms was reported in 78% of the patients, and 92% were satisfied with the treatment. No significant complications were reported.

### Hysteroscopic Technique

Several variations of hysteroscopic procedures are now available to manage submucous myomas. Current resectoscopic...
Endometrial Ablation

More than 600,000 hysterectomies are performed annually in the United States, although the advent and growth of integrated health care will target this largely elective operation for reduction because of its substantial cost. The numbers will be further reduced because 40% of hysterectomies are unnecessary and 20% show no pathology; hence, cheaper alternatives are continuously sought. According to a recent study of hysterectomy by the New York State Department of Health, 10,063 hysterectomies were performed in that state during 1986, 10% of which were performed for the principal diagnosis of disorders of menstruation. A very large recent study from the United Kingdom (2005) observed that 16,100 out of a total of 37,298 hysterectomies were performed for dysfunctional uterine bleeding. Endometrial ablation or resection is the hysteroscopic alternative to hysterectomy as treatment for abnormal uterine bleeding. Two earlier reports by Doergenmauer and colleagues describe blind procedures such as cryocoagulation that were used in an attempt to control dysfunctional uterine bleeding by creating physical destruction of the endometrium without sacrificing the uterus. Unfortunately, either the techniques themselves were associated with significant side effects or the endometrium promptly regenerated.
Since the first practical method of hysteroscopic ablation was described in 1981, several thousand cases have been performed by a variety of techniques, including the Nd:YAG laser, the resectoscopic roller ball or loop, and, most recently, the long hysteroscopic ball electrodes. Garry and associates (1995) reported 600 endometrial laser ablations performed on 524 women. No major operative morbidity was reported. The success rate (mean age, 43 years) was 83.4%. Baggish and Sze have performed 568 ablations; 401 of these were performed with the Nd:YAG laser, 167 by electrosurgery. Excellent results were obtained in 89% of the women treated, and amenorrhea was achieved in 58%. Again, no major operative complications occurred.

**FIGURE 18.28.** A: The shaving technique for the elimination of a submusosal myoma is shown using an angled loop electrode via the resectoscope. were observed. Magos and co-workers reported 250 cases of endometrial resection with a 92% improvement in abnormal bleeding. However, data obtained from the Royal College of Obstetricians and Gynaecologists’ Mistletoe (Minimally Invasive Surgical Technique Laser, Endothermal or Endoresection) Study in 1997 revealed a 6.4% rate of significant complications associated with endometrial resection alone and a rate of 11.4/1,000 with emergency hysterectomy. This compares with complication rates of 2.7% and 2.1% for laser and roller ball, respectively. The latter two techniques had emergency hysterectomy rates of 1.3/1,000 (i.e., 11 times less than endometrial resection).

Two large controlled, randomized studies compared hysterectomy with hysteroscopic ablation/resection. Dwyer and colleagues prospectively compared 100 cases of endometrial resection and 100 cases of abdominal hysterectomy for menorrhagia. Postoperative morbidity, length of hospital stay, time to return to work, normal daily activities, and sexual intercourse were significantly lower for the endometrial resection group. Dysmenorrheic premenstrual symptoms were significantly higher in the endometrial resection group. Pinion and associates randomized 204 patients to abdominal or vaginal hysterectomy (n = 99), endometrial laser ablation (n = 53), or endometrial resection (n = 52). Women treated by ablation or resection had less morbidity and a shorter recovery time. After 12 months, 89% of the hysterectomy group and 78% of the hysteroscopy group were very satisfied with the effect of surgery; 95% in the first group and 90% in the second reported acceptable improvement in symptoms. Equal numbers in each group stated that they would recommend the same operation to others. Mints and colleagues reported on 104 premenopausal women who underwent endometrial resection (1990–1995) with a mean follow-up period of 29 months: 21% reported amenorrhea postoperatively; 51% described minimal bleeding; 11% reported the postoperative onset of dysmenorrhea; and 12.5% underwent subsequent hysterectomy. Seidman and associates reported higher rates of amenorrhea in women older than 45 years of age. Lefter reported a telephone survey following resectoscopic resection followed by ball electrode ablation for 109117 women. He reported 53% amenorrhea, 19% reduced menses, and 16% subsequent hysterectomy rate. Sower and colleagues performed a metaanalysis about preoperative administration of agents producing endometrial atrophy before hysteroscopy surgery. The use of GnRH analogues was associated with shorter operative times, greater rates of amenorrhea, and reduced dysmenorrhea. GnRH produced more consistent atrophy than danazol or progestogens. Several published reports confirm the cost-effectiveness and efficacy of endometrial ablation for the control of abnormal uterine bleeding compared with hysterectomy.

Hysteroscopic Technique

All patients who might be candidates for endometrial ablation should have been managed first by hormonal treatment in an attempt to control the abnormal uterine bleeding. If this strategy

FIGURE 18.30. A: The ball electrode is dragged from side to side via moving the entire hysteroscope, thereby ablating the uterine fundus. B: The anterior and posterior walls are ablated by dragging the energized ball electrode from above downward. This creates 2- to 3-mm furrows in the endometrium. Conduction heat damage can extend another 1 to 2 mm. (By permission: Baggish MS, Valle RF, Guedj H. Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology. 3rd ed. Lippincott Williams & Wilkins, 2007.)
fails, and if the woman does not desire to bear children, then she is a candidate for endometrial ablation. A preoperative diagnostic hysteroscopy, endometrial sampling, or both should be performed to exclude endometrial carcinoma or atypical hyperplasia, and all pertinent hematologic studies and consultations should be performed. All patients are pretreated to atrophy the endometrium. The drugs available to accomplish this effect include Danocrine, Lupron, Zoladex, Megace, and Depo-Provera. It is our experience that the best endometrial suppression is seen after 6 weeks of drug therapy.

A simultaneous laparoscopy is not performed during endometrial ablation unless a perforation or other transmural injury is suspected. Depending on the technique selected, either 3% mannitol or 0.9% saline is used as the distending medium. The operating hysteroscope or resectoscope is inserted into the uterine cavity. With the hysteroscope, a 9F aspirating cannula (Cook OB/GYN) is inserted, and blood and debris are evacuated until the cavity is clear. We prefer to treat the fundus by dragging the laser fiber or the ball electrode from side to side (cornu to cornu) (Fig. 18.30A). The anterior and lateral walls are ablated next, before the posterior wall. Ablation should not be extended below the internal os into the cervix (Fig. 18.30B). Power settings for the electrosurgical generator range from 50 to 150 W, depending on the size of the ball, barrel, or loop electrode (Figs. 18.31 and 18.32). Laser power is set at 40 to 60 W. The goal of the ablation operation is to destroy the visible endometrium, including the cornual endometrium, to a depth of 1 to 2 mm. The conduction heat will actually spread deeper, usually to 3 to 5 mm, depending on how long the device remained on the tissue. This penetration translates into extensive superficial myometrial destruction and coagulation of the radial branches of the uterine cavity (Fig. 18.33). When the endometrium sloughs, regeneration is prevented because basal and spiral arterioles do not survive the 100°C heat exposure. Over a period of 6 to 8 weeks, the uterine walls scar and shrink. Subsequent sampling or hysteroscopy is possible after

FIGURE 18.31. The resectoscope with ball electrode attached is inserted into the uterine cavity. Initially, the cornu and fundus are carefully ablated, taking care to keep dwell time low to reduce the risk of deep heat-conduction injury. Next, the anterior wall is ablated, followed by the posterior wall. (By permission: Baggish MS, Valle RF, Guedj H. Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology. 3rd ed. Lippincott Williams & Wilkins, 2007.)

FIGURE 18.32. Endometrial resection is performed in a manner similar to ablation; however, instead of a ball electrode, a cutting loop is substituted. This is clearly a riskier procedure compared with ablation by either laser or ball electrode, particularly relative to deep myometrial resection with the accompanying risks of hemorrhage and/or perforation. (By permission: Baggish MS, Valle RF, Guedj H. Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology. 3rd ed. Lippincott Williams & Wilkins, 2007.)
Operative Hysteroscopy

endometrial ablation. The mean duration of the operation is about 30 minutes. Patients usually are sent home on the day of surgery. The operation is usually completed with little or no blood loss (Fig. 18.34A–C).

Nonhysteroscopic Minimally Invasive Techniques for Endometrial Ablation

Although these new techniques are not hysteroscopic in the strictest sense, they are nonetheless closely related and should be included in this chapter. The basis for those methods encompass the following logic:

1. Removal of the skill factor as a variable for endometrial ablation
2. Elimination of requirement for a distending medium
3. Reduction in the time required to perform the operation
4. Equivalency of efficacy compared with hysteroscopic ablation
5. Performance in an office setting

![Figure 18.33](image1.png) The uterus was removed 5 days after a Nd:YAG laser ablation. Note the extensive laser injury involving about half the thickness of the myometrium. Laser penetration depends not only on power but also on the length of time the laser beam remains in contact with the tissue.

![Figure 18.34](image2.png) A: Complete destruction of the endometrium has been afflicted by means of Nd:YAG laser ablation. The fiber is seen at the 11 o’clock position. B: Close-up view of ablated endometrium shown in Fig. 18.34A. Note the laser fiber to the left. C: Endometrial resection is performed via a shaving technique utilizing the resectoscope.
FIGURE 18.35. Innerdyne (Tyco) “Enable” cannula. The terminal mushroom fitting and the acorn seal the cervix and isolate the corporal cavity from the cervical canal. The apparatus contains an in situ heater and thermistors.

The first practical technique described by Phipps and colleagues used a microwave technique of heating the endometrium by a probe inserted into the uterine cavity, exposing the endometrium to temperatures of 60°C to 65°C for 15 minutes. Thijssen reported a large multicenter study using this technique. The report described a number of serious complications, including fistula formation and third-degree burn injuries. Several techniques using balloons containing hot water, balloons covered with monopolar electrodes, computerized continuously circulating in situ hot saline, and cryosurgical and photothermal techniques have been reported (Figs. 18.35 to 18.37). One of the first devices approved for the market was the Thermachoice balloon apparatus (Ethicon Inc., Somerville, NJ), which was developed by Neuwirth. A cannula fitted with a thermal balloon is placed in the uterine cavity (Fig. 18.38). Sterile water distends the balloon and is heated in situ to 80°C to 90°C. Thermistors mounted on the balloon give a continuous readout of temperature within the uterine cavity. NADH diaphorase staining showed destruction to a depth of 3.3 to 5 mm. The published data show efficacy to be lower than that for hysteroscopic ablation and cost to be no less than that for hysteroscopic ablation. The dream of an office-based procedure has not yet been realized.

Since the publication of the last edition of this book, several additional ablation devices have obtained approval.
from the U.S. Food and Drug Administration, including HTA system (Hydro-Therm Ablation), Cavaterm, Novasure, and microwave. Cooper and colleagues published data comparing the Novasure device versus roller-ball ablation. Abbott and colleagues compared the Cavaterm and Novasure devices at 6 and 12 months relative to accomplishing amenorrhea/pomenorrhcea in menstruating women and found comparable results between the two systems. Glasser and Zimmerman evaluated the HTA system in women with irregular uteri with a control and abnormal (dysfunctional) uterine bleeding; 253 cases were treated, follow-up was available for 147 cases, and 25 cases required additional therapy to control the bleeding. Fifty-eight balloon treated and 59 roller-ball treated reported normal or less bleeding (out of 147 interviewed cases). Baggish and Savells recently published data on complications with the HTA, Novasure, Thermachoice microwave devices.

**Miscellaneous Procedures**

**Intrauterine Device Removal**

Although the number of IUD insertions has diminished over recent years, the gynecologist is occasionally called on to search for and remove a device with an indicator string that is not seen in the cervix. In such circumstances, the operating hysteroscope is a vital tool with which to locate the device and remove it under direct vision, according to Valle and colleagues. The hysteroscope is inserted, and the device is viewed. If a string is seen, an alligator-jaw forceps is inserted, and the string is grasped. The hysteroscope is withdrawn, pulling the device through the uterine cavity and the cervix to the exterior. If the IUD is embedded, then a rigid grasping forceps is required. The IUD is located, and the large jaws of the rigid instrument grab the extruded portion of the IUD itself. Strong pressure is exerted on the jaws as the sheath of the hysteroscope is slowly withdrawn from the uterus, into the cervix, and out of the vagina. When a tumor is suspected, the operative hysteroscope is inserted into the cavity, a 9F biopsy forceps is directed to the tumor site, and multiple biopsy specimens are obtained in a fashion analogous to that used with colposcopic biopsies. A 9F plastic cannula is inserted by way of the operating channel, and strong suction is applied to the mouth of the cannula by means of a 30-ml syringe. The cannula is removed, and the contents are flushed out with saline into a bottle of fixative. Similarly, a 9F Novak curette can be inserted under direct vision. Alternatively, a diagnostic hysteroscope can be inserted into the uterus. The site of pathology is noted. The endoscope is withdrawn, a Novak curette is inserted into the cavity, and biopsy specimens are taken at the previously located site. Finally, the hysteroscope is pulled back to the level of the internal cervical os, a small Novak curette is inserted alongside the hysteroscope, and a directed biopsy specimen is obtained.

**Hemangiomas and Arteriovenous Malformations**

Hemangiomas and arteriovenous malformations can be diagnosed by their characteristic hysteroscopic appearance and by a history of massive unresponsive bleeding. Historically, women with these conditions are young and of low parity. Hysteroscopic examination shows the subsurface of the endometrium to be covered with irregular blush-purple vessels that form an abnormal tangle of distended channels that differ markedly from the normal fine-capillary net pattern. The abnormal channels are not unlike the vessels that cover the surface of submucous myomas. The Nd-YAG or holmium YAG laser fiber is inserted through the operating channel, and the fiber is held several millimeters above the vascular abnormality at a power up to 50 to 60 W. The laser is discharged without touching the vessels or the surface of the endometrium (Fig. 18.39). The laser energy causes the vessels to collapse and coagulate and the surface to blanch white. The endometrium neighboring the abnormality is also treated and coagulated. The fiber is then withdrawn, the field is aspirated clear, and the hysteroscope is withdrawn. Similar treatment is repeated two to three times at 1-month intervals or until all evidence of the abnormality is obliterated. Alternatively, angomas may be managed via invasive radiologic techniques (e.g., embolization).

**Complications**

Unfortunately, accurate data concerning complications are hard to obtain, although one simple fact is clear: As greater numbers of gynecologists have begun to perform operative hysteroscopy, the rate of complications has increased. Voluntary surveys are worthless. Only state-mandated reports, such as those that are required for laparoscopic cholecystectomy in New York, have rendered any useful information. The exception to this is an excellent report by Smith and colleagues, which details complications encountered by 42 gynecologists.
Principles of Gynecologic Surgical Techniques and Management of Endoscopy

Intraoperative and Postoperative Bleeding

The most common complications inherent to hysteroscopic surgical procedures are intraoperative and postoperative bleeding. Generally speaking, intraoperative bleeding can be managed by aspirating the blood and by increasing the pressure of the distending medium so that it exceeds arterial pressure and compresses the walls of the uterus sufficiently to stop bleeding. Then the bleeding vessel may be coagulated with a 3-mm ball electrode with the use of force coagulation at 30 to 40 W of power or by multiple jabs with bipolar needles at 20 to 30 W of power with the generator set for automatic bipolar. If the counterpressure of the medium is relaxed (at the termination of the procedure) and bleeding continues, then control is best obtained by inserting an intrauterine balloon initially inflated to 2 to 5 mL. If this pressure does not promptly stop the bleeding, then a larger balloon can be distended to 10 mL until the bleeding has stopped (Fig. 18.40). More distension may be required for larger uteri. Care must be taken because overinflation of an intrauterine balloon can itself rupture the uterus. The balloon remains in place for 6 to 8 hours, is partially deflated for 6 hours, and, finally, is totally deflated before removal. When the bleeding is pulsatile, the source is arterial rather than venous. If this type of bleeding is not immediately controlled by balloon compression, then hysterectomy will usually be required. Delayed postoperative bleeding is most commonly associated with endometrial slough (after ablation), chronic endometritis, or spontaneous extrusion and expulsion of the intramyometrial portion of a previously resected submucous myoma (Figs. 18.38 and 18.39). Bleeding-clotting studies should be obtained in cases of late postoperative bleeding, particularly if these studies were not performed preoperatively in women with a diagnosis of abnormal uterine bleeding (preoperative endometrial ablation or myomectomy). A French group (2003) prospectively studied a decade of operative hysteroscopies (2116 cases). Thirteen cases of major bleeding were reported, with six requiring intrauterine catheter placements. The highest-risk procedure for associated hemorrhage was hysteroscopic adhesiolysis.

Uterine Perforation

Uterine perforation can occur during any operative hysteroscopy procedure but is most common during septum resection, myomectomy operations, and adhesion takedown. The best insurance against this complication is simultaneous laparoscopy. Among novice operators, perforation can occur even during insertion of the hysteroscope. With appropriate care, this sort of perforation should not happen, because the cervix and internal os should be negotiated under direct vision, and the cavity should likewise be entered under direct vision. Examination under anesthesia is also simple and lets the operator know the direction of the uterine axis.
FIGURE 18.41. The operator should never apply power to an energy device while advancing the electrode. The power can safely be applied as the electrode returns toward the sheath. (By permission: Baggish MS, Valle RF, Guedj H. Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology. 3rd ed. Lippincott Williams & Wilkins, 2007.)

As we noted above, the most dangerous perforations are those associated with lasers and electrosurgical devices. The risk of this type of injury can be reduced by not activating the energy device during a thrusting or forward movement. The foot pedal is activated only during the return phase of the laser fiber or electrosurgical electrode. If a perforation does happen with an energy device, then laparotomy is required to ensure that no injury has been inflicted on the intestine, bladder, or ureter (Fig. 18.41).

FIGURE 18.42. Perforation should be immediately suspected when the endometrial cavity depressurizes and collapses around the hysteroscope, creating a compromised view of the cavity. (By permission: Baggish MS, Valle RF, Guedj H. Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology. 3rd ed. Lippincott Williams & Wilkins, 2007.)

Poor Visibility in the Operative Field

Inability to see the operative field is a common problem. The usual cause of this problem is deep insertion of the hysteroscope so that the telescope lies directly in contact with the endometrium. The surgeon will see nothing but a red blur. The natural tendency is to push the hysteroscope deeper in. This strategic mistake invariably leads to perforation. Another cause of visibility problems is blood within the uterine cavity secondary to dilatation. The fastest way to deal with a bloody cavity is rapid flushing with the hysteroscopic medium combined with aspiration using a cannula placed into the cavity via the operating channel.

Overdilatation of the cervix is an equally common mistake that results in excessive leakage of distending medium and an inability to maintain distension, with the resultant inability to perform the operative hysteroscopy. Blood and debris can cloud
Abnormal uterine bleeding is most comprehensively eval-
uated by hysteroscopy and sampling as opposed to blind
curettage. Difficult cases beyond the capability of the
currently available instrumentation may require referral to the expert hys-
teroscopist. Skill in one area of endoscopy (e.g., operative la-
paroscopy) does not confer similar expertise in operative hys-
teroscopy. Indeed, the opposite may be true.

During the postoperative period, operative complications
should be the initial exclusion diagnosis for any patient who is not
recovering according to the usual pattern. Worsening post-
operative pain, fever, nausea, distension, and free intraperi-
toneal air are the signals of bowel injury. Diminished uri-
nary output, fever, and distension suggest bladder or ureteral
trauma. Falling blood pressure and rapid tachycardia, with or
without distension, should raise concerns of a vascular problem
and third-space hemorrhage.

Most negligence cases adjudicated in favor of the plaintiff
have involved delayed initiation of appropriate treatment for
an operative complication. Cases involving injury recognized
at the time of surgery and correctly managed in a timely fashion
do not usually become medicolegal problems.

Infection

The endometrium seems to be peculiarly resistant to infection,
and infection is an unlikely complication associated with or
coming after hysteroscopy. Hysteroscopy should be avoided in
the presence of gross cervical infection, uterine infection, or
salpingitis. Infection is otherwise uncommon after even exten-
sive intrauterine surgery (e.g., adhesiomyotomy or myomectomy).
Prophylactic antibiotics should be administered only when in-
dications exist such as a history of rheumatic carditis, con-
genital heart defect, or prolapsed mitral valve, or in cases of
suspected chronic endometritis (submucous myoma or imbed-
ded IUD). Baggish and colleagues (1999) observed only 13 in-
fec tions out of 5,000 cases that could be casually related to
the hysteroscopic operation. Salat-Baroux and associates re-
ported seven mild infections out of 4,000 hysteroscopic ex-
aminations. On the other hand, McCasland and co-workers
reported three cases of tuboovarian abscesses after operative hy-
teroscopy. Agostini and associates reported 30 infections asso-
ciated with 2,116 operative hysteroscopies. Eighteen of these
infections were cases of endometritis.

Operator Technique

The most serious complications happen because of operator
error. Most often, these are the result of inexperience and are
avoidable. Difficult cases beyond the capability of the
primary care gynecologist should be referred to the expert hys-
teroscopist. Gynecologists must work together to ensure that
best surgical practices are followed.

BEST SURGICAL PRACTICES

- Abnormal uterine bleeding is most comprehensively eval-
uated by hysteroscopy and sampling as opposed to blind
curettage.

- A gynecologist or gynecologist in training can best learn hys-
teroscopy by performing 25 to 50 diagnostic hysteroscopic
 procedures before initiating operative procedures.

- The distending medium of choice for diagnostic hy-
teroscopy is Hyskon (32% dextran), which is easily delivered
via a handheld pump.

- Infusion of fluid, low-viscosity media during operative hy-
teroscopy must be accurately measured and recorded. The
medium infused should be isoosmolar.

- Perforation during operative hysteroscopy with an energy
device requires laparotomy to inspect intraabdominal struc-
tures for thermal injury.

- A clear, unobstructed view of the intrauterine milieu is nec-
essary before the initiation of any endo uterine surgery.

The prevention and control of bleeding are fundamental to the success of any operation. Preoperative, intraoperative, and postoperative hemorrhage are potential complications in every patient undergoing gynecologic surgery. Preoperative hemorrhage is encountered in a variety of circumstances, such as in women with intraperitoneal bleeding from a ruptured tubal pregnancy or in patients taking heparin who have intraperitoneal hemorrhage associated with ovulation. Intraoperative hemorrhage can result from vascular injury, and postoperative bleeding is often a carryover from failure to control bleeding during surgery that was not apparent when the abdomen was closed because of reflex vasoconstriction or hypotension.

A knowledge of the normal coagulation mechanism and potential abnormalities of this important system is important for every surgeon. Preoperative evaluation will minimize the risks of abnormal surgical bleeding. Surgical techniques and operations are designed to control bleeding and avoid hemorrhage; but, from time to time, every surgeon is confronted with heavy and uncontrolled bleeding during an operation. The surgeon who has the knowledge and experience in these difficult situations will not only have the skills required, but also will exhibit the leadership and confidence necessary to direct the whole operative team so that control of bleeding can be accomplished promptly and effectively.

Many benign gynecologic conditions are associated with an increase in menstrual blood loss (menorrhagia), an increase in the duration of menstrual flow (menometrorrhagia), an increase in the frequency of menstrual periods (polymenorrhea), or combinations of all three. Repeated small menstrual hemorrhages, such as those that occur with menorrhagia, will reduce the iron stores in the body over time. The daily dietary intake of iron is usually sufficient to replace the iron lost with normal menstruation, but it is inadequate to replace the increased loss of iron associated with heavy menstruation. In gynecologic patients with a history of heavy or prolonged menstrual blood loss, it is a good idea to check the hematocrit or hemoglobin before setting a date for elective surgery. Preoperative iron supplementation is indicated in these women because a good hematocrit level and adequate iron stores are the first step in managing perioperative hemorrhage. Transfusion before elective gynecologic surgery is rarely if ever indicated in women with chronic blood loss anemia. Menstrual blood loss may be controlled with hormonal therapy while surgery is delayed and iron supplementation given to enable the patient to replace her own hemoglobin stores.

The preoperative use of epoetin alfa (recombinant erythropoietin) for correction of preoperative anemia has been used successfully in orthopedics. Its application in gynecologic surgery remains unclear. It is probably most applicable in gynecologic patients with chronic renal failure, nonmyeloid (hematopoietic) leukemia, or human immunodeficiency virus (HIV). Occasionally, other forms of anemia will be encountered that require a more extensive evaluation and treatment before elective surgery. On the other hand, some women who present with acute blood loss from a ruptured ectopic pregnancy, or blood products from another human being.

DEFINITIONS

Autologous blood transfusion—A transfusion done with the patient’s own blood. Blood is usually drawn 2-4 weeks before anticipated surgery and stored. It, or the components, can be transfused if the patient requires a blood transfusion during surgery. This minimizes the risk of a transfusion reaction.

Hemostatic clips—Small V-shaped clips of stainless steel, titanium, or plastic that can be applied on small vessels or tissue for hemostasis.

Homologous blood transfusion—Transfusion of blood or blood products from another human being.

Parachute pack—Sometimes called an umbrella pack. A towel or large sheet is inserted through the vagina into the pelvis, and it is then filled from below with gauze packing. The edges are twisted together, and the pack is pulled down against the pelvic floor to control deep pelvic bleeding after pelvic exenteration.

Peanut dissector—A long clamp with a small cotton bud placed in the tip of the jaws. It is a useful tool for blunt pressure dissection of small spaces.

Total blood volume—About 8% of total body weight or between 4.5 and 5.0 liters in the average woman. Acute blood loss of 25% of total blood volume (about 1,500 cc) produces symptoms of tachycardia, hypotension, and decreased urine output. Transfusion should be considered when operative blood loss exceeds 15% of total blood volume. This can be roughly calculated by multiplying the patient’s weight in kilograms by 10 (750 cc for a 75-kg woman).

The prevention and control of bleeding are fundamental to the success of any operation. The daily dietary intake of iron is usually sufficient to replace the iron lost with normal menstruation, but it is inadequate to replace the increased loss of iron associated with heavy menstruation. In gynecologic patients with a history of heavy or prolonged menstrual blood loss, it is a good idea to check the hematocrit or hemoglobin before setting a date for elective surgery. Preoperative iron supplementation is indicated in these women because a good hematocrit level and adequate iron stores are the first step in managing perioperative hemorrhage. Transfusion before elective gynecologic surgery is rarely if ever indicated in women with chronic blood loss anemia. Menstrual blood loss may be controlled with hormonal therapy while surgery is delayed and iron supplementation given to enable the patient to replace her own hemoglobin stores.

The preoperative use of epoetin alfa (recombinant erythropoietin) for correction of preoperative anemia has been used successfully in orthopedics. Its application in gynecologic surgery remains unclear. It is probably most applicable in gynecologic patients with chronic renal failure, nonmyeloid (hematopoietic) leukemia, or human immunodeficiency virus (HIV). Occasionally, other forms of anemia will be encountered that require a more extensive evaluation and treatment before elective surgery. On the other hand, some women who present with acute blood loss from a ruptured ectopic pregnancy, or blood products from another human being.
remedy excessive bleeding can be found. Hemostasis is a complex, intricate, integrated, complementary, and countervailing system that maintains a delicate balance between normal coagulation and hypocoagulation or hypercoagulation. Unusual clinical situations can arise that require hematologic consultation for resolution. A specialist in coagulation disorders can provide invaluable assistance in the diagnosis and treatment of many rare disorders of coagulation.

The following is a discussion of the principles and concepts of normal hemostasis, abnormal hemostasis (congenital and acquired), and management techniques.

Effective hemostasis is the result of all aspects of the coagulation system functioning together to stop bleeding. Coagulation is the working interrelation of five aspects of a complex biochemical and vascular system that causes the formation and dissolution of the fibrin platelet plug. These five aspects are (a) vasculature, (b) platelets, (c) plasma clotting proteins, (d) fibrinolysis and clot inhibition, and (e) the hypercoagulable response. How these five components interrelate in the normal setting must be understood before one can appreciate how the five relate to bleeding or abnormal clotting in disease states.

**Vasculature**

The vasculature presents an endothelial-lined flexible conduit through which red cells, white cells, platelets, and all of the plasma proteins flow. At the interface between the flowing blood and vessel wall are several inhibitory biochemical systems that prevent the generation of the platelet-thrombin clot. The antiprotein substance prostacyclin, produced in the vessel wall, inhibits platelet adhesion to the vessel wall. The surface antithrombin III–heparan sulfate complex inhibits deposition of thrombin and fibrin. A tear in the vessel wall removes the endothelial cell layer, exposing the basement membrane, smooth muscle, collagen, and supporting adventitia. These substances are biochemical activators of platelets and have their own thromboplastogenic activity, which initiates fibrin generation and deposition. Therefore, the disruption in the vessel wall removes the protective covering of the endothelial cells, exposing platelet clumping and clot-maintaining substances that produce a platelet-fibrin mass that will plug the tear in the vessel wall. A disease or medication that interferes with or intensifies this process can cause bleeding or inappropriate clotting. The vessel wall is diagrammed in Figure 19.1.

Congenital diseases associated with inadequate connective tissue and vascular dysfunction associated with bleeding are rare. The more frequently seen conditions are hereditary hemorhagic telangiectasia, Ehlers-Danlos syndrome, and Marfan syndrome, which are characterized by defects in the quality of collagen. Defective collagen is responsible for poor clot formation and platelet activation at the injured site. No disease is known to be associated with excessive inappropriate clotting related to the vasculature as a structure. The congenital diseases closest to that definition are a predisposition to artherosclerosis owing to abnormalities in lipid metabolism, such as hypercholesterolemia, homocystinemia, and diabetes mellitus.

Acquired diseases of the vessel wall associated with bleeding include deficiencies in vitamin C; Cushing syndrome; acute and chronic inflammatory diseases, such as infectious vasculitis and immune vasculitis; pyogenic purpura; embolic purpura, and anaphylactoid reactions from drugs, Mycosis fungoides, disorders, such as multiple myeloma and Waldenström macroglobulinemia, produce abnormal proteins that interfere with vascular function and therefore permit bleeding.

**Platelet Function**

Platelets are disk-shaped fragments of the large multinucleated megakaryocytes released from the bone marrow on a daily basis (normal count is 150 × 10^3/mL to 400 × 10^3/mL) (Fig. 19.2). Their life span is 8 to 10 days. These microscopic fragments have a well-defined substructure that can be directly correlated with platelet function.

**Figure 19.1.** Vessel cross section.

Routine laboratory assessment of vascular function is extremely primitive. The capillary fragility test, the only routinely available test used to assess vascular function, has limited value. It is sensitive to only the superficial vascular structure abnormalities. More in-depth studies include vascular biopsies and skin window testing procedures, which are research procedures. There are no routinely available methods for assessing increased vascular activity in the area of inappropriate clotting.
vascular trauma. Its absence results in the failure of platelets to bind normally to disruptions in the vasculature, preventing formation of the platelet plug necessary for normal hemostasis. The condition remains undetected in most patients until some form of vascular trauma occurs or surgery is performed. In addition, such patients are particularly sensitive to aspirin or other antiplatelet medications and bleed excessively in surgery while taking this kind of medication. von Willebrand disease is the most common congenital platelet disorder and is the disease most likely to go undetected until surgery. This disorder is particularly dangerous because, in its milder forms, a history of bleeding in surgery is negative and the preoperative coagulation screen is normal. Acquired defects in platelet function are much more common and can be classified into two groups: (a) those that are the result or consequence of a disease, such as renal failure, myeloproliferative disorders (polycythemia vera, chronic myelogenous leukemia), and increased fibrin split products in consumptive coagulopathies; and (b) those that are iatrogenic, such as defects caused by medications (aspirin, nonsteroidal anti-inflammatory drugs, antibiotics, antihistamines, tricyclic antidepressants, dextran) and cardiopulmonary bypass surgery.

Congenitally increased platelet function has not been described. Acquired disorders associated with increased platelet function, however, are common. The stress of routine surgery or trauma (fractured hip, femur, or pelvis) can create a hypercoagulable state with thrombocytosis and increased platelet activity.

The laboratory assessment of platelet function has been expanded from the research laboratory and is more readily available to the surgeon. The routine analysis of platelet function should begin with a platelet count and PFA-100. In special cases, platelet adhesion and platelet aggregation are useful in identifying the inadequate or overstimulated platelet. In addition, biochemical markers for increased platelet use or turnover can be demonstrated with platelet factor IV and β-thromboglobulin assays. Studies by Gewirtz and colleagues confirm previous studies that the bleeding time is not a good prediction of surgical bleeding.

DDAVP, Deamino-8-D-arginine vasopressin. The remainder of the known congenital clotting disorders are very rare and occur with such low frequency that their discussion, diagnosis, and management can be found elsewhere. (See Harker LA. Hemostasis manual, 2nd edition. Philadelphia: FA Davis; 1974; Corriveau DM, Fritsma GA. Hemostasis and thrombosis. Philadelphia: JB Lippincott Co; 1988; Triplett DA, ed. Laboratory evaluation of coagulation. Chicago: ASCP Press; 1982.)
Plasma-clotting proteins are a group of serine proteases and cofactors that interact in a synergetic system to generate fibrin. The activation of the clotting system can be initiated in two ways: either by contact activation with factor XII or through thromboplastin activation of factor VII. The clotting cascade is diagrammed in Figure 19.3. As we will see later in the discussion of fibrinolysis and antithrombin systems, anticoagulation forces are initiated at the inception of clotting. The tear in the vessel wall, described earlier, begins the orderly activation of the plasma-clotting system. The fibrin contribution to the platelet-fibrin plug is initiated with the activation of factor XII by collagen and of factor VII by tissue juice (thromboplastin). Any congenital or acquired disorder of the clotting factors can lead to inadequate or no generation of fibrin. Each clotting factor has a different role and significance in the overall generation of fibrin. This also is true with abnormal increases in some clotting factors that are associated with inappropriate clotting.

The congenital-factor deficiencies associated with bleeding are either relatively common or rare. The relatively common group includes hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency). Both are seen in the male and rarely in the female disorders with sex-linked inheritance patterns. The rare group includes all the remaining factors that have an autosomal recessive inheritance pattern or a dominant pattern with variable penetrance.

The acquired factor deficiencies are common. Multiple deficiency is usually owing to iatrogenic vitamin K deficiency with loss of factors II, VII, IX, and X. This deficiency often is the result of multiple-antibiotic therapy, which kills the vitamin K-producing bacterial flora in the intestine, and the nothing-by-mouth status of many critically ill patients, which results in the loss of food sources of vitamin K. Other common acquired multifactor deficiencies are seen in acute and chronic liver disease, as in viral hepatitis and alcoholic cirrhosis; consumptive coagulopathies, as in sepsis and placenta abruptio; and major trauma, as from automobile accidents or gunshot wounds.

The laboratory assessment of the plasma clotting factors has traditionally begun with the prothrombin time (PT; factors V, VII, and X, prothrombin, and fibrinogen) and the activated partial thromboplastin time (APTT; factors VIII, IX, XI, and XII). Specific factor assays also can identify the exact deficiencies. One must remember that a factor deficiency as low as 30% can generate a normal PT and APTT. This relation is important in investigating minimal prolongations of the PT or APTT that appear insignificant but could be hiding a moderately severe deficiency. The tissue factor pathway inhibitor modulates activated factors X and VIII but is not apparently significant in disease.

The sensitivity of the PT and APTT reagents is essential to the appreciation of the proper use of these tests as preoperative...
stress, there is a response of fright or flight. This response to
With physiologic stress, such as emotional stress and surgical
lyses fibrin clots and destroys fibrinogen. This enzyme is mod-
plasmin. Plasmin is the active enzyme that if free or clot-bound
conversion of fibrinolysis normally is initiated by plasminogen activator inhibitor-1 (PAI-1). Sometimes direct activation is seen in liver disease and during extracorporeal bypass. This activation also can be secondary to disease, as
increased need. When this process is exaggerated, uncontrolled,
or unmodulated, inappropriate clotting can occur, which pro-
duces venous and arterial clots and all their sequelae. In gyne-
ocologic surgery, the normal physical hypercoagulable state, as
well as the inappropriate state, must be understood to appreci-
ate the diagnosis, intervention, and management of postoper-
ative vascular occlusive complications. Virchow, in 1845, was
the first to conceptualize the triad of blood flow, vessel wall,
and content of blood itself as a basis for inappropriate clotting.
An understanding of the relation of the three parts is essential
to explain what has occurred in the problem patient.

**Fibrinolysis**

The activation of the fibrinolytic system begins with the acti-
vation of the plasma substrate plasminogen. This substrate is
converted by naturally occurring activators such as urokinase,
kallikrein, and clot-activated proteases to the active enzyme
plasmin. Plasmin is the active enzyme that if free or clot-bound
lyses fibrin clots and destroys fibrinogen. This enzyme is mod-
ulated by α2-antiplasmin and antitrypsin, which destroy the
active enzyme plasmin.

This enzymatic conversion of fibrinolysis normally is initi-
at ed by clot formation or by a direct activator such as uroki-
nase or tissue plasminogen activator (tPA). tPA released from
the endothelium activates tissue plasminogen and is neutral-
ized by plasminogen activator inhibitor-1 (PAI-1). Sometimes
direct activation is seen in liver disease and during extracorporeal bypass. This activation also can be secondary to disease, as
in a consumptive coagulopathy—such as bacterial sepsis—or a
large abdominal aneurysm.

**Hypercoagulable State**

With physiologic stress, such as emotional stress and surgical
stress, there is a response of fright or flight. This response to

**CONGENITAL CAUSES OF INAPPROPRIATE CLOTTING**

The congenital etiology of inappropriate arterial and venous
clothing has long been ill defined. Only recently has it been more
completely elucidated (Tables 19.3 and 19.4). Procoagulants,
when increased on a congenital basis, have been associated
with a propensity to generate clots. These procoagulants in-
clude fibrinogen and factor VIII; however, they are not present
frequently enough to warrant testing every suspect case. Natu-
really occurring inhibitors of clotting are defined as those factors
that actively destroy clotting factors or substrates as they are
formed. The more common of these rare deficiencies are an-
tithrombin, protein C, protein S, factor V Leiden (R506Q),

factor II mutation (G21201A), PAI-1 polymorphisms 4G/5G, and methylenetetrahydrofolate reductase mutations (C677T, A1298C).

IMPAIRED FIBRINOLYSIS
A congenital decrease in the plasma substrate plasminogen results in inadequate fibrinolysis of thrombi. This deficiency can be qualitative and quantitative, with similar effects.

A congenital decrease in tPA that normally is released from the vascular endothelium is associated with impaired fibrinolysis. An abnormal increase in plasminogen activator inhibitor also will reduce the level of tPA, resulting in inappropriate clotting, elevated PAI-1 secondary to obesity, metabolic syndrome, or acute phase reactions.

The decrease or absence of Fletcher factor (prekallikrein) and factor XII also can result in impaired fibrinolysis because of a decrease in activation of circulating plasminogen at the time of clot activation.

ACQUIRED CAUSES OF INAPPROPRIATE CLOTTING
The number of acquired causes of inappropriate clotting is much greater than the number of congenital causes and is expanding every day because the same chemistry found in the congenital mechanism can be identified as a deficiency in an ongoing disease process. These include such risk factors as an elevated factor VIII, fibrinogen, metastatic cancer, myeloproliferative disorders, and diabetes/metabolic syndrome.

Iatrogenic causes of inappropriate clotting are common findings in the hospital setting and generate great concern. Such causes include the postsurgical state, medication, vascular prothropic devices, and immobilization for any reason.

As a physiologic acute-phase response to surgical stress, an exaggerated outpouring of clotting factors and platelets in combination with a decrease in physiologic inhibitors can result in clot formation. This occurs in deep leg veins, particularly in association with venous stasis.

Prosthetic devices such as grafts, shunts, and artificial heart valves can provide a clottable surface that will form a nidus for initial thrombosis quickly followed by further clot formation, resulting in obstruction or embolization.

The vascular component of acquired thrombotic disease has only recently been described in detail. It appears that decreased blood flow through a vein can decrease the contact between thrombin and thrombomodulin, diminishing the contact with protein C and predisposing the vein to thrombosis. However, the arterial side with high blood flow rates has a rich capillary bed with greater contact with protein C, lysing clots more efficiently. Local thrombus formation can be generated by direct mechanical disruption of the vascular endothelium, traumatic damage to the vessel wall, infectious or chemical damage to the vessel wall, and vasculitis.

PREOPERATIVE COAGULATION ASSESSMENT FOR SURGICAL PATIENTS
For the preoperative evaluation, gynecologic patients must of necessity be divided into two categories: those having routine or elective surgery and those having emergency surgery.

Elective Surgery
The elective gynecologic surgical patient must be evaluated in two ways: general medical history and specific nature of the surgery. The medical history taken at bedside, with review of the medical chart when available, is an excellent place to begin. Table 19.5 highlights the most important positive and negative findings to be identified.

Preoperative coagulation screening is of limited value without complete knowledge of the patient’s past and current medical history.

†Reference ranges may vary in each laboratory, reflecting method, instrumentation, and reagents.
replacement therapy and the complications of such therapy depends on a clear understanding of the following concepts.

1. As bank blood replacement with just packed red cells corrects the blood loss problem, it may create an acquired bleeding disorder, thrombocytopenic hemophilia. Platelets and fresh-frozen plasma may be indicated.

2. The patient’s bleeding will slow and will change rapidly and frequently with the loss of blood and replacement therapy.

3. Direct monitoring before, during, and after surgery offers the best chance to diagnose and manage the bleeding. Direct monitoring also allows formulation of plans and adjustment of the replacement therapy program.

COMPONENT THERAPY FOR REPLACEMENT BEFORE SURGERY

With surgery planned, the preoperative data can be evaluated. Assuming the patient does not have hemophilia, von Willebrand disease, severe liver disease, or liver failure, a prolonged PT and APTT may suggest a less common acquired or congenital bleeding disorder. (The blood sample must be properly drawn and mixed well and must not be taken from an A-line containing heparin or from an infusion site.) Assistance from a clinical pathologist or hematologist should be requested if an intrinsic bleeding disorder is suspected.

According to Schiffman and Steinhron, when intraoperative blood loss exceeds 15% of the patient’s estimated blood volume, the surgeon should consider red blood cell transfusion to replace the acute blood loss. As a general rule, 15% of an adult’s blood volume equals the patient’s weight (in kilograms) times 10. For example, for a 50-kg woman (110 lb), 15% of blood volume is (50 × 10) 500 mL; for a 75-kg woman (165 lb), 15% of blood volume is (75 × 10) 750 mL; for a 100-kg woman (220 lb), 15% of blood volume is (100 × 10) 1,000 mL. The patient’s estimated blood volume, the estimated intraoperative blood loss, the anticipation of additional blood loss, the presence of preoperative anemia, and the risk of hypovolemic complications must all be taken into consideration when deciding whether to transfuse.

When massive blood replacement therapy is under way, intraoperative monitoring of coagulation at 2-hour intervals, or after every 10 U of blood transfused, usually is sufficient. One should remember that a patient bleeding during a surgical procedure has a higher demand for clotting factors and platelets than does a patient at bed rest. In many oncology cases in which the patient is undergoing chemotherapy, a platelet count of 50,000/mL is adequate; in a surgical case in which the patient is bleeding, a 50,000/mL platelet count is not adequate to achieve a good platelet plug. The use of blood and blood components in the management of massive bleeding that is due to a major vessel rupture has the following objectives:

1. To maintain sufficient blood volume and circulating red cells to sustain life

2. To replace blood sufficiently to achieve adequate coagulation and hemostasis, assuming there was extensive loss of plasma-clotting factors and platelets

3. To avoid falling so far behind in replacement that management involves not only bleeding from a vascular tear but also bleeding at the microvascular level because of insufficient clotting factors and platelets

Each of these objectives requires repeated assessment of the patient throughout the surgical procedure. Careful monitoring by established routine policies often is the best way to handle a crisis situation created by massive bleeding.

Formulas for blood transfusion that are applied ritualistically without the benefit of laboratory data may resolve the need to treat but do not answer the needs of the patient. The formulas described below are designed to initiate the marshaling of blood bank resources. They do not replace the thoughtful analysis of laboratory data coupled with the selection of a specific blood component to correct a specific deficit. The following guidelines are recommended for component therapy in clinical situations requiring massive blood replacement to maintain normal hemostasis.

For every 6 to 8 U of packed red blood cells, 2 U (500 mL) of fresh-frozen plasma should be given. The size and age of the patient affect blood replacement. If the patient’s blood volume can accommodate an additional 500 mL of fresh-frozen plasma, this amount should be transfused and the PT and APTT monitored.

Platelets should be given when the platelet count falls below 100,000/mL in massive hemorrhage. (Measurement error of a platelet count can be as high as 62,000/mL in a bleeding patient.) When a long surgical procedure is anticipated, or when more than 6 U of blood are given, 6 U of platelets in a volume of 300 mL should be given toward the end of the surgical procedure or when surgical hemostasis is achieved. This amount should be administered once to provide a maximum bolus effect. Because platelets are often difficult to obtain, their use should be reserved until near the end of the procedure. Otherwise, they may be lost and therefore unavailable when needed because of continued blood loss and replacement during extensive surgical repair. Pooling and transporting the platelets can take up to an hour, so the blood bank should be given sufficient notice to have them available in surgery when needed.

When massive blood replacement therapy is under way, intraoperative monitoring of coagulation at 2-hour intervals, or after every 10 U of blood transfused, usually is sufficient. Six units of platelets will achieve maximum bolus effect in an average patient (3 U in a child or small adult) and will also enable evaluation of platelet use. A platelet count of 40,000 to 60,000/mL should be expected in a 70-kg person after transfusion of 6 U of platelets. Monitoring the platelet count after transfusion and for the next several hours will reveal the success of replacement, consumption, and life of the platelets.

When the PT and APTT are prolonged (more than 14 seconds and 40 seconds, respectively) after replacement therapy, intrinsic disease must be considered initially, if only to be ruled out later. A borderline hemophilia or patient with liver disease may manifest excessive bleeding after stress, trauma, or blood replacement because of the increased coagulation needs. A mild hemophilia or liver disease is rare as an unknown, but it is possible. Therefore, administration of fresh-frozen plasma in these 2 U (500 mL) doses should begin to correct the deficiencies caused by massive red blood cell replacement. If oozing continues despite the rapid transfusion of 6 U of fresh-frozen plasma, a clotting problem or other ongoing bleeding disorder should be suspected and additional support sought.
When the fibrinogen level falls below 100 mg/dL, transfusion of 20 U of cryoprecipitate will provide about 130 mg/dL fibrinogen in a 70-kg person. A low fibrinogen level is rare because fibrinogen is stable and present in fresh-frozen plasma.

LIVER DISEASE OR INTRAVASCULAR CONSUMPTION

Liver disease or intravascular consumption must be suspected if the fibrinogen level is initially less than 100 mg/dL and remains low throughout surgery and recovery. The 20 U of cryoprecipitate will achieve therapeutic levels quickly and permit monitoring over several hours.

The goals of intraoperative monitoring are as follows:

1. To assess changes in the coagulation mechanism resulting from blood loss and replacement therapy
2. To identify the coagulation components affected and determine the correct components to initiate therapy
3. To determine the success of replacement component therapy in an extensive operative procedure
4. To enable selection of components to achieve the following values: PT less than 14 seconds, APTT less than 40 seconds, fibrinogen more than 100 mg/dL, and platelets more than 80 × 10^9/L. If surgical hemostasis appears to have been achieved from a technical viewpoint and bleeding is present but mild, one can “wait to see” for 2 hours. If bleeding is profuse and worsening, 2 to 4 U of fresh-frozen plasma and a 6- to 10-U dose of platelets are given, and then packed red cells are given as needed. The patient is monitored when the transfusion is completed. Laboratory monitoring is repeated after 1 to 2 hours, whether the patient is bleeding or not, to determine the success of replacement.

COMPONENT THERAPY FOR POSTOPERATIVE REPLACEMENT

The presurgical and intraoperative alarm levels for hematocrit, platelet count, PT, APTT, fibrinogen, and clot retraction also apply postoperatively, and a comparison of these values provides an accurate assessment of the bleeding patient. Significant clinical bleeding with good postoperative coagulation values suggests surgical bleeding. When laboratory values are abnormal, however, further surgery can be delayed until an attempt at aggressive specific component therapy is made. We have found that when abnormal coagulation studies exist, the following causes predominate, in order of frequency (most frequent first):

1. Low platelet count owing to transfusion of only packed red cells or fresh-frozen plasma
2. Prolonged PT and APTT owing to replacement with packed red cells without fresh-frozen plasma. In administering aggressive replacement therapy, it should be remembered that some patients have a meager blood volume. Careful monitoring of venous and arterial pressure, as well as cardiac output, should be considered in blood component therapy. Often a slower rate of administration can achieve hemostasis without cardiovascular overload. In rare cases, phlebotomy may be required to create needed space for transfusion. If nearly normal coagulation values are achieved but bleeding continues, surgical causes for bleeding should be considered.
3. Low fibrinogen level owing to dilution with plasma expanders or concurrent development of a disseminated intravascular coagulation (DIC) syndrome.

The goals of postoperative monitoring are as follows:

1. To determine whether a coagulopathy was created by blood replacement and to determine current status
2. To determine the success of specific component therapy and identify the need for additional components
3. To enable the surgeon to distinguish surgical from nonsurgical bleeding

The routine use of postoperative monitoring, whether the patient is bleeding or not, will achieve these goals. As the surgeon reviews the results of each case, he or she will develop a valuable assessment of the patient’s usual postoperative coagulation states. With this knowledge, the unexpected is recognized and resolved in a more timely manner.

RISKS OF BLOOD TRANSFUSION

Transfusions of whole blood were given sporadically before 1900, usually to treat specific diseases rather than to replace lost blood volume. Indeed, heavy bleeding was thought to be beneficial and therapeutic for many diseases. Even as late as World War I, the importance of blood loss and replacement was not recognized, because shock was thought to be owing to toxins released from traumatized tissue. It was the work of Cannon and Bayliss in 1919 and of Blalock in 1930 that proved the important factors in shock were the loss of circulating blood volume and the decreased return of venous blood to the right heart.

Landsteiner discovered the four major blood groups in 1900. Banking and storage of donated blood became possible with refrigeration and the addition of sugar and later sodium citrate as an anticoagulant. In World War II, a remarkable program was organized to collect and store large quantities of type O (so-called universal donor) blood for shipment to U.S. military hospitals throughout the world. Many lives were saved by the use of this banked blood to treat the shock associated with battle casualties. This experience firmly established the need for blood banks and the importance of blood transfusions in combatting hypovolemic shock from hemorrhage before, during, and after surgery.

To be safe, homologous blood must be collected from carefully selected volunteer donors and properly matched to the potential recipient. Although many lives have been saved by properly administered transfusions, gynecologic surgeons must be aware of the potential hazards of perioperative transfusions. The risks of red blood cell transfusion were reviewed by a National Institutes of Health and Food and Drug Administration Consensus Development Conference on Perioperative Red Cell Transfusion and published in 1988. The following excerpt is taken directly from their report.

In deciding whether to use red blood cell transfusion in the perioperative period, the need for possibly improved oxygenation must be weighed against the risks of adverse consequences, both short term and long term. The disadvantages are of two general types: transmission of infection and adverse effects attributable to immune mechanisms.

Any infectious agent that is present in the blood of a donor at the time of donation is potentially transmissible to a susceptible recipient. The consequence may be seen as clinical morbidity and mortality after an incubation period characteristic of the agent or recognized only by serological or other types of laboratory testing. If the agent produces chronic infection, clinical mortality may not be seen until years after the transfusion (Table 19.8).
Cytomegalovirus infection occurs with moderate frequency in transfusion recipients. Human T-cell lymphotropic viruses occur with low but not negligible frequency among donor populations in the United States. It is not known whether transfusion-transmitted infections with these viruses are currently occurring. Patients with cancer, in particular those receiving immunosuppressive therapy, are at increased risk for these infections. Epstein-Barr virus, and other paroviruses, are common in the United States. It is known for the human hepatitis viruses that the incidence of infection in recipients increases with the number of red blood cell units transfused. The use of the newer leukocyte reduction filters (<5 × 10^6) is under extensive clinical study and application as an alternative to cytomegalovirus-negative red blood cells. There are alternatives to blood and blood component transfusion that may be considered in critically ill patients such as those with sepsis and deseminated intravascular coagulation. The drug activated protein C, drotrecogin alfa (Xigris), is recombinant human activated protein C (drotrecogin alfa, activated). It is used in replacement therapy in sepsis and holds a great promise in the management and survival in sepsis. Replacing this essential naturally occurring anticoagulant, there is reversal of the bleeding and thrombosis seen with sepsis. Its specific application in septic gynecologic surgical patients has recently been reported in the transplant and cardiac surgery setting. It has been demonstrated to successfully manage patients with FVIII and FIX inhibitors. It has also been used in management of bleeding in cardiovascular surgery, liver failure, and in sepsis. There is limited experience with drotrecogin alfa in the treatment of similar complications in gynecologic surgery.
According to Friedman and colleagues, in every age range the mean hematocrit of men is higher than that of women. Women adapt to this relative state of anemia physiologically by a variety of mechanisms. Their red blood cells have a greater capacity than those of men to release oxygen. The erythrocyte oxygen dissociation curve of women is right-shifted when compared with that of men. Levels of 2,3-diphosphoglycerate, adenosine triphosphate (ATP), and glucose-6-phosphate are higher in the red blood cells of women than in those of men. Because of these physiologic adaptations, Friedman and colleagues suggest that a lower hematocrit support level to govern the blood transfusion of female surgical patients be considered.

There are a variety of methods to support circulating volume, but there is no available material to support oxygen transport. Future research may be successful in developing modified hemoglobin solutions and perfluorocarbon emulsions for oxygen transport, but there currently is no substitute for red blood cells for this purpose.

In a comprehensive discussion of perioperative interventions to decrease transfusion of allogeneic blood products, Ereth and associates suggest that an increased awareness of transfusion-related morbidity from allogeneic blood products has resulted in increased development and application of alternatives to allogeneic transfusion. As an indication of what can be accomplished, a program instituted by the Transfusion Committee of the Methodist Hospital of Indianapolis modified transfusion practice in the hospital by establishing new transfusion guidelines based on national standards rather than on local practices and by implementing educational and monitoring systems. As reported by Rosen and colleagues, over a 3-year period, the total decrease in donor exposures for patients was 42,072. Overall savings amounted to $3,627,148. This program was able to effect substantial cost and patient risk reductions, even though hospital services involving blood transfusion increased. A comprehensive update titled “Transfusion Medicine in Obstetrics and Gynecology” was published recently by Santoso and associates.

**AUTOLOGOUS BLOOD TRANSFUSION**

Blood collected from a patient for transfusion at a later time into the same patient is called autologous blood. Autologous blood transfusions have been endorsed by the Council on Scientific Affairs of the American Medical Association and by the Committee on Hospital Transfusion Practice of the American Association of Blood Banks. If established guidelines are followed, autologous blood is the safest type of blood for transfusion. It does not eliminate all risks associated with red blood cell transfusion, because there is still the possibility of a hemolytic reaction caused by the rare clerical error or bacterial contamination. It does eliminate the risk of alloimmunization and the risk of transferring such infections as hepatitis, malaria, cytomegalovirus, and AIDS. In patients with rare blood types who have antibodies to common blood antigens, it may be the only blood available for transfusion. Autologous blood transfusion is acceptable to most Jehovah’s Witnesses who have a variety of other patients, including gynecology/obstetric patients, were represented.

A general subject review of intraoperative autologous transfusion was published by Popovsky and associates in 1985. These investigators stated that although the technology of the earlier experiences was comparatively crude and associated with technical problems and complications, better methods have been developed in recent years to eliminate problems in the operation and maintenance of the machinery and to make intraoperative autologous transfusion safe. Our experience in gynecologic surgery reported by Shapiro and Fordko, although limited at this point to a series of 25 myomectomy operations, has demonstrated to our satisfaction that intraoperative autologous transfusion is convenient to use and does not in any way interfere with the performance of the procedure.

The Haemonetics Cell Saver operates by retrieving blood from the operative site by suctioning it into a double-lumen catheter, in which it is immediately anticoagulated with heparin. It is then collected in a cardiomyocyte reservoir, where a filter removes gross debris. The blood is then pumped to a spinning centrifuge bowl, where the red blood cells are separated, washed with normal saline solution, and then concentrated to a hematocrit of about 50%. The supernatant waste that is subsequently collected contains saline, anticoagulant, activated coagulation factors, platelets, leukocytes, free hemoglobin, and other small debris. The washed packed red blood cells are pumped into a reinfusion bag. The blood is then directly transfused to the patient through a filter. The reagents and the collecting system are sterile and disposable. The entire process takes 8 to 10 minutes to process about 250 mL of packed cells. The machine is maintained and operated by a trained technican.

At least until additional data are available to the contrary, intraoperative autologous transfusion is contraindicated in patients with malignant disease and in patients with bacterial contamination of blood in the operative field. Although the addition of antibiotic agents to the cell-washing system can reduce or eliminate contaminating bacteria, some bacteria with the potential of causing systemic infection if reinfused may remain. There is a theoretical concern that malignant cells contained in reinfused blood may be responsible for generalized seeding of the malignant process. Although there are no data to support or deny this position for medicolegal reasons at least— intraoperative autologous transfusion should be considered contraindicated in a patient with cancer unless the need is desperate. It is difficult to distinguish the hematologic changes induced by intraoperative autologous transfusion from the changes induced by hemorrhage and massive transfusion with homologous blood products for the use of component therapy are the same for both groups.
Merrill and colleagues reported the use of intraoperative autotransfusion in 38 patients with ruptured ectopic pregnancy. Transfusion-related morbidity occurred in six patients; two patients developed clinical coagulopathy, two patients developed pulmonary edema, and two patients developed minor transfusion reactions from concomitantly used bank blood. The total amount of retransfused blood was 49,473 ml, or 59% of the total amount of blood administered. This saved about 90 U of banked blood.

Merrill and colleagues reported the use of intraoperative autotransfusion in 38 patients with ruptured ectopic pregnancy. Transfusion-related morbidity occurred in six patients; two patients developed clinical coagulopathy, two patients developed pulmonary edema, and two patients developed minor transfusion reactions from concomitantly used bank blood. The total amount of retransfused blood was 49,473 ml, or 59% of the total amount of blood administered. This saved about 90 U of banked blood. It must be remembered that both autologous (intraoperative) and homologous blood are essentially packed red blood cells. One risk with autologous blood transfusions is forgetting that only the patient’s packed cells are transfused. The patient will still need fresh-frozen plasma and platelets when massive transfusion of autologous blood is used.

**Predonote Autologous Blood Transfusion**

Because blood transfusion is so rarely required in gynecologic surgery for benign disease, predonote of autologous blood for intraoperative transfusion is rarely indicated. However, certain patients may strongly desire this approach if there is any possibility of requiring a transfusion; in some patients with malignant disease or other extensive surgery, the risk of transfusion may be significant. Experience has shown that autologous blood can be collected and stored as whole blood, red blood cells, plasma, or platelets for retransfusion into the same patient during surgery if needed or at some other time. Donation can be scheduled at weekly intervals up to 3 days before surgery. Oral iron therapy is administered, and the hematocrit and hemoglobin levels must not be low. The American Association of Blood Banks’ standards for elective preoperative autologous blood donation include the following guidelines:

- A hemoglobin of no less than 11 g/dL or a packed cell volume of no less than 34%.
- Phlebotomy no more frequently than every 3 days and not within 72 hours of surgery.

If a patient’s condition is stable enough to allow elective surgery, then preoperative donation for autologous transfusion is not contraindicated. Mann and associates studied the safety of autologous blood donation before elective surgery for a variety of potentially high-risk patients. Of 300 patients in the study, 46 were at least 70 years old. Four percent of patients experienced a minor reaction to blood donation. This method of providing autologous blood should have applicability in gynecologic surgery. Experience suggests that it should be encouraged when practical.

The number of centers providing autologous blood transfusion programs will probably continue to increase as a result of AIDS and public knowledge of the possibility of spread of this disease by homologous blood transfusion, even though rare. Programs encouraging selected patients to donate their own blood before surgery are becoming increasingly popular, despite the numerous logistical problems that must be solved. Only 2% of the blood collected in the United States is for predepost autologous transfusion.

Much of gynecologic surgery is elective, and many patients are comparatively healthy. Elective gynecologic surgery often is scheduled 3 to 4 weeks in the future. During this time, many patients will have blood predonote for use during operation. Only about 2% of patients undergoing elective hysterectomy require blood transfusion, depending on the skill of the operator and the extent and nature of the gynecologic pathology.

Routine predonote of autologous blood is not recommended for hystereotomy for benign disease.

Goodnough and colleagues have found that the administration of recombinant human erythropoietin increases the amount of autologous blood that can be collected before surgery. The volume of red cells donated by patients treated with erythropoietin during the study was 41% greater than that donated by patients given placebo.

**BASIC SURGICAL PRINCIPLES TO AVOID EXCESSIVE BLEEDING IN PELVIC SURGERY**

It is easier to stay out of trouble than to get out of trouble! A good knowledge of the surgical anatomy is the basis for avoiding hemorrhage. A well-planned surgical procedure with good exposure, precise placement of the clamps, skillful dissection technique, and careful suture placement are all important. In addition to good technical ability, surgical judgment is a key ingredient to a consistently excellent surgical outcome. Should the densely adherent bladder be dissected a little more before clamping across the vagina? Should the endometriosis in the posterior cul-de-sac be dissected free from the sigmoid colon or just cauterized? These decisions occur constantly during any operation, and the surgeon who knows the patient, the disease entity being treated, the technical details of the planned surgical procedure, and his or her own technical abilities can confidently make these judgments that will result in a successful surgical outcome and avoid complications such as intraoperative hemorrhage.

Among the many contributions to surgery made by William S. Halsted, chief of surgery at Johns Hopkins Hospital, was a surgical technique that emphasized meticulousness in dissection, gentleness in the handling of tissues, accuracy in hemostasis, precision in wound approximation, and absolute asepsis. This meticulous technique has become widely known in the United States as the Halstedian technique. It promotes good tissue healing by reducing tissue damage and wound infection. The accuracy of dissection, hemostasis, and tissue approximation is emphasized rather than speed, but wasting time with unnecessary hesititation, indefiniteness, and indecision can increase blood loss and the risk of infection. The experienced surgeon will be able to finish the operative procedures in a deliberate, purposeful, timely, and precise manner. The speed with which the dissection is performed should be varied from one phase of the operation to the other, but the operation should progress in an orderly manner. For example, the incision can be fashioned with some haste, but dissection around deep pelvic veins must be performed with great caution to avoid injury and bleeding. Although shorter operative procedures are generally associated with less blood loss and lower rates of infection, the pace of the procedure should be governed by the difficulty of the surgery and the skill and experience of the surgeon. Too much haste will sooner or later result in excessive blood loss or injury to adjacent organs or structures, which will ultimately prolong the operation. Technical aspects of surgical technique, including good exposure, gentle handling of tissues, accurate clamp placement, and good suture technique—which includes secure knot tying—are all important characteristics that will minimize blood loss and contribute to a successful and well-executed operative procedure. It is impossible to place too much emphasis on the need for optimum exposure to limit blood loss. During vaginal operations, a contracted pelvic outlet will limit exposure for vaginal
Control of Pelvic Hemorrhage

A leiomyomatous uterus may require morcel-
lization to allow sufficient exposure for safe vaginal removal. A Schuchardt incision may be required to improve exposure
during vaginal operations. If exposure is inadequate, bleed-
ing from vessels in the upper broad ligament may not be
controllable from below, and an abdominal incision may be
necessary to achieve final hemostasis from above. When hem-
orrhage is not controlled by vaginal or laparoscopic surgery,
the question always arises, “When should the operation be
converted to an open abdominal procedure so that improved
exposure and better access can be used to control the bleed-
ing?” The answer to this question will vary depending on a
variety of circumstances, but good exposure will go a long way
toward solving many surgical difficulties. During abdominal
operations, the exposure achieved will depend on the choice
of incision, the method of retracting, the placement and intensity
of the lights, and the presence of willing and skilled assistants.
Suction should be available to keep the field as free of blood as
possible and is preferred over sponges for two reasons. First,
sponges can cause damage to delicate serosal surfaces. Second,
a determination of the amount of blood lost can be more accu-
rate if the largest percentage has actually been suctioned into a
calibrated bottle and measured. One can then add to this exact
amount an estimate of the amount of blood lost on the drapes,
sponges, and lap packs. The record of the amount of blood
lost should be as accurate as possible and can be of great value
in making correct decisions subsequently about the patient's
care, especially regarding the need for blood replacement in
case there is a suspicion of hypovolemia. Good lighting of the
surgical field is important. In addition to the standard surgical
lights, we have found that a headlight worn by the surgeon
and/or the assistants is very useful in providing excellent light-
depth in the pelvis. There are also lighted retractors, which
can be helpful in laparoscopy.

For pelvic laparotomy, the patient usually is placed in a mod-
est Trendelenburg position. In this position, the packs required
to keep the intestines displaced in the upper abdomen tend to
stay in place better, thereby enhancing exposure. An anesthetic
 narcotic is usually needed to keep the patient from pushing
her bowels into the operative field, especially when the dis-
section is tedious, and good exposure is mandatory for safe
performance of the operation. A retractor with an upper blade
or blades to retract the intestines out of the pelvis is very use-
ful and reduces the requirement for Trendelenburg positioning
and anesthetic muscle relaxation.

It usually is possible, and always desirable, to keep the num-
ber of clamps in the operative field to an absolute minimum.
If the field is cluttered with clamps, the operators cannot see
as well to operate. The length of the instruments must vary, de-
pending on the thickness of the abdominal wall, the depth of the
pelvis, and other variables. Pedicle clamps, tissue forceps,
dissecting scissors, needle holders, and all other instruments
must be longer for operations on obese patients and for exten-
sive operations in a deep pelvis. The handles of the instruments
must come all the way out and above the level of the incision so
as not to interfere with the operator’s view of the pelvis. There
is an unfortunate tendency for gynecologic surgeons to use in-
struments that are too short and not properly curved. The operator
must stand high enough to see down into the pelvis. The patient's abdominal
wall should be at about the level of the operator’s umbilicus,
not too high or too low.

Cushing, a neurosurgeon, introduced the hemostatic silver
clips in 1911 to occlude arterial vessels inaccessible to lig-
ation. More recently, clips have been made of stainless steel,
tantalum, and the new synthetically absorbable nonopaque poly-
dioxanone polymer. The latter has the advantage of not causing
the streaked artifact of metal clips when subsequent computed
tomography (CT) of the pelvis is performed. Clips cause little
tissue reaction, usually are easily and rapidly applied, and pro-
vide secure control of bleeding vessels in relatively inaccessible
places in the pelvis where ligature would be more difficult. A
small vessel can be quickly occluded with a clip even before the
vessel is cut, thus keeping the field dry and the tissues to be
sutured free of blood or laparoscopy. Clips are especially useful
in retroperitoneal dissections. They are available in several sizes.
Disposable applicators loaded with multiple clips are available,
obviating the need for reloading and facilitating rapid use. If
appropriately used, clips can reduce blood loss, facilitate dis-
section, and reduce operating time.

Working with Bovie, Cushing also pioneered the use of elec-
trosurgery for hemostasis. Modern electrosurgical units are
radiofrequency generators that supply 500,000 to 2 million
Hz of alternating current to the tip of the electrode. The best
techniques for use of electrosurgical equipment and important
safety information are well discussed in Chapter 15, but sev-
eral points should be emphasized. An electrosurgical instru-
ment can be used to coagulate small vessels or to cut through
fat or muscle. If a “blend” cut is used, small vessels will be
coagulated as the instrument divides the tissue.

The needlepoint electrode can be used for precise incisions
with minimal tissue injury from collateral thermal effect. Su-
perficial coagulation of small vessels can be achieved by hold-
ing the electrode close to the tissue, pressing the “coagulation”
button, and allowing the sparks to jump to the tissue surface.

The blood should not be allowed to pool. Dry surfaces are
much more effectively coagulated with the electrosurgical in-
strument. If bleeding is brisk, the vessel is grasped with a fine-
pointed clamp or forceps, and hemostasis can be achieved by
touching the metal clamp with the tip of the electrosurgical in-
strument and apply the “cutting” current. This may seem para-
doxical, but the “cutting” current actually results in a deeper
tissue effect in these circumstances, leading to better sealing
of large vessels. Bipolar electrodes built into tissue forceps are
also very effective for coagulating smaller vessels during te-
dious dissections. Experience with the electrosurgery will
result in maximum efficiency with minimum tissue damage and
a shorter operating time.

With a thorough knowledge of pelvic anatomy, the surgeon
should emphasize the development of pelvic planes and spaces.
This will avoid unnecessary bleeding and allow more accurate
placement of clamps on vessels. Certain parts of the dissection
can be delayed until later, especially if they are not needed now
and blood loss is likely to be increased. For example, when
abdominal hysterectomy is performed, dissection of the blad-
er away from the cervix and vagina may be associated with
bleed loss and should not be performed at the beginning of the
operation. Exposure of the anterior lower uterine segment and
cervix is not required until the uterine vessels and broad
ligament need to be clamped. Until then, there is no need to
start this potentially bloody dissection.

In the early days of abdominal pelvic surgery, postoperative
hemorrhage was common because an effective technique of
hemostasis was not known. The usual method of performing
abdominal hysterectomy involved use of a ligature on masse
around the lower uterus. This mass ligature saved time and
was used to occlude both uterine and ovarian vessels simulta-
neously. The uterine corpus with adnexa attached was simply
amputated above the ligature. The stump thus formed was such
a large mass of tissue that it could not be safely returned to the
peritoneal cavity because of the danger of intraperitoneal bleed-
ing. Therefore, sometimes the stump was fixed extraperi-
toneally in the incision so that it was available for hemostatic
clamping if the need arose. It was not until 1889 that Simons published a technique for secure individual ligation of the uterus and ovarian vessels that was responsible for significantly reducing the incidence of postoperative hemorrhage. Kelly published a similar technique with illustrations in 1891. The technique of ligation of large tissue pedicles with large sutures has been suggested for some types of total laparoscopic hysterectomy in recent years. In such large pedicles it is a step backward that will, sooner or later, lead to significant hemorrhage.

In abdominal operations today, all major vascular pedicles should be individually ligated, twice if technically feasible. Delayed-absorbable suture should be used and the knots firmly tied. Vascular pedicles should be small and the vessels skeletonized as much as possible so that a secure ligature with little extraneous tissue can be accomplished. A vascular pedicle where the tip of the clamp is free, such as the infundibulopelvic ligament, should always be ligated first with a free tie to occlude the vessels. The pedicle is then secured with a transfixed suture ligature placed between the previous free tie and the clamp. This technique avoids hematoma formation and the rare occurrence of a traumatic arteriovenous fistula. If a suture ligature is to be held long for traction or later identification, there is a danger that it will become loosened or be pulled off, with resulting hematoma or bleeding. Sutures used to ligate vessels should usually be cut and rarely held for traction for this reason. During vaginal hysterectomy, the upper broad ligament containing the uteroovarian ligament and the fallopian tube should be doubly clamped. The lateralmost clamp is replaced by a free tie completely around the pedicle. Tied tightly, this ligature compresses the vessels in the pedicle so that the most medial clamp (the one closest to the uterus) can then be replaced with a suture ligature placed through the pedicle, passed around the clamp and tied tightly around the pedicle. This is one vascular ligature that can be held long for identification and traction with minimal risk of bleeding.

“The finer the suture, the finer the surgeon” is an aphorism that is associated with meticulous surgical technique. The aphorism is good advice, up to a point. The newer delayed-absorbable sutures are strong, and smaller-gauge sutures are strong enough to ligate vessels. However, it is dangerous to use fine suture to ligate large pedicles. The suture may break or cut through the tissue if there is too much tension on the pedicle. Fine needles with small sutures are useful for controlling localized venous or arterial bleeding, but larger suture with bigger bites are less likely to pull through infected or malignant tissue. Proper suture selection for the specific technique and patient is an important part of obtaining the best result from any given surgical procedure.

**INTRAOPERATIVE MEASURES TO CONTROL PELVIC HEMORRHAGE**

Despite adequate technical skills and careful dissection, serious hemorrhage can suddenly complicate almost any operative procedure. These occasions call for a maximum use of a surgeon's knowledge, technical ability, and leadership to produce a happy outcome. The first task is to control the hemorrhage. A finger should immediately be placed on the bleeding point for pressure, and continue with pressure. When the blood has been suctioned out and the fingertip exposed, it may be gently rolled off the bleeding point while a fine-tipped clamp of adequate length is poised to clamp the bleeding vessel and suction is ready to provide exposure. In most instances, this will adequately control the hemorrhage, although it is often necessary to place another clamp, clip, or suture adjacent to the first clamp to control the other side of the lacerated vessel or other nearby bleeders. It is most important to avoid placing too many clamps in the area because this will obscure the bleeding site and cause additional trauma to the vessels. Multiple sutures and/or clips may also cause more bleeding and further injury to adjacent structures, such as the ureter, bladder, pelvic vessels, and nerves. Caution should not be used to attempt to control significant bleeding. It will only cause increased bleeding and more tissue injury.

If an immediate attempt to control the hemorrhage by simple means is unsuccessful, the bleeding should be controlled again with pressure, either with a fingertip, a sponge forceps, or occasionally by packing. The surgeon should step back, take a deep breath, and carefully consider the situation. The anesthesiologist should be made aware of the hemorrhage and consulted about the patient's stability, blood loss up to this point, availability of blood for transfusion, intravenous lines, and so forth. The anesthesiologist will play an important role in fluid and blood replacement, monitoring coagulation factors and ensuring perfusion of vital organs. Therefore, it is important that he or she be fully aware of the situation and an active participant in such decisions as how long to safely continue surgery. The anticipated difficulty in controlling the hemorrhage must be honestly evaluated, and the patient's overall condition and the planned operative procedures should be considered and discussed with the surgical team. If additional suction or instruments are needed, they should be requested. If additional or more experienced assistants or additional scrub and circulating nurses are needed, they should be requested. Would it be helpful to have your partner, a gynecologic oncologist, a urologist, a general surgeon, or any other gynecologic surgeon available? They are probably not immediately available, so it is important to request their help sooner rather than later.

If the patient is stable and any necessary equipment—such as a second suction, deeper retractors, or hemostats—has been readied, it is reasonable to reconsider the anatomy, obtain good exposure, and have another try at controlling the bleeding. If you are lucky, the 10 minutes or so that the hemorrhage has been controlled by pressure will result in a substantial reduction in the bleeding. Perhaps the vessel or bleeding site can be more clearly seen and controlled with a clamp and a few small sutures or a clip or two. Arterial bleeding in the pelvis usually is easily controlled. The vessels have thick walls and are not easily torn further. Blood spurting from the vessel leads to its easy identification. If the artery can be clamped, it usually can be ligated, a clip can be applied, or both. If an artery has mostly retracted from view with only one small edge still visible, that edge may be grasped with a clamp and gently twisted, thus decreasing the amount of bleeding sufficiently to allow clipping or ligation. Venous hemorrhage in the pelvis may be a much more difficult problem. Such bleeding can vary in magnitude from a trivial ooze to life-threatening hemorrhage. Pelvic veins can be fragile, tortuous, hidden from view, and distended. Blood returning through the lacerated vein can come from multiple deeper sources that are unavailable for ligation. Placing clamps and sutures blindly is dangerous and can even make the problem worse. Electrocoagulation of a laceration in a large vein should not be attempted because it will inevitably result in a larger hole that will be even more difficult to secure. Sometimes the best procedure is to hold a finger or a pack against the bleeding site for a minimum of 5 minutes, after which the bleeding may stop or decrease so that the bleeding vessel can be identified and controlled with a clip or a suture. Digital...
If coagulation factors have been depleted because of multiple transfusions, the Gelfoam can be soaked in thrombin. When the material is applied, the field should be as dry as possible. Constant pressure can be applied by placing sponges that can be tied on top of the sandwiches. There is a new commercial product made of absorbable collagen sponge coated with human coagulation factor and thrombin that sounds very good, but it is not yet U.S. Food and Drug Administration (FDA) approved for use in the United States (TachoSil, Nycomed, Denmark).

Malviya and Deppe have reported the successful use of fibrin glue, a biodegradable tissue adhesive and sealant and topical hemostatic agent, to control life-threatening hemorrhage in one obstetric and two gynecologic patients. The fibrin glue (Tissel@®, Baxter Pharma, USA or Cross®®, Ethicon, USA) is prepared from equal amounts of cryoprecipitate (highly concentrated human fibrinogen) and bovine thrombin. It mimics the last stages of physiologic coagulation at the local site. It is available as a spray applicator or in a dual syringe set. This technique has been used successfully in microvascular, cardiovascular, and thoracic surgical procedures and has recently been reported in controlling hemorrhage in liver transplantation. Schwartz and colleagues compared spray on fibrin sealant to standard techniques for hemostasis in 121 patients undergoing liver resection. Time to achieve hemostasis and postoperative complications were significantly less in the patients randomized to fibrin sealant. This technique should be helpful in extensive pelvic dissections for gynecologic cancer, especially to control low-pressure pelvic vein bleeding that is not controllable by other standard measures.

Gynecologic surgeons usually do not have the luxury of using tourniquets to control bleeding. There are, however, two special procedures in which tourniquets have been used to advantage. These are myomectomy and uterine unification operations. The tourniquets are fastened to the uterus or anterior abdominal wall with sutures, and there is little literature comparing these agents with each other in human subjects.

Older agents such as oxidized, regenerated cellulose come in a thin, pliable, woven sheet (Surgicel® NuKnit®, Johnson & Johnson, USA) or a soft, multiple-layered, fuzzy pad that can be separated into thin sheets or used as a pliable pad (Surgicel® Fibrillar®, Johnson & Johnson, USA). Absorbable, gelatin foam pads (Gelfoam, Pharmacia and Upjohn, USA) are also available in several sizes, and can be cut to fit. These stiff sponges are about 4 mm thick and can be applied dry or moistened with saline to make them pliable. Both of these sheets or pads can be applied to an oozing surface and covered with a pressure pack for 5 to 15 minutes. When these techniques are not effective, various hemostatic agents may be considered. Novel techniques for controlling hypovolemic shock in nonhuman animals, and there is very little literature comparing these agents with each other in human subjects.

Special Techniques

Diffuse venous oozing, which may be associated with malignancy, inflammation, or extensive lysis of adhesions, can usually be controlled by electrocautery (sometimes on the “spray” mode) or packing for 5 to 15 minutes. When these techniques are not effective, various hemostatic agents may be considered. These are myomectomy and uterine unification operations. The tourniquets are fastened to the uterus or anterior abdominal wall with sutures, and there is little literature comparing these agents with each other in human subjects.

Hypogastric artery ligation was later introduced by Mengert and colleagues and was then extensively investigated by Burchell. Burchell demonstrated that the pulse pressure in the artery just distal to the point of ligation was decreased significantly (77%) on the same side. If both hypogastric arteries are ligated, the pulse pressure is decreased by 85%. This reduction in pulse pressure presumably allows blood clots to form at the site of bleeding from damaged vessels. Blood flow in vessels distal to the point of ligation is decreased by only 48%.

Because it is important to preserve some of the collateral circulation to the pelvis—including the lumbar, iliolumbar, middle sacral, lateral sacral, superior and middle hemorrhoidal, and gluteal arteries—it is important to ligate the anterior division of the hypogastric artery distal to the posterior parietal branch, as demonstrated in Figure 19.4. In ligating the hypogastric artery, the peritoneum is opened over the external iliac artery from the round ligament to the infundibulopelvic ligament. The ureter is left attached to the medial peritoneal reflection to avoid disturbing its blood supply. The hypogastric artery is gently cleaned off with a fingertip or the tip of the suction. The hypogastric vein is also identified on the pelvic sidewall, if possible; but as long as the artery is well visualized and separated from the sidewall, it is not necessary to dig around risking more bleeding to isolate the hypogastric vein. The posterior branch of the hypogastric artery must be clearly identified before double ligation of the anterior division is performed. Nonabsorbable suture is passed around the artery with a right-angle clamp and tied. A second free-tie suture is placed distal to the initial ligature to avoid recanalization. Transfixion or division of the vessel is not recommended in this procedure. The hypogastric arteries should be ligated bilaterally, if possible, to obtain the best results. When possible, we believe that the arterial branch closest to the bleeding point should be ligated. Because the uterine artery is the first visceral branch of the hypogastric artery, it may be feasible to identify this artery and ligate it separately if the bleeding is from the uterus. This may be a somewhat more difficult procedure than ligating the entire anterior division of the hypogastric artery and should not be attempted in the face of massive pelvic bleeding, distorted pelvic anatomy, or shock.

When massive bleeding is present but the uterus has not been removed (as may occur in certain obstetric operations), it is important to ligate both ovarian arteries also. This procedure is easily accomplished by extending the lateral peritoneal incision up to the infundibulopelvic ligaments. The ureter must be identified. The artery should be ligated with a single, permanent ligature, but the artery should not be cut. This avoids the need for multiple ligatures and the risk of retraction and retroperitoneal bleeding of the vessel. A single hemoclip also can be placed on each ovarian artery as a quicker and easier method of occlusion. Care should be taken to avoid injury to the ovarian vein. If there is difficulty in distinguishing the artery from the ovarian vein, ligation of both the ovarian artery and vein within the infundibulopelvic ligament is acceptable. Even though ligating both the arterial and venous circulation to the ovary leads to a high incidence of postoperative cystic enlargement of the ovary, this complication is preferable to the risk of recurrent pelvic bleeding when the ovarian arteries are not ligated.

As an alternative to ligating the ovarian artery in the infundibulopelvic ligament, Cruikshank and Stoelk have described a technique of ligating this artery at the point of its anastomosis with the uterine artery in the medial mesosalpinx. This point of ligation allows maintenance of the blood flow to the tube and ovary but occludes the ovarian artery.

FIGURE 19.4. Ligation of the right hypogastric artery. The clamp is passed laterally to medial and the ligature is placed around the anterior division of the hypogastric artery. Note the ureter is attached to the peritoneum, which is reflected medially.
blood flow to the uterus (Fig. 19.5). Because this technique allows uninterrupted blood supply to the ovaries, it is probably preferable.

For post-cesarean delivery hemorrhage, Fehrman has recommended bilateral ligation of the uterine arteries as primary treatment. When this method was used in 66 patients, only 6 required hysterectomy to achieve hemostasis. If bilateral uterine ligation is not effective in controlling the uterine bleeding, Fehrman recommends supplementary ligation of the round ligaments and the ovarian ligaments at their junction with the uterine corpus. He also believes that bilateral uterine artery ligation is a more effective treatment for life-threatening uterine hemorrhage than is bilateral hypogastric artery ligation.

The vaginal artery can originate as a separate branch from the hypogastric arteries. Uncontrollable bleeding from the vagina may not be stopped by hysterectomy or by ligation of the uterine arteries. Hypogastric artery ligation is required.

Pregnancy after Hypogastric Artery Ligation. Amazingly, there are many reports of full-term deliveries after bilateral hypogastric artery ligation with and without bilateral ovarian artery ligation. This is ample testimony to the abundant collateral blood supply to the pelvis. According to Burchell, the blood flow to the pelvis is reduced by as much as 50%, and yet there remains an adequate reserve for nourish a future term pregnancy. Ischemic necrosis of pelvic tissues does not occur unless additional collateral pathways are destroyed.

The collateral circulation of the female pelvis is extensive and provides a variety of communicating sources of arterial blood from various sites along the arterial tree. These collateral vessels anastomose with the hypogastric artery and the blood supply to the uterus through a number of circuitous arterial pathways in the pelvis. During a difficult hysterectomy, the collateral circulation can create problems in achieving adequate hemostasis. Therefore, it is important to have a clear understanding of the various extrapelvic arteries that communicate with the pelvic circulation.

Packing Techniques

In rare cases, standard techniques of pressure, clipping, ligation, or application of hemostatic agents is unsuccessful for controlling bleeding. Several techniques may be considered in these cases. Trauma surgeons will occasionally pack persistent venous bleeding and close the abdomen when the procedure has been prolonged and/or the patient is unstable. The patient may be reclamped from time to time to maintain pressure on the towel as it stretches. The pack can be left in place for 24 to 48 hours until the bleeding has ceased. It is removed vaginally by first withdrawing the internal gauze and then the outside bags, sheet, or towel.

Potentially Troublesome Anatomic Locations

Iliac Vessels

One of the most dangerous places in the pelvis to dissect is in the region of the bifurcation of the common iliac artery and vein. This is the “axilla” of the pelvis, where many lymph nodes that drain the cervix are found. The hypogastric vein and its branches are at risk of injury when dissecting between the distal common iliac artery and the psoas muscle and deeper in the area of lumbar sacral nerve trunks. When the surgeon pulls on surrounding areolar tissue, a relatively loose and thin-walled vein may inadvertently be torn or pulled into the dissecting scissors. The vein wall may not be distinct, especially when the tissue is bloodstained. One is wise to proceed cautiously. Fervid hemorrhage threatening exsanguination can result from laceration of either the external iliac vein or the hypogastric vein where they join together, or from laceration of their major branches in the area. On the medial side of these veins, the lateral sacral veins disappear into the sacral foramina. False hemorrhage can result from laceration of these vessels. If they are torn where they enter the foramina, they cannot be
clamped and ligated. They cannot be clipped. They are kept open by their attachment to the walls of the foramina. Extreme measures may be required to control such bleeding. One can try to pack the foramen with bone wax, but this usually is not successful. Alternatively, multiple layers (sandwiches) of absorbable gelatin sponge (Gelfoam) and microfibrillar collagen (Avitene) can be held in place with a strong pressure pack for 20 minutes and, perhaps, ultimately the packing can be fixed with sutures. This area deserves its reputation as the “corona mortis” of the pelvis.

Obturator Fossa
Numerous variations in the branches of the hypogastric artery and vein are encountered in dissecting the obturator fossa, especially in the floor of the fossa. The “web” of paracervical tissue separating the paravesical and pararectal spaces contains branches of the hypogastric artery and vein. These vessels must be carefully ligated with clips or sutures during a radical hysterectomy. The dissection can be carried to the depths of the paravesical space and pararectal space by carefully ligating or clipping each vessel encountered. The obturator artery and vein are usually found just below the obturator nerve. In a radical hysterectomy or even a pelvic exenteration, these vessels are usually not disturbed. If injured, they may be ligated or clipped. If these vessels are allowed to retract through the obturator foramen into the upper thigh without being ligated, bleeding into the thigh may be a significant problem.

Pararectal Space
When dissecting in the pelvis, one should avoid making a deep, narrow hole with a bottom that cannot be exposed in case a deep vein might be lacerated. For example, development of the pararectal space must be done carefully because of the danger of injuring the internal iliac veins against the pelvic sidewall. The space is developed between the ureter and the hypogastric artery. The dissection is directed posteriorly at first but soon changes to a more caudal direction. Failure to make this directional change can result in laceration and bleeding from veins in the bottom of the space. If development of the pararectal space is difficult, such as after pelvic radiation therapy, the paravesical space should be opened, then the cardinal ligament or “web” can be taken down bit by bit, starting with the uterine vessels at their origin or insertion into the internal iliac vessels. As clips or small clamps are used to take down the cardinal ligament, the pararectal space gradually is opened inferiorly, with the ureter identified medially and the iliac veins visualized laterally. The pararectal space can be expanded with sharp dissections or with pressure from a small cotton bud in the tip of a long clamp (we call it a “peanut dissector” because the

of the patient. In addition to measuring the vital signs such 
occult bleeding. The intensity and duration of the monitoring 
ations. The patient will alert the vigilant recovery room or ward staff that a 
problem is present; the surgeon should be notified. Once again, a 
surgeon with good leadership and team-building skills should 
educate nurses and other caregivers responsible for the post-
operative care of the patient to be observant for these findings, 
and they should be encouraged to call too soon rather than too 
late with any concerns about the patient's postoperative 

The diagnosis of intraoperative bleeding in the postoper-
patient can be difficult. Peritoneal signs are subtle and 
can be masked by incisional pain and analgesic medications. 
Unfortunately, the initial examination of the abdomen may be 
quite benign. The peritoneal cavity has an enormous capacity 
for occult blood loss without appreciable abdominal disten-
As much as 3,000 mL of blood (about 65% of the total 

Abdominal ultrasound is a rapid, 
noninvasive, readily available method of confirming the diag-
osis of intraoperative bleeding. A rapid, low-tech method of 
testing for intraoperative blood is to insert a long 18-gauge 
spiral needle into the abdominal cavity in one of the lower 
quadrants under local anesthesia. This is definitely not a “non-
nvasive” technique and may not demonstrate intraoperative 
bleeding unless the abdomen is grossly distended. If a patient 
has experienced an unexpected drop in hematocrit postoper-
atively but is very stable, an abdominal and pelvic CT scan 
is another good way to identify (or rule out) intraabdominal 
hemorrhage or a hematoma (Fig. 19.7).

Sometimes it is difficult for the surgeon who performed the 
original operation to convince himself or herself that bleed-
ing is persistent and intervention is urgently needed. A consult 
with a colleague is often helpful. There may be a temptation 
to blame the coagulation system and look for some defect in 
clotting factors. A routine coagulation profile, ordered at the 
first suspicion, or even simple observation of clot formation in 
a tube of blood at the bedside will eliminate this possibility. 
However, the experienced surgeon knows that the most com-
mon reason for intraoperative blood and postoperative shock 
is loss of surgical hemostasis—a vessel has become disligated. 
The question now becomes: Should the patient be immediately 
operated on again to identify and control the bleeding or taken 
to the radiology suite in an attempt to control the bleeding 
by embolization? Both techniques are highly effective, and we 
have generally used the stability of the patient as a guide. For 
instance, if the patient is unstable with a rapid pulse, failing
FIGURE 19.7. Axial CT image of the pelvis in a 52-year-old woman who is 5 hours postop from a vaginal hysterectomy. Note the extravasation of contrast from an arterial injection into the right internal iliac artery.

blood pressure, and/or low urine output, or if the interval since surgery is short, suggesting fairly rapid hemorrhage, we would prefer to quickly return to the operating room where we have a team of anesthesiologists and other personnel to monitor the patient, assist with blood replacement, and treat hemorrhagic shock. On the other hand, if the patient is reasonably stable and bleeding does not appear too brisk based on time from surgery and the volume of blood in the abdomen or retroperitoneal space by ultrasound estimate, then it is reasonable to try to identify the bleeding artery and embolize it by transcatheter interventional radiological techniques.

Whichever plan is selected, one or more large-bore intravenous lines should be started, and fluid replacement should begin with packed red blood cells ordered and started as indicated and available. A Foley catheter should be inserted and urine output monitored. Broad-spectrum antibiotics should be started. If the patient is not in the recovery room, she should be transferred there or to a monitored bed with easy access to the operating room. Preop labs should be obtained, and the operating room and anesthesia service should be notified, as well as the interventional radiology team if appropriate.

Arterial Embolization

In 1969, Nusbaum and colleagues described arterial embolization to control bleeding from esophageal varices by selectively cannulating the superior mesenteric artery and infusing small doses of vasopressin into terminal vessels. The subsequent use of particulate matter to achieve hemostasis within bleeding viscera developed rapidly. Selective angiographic arterial embolization has been used to control hemorrhage after abdominal and vaginal hysterectomy and other gynecologic operations, hemorrhage from cervical cancer and gestational trophoblastic disease, postpartum hemorrhage, hemorrhage from abdominal pregnancy, and retroperitoneal hemorrhage. Experience has shown that selective pelvic artery embolization is a comparatively simple and safe procedure. Dramatic results can be seen. Clinical success rates of more than 90% are routinely reported when embolization is used for postsurgical and post-traumatic hemorrhage. Therefore, embolization rather than surgical ligation is appropriately selected as the primary procedure to control bleeding in patients who are stable or who cannot tolerate another operation.

The method of intravascular embolization is quite simple, although it requires the expertise of a skilled interventional radiologist. Percutaneous catheterization of the femoral artery under local anesthesia provides direct access in a retrograde manner to the hypogastric artery (Fig. 19.8). The brachial artery can also be used for access to the vascular system. If prior hypogastric artery ligation has obstructed this pathway, arteriography of the pelvic vasculature through one of the collateral arteries usually localizes the specific bleeding vessel or vessels, although with greater difficulty. The site of bleeding can be accurately identified with angiography and fluoroscopy if the rate of bleeding is 2 to 3 mL per minute or more. The hypogastric artery or the specific collateral vessel is cannulated for injection (Fig. 19.9A–C). A variety of materials can be used for embolization, including small pieces of Gelfoam, metal coils, small Silastic spheres, autologous clot, subcutaneous tissue, and other hemostatic materials. Gelfoam is one of the most practical and easily injected materials. It is sterile, nonantigenic, remains in the vessel for 20 to 50 days, and forms a fibrin mesh framework on which blood clots can develop. Its immediate effect is to obstruct the distal artery or arteriole and reduce pulse pressure in the bleeding vessel, thereby permitting clot formation and cessation of bleeding. Material is injected under angiographic observation. When it becomes evident by repeat angiography that the bleeding vessel has been occluded, the catheter is removed and the patient is carefully monitored for evidence of further bleeding.

Arterial Embolization

After embolization, patients usually have no complications or evidence of the effects of local ischemia. Those who have not had a hysterectomy will resume normal menstruation. Some patients will exhibit evidence of a mild postembolization syndrome, including pain, fever, leukocytosis resulting from...
vascular thrombosis, and tissue necrosis. A few isolated cases of more serious problems have been reported, including bladder necrosis, vesicovaginal fistula, neuropathies, and renal toxicity from the contrast medium. The overall complication rate should be less than 10%.

Reoperation

If reoperation is selected, the patient should be as stable as possible, with blood running or at least available in the room. Two suctions should be ready and an adequate staff and assistants involved. If the patient has previously had an abdominal operation, the incision should be reopened. A preoperative ultrasound or CT scan should have identified the bleeding as intraperitoneal or retroperitoneal. The previous procedure should be mentally reviewed to identify any possible ligatures that were tentative or any troublesome bleeding sites that may have continued to bleed. When the abdomen is opened, the clots should be evacuated and a search instituted for the bleeding sites, starting with the most likely locations. Care should be taken when removing clots from the pelvic area.

FIGURE 19.9. Selective angiogram with the catheter tip positioned in the right internal iliac artery (same patient as shown in Fig. 19.8). A: The tortuous right uterine artery is filled and some wispy extravasation is seen. B: A delayed image shows more extensive extravasation. C: After 5 microcoils have been injected, the bleeding has been controlled. No extravasation is seen with an injection of contrast in the common iliac artery. (Courtesy of Dr. Leann Stokes, Vanderbilt University.)
Bleeding sites should be carefully ligated, sutured, or clipped. It is not unusual to reopen the abdomen and find no active bleeding sites. This is somewhat disconcerting because of the concern that the problem will repeat itself after the abdomen is again closed. Every attempt should be made to get the pelvis and abdomen completely dry before closing a second time.

During reoperation, patients are at increased risk of ureteral injury. In addition to exercising care in clamping and ligating bloodstained tissue with distorted anatomy, it may be wise to prove ureteral integrity at the end of the operation. This can be done by injecting 5 mL of indigo carmine dye intravenously and observing either of dye from each ureteral orifice through the cystoscope or by opening the bladder dome (see Chapter 38).

After reoperation, patients are also at increased risk of developing postoperative complications such as pulmonary atelectasis, abdominal distention from ileus, postoperative infection, incisional complications, and coagulation disorders from multiple transfusions. The anticipation of these complications allows the adoption of measures to prevent or manage them correctly should they occur.

Postoperative hemorrhage from the vaginal vault usually comes from the vaginal artery in the lateral vaginal fornix or from one of its branches. Most often, the lateral vaginal angle, including the vaginal artery, is not properly secured or becomes disligated. To prevent such bleeding, the lateral vaginal angle stitch should be anchored in tissue lateral to the angle so that the angle cannot slip out. This stitch should not be held because traction will loosen it. Excessive vaginal bleeding may be noted in the recovery room or after the patient has returned to her room. Every attempt should be made to establish an objective measurement of the amount of blood lost and to follow vital signs and changes in hemocrit values. One must realize that larger amounts of blood lost from the vagina indicate a problem. If a clot occludes the vaginal introitus, a large amount of blood—sometimes several hundred milliliters—can distend the vagina behind it and not be evident on a perineal pad. When significant vaginal bleeding is present, the patient should be examined. Vaginal packing for significant vaginal bleeding is usually ineffective. Sometimes adequate examination can be performed in the recovery room with analgesia, but a return to the operating room for an examination under anesthesia should be used necessary.

The vaginal apex should be inspected. If the bleeding point can be seen, it should be clamped and ligated from below. Figure-of-eight no. 0 or 0 delayed-absorbable transfixed sutures should be placed to include the vaginal mucosa and underlying paravaginal tissue. Care must be taken to avoid the inadvertent placement of a suture into the musculature of the bladder wall, the ureter, or the underlying rectum. If bleeding is not controlled by this technique, it iswise to continue to add suture on suture in a frantastic effort to control the vaginal bleeding. In such cases, it is probable that the bleeding vessels have retracted well above the vaginal apex and cannot be reached by this approach.

If surgical hemostasis cannot be achieved transvaginally, laparotomy may be necessary. A vaginal pack will not control significant bleeding from the vaginal vault that has already required a return to the operating room, although a temporary pack may slow the blood loss while the patient is prepared for laparotomy. In some patients, the hemorrhage will be delayed until 10 to 14 days after surgery, when the sutures lose their tensile strength. Posthysterectomy disruption of the vaginal vault with hemorrhage can result in a hematoma.

Blending from anterior and posterior colporrhaphy usually is from veins that have not been secured. In this situation, a fairly tight vaginal pack effectively compresses these vessels and controls the bleeding. It seldom is necessary to reexplore an anterior or posterior colporrhaphy to locate and ligate a specific bleeding vessel. The patient will feel an uncomfortable sensation of urgency of urination that will be relieved when the pack is removed in 24 to 48 hours. A Foley catheter will be needed while the pack is in place.

A postoperative pelvic hematoma can cause serious morbidity, especially if it is large and becomes infected. Hematomas can develop above the vaginal vault, along the pelvic sidewall, in the retroperitoneum extending up to the kidneys, in the paravesical space, in the abdominal wall, and in the ischio-rectal fossa and vulva. A hematoma in the ischiorectal fossa and on the vulva may be obvious on examination when the patient reports discomfort in the area. If it is below the pubococcygeal muscle attachment to the vagina, it will not dissect into the pelvis above but will be limited to the perineum and buttocks. A pelvic hematoma may be recognized in a patient whose postoperative discomfort and anemia exceed what is normally expected, whose temperature is progressively increasing, and whose postoperative abdominal distention is slow to resolve. If a patient is on anticoagulant therapy, even simple coughing can spontaneously cause a tremendous postoperative pelvic hematoma. Abdominal and pelvic examinations may reveal a mass. A definitive diagnosis can be made by ultrasound or CT scan, which is helpful in delineating its exact size and location. An extended, morbid, and complicated postoperative course may be alleviated if a large hematoma can be drained. Sometimes simple drainage through the vaginal vault can be accomplished by probing with a uterine dressing forceps. A small Penrose drain can be inserted through the drainage tract and left in place for a day or so. If drainage cannot be achieved in this simple way, drainage with guidance of CT or through an abdominal incision may be necessary. In our experience, if a large hematoma can be confirmed, patient’s recovery will be expedited. But in some cases, drainage is difficult or contraindicated and infection is not present. In such a patient, it may be preferable to allow the hematoma to gradually resolve over a few months. Unfortunately, sometimes a hematoma will not resolve completely, and residual fibrosis will persist and continue to cause pain. We have removed large pieces of an organizing hematoma as late as 1 year after operation. For these reasons, we prefer to drain it if necessary.

There are a few other special circumstances. Hemorrhage after uterine curettage is extremely rare, even with perforation of the uterus. The perforation is usually caused by the uterine sound and occurs through the corpus. Under most circumstances, the curettage should be stopped and the patient’s vital signs checked for several hours. It is extremely unlikely that any problem will develop, and overnight hospital admission as a precautionary measure may be unnecessary. However, if the perforation was caused by a wide, blunt instrument (such as a curette or a suction device), if the uterus is pregnant or contains cancer, or if fatty tissue appears in the curettement specimen, then overnight observation should be considered and the patient closely observed for intraperitoneal bleeding or a broad ligament hematoma. Ultrasound, CT scan, or laparoscopy also may be performed to rule out these complications. In such cases, laparotomy or laparoscopy should be considered to evaluate and control the bleeding and evacuate the hematoma. A hysterectomy may or may not be necessary, depending on the damage to the uterus.
Hemorrhage from cervical conization can occur in the first 24 hours or 7 to 14 days later, when cervical sutures lose their tense strength. If the patient is bleeding heavily at any time after conization, the cervix should be inspected. Measures to control the bleeding include resuturing, cautery, and Monsell’s solution. If bleeding is not profuse, Monsell’s solution, Gelfoam, and/or a small pack can be tried. In taking the conization specimen, one must be certain that the apex of the cone intersects the endocervical canal. If the cervical incision is misdirected to one side or the other, the uterine vessels are in danger of laceration. An uncontrolled hemorrhage or broad ligament hematoma may result. To prevent this problem, the cervix should first be sounded to ascertain the direction of the endocervical canal and the incision planned accordingly.

SUMMARY

Careful preoperative evaluation of the patient and thoughtful preoperative planning on the part of the surgeon and surgical team will help prevent or minimize significant operative blood loss. However, intraoperative or postoperative hemorrhage does occur from time to time and represents a significant challenge to the technical skill and the emotional control of the surgeon. He or she must take charge of the situation, organize a plan to control the bleeding, instruct and motivate the other members of the surgical team, and, finally, execute the technical steps necessary to obtain hemostasis. Each part of this approach is important. We hope that the ideas and techniques discussed in this chapter will make the reader more prepared to meet this challenge.

BEST SURGICAL PRACTICES

I Preparation to prevent and control operative bleeding starts before the surgical procedure. The patient should be thoroughly evaluated for any risk factors that may increase the possibility of hemorrhage. Congenital and acquired coagulation disorders need to be diagnosed by a careful and thorough history and appropriate lab tests. The problem to be treated surgically should be thoughtfully considered and the surgical approach devised, adjusted, or modified to suit the patient, her history, and the abilities of the surgical team. Preoperative consultations with other specialists should be sought if indicated. The medical conditions of the patient should be optimized.

II The possibility and risks of blood transfusion should always be discussed with the patient as part of informed consent before surgery. The risk of a febrile reaction to transfusion is approximately 1%. Transmission of hepatitis B via transfusion occurs about 1 in every 100,000 transfusions, whereas the risk of HIV transmission with modern blood banking procedures is approximately 1 in 1.9 million.

During the operative procedure, the surgical approach should be well planned, and possible problems and their management should be considered. Good exposure, proper use and awareness of the anatomy, and careful dissection, clamping, and suturing are all important technical skills that will reduce the risk of uncontrolled hemorrhage. Finally, and perhaps most importantly, good surgical judgment must be used to reduce risk and obtain the best outcome for the patient.

When life-threatening intraoperative hemorrhage occurs, the surgeon should control the bleeding by pressure and organize and lead the operative team in the complex task of identifying and controlling the hemorrhage. This is one of the most challenging of all emergencies and requires leadership, judgment, knowledge, and technical skill.

When intraoperative blood loss exceeds 15% of the patient’s blood volume (about 500–1,000 mL), transfusion should be considered. The patient’s medical history, her vital signs, the probability of additional blood loss, and response thus far will all determine how quickly transfusion is initiated. Packed red blood cells or other appropriate blood components should be used for transfusion rather than whole blood.

Hemostatic and coagulation factors—as well as serum calcium, electrolytes, and glucose—should be followed every 120 minutes or after 10 U of transfusion. Although it is best to use actual serum levels of coagulation factors, as a rough guide, after every 6 to 8 U of packed red cells, 2 U of fresh frozen plasma should be given. If fibrinogen levels fall below 100 mg/dL, 20 U of cryoprecipitate should be given. A bolus of 6 U of platelets should be given if the platelet count falls below 100,000 and the patient is actively bleeding.

The pelvic surgeon should be able to use special techniques such as packing, thrombotic agents, and hypogastric artery ligation and know their indications for the control of pelvic hemorrhage.

Postoperative bleeding may be difficult to diagnose. Attractive and well-trained recovery room and ward nursing personnel are essential. Abdominal and pelvic ultrasound and/or CT scanning are very helpful in making the diagnosis of postoperative bleeding and localizing the site of bleeding.

Embolization of arterial bleeders by interventional radiology techniques and reoperation are both effective techniques to manage postoperative hemorrhage. When the patient is relatively stable and an experienced interventional radiology team is available, embolization is generally preferred today because it is associated with less morbidity.

CHAPTER 20 THE IMPACT OF ASSISTED REPRODUCTIVE TECHNOLOGY ON GYNECOLOGICAL SURGERY

HOWARD W. JONES, Jr.

DEFINITIONS

- Conceptus—The derivates of a fertilized oocyte at any stage of development from fertilization to birth, including extraembryonic membranes; the preembryo, embryo, or fetus; the products of conception; and all structures that develop from the zygote, both embryonic and extraembryonic. This term is commonly interchanged with the term preembryo during in vitro fertilization treatment.
- Controlled ovarian hyperstimulation—Pharmacologic stimulation of the ovaries, generally with gonadotropins and/or clomiphene citrate, with the objective of multifollicular recruitment and hence retrieval of multiple oocytes.
- Cryopreservation—Maintaining the viability of cells or tissue by storing at very low temperatures; freezing.
- Developmental states—Preembryo: The conceptus during early cleavage stages until development of the embryo. The pre-embryonic period ends at approximately 14 days after fertilization with development of the primitive streak. Morula: The 16-cell stage upward until blastocyst formation; the stage commonly observed between 72 and 96 hours postinsemination. Some authors believe that the term morula is inappropriate for mammals. Blastocyst: The conceptus in the postmorula stage possessing a fluid-filled cavity. Attached to the inner surface of the trophoblast is an inner cell mass from which the embryo develops. Embryo: The stage of the organism after development of the primitive streak; persists until major organs are developed. Once the neural groove and the first somites are present, the embryo is considered formed. In the human, the embryonic stage begins at approximately 14 days postfertilization and encompasses the period when organs and organ systems are coming into existence. Embryo transfer—Replacement of embryos after in vitro fertilization either transferviscally or via cannulation of the fallopian tubes.
- In vitro fertilization—An assisted reproductive technique wherein oocytes are retrieved from the ovaries and fertilized extracorporally with subsequent embryo replacement.
- Natural cycle in vitro fertilization—In vitro fertilization after retrieval of preovulatory oocyte(s) from unstimulated ovaries.
- Oocyte—The female gamete from inception of the first meiotic division until fertilization. In oogenesis, a cell that develops from an oogonium. Metaphase I oocyte: An oocyte with chromosomes at MI; characterized by the absence of both a first polar body and a germinal vesicle. An oocyte at an intermediate stage of maturation. Prophase I oocyte: An oocyte with chromosomes at PI; characterized by a germinal vesicle.
- Oocyte retrieval—Harvest of oocytes from the ovaries, either with laparoscopic- or ultrasound-guided follicular aspiration.
- Ovarian reserve—Biologic age of an individual’s oocyte. Diminished ovarian reserve, which may be reflected by an elevated early follicular phase follicle-stimulating hormone and/or estradiol level, correlates with reduced chances for success after in vitro fertilization.
- Prezygote—The penetrated oocyte that displays pronuclei and the second polar body; a pronuclear stage conceptus. The stage of development before syngamy. Some authors refer to this stage as an ootid. Pronuclei are commonly observed 10 to 20 hours after insemination.
- Zygote—The one-cell stage after pronuclear membrane breakdown before first cleavage. This stage is characterized by maternal and paternal chromosomes assuming positions on the first cleavage spindle, thus the lack of a nucleus. Commonly observed 18 to 24 hours after insemination. Syngamy: The union of two gametes in fertilization to form a zygote. The process or reorganization and pairing of maternal and paternal chromosomes in the zygote after pronuclear membrane breakdown.

ASSISTED REPRODUCTIVE TECHNOLOGY AND THE EXPECTATIONS OF PREGNANCY

By law, in vitro fertilization (IVF) centers are required to report their results annually to the Centers for Disease Control and Prevention (CDC). At this writing, results for 2003 are available. The number of reported cycles in the United States was 112,872 with 35,785 live births, for a live birth rate of 31.7%. However, the results are very much age related. This is best seen in the 91,322 cycles using fresh, nondonor eggs (the other cycles used frozen or donor eggs/preembryos). Thus, for those younger than age 35, there is a 37% chance of a live birth, but at age 41 to 42, the expectation is 11%, and older than 42, it is but 4% for a single cycle of treatment.

These are the results against which surgical results must be judged. However, the judgment is not easy—indeed, a sophisticated comparison is impossible. This is because the IVF CDC data are cycle based, and reported surgical data are patient based on results after a certain interval, usually about 2 years.
In an ideal world, in cases of tubal infertility, the relative roles of IVF and/or surgery in such situations? There has been some discussion as to whether infertility can be explained on the basis of endometriosis per se. This observer is persuaded that endometriosis per se can be closely associated with infertility. The possibility of pregnancy with a viable delivery per menstrual cycle of exposure is referred to as fecundity. Normal fecundity is in the 20% to 25% range. In the patient with endometriosis and infertility, monthly fecundity ranges from 2% to 10%. To be sure, even though pregnancy may follow removal of all visible endometriosis in patients with endometriosis as a single factor, fecundity remains below normal. In a study by Rock and colleagues, the postoperative fecundity rate was found to be but 3.2%.

The issue of the usefulness of surgery for endometriosis was prospectively tested by a Canadian collaborative group who studied the outcome in 341 patients with early disease followed for 36 weeks after laparoscopy. For those who had ablation, the fecundity rate was 4.7%, compared with 2.4% in the diagnosed but untreated group. Thus, surgery seems to be marginally helpful in the therapy of infertility that is due solely to endometriosis. The problem may well be that in peritoneal endometriosis, many lesions are not visible to the naked eye and therefore not available to treatment. Contrariwise, IVF works very well in this circumstance. For example, Suzuki and colleagues studied the outcome from IVF in 248 cycles comparing the outcome in (a) 80 cycles with ovarian endometriomas, (b) 248 cycles with endometriosis without ovarian endometriomas, and (c) 283 cycles without endometriosis but with tubal infertility. The pregnancy rates were—and these can be considered fecundity rates—25.3%, 22.1%, and 21.9%, respectively. It is true that patients with advanced endometriosis—especially with endometriomas, which destroy ovarian tissue—will make follicular aspiration difficult. In this circumstance, the IVF pregnancy outcome is diminished. There are, of course, nonsurgical options for therapy, but if the primordial goal is pregnancy, there seems little doubt that the treatment of choice for patients with endometriosis is IVF.

In patients who have pain and endometriosis, there can be little doubt that surgical ablation of all visible lesions is an attractive therapeutic option. Our concern here is with those patients who are infertile and have no other factor than endometriosis. What is the relative role of IVF and/or surgery in such situations? There has been some discussion as to whether infertility can be explained on the basis of endometriosis per se. This observer is persuaded that endometriosis per se can be closely associated with infertility. The possibility of pregnancy with a viable delivery per menstrual cycle of exposure is referred to as fecundity. Normal fecundity is in the 20% to 25% range. In the patient with endometriosis and infertility, monthly fecundity ranges from 2% to 10%.

To be sure, even though pregnancy may follow removal of all visible endometriosis in patients with endometriosis as a single factor, fecundity remains below normal. In a study by Rock and colleagues, the postoperative fecundity rate was found to be but 3.2%.

The issue of the usefulness of surgery for endometriosis was prospectively tested by a Canadian collaborative group who studied the outcome in 341 patients with early disease followed for 36 weeks after laparoscopy. For those who had ablation, the fecundity rate was 4.7%, compared with 2.4% in the diagnosed but untreated group. Thus, surgery seems to be marginally helpful in the therapy of infertility that is due solely to endometriosis. The problem may well be that in peritoneal endometriosis, many lesions are not visible to the naked eye and therefore not available to treatment. Contrariwise, IVF works very well in this circumstance. For example, Suzuki and colleagues studied the outcome from IVF in 248 cycles comparing the outcome in (a) 80 cycles with ovarian endometriomas, (b) 248 cycles with endometriosis without ovarian endometriomas, and (c) 283 cycles without endometriosis but with tubal infertility. The pregnancy rates were—and these can be considered fecundity rates—25.3%, 22.1%, and 21.9%, respectively. It is true that patients with advanced endometriosis—especially with endometriomas, which destroy ovarian tissue—will make follicular aspiration difficult. In this circumstance, the IVF pregnancy outcome is diminished. There are, of course, nonsurgical options for therapy, but if the primordial goal is pregnancy, there seems little doubt that the treatment of choice for patients with endometriosis is IVF.

In an ideal world, in cases of tubal infertility, the relative roles of surgery and/or assisted reproductive technology (ART) could be evaluated by a prospective randomized trial. Such a trial has not, nor is never likely, to be done. Indeed, no prospective trial exists comparing open surgery with laparoscopic surgery in the treatment of tubal disease. Nevertheless, on the basis of evidence and nonrandomized surgical end results, it seems to be agreed that if any surgical treatment is to be done for tubal disease, it should be done by the laparoscopic route. Thus, it is necessary, on the basis of experience and nonrandomized surgical end results, to evaluate the relative roles of surgery and ART in the treatment of infertility that is due to tubal malfunction. Interestingly enough, during the last decade, there have been far fewer end results reports from laparoscopic treatment for tubal disease than appeared in the latter decades of the 20th century. This certainly signifies that IVF has become the treatment of choice for most patients with tubal obstruction. Indeed, some authors have flat out stated that surgery has a very limited place in the treatment of tubal infection causing infertility.

After an extensive review, Sacks and Trew concluded that surgery may be an option for selected patients with some types of tubal disease. They pointed out, however, that if tubal surgery is to be done, it must be restricted to specialized centers with sufficient volume and experience to produce consistent and satisfactory results. It may be added that patients considered for tubal surgery should not be older than the early 30s to allow for IVF if the surgery fails and that there must be no other infertility factor.

This is a tricky diagnosis. There is a high false-positive rate—i.e., tubal obstruction may seem to be diagnosed by hysterosalpingogram or even hydrotubation only to discover that soon after the procedure, these patients have a spontaneous pregnancy. Debris that can be removed by catheterization—or even a hysterosalpingogram or hydrotubation that seems to fail—seems to be sufficient to explain such clinical puzzles. If the isthmic end of the tube is clear and the proximal obstruction is just distal to the isthmus, and if the remainder of the tube appears normal, such lesions are very likely to be due to a polyp or salpingitis isthmica nodosa. For such patients in a specialized center, a pregnancy rate in the 50% to 60% range has been reported. For all other circumstances with proximal tubal obstruction, and especially where experienced care is unavailable, IVF is the preferred therapy.

There are innumerable classifications of distal tubal disease that is due to an inflammatory process. However, the experienced clinician clearly understands what is meant by mild tubal disease. These cases can be considered for surgery if all other ancillary criteria are met. Thus, the peritubal adhesions must be delicate and easily lysed by laparoscopic surgery. The tube must be normal, or at the most only slightly enlarged and not thickened or subject to hydrosalpinx. The endosalpinx, if visible, must not appear to be edematous or dusky.

If an experienced reparative surgeon is available, laparoscopic treatment may give an expectation of pregnancy in the range of 50% over two years.
the cause of infertility. This one, were persuaded that fibroids per se were sometimes followed by pregnancy.

Tramural and/or subserous fibroids, the removal of which was there were patients with normal endometrial cavities with in- can cause the mischief. However, in the study referred to above, there were findings of normal endometrial cavities with intra- mammary and/or subserous fibroids, the removal of which was followed by pregnancy.

Thus, going into the days of ART, many observers, including one, were persuaded that fibroids per se were sometimes the cause of infertility. In the era of ART, the clinical problem takes a special twist. Specifically, what is the proper clinical action when a patient is required to have ART for whatever reason only to find that she also has fibroids? The author, prejudiced from the days before ART, is persuaded that removal of the fibroid before proceeding with ART is the proper course of action. Fortunately, in the ART era, there are studies directed to exactly this point. Bulhers and colleagues studied a group of patients who underwent surgical removal of myomas before in vitro fertilization (Group A) and found that such patients had a cumulative success rate of 33%. On the other hand, patients who underwent in vitro fertilization without previous surgery had a 15% clinical pregnancy rate and a 12% delivery rate. The authors were persuaded of the beneficial effects of surgical re- moval of fibroids before undergoing ART procedures. Benecke and associates studied the impact of intramural leiomyomas on pregnancy outcome as compared with the control group. They found a significant negative impact on implantation rates in the intramural myoma group versus the control group. The im- plantation rate in the myoma group was 16.4% versus 27.7% in the control group; the delivery rates 31.2% in the myoma group and 40.9% in the control group. They concluded that patients with intramural fibroids have a lesser expectation of pregnancy with the ART technology. Giaranoli and colleagues studied 129 IVF intracytoplasmic sperm injection cycles in 71 patients with one or more intramural or submucosal fibroids and compared them to 127 patients without fibroids. In the fibroid group, the implantation rate was significantly lower than in the study group, 18% as compared with 26.5%.And finally, Surrey and associates were interested in whether postmyomectomy patients had a different pregnancy rate from those patients with a normal uterus from the start. Their find- ings were that the IVF-embryo transfer results were similar in the two groups, and they concluded that posthysterectomy the IVF results that are similar to patients who do not have fibroids. The results of these studies, as well as clinical experience, clearly suggest that patients who require IVF and who are found to have fibroids would benefit from the removal of those fibroids. The only possible exception could be for very young patients—that is, younger than age 30—who when properly informed are prepared to have a trial of IVF with the under- standing that if it fails, myomectomy would be desirable before a subsequent IVF trial.

ASSISTED REPRODUCTIVE TECHNOLOGY AND UTERINE FIBROIDS

Long before the days of ART, the relation of fibroids to infertil- ity was vigorously debated. On one hand, there were certain patients who at delivery were found to have fibroids that were surely there at conception. On the other hand, every gynecol- ogist of experience with infertility patients has identified indi- viduals whose only finding was a fibroid, the removal of which was followed by a term delivery.

Attempts to quantify and characterize these observations are elusive largely because the size and localization of fibroids are of infinite variety. In pre-ART days, there were a number of studies reporting pregnancy rates of more or less 50% after myomectomy in patients with infertility when the fibroid was the only determined abnormality. Just before the ART era, the author reported one such series and reviewed others. Among 42 patients, there was a 45% term delivery rate within 2 years. For the 19 patients younger than age 30, the pregnancy rate was an interesting 76%.

Such studies do not impress those who emphasize evidence-based medicine by prospective two-arm studies, but those with experience, including the author, are persuaded that in some patients, fibroids can be the only cause of infertility. There is much speculation about why fibroids cause infertility. It is understandable that lesions that distort the endometrial cavity and therefore presumably the overlying endometrium can cause the mischief. However, in the study referred to above, there were patients with normal endometrial cavities with intra- mammary and/or subserous fibroids, the removal of which was followed by pregnancy.

In the era of ART, it was standard practice to totally re- move the uterus if adnexal ablation was required, for whatever cause. This was to prevent future mischief from diseases of the uterus, especially carcinoma of the cervix or corpus. This has changed. The uterus, if otherwise free of disease, can be left in patients requiring bilateral oophorectomy who wish to retain their reproductive potential using a donor egg or perhaps even cryopreserved oocytes or preembryos. Gener- ally speaking, donor eggs are used only for those who are of reproductive age, but donor-egg children have been reported in women in their 30s.
ASSISTED REPRODUCTIVE TECHNOLOGY AND THE PRESERVATION OF FERTILITY AFTER OVARIAN DESTRUCTION

The first decade of the 21st century has witnessed for the first time the possibility of preserving reproduction by the host's own genome after removal of the host ovary or its destruction by radiation or chemotherapy. This goal can be achieved if bits of ovarian tissue, oocytes, or fertilized eggs are cryopreserved or vitrified before the ovary is exposed to the procedure that would result in this destruction. It should be emphasized that although all procedures above have been implemented, such procedures must be considered experimental until more data accumulate and the efficiency and safety have been established. The purpose of this section is not to discuss technological details but simply to provide the gynecological surgeon with the possibilities that should be offered to appropriate patients to preserve their reproductive potential in spite of therapy which of itself would destroy any remaining ovarian tissue. It should also be pointed out that this discussion is limited to situations in which ART technology involving cryopreservation or vitrification is involved. Ir, therefore, does not discuss patients in whom it is possible to preserve a small portion of ovarian tissue in borderline ovarian tumors, for instance, or other situations whereby ovarian tissue can be preserved in situ.

To be a candidate for ovarian or oocyte harvest before treatment that will eliminate the oocytes, the patient must be relatively young, as oocytes degenerate in number and quality with age. Stating an exact age is difficult, as patients vary in regard to ovarian reserve. Indeed, a test of ovarian reserve may be in order to offer some patients more precise information. Such a test can be done by evaluating basal estradiol 17-β (E2) and follicle-stimulating hormone, as well as by challenge tests designed to evaluate ovarian reserve. Generally speaking, patients older than age 35 become poor candidates unless tests indicate a robust ovarian reserve. Furthermore, such testing and the harvest of eggs or ovarian tissue requires time, and all concerned must evaluate the delay in terms of its effect on the prognosis as far as tumor therapy is concerned. It goes without saying that those offered cryobanking should have a reason-able prognosis for their malignancy and that the gonadotropic stimulation—if used and if it causes a rise in E2—would not have an adverse stimulatory action on the neoplasm under treatment.

This entire matter has been reviewed by the Practice Committee of the American Society for Reproductive Medicine. There are three options for cryobanking.

Cryopreservation of Fertilized Eggs

Cryopreservation of fertilized eggs is a routine procedure in contemporary IVF programs. This is by far the most efficient cryobanking option. There are realities. Results are highly individualistic. However, for a patient with average ovarian reserve, there should be adequate surviving fertilized eggs to expect a pregnancy rate of about 40% following a single cycle of egg harvest. The number of harvested fertilized oocytes is the key, and if time is available to harvest eggs from more than one cycle, the pregnancy rate would be substantially increased. The feasibility of this must be obviously individualized.

Cryopreservation of Mature Oocytes

At the moment, cryopreservation of immature oocyte rather than mature (M2) oocytes is not to be considered, as this involves not only cryopreservation but the maturation of the immature oocyte or eggs, which itself is extremely inefficient. However, cryopreservation of mature oocytes either by standard slow freezing or by vitrification with fast freezing and with subsequent thawing, fertilization, and live-born children has been reported.

At the moment, this is far less efficient than the cryopres-ervation of fertilized eggs. With few exceptions, this procedure is in the case-report mode. However, a few active centers have quantified their data. Borroni and colleagues cryopreserved 927 oocytes from 146 patients with a thaw survival rate of 74.1%. There was a 90.2% fertilization rate. They reported 18 clini-cal pregnancies, for a 9.7% pregnancy rate per transfer and a 12.1% pregnancy rate per patient among those patients who had had more than one transfer. Thus, the procedure has but a modest clinical efficiency.

Cryopreservation of Ovarian Tissue

Cryopreservation of bits of ovarian tissue with later transplantation has shown maintenance of ovarian function in mice, sheep and subhuman primates. Indeed, a viable sheep from such a procedure has also been reported.

Schnorr and colleagues reported the restoration of ovarian function in the monkey by subcutaneous forearm trans-plantation, and Oktay and associates have reported the same in the human. With the same technique, a single preg-nancy followed by a miscarriage was reported by the same group.

The first human live birth after freeze-thawing and au-totransplantation of ovarian cortical tissue was reported by Donnez and colleagues in 2004. The patient at age 25 was treated by chemotherapy for Hodgkin’s lymphoma. Before treatment, five biopsy samples were removed from the left ovary. At age 32, after chemotherapy—which caused the pa-tient to be amenorrheic—the thawed fragments of ovary were returned to the ovary. Periods resumed, and 9 months after the transplant, a spontaneous pregnancy occurred. A healthy live-born girl was born at term.

A second live birth was reported from Israel in a patient treated for non-Hodgkin’s lymphoma. In this particular case, IVF was required. Other live-born children using this technique will undoubtedly be reported.

At this writing, it would seem that oocyte cryopreserva-tion is more efficient than ovarian tissue cryopreservation if premature cryopreservation is not feasible. However, the cir-cumstances surrounding a particular patient may require one or another of the techniques quite aside from their intrinsic efficiency.

BEST SURGICAL PRACTICES

- In patients whose infertility is probably due to asymptomatic endometriosis, surgery can be marginally helpful, but post-operatively the fecundity of these patients is far below normal.
- In patients with infertility who require IVF and who have asymptomatic inflammatory damage to the fallopian tubes,
no surgical procedure is required unless the patient has one or both hydrosalpinges.

In patients who require a bilateral adnexectomy for whatever reason, it may be desirable to not remove a residual normal uterus so that reproductive potential with cryopreserved donor oocytes or preembryos is retained.

Before removing normal ovarian tissue in patients whose reproductive goal has not yet been realized, it is necessary to consider whether her reproductive potential can be maintained by assisted reproductive technology.

The uterus, if otherwise free of disease, can be left behind in patients requiring bilateral oophorectomy who wish to retain their reproductive potential using a donor or cryopreserved ovaries or preembryos.

Those offered cryobanking should have a reasonable probability of ovum fertilization to ensure pregnancy success following oocyte cryopreservation if preembryo cryopreservation is not feasible.

If the primary goal is pregnancy, the treatment of choice for patients with endometriosis is in vitro fertilization.

CHAPTER 21 ■ RECONSTRUCTIVE TUBAL SURGERY

VICTOR GOMEL AND ELIZABETH TAYLOR

DEFINITIONS

Fallopian tubes—A transvaginal endoscopic procedure to examine the fallopian tubes, especially in intramural and isthmic segments.

Fimbrioplasty—Agglutination of the fimbriae.

Hysterosalpingography (HSG)—An X-ray based contrast test to assess the uterine cavity and the fallopian tubes.

Hydrosalpinx—A distally occluded tube, usually secondary to infection, which distends with accumulation of serous fluid.

Pelvic inflammatory disease (PID)—An inflammatory disorder of the uterus, fallopian tubes, and adjacent pelvic structures usually secondary to a sexually transmitted infection.

Salpingoovarotomy—The division and/or excision of peritubal adhesions with the aim of restoring normal anatomy.

Salpingoscopy—An endoscopic examination of the ampullary portion of the fallopian lumen.

Salpingostomy—The creation of a new stoma in a tube with a completely occluded distal end.

Tubal cannulation—The passage of a flexible guide wire and narrow-gauge cannula through the proximal tubal ostia along the length of the tube.

Tubal sterilization—The surgical approximation of tubal segments after tubal sterilization or excision of an occluded or diseased portion of tube.

The physiologic functions of the human oviduct include proovarian sperm transport to the site of fertilization; ovum pickup and pronuclear transport of the ovum; ampullary retention of the ovum (approximately 72 hours); provision of a suitable environment for fertilization to occur and for the zygote to survive; and eventually, transport of the zygote from the ampulla to the uterine cavity. Alterations in any of these functions (caused by either damage to the ciliated epithelium or tubal distortion or occlusion) can result in tubal implantation (owing to the lack of transport of the zygote to the uterus) or infertility (owing to the prevention of sperm meeting the oocyte).

TUBAL FACTOR INFERTILITY

Much of the increase in the incidence of both infertility and tubal pregnancy in the past three decades has been the result of tubal damage after sexually transmitted pelvic infections. The most commonly isolated organisms are Chlamydia trachomatis, Neisseria gonorrhoeae, and Mycoplasma hominis. These organisms appear to account for most primary invasions; however, in 15% to 60% of cases of acute pelvic inflammatory disease (PID), aerobic or anaerobic bacteria, or both, can also be identified. The clinical picture can vary from an almost asymptomatic condition to a life-threatening event. Patients with a more severe clinical appearance often have both aerobic and anaerobic infection.

The classic clinical condition of PID, which includes pain, fever, and lower genital tract infection, occurs in less than 50% of affected patients. Gomel reported (1983a) that more than half of the patients who were investigated for infertility and were found to have a hydrosalpinx gave no previous history of acute PID. This observation has since been confirmed. Indeed, the wide variation in the clinical presentation makes the diagnosis problematic.

It has been estimated that acute PID occurs at a rate of 10 cases per 1,000 women per year in the age group 15 to 39 years, and at a rate of 20 cases per 1,000 women in the age group 15 to 24 years. Just as there is difficulty in diagnosing PID, there is difficulty in ascertaining the trend in its incidence. Chlamydia, the most frequently isolated organism in PID, is increasing. Since 1984, the rate per 100,000 population has increased annually.

The infertility rate after a single episode of PID correlates with the degree of residual tubal damage. Tubal infertility also increases with recurrent episodes of PID. Infertility occurred in 8% of patients with one episode, 20% with two episodes, and 40% in those with three or more episodes of PID. Further, up to two thirds of cases of tubal-factor infertility and one third of cases of ectopic pregnancy may be attributable to C. trachomatis infection.

Reconstructive tubal surgery, by open access, was at one time the only treatment option for infertile women with damaged fallopian tubes. This is no longer the case. Improvement in the outcomes, simplification of the techniques, and much wider availability of in vitro fertilization (IVF) and assisted reproductive technology (ART) provide such couples with a realistic therapeutic alternative. In addition, tubal cannulation has been shown to have a role in women with apparent cornual occlusion. Furthermore, it has been demonstrated that many tubal reconstructive procedures can be performed by laparoscopic access. Thorough investigation of both the male and female partners will aid in the selection of the most appropriate treatment option.
possible. In addition, the emotional needs of the couple must be recognized and addressed. This chapter will discuss only investigations specific to tubal and peritoneal factors of infertility.

**Tubal Insufflation**

Tubal insufflation is a tubal patency test that is now rarely performed. The test was first described by Rubin in 1920, and although there have been modifications of the original technique, the test rightfully bears his name: Rubin’s test. The procedure uses an endocervical cannula connected, by rubber tubing, to a mercury manometer and a source of carbon dioxide (CO\(_2\)). The rate of gas flow through the system is gradually increased to about 30 to 60 mL per minute. The cervix can be submerged in sterile water in the upper vagina to detect any leakage of the gas from the cervical canal. Tubal patency can be determined by one or more of the following: a written record of the rise and fall of gas pressure, auscultation of the lower abdomen for the gas passing through the tubes into the peritoneal cavity, or direct visualization of the pressure changes on a mercury manometer. Although normal fallopian tubes demonstrate patency by the rapid escape of gas at pressures below 100 mm Hg, the test is still considered in the normal range if patency is demonstrated below 180 mm Hg. A negative Rubin’s test cannot be interpreted as conclusive for tubal obstruction. A recent Cochrane meta-analysis concluded that use of an oil-soluble media increases subsequent pregnancy rates when compared with intervention (odds ratio 3.30; 95% CI 2.00–5.43), however there was no significant difference in the odds of pregnancy with oil-soluble versus water-soluble media (odds ratio 1.49; 95% CI 0.95–2.34). Water-soluble media are most widely used, however, as pelvic granuloma formation has been reported after use of oil-soluble media. Further, patients tolerate the water-soluble media better, and water-soluble media coat the surfaces without sticking to them, producing sharp and finely shaded images and greater visual detail of the lesions. These characteristics enable better assessment of the intraluminal architecture (Fig. 21.1). The contrast material is eliminated within 30 minutes.

After the patient has emptied her bladder, she is placed on the radiographic table. A bivalve speculum is inserted into the vagina, and the cervix and upper vagina are washed with an antiseptic solution. The appropriate cannula, which is filled with contrast material and emptied of any air, is attached to the cervix in such a way as to ensure a tight seal. The speculum is removed before the injection of contrast material. Removal of the speculum is important (especially if the metal variety is used), not only to decrease the patient’s discomfort, but also to avoid obscuring the cervical canal and vaginal fornice on the x-ray film.

**Hysterosalpingography**

Hysterosalpingography (HSG) is a contrast study of the uterine cavity and fallopian tubes. It is a simple, inexpensive, safe, and rapid diagnostic procedure that, when performed properly, provides valuable information about the uterine cavity and tubal architecture. Contraindications to HSG include pregnancy, uterine bleeding, lower genital tract infection, PID, and allergy to the contrast material. In women with a history of recurrent PID, or with any suggestion of a recent exacerbation, there is a significant risk of reactivation of quiescent PID. This occurs in about 3% of such patients. To combat this risk, some centers prophylactically administer antibiotics. During the preliminary history and physical examination, the physician must search for possible contraindications and screen for and treat any lower genital tract infections.

**Technique**

HSG must be timed to occur between the complete cessation of menstruation and ovulation. This will avoid the risk of disturbing a luteal phase pregnancy. Such timing also avoids radiation exposure to the oocyte that will resume meiosis after the luteinizing hormone surge. Administration of a nonsteroidal anti-inflammatory before the procedure reduces the patient’s discomfort and diminishes errors associated with hysterosalpingography. The latter is especially applicable to errors regarding cornual occlusion. This has been clearly demonstrated in a study by Lang and Dunaway.

An oil-soluble or water-soluble contrast medium can be used. A recent Cochrane meta-analysis concluded that use of an oil-soluble media increases subsequent pregnancy rates when compared with intervention (odds ratio 3.30; 95% CI 2.00–5.43), however there was no significant difference in the odds of pregnancy with oil-soluble versus water-soluble media (odds ratio 1.49; 95% CI 0.95–2.34). Water-soluble media are most widely used, however, as pelvic granuloma formation has been reported after use of oil-soluble media. Further, patients tolerate the water-soluble media better, and water-soluble media coat the surfaces without sticking to them, producing sharp and finely shaded images and greater visual detail of the lesions. These characteristics enable better assessment of the intraluminal architecture (Fig. 21.1). The contrast material is eliminated within 30 minutes.
Selective salpingography is the injection of a contrast medium directly into the uterine tubal ostium with the use of a special radiopaque cannula inserted through the cervix. The increased pressure generated by the direct injection helps to overcome obstructions associated with mucous plugs or minor synechiae. Selective salpingography is technically possible in approximately 90% of available tubes.

Cannulation of the tube requires the use of a special flexible guide wire and narrow-gauge cannula. This cannulation system is introduced through the larger cannula, which is used for selective salpingography.

If HSG demonstrates a cornual or proximal tubal obstruction (Fig. 21.7), selective salpingography with or without tubal cannulation (Fig. 21.8) should be the next step. This is ideally performed in the same setting. These techniques are useful in differentiating true from false cornual occlusion. The benefits of this approach have been shown for apparent cornual spasm, obstructions caused by amorphous material (tubal plugs), and tubal synechiae. Indeed, half of tubes that were proximally blocked at selective salpingography were found to be normal after tubal catheterization in the largest series reported to date.

In many instances, HSG demonstrates the presence of severe tubal damage or conditions deemed inoperable. Severe intratubal adhesions and distal tubal occlusion in association with cornual lesions, such as salpingitis isthmica nodosa, are examples of contraindications of reconstructive surgery. In such instances, the couple may be advised of the significance of the findings, and IVF may be recommended as primary treatment, without recourse to laparoscopy.

*FIGURE 21.3.* Hysterosalpingogram showing bilateral proximal isthmic lesions typical of salpingitis isthmica nodosa. The right tube is occluded, whereas the left is still patent. (From: Gomel V, Taylor PJ. Diagnostic and operative gynecologic laparoscopy. St Louis: Mosby; 1995, with permission.)

FIGURE 21.5. Hysterosalpingogram showing bilateral hydrosalpinx. The longitudinal epithelial folds are preserved in the left tube. (From: Gomel V, Taylor PJ. Diagnostic and operative gynecologic laparoscopy. St Louis: Mosby; 1995, p. 106, with permission.)

Salpingoscopy

Salpingoscopy is the endoscopic examination of the ampullary portion of the tubal lumen. This can be accomplished with a rigid or flexible hysteroscope during either laparoscopy or laparotomy. If the distal tube is totally occluded (hydrosalpinx), it is necessary to make a small opening at the fimbriated end to permit the introduction of the scope. The tubal lumen is visualized while distended with physiologic solution injected through the outer sheath of the rigid hysteroscope or the channel of the flexible hysteroscope. The distal end of the tube must be appropriately manipulated to bring it into the axis of the scope. Salpingoscopy permits direct assessment of the tubal epithelium. The findings have been classified into five grades. Grade 1 refers to normal mucosal architecture. Grade 2 refers to tubes that demonstrate variable degrees of flattening of both major and minor mucosal folds, which are largely preserved. Grade 3 refers to tubes that demonstrate focal adhesions between mucosal folds. Grade 4 refers to tubes with extensive intraluminal adhesions or disseminated flattened epithelial areas. Grade 5 refers to tubes that are rigid and hollow with a complete loss of epithelial folds. Findings at salpingoscopy appear to be predictive and prognostic of pregnancy outcome, as demonstrated by Henry-Suchet et al., Brosens and Puttemans, Bowman and Cooke, Marana et al., and Marchino et al.

Microsalpingoscopy has been used to examine the integrity of the tubal mucosa more closely. Microsalpingoscopy uses an endoscope that has magnification capability enabling visualization of individual cells of the tubal epithelium. The epithelium is stained with concentrated methylene blue solution injected through the cervical cannula. It is then assessed under magnification. The level of staining of the nuclei of the tubal cells is inversely proportional to functional integrity of the mucosa. This technique is at present investigational; thus, its value remains to be determined.

Falloposcopy

Falloposcopy is a transvaginal microendoscopic technique aimed at exploring the entire length of the tube, especially the intramural and isthmic segments. A linear eversion catheter system has been used to perform falloposcopy without the need for preliminary hysteroscopy and anesthesia. The patient requires
Laparoscopy

Laparoscopy permits direct visualization of the peritoneal cavity, pelvis, and internal reproductive organs. It can also test tubal patency with the use of concomitant chromopertubation. Laparoscopy is an invasive procedure that usually requires a general anesthetic. It is the most accurate way to identify periadnexal adhesive disease and endometriosis.

There are those who argue in favor of an immediate laparoscopy bypassing HSG. An analysis of 18 published series demonstrates good congruence between laparoscopic and HSG findings. These collected data indicate that the sensitivity and specificity of HSG are approximately 76% and 83%, respectively. These studies represent a selected population of patients in whom the prevalence of tubal occlusion was 38%. This prevalence figure falls to 10% in studies of large numbers of unselected patients, which reflects more accurately the general population. If the sensitivity and specificity figures reported above are applied to a hypothetical group of patients with a 10% rate of tubal occlusion, 3% of those with a normal HSG will have an abnormal laparoscopy. Thus, the laparoscopy will be normal in about 97% of patients. These data support delaying endoscopy for 4 to 6 months in those with an apparently normal HSG, except in women of older reproductive age.

Based on the preceding information, a well-performed HSG should be the preliminary investigation for tubal factor infertility. This approach permits the identification of (a) uterine anomalies and lesions; (b) cornual occlusion or lesions, even in the presence of cornual patency; (c) distal tubal occlusion; and (d) assessment of intratubal architecture. This information is of paramount importance to the surgeon at the time of laparoscopy, especially if the condition is amenable to laparoscopic surgery, which should be performed during the same time. Indeed, with the advanced imaging techniques and newer therapeutic modalities available today, laparoscopy solely for the purpose of diagnosis should be rarely required.

Laparoscopic Survey

A thorough laparoscopic survey will identify any adhesions, along with their extent and nature, and the presence of endometriosis, its extent, and other abdominal and pelvic lesions; and permit assessment of the uterus, ovaries, and tubes. The information yielded by the prior HSG and this survey enable the surgeon to undertake reconstructive laparoscopic surgery and to recommend surgery by open access or the use of assisted reproductive technologies. These will be discussed later (see Selection of Treatment).

A bimanual pelvic examination is performed on the anesthetized patient. The cervix is then exposed, and a uterine cannula is attached to the cervix. In addition to permitting intraoperative chromopertubation, the cannula enables manipulation of the uterus and enhances laparoscopic visualization.

Once the laparoscope is inserted, the entire peritoneal cavity is inspected. Inspection commences in the upper abdomen and includes the liver and the undersurface of the diaphragm, which are inspected in a clockwise fashion. Particular attention is then focused on the lower abdomen and pelvis. To improve access to the pelvis, the patient is placed in the Trendelenburg position. The bowl is placed upward, initially by manipulating the uterus and thereafter by using the probe inserted through a second puncture, usually placed suprapubically in the midline, or in one of the lower quadrants.

A general panoramic inspection of the pelvis is performed with the laparoscope at some distance from the pelvic organs. 

Reconstructive Tubal Surgery

Tests Designed to Assess Tubal Function

Salpingography, salpingoscopy, and falloposcopy are designed to assess tubal morphology.

Procedures designed to assess function are being developed. Early attempts at using radioactive microspheres as oocyte surrogates to evaluate egg transport did not appear to be clinically valuable. Uter and colleagues have introduced biodegradable microspheres into the pouch of Douglas by either cul-de-sac puncture or laparoscopy. These microspheres, which were recognizable by fluorescence, were collected in a cervical cup 24 hours later. Microspheres were present in the cup in 66% of 69 patients with unexplained infertility and in 100% of 24 patients with male factor infertility.

Radionuclide Hysterosalpingography

Radionuclide HSG is a scintigraphic procedure designed to evaluate the spontaneous proovarian transport of microspheres in the general tract. A solution containing Tc-labeled albumin microspheres is squirted toward the external cervical os of the cervix and upper vagina. The subsequent transport of the microspheres through the cervix, uterus, and tubes is monitored by a gamma camera equipped with a pinhole collimator. The pro-ovarian transport of microspheres depends on both the anatomic patency and the functional integrity of the uterus and oviducts. This test is designed to assess primarily the sperm transport function of the uterus and tubes. This technique is still experimental but preliminary work indicates it is not predictive of fertility potential, and so this technique may have only limited use in the future.

premedication to decrease the discomfort associated with the procedure.

The system includes a linear eversion catheter with an outer plastic polymer body 2.8 mm in diameter and a sliding stainless-steel inner body 0.8 mm in diameter, containing a 0.48-mm fiber-optic endoscope. The tip of the outer catheter is angled so it can be directed toward the uterotubal junction. Once the tubal ostium is identified, the tip of the catheter is held against the ostium. The pressure within the eversion catheter is increased, and the membrane of the eversion catheter is introduced into the fallopian tube for a short distance. The endoscope is pushed down the lumen to the tip of the introduced catheter. The image obtained is displayed on a high-resolution color monitor. The eversion catheter and the endoscope it houses are advanced in the described manner, slowly and gradually, with the endoscope always maintained within the inverting membrane to prevent the tip of the endoscope from piercing the tubal wall.

Fallopometry may be used as a means of tubal catheterization and has the added benefit of permitting assessment of the lumen of the tube, especially its intramural and isthmic segments. In 1992, Kerin proposed a classification based on a scoring system that takes into account the degree of tubal patency, tubal dilatation, epithelial and vascular changes, intratubal adhesions, and other abnormal findings.

This technique, which requires expensive disposable equipment, did not gain clinical acceptance. Technical improvements, amelioration of the image quality, and parallel reduction in cost may trigger reassessment of the cost-effectiveness of this procedure in the future.

Laparoscopy

A thorough laparoscopic survey will identify any adhesions, along with their extent and nature, and the presence of endometriosis, its extent, and other abdominal and pelvic lesions; and permit assessment of the uterus, ovaries, and tubes. The information yielded by the prior HSG and this survey enable the surgeon to undertake reconstructive laparoscopic surgery and to recommend surgery by open access or the use of assisted reproductive technologies. These will be discussed later (see Selection of Treatment).

A bimanual pelvic examination is performed on the anesthetized patient. The cervix is then exposed, and a uterine cannula is attached to the cervix. In addition to permitting intraoperative chromopertubation, the cannula enables manipulation of the uterus and enhances laparoscopic visualization.

Once the laparoscope is inserted, the entire peritoneal cavity is inspected. Inspection commences in the upper abdomen and includes the liver and the undersurface of the diaphragm, which are inspected in a clockwise fashion. Particular attention is then focused on the lower abdomen and pelvis. To improve access to the pelvis, the patient is placed in the Trendelenburg position. The bowl is placed upward, initially by manipulating the uterus and thereafter by using the probe inserted through a second puncture, usually placed suprapubically in the midline, or in one of the lower quadrants.

A general panoramic inspection of the pelvis is performed with the laparoscope at some distance from the pelvic organs.
Abdominal, pelvic, and periadnexal adhesions may impede ovum pickup. Two treatment options for achieving pregnancy are available to the infertile woman with damaged fallopian tubes: reconstructive surgery and IVF. Surgery and IVF must not be regarded as competitive treatments but rather as complementary treatments necessary to achieve the desired goal. The choice of treatment is ideally dependent on various considerations, both technical and nontechnical.

**SELECTION OF TREATMENT**

Two treatment options for achieving pregnancy are available to the infertile woman with damaged fallopian tubes: reconstructive surgery and IVF. Surgery and IVF must not be regarded as competitive treatments but rather as complementary treatments necessary to achieve the desired goal. The choice of treatment is ideally dependent on various considerations, both technical and nontechnical.

**Technical Considerations**

In vitro fertilization is the only treatment option for women with inoperable fallopian tubes and tubal disease coincident with another important fertility factor, such as male factor infertility. In many instances, reconstructive tubal surgery should be the first treatment option. Specifically, patients with a tubopelvic factor whose surgical treatment will improve their fertility or increase the success rate of an IVF cycle should be offered reconstructive tubal surgery. IVF may be attempted if reconstructive tubal surgery proves unsuccessful.

The provision of accurate information regarding both IVF and tubal surgery is essential in the decision-making process of the couple. The couple must be given the live birth rate per cycle of each treatment is ideally dependent on various considerations, both technical and nontechnical.

**In Vitro Fertilization and Embryo Transfer**

Data collected prospectively for ART treatments during the year 2003 from 399 programs in the United States provided the following outcome data, which were tabulated by the Centers for Disease Control and Prevention (CDC). There were 112,872 cycles of ART in 2003. Of these cycles, 85,032 (74%) were standard IVF cycles (fresh, nondonor gametes), and of these standard IVF cycles started, 79,602 (90.7%) had oocyte retrieval and 74,295 (81.6%) progressed to embryo transfer. Overall, the live birth rate per cycle initiated was 28.3%, and the live birth rate per embryo transfer was 34.7%.
that resulted in a clinical pregnancy, 82.2% resulted in a live birth. Of live births, 65.8% were singleton births and 34.2% multiple births.

Of note, the number of ART cycles performed in the United States has almost doubled from 64,036 cycles in 1996 to 122,872 in 2003. The number of live babies delivered in 2003 (48,736) was almost two and a half times higher than in 1996 (20,659). The explanation for this increase is most certainly multifactorial. One important factor is the improved success rate of ART in the last decade. Whereas in 1992 the live-birth rate per cycle initiated was 14.5%, this rate in 2003 was 28.3%.

Intracytoplasmic sperm injection (ICSI) represents a very important progress in ART, especially in the treatment of male infertility. In 2003, 56% of ART cycles used ICSI for fertilization of eggs, representing an increase from previous years. This increase largely reflects the expanding use of ICSI to couples not diagnosed with male factor infertility. In male factor infertility, the use of ICSI is associated with a success rate that almost equals that of standard IVF in the absence of male factor infertility (Table 21.2).

The outcome of both standard IVF and ICSI is adversely affected by the age of the female partner. In standard IVF, with couples who had no associated male factor infertility, the live birth per oocyte retrieval rates based on the age of the female partner were as follows: 34 years or less, 42.6%; 35 to 37 years, 35.9%; 38 to 40 years, 26.2%; 41 to 42 years, 16.1%; and more than 42 years, 6.0%. The live birth per oocyte retrieval rates for IVF using ICSI in couples that had male factor infertility were approximately the same for each group, demonstrating a similar decline with increasing age. These rates were 41.8%, 35.0%, 24.1%, 13.5%, and 4.2%, respectively. This trend is also observed in couples with and without male factor infertility (Table 21.2).

Success with transfer of cryopreserved embryos has improved significantly. Frozen embryos were used in approximately 14% of all ART cycles performed in 2003 (17,517 cycles). The rate of live birth per transfer was 27% as compared with 34.7% for fresh embryo transfer. So, although replacement of frozen embryos improves the cumulative success rate for a couple, the overall net effect remains limited because not all of the cycles provide spare embryos, and not all of the frozen embryos withstand the thawing process.

IVF and embryo transfer is not risk free, especially in stimulated cycles. Although uncommon, ovarian hyperstimulation, bleeding, and infection can occur. Pregnancies resulting from IVF have an abortion rate of about 16%. The overall tubal pregnancy rate is approximately 1% to 2% of ART cycles. A study from our center demonstrated a tubal pregnancy rate of 2.6% (of clinical pregnancies) among IVF patients without tubal factor infertility. However, this rate was 12% in patients with prior tubal disease (these are the patients who must choose between IVF and tubal surgery).

ART procedures are associated with a significant increase in the rate of multiple pregnancy (relative risk: [RR] > 20). The CDC Assisted Reproductive Technology report for 2003 indicated that of the resulting live births, only 65.8% were singleton; 41.0% were twins, and 3.2% were triplets or higher order. This high rate of multiple births has a tremendous personal and social impact. Perinatal morbidity and mortality are markedly increased in pregnancies complicated by multiple gestation. The cost, both emotionally and financially, of caring for premature or abnormal children is great. It is important to note that monofetal pregnancies also are associated with elevated risk as compared with non-ART singleton pregnancies; more than 10% of monofetal births are preterm, and the perinatal mortality rate (about 19 per 1,000) is higher than non-ART singleton pregnancies. Indeed, an important study from Sweden that compared the obstetric outcomes of babies conceived with IVF (n = 5,856) to all babies born in the general population during a span of 13 years (1982–1995) demonstrated the following: Children resulting from an IVF conception had increased rates of low birth weight (RR = 5), major malformations (RR = 1.4), cerebral palsy (RR = 4), and death (RR = 2). Such elevated personal and societal costs must be considered when embarking on any ART procedure.

Reconstructive Surgery

The overall risks of reconstructive tubal surgery are small and include the recognized complications of anesthesia and surgery. Success, if successful, offers multiple cycles in which to achieve conception and the opportunity to have more than one pregnancy. The abortion rate subsequent to reconstructive tubal surgery is not increased over that of the normal population. The live birth and ectopic pregnancy rates depend on the specific nature of the tubal disease and the extent of tubal damage.

After thorough investigation of the couple, a decision must be made regarding whether to proceed with reconstructive

surgery. The preceding arguments and results yielded by IVF must be taken into consideration in this decision-making pro-
cess. In addition, the results achieved by the center in which the patient will be treated must be considered. The results are
dependent on the proper selection of patients and the technical
expertise of the team and the surgeon.

Nontechnical Considerations

The nontechnical considerations include age, cost, and the
wishes of the couple. Female fecundity is adversely affected
by age. Fecundity begins to decline at about 31 years of age.
This trend has been observed both in “normal” couples and in
those with unexplained infertility. This decline becomes more
evident after 37 years of age.

In women of advanced reproductive age, the marked decline
in fecundity rate per cycle of IVF must be weighed against the
fact that reconstructive surgery offers multiple cycles during
which conception can occur. Therefore, although the younger
woman may consider surgery first and IVF thereafter (if this
becomes necessary), those between 37 and 40 years of age may
be advised to consider IVF first.

Health insurance coverage and the cost of the procedure,
depending on the jurisdiction, and the resources of the couple
play important roles in the decision-making process. Another
often underestimated potential factor is the economic impact
of a multiple pregnancy, which occurs much more frequently
with IVF.

The perceptions and wishes of the couple regarding treat-
ment options depend on many influences, including their own
values and ethical views. There may be disagreement between
partners. The physician should provide detailed information
for the couple as clearly and accurately as possible and should
abstain from interfering with their decision making except to
clarify misunderstandings and misinterpretations. The physi-
cian must advise against active treatment when the prognosis
is poor because treatment with essentially no chance of success
cannot be justified.

Selection

Periadnexal adhesive disease may be the only apparent lesion
or may be present in addition to tubal occlusion. The tubes may
be occluded at their outer end or proximally as the end result
of disease processes, or the tubes may have been interrupted by
a previous sterilization.

If periadnexal adhesive disease is the sole lesion, laparo-
scopic salpingo-oophoroscopy, performed preferably at the time
of the initial diagnostic laparoscopy, is the approach of choice.
For patients who have undergone this procedure, the reported
intrauterine pregnancy rates range from 51% to 62%, and the
etopic pregnancy rates range from 5% to 6%.

Agglutination of the fimbriae (fimbrial phimosis) necessi-
tates a fimbrioplasty, which can also be performed laparosopi-
cally. This condition often coexists with periadnexal adhesions,
which are dealt with first. The reported intrauterine pregnancy
rates after laparoscopic fimbrioplasty range from 40% to 48%,
and the ectopic pregnancy rates range from 5% to 6%.

Distal tubal occlusion (hydrosalpinx) can be treated surgi-
cally. Indeed, removal or proximal occlusion of a hydrosalpinx
is recommended by the American Fertility Society (AFS) in 1995.
A recent Cochrane meta-analysis confirms the earlier work of Strandell et al in demonstrat-
ing that the odds of ongoing pregnancy and live birth (OR 2.13, 95% CI 1.24–3.63) were increased after laparoscopic
salpingectomy for unilateral or bilateral hydrosalpinges before
IVF.

In major published series, the live birth rates after micro-
surgical salpingostomy range from 20% to 37%, and ectopic
pregnancy rates range from 5% to 18%. The improved results
achieved with the use of microsurgical techniques are much
less impressive with salpingostomy than with other tubal proce-
dures. Furthermore, salpingostomy, performed by laparoscopic
access, yields almost similar results to those achieved by open
access.

The factors that affect the outcome of salpingostomy in-
clude distal ampullary diameter, tubal wall thickness, nature
of the tubal endometrium, extent of adhesions, and periad-
nexal fibrosis. These prognostic factors have been quantified in a
numerical scoring system (approved by the American Fertility
Society in 1988). In cases deemed favorable (mild), the reported
live birth rates after microsurgical salpingostomy range from
40% to 60%. This rate drops to less than 20% in cases con-
sidered unfavorable (severe). In such cases, IVF may be the
initial treatment of choice. If surgery is the initial treatment of
choice, the decision of whether to proceed with an immediate
laparoscopic salpingostomy or undertake reconstructive mi-
rosurgery must depend on local experience and success rates
with both approaches.

In cases of proximal tubal occlusion, selective salpingogra-
phy or transcervical fallopian tube cannulation may be use-
ful in elucidating false-positive results obtained by HSG and
in overcoming obstruction associated with a mucous plug or
synechiae. True pathologic tubal occlusion resulting from sal-
ipinstis isthmic nodosa, endometriosis, or extensive post-
infarctive fibrosis may be treated by microsurgical tubocor-
nal anastomosis using a minilaparotomy as access. The re-
ported live birth rates after such procedures range from 33% to
56%, and ectopic pregnancy rates range from 5% to 7%.
Because in the vast majority of cases of reversal of tubal
sterilization the available tubal segments are normal, the out-
come of a microsurgical anastomosis is an anatomically and
physiologically normal, albeit shortened, fallopian tube. In our
institution, the intrauterine pregnancy rate in those less than
35 years of age at the time of reversal is approximately 70%,
with most pregnancies occurring within 18 months of surgery;
in those 35 years or more, it is 55%. The ectopic pregnancy
rate is approximately 2%.

Repair of Fimbriectomy

Surgical correction of a Krausen’s sterilization (fimbriectomy)
is possible, but the outcome depends on the remaining am-
pullary length. Live birth rates of about 30% have been re-
ported when more than 50% of the ampulla has been pre-
served. Tubal length, in such cases, can be determined by HSG,
and in the absence of sufficient ampullary length, IVF should
be recommended as the initial treatment. Fortunately, this type
of sterilization is now rarely performed.

Summary

The choice of the primary treatment and any subsequent treat-
ment depends on a careful consideration of both nontechnical
and technical factors. These must be individualized for each pa-
tient. Information about success and complication rates of the
available treatment options must accurately reflect local expe-
rience. Active involvement of the couple in the decision-making
process is more likely to result in resolution of the conflict of
infertility if treatment proves unsuccessful.
MICROSURGERY

Microsurgery has been defined as “surgery under magnification.” In fact, magnification is only a single facet of microsurgery, which embraces a broad concept of tissue care designed to minimize tissue damage. The basic principles of microsurgery include the following:

- Using a technique designed to minimize tissue injury. In addition to delicate handling of tissues and judicious use of electrical or laser energy, frequent intraoperative irrigation with heparinized lactated Ringer solution is performed to keep serosal surfaces moistened and prevent desiccation.
- Preventing foreign body contamination of the peritoneal cavity.
- Obtaining meticulous pinpoint hemostasis while minimizing adjacent tissue damage.
- Identifying proper cleavage planes.
- Precisely aligning and approximating tissue planes.
- Obtaining meticulous pinpoint hemostasis while minimizing adjacent tissue damage.
- Identifying proper cleavage planes.
- Completely excising abnormal tissues.

- Using magnification, which permits prompt identification of abnormal morphologic changes, recognition and avoidance of surgical injury, and application of the preceding principles with the use of fine microsurgical instruments and suture materials.
- Performing a thorough pelvic lavage at the close of the procedure to remove from the peritoneal cavity any blood clots, foreign body, or debris that may be present.

Thus, microsurgery is a surgical attitude as much as a technique.

In the late 1960s, Svolin used magnification with electrocautery for the reconstruction of distal tubal occlusion. In addition, he strived to reduce peritoneal trauma and kept the operative site wet by frequent irrigation. Magnification, including the use of an operating microscope, and microsurgical techniques were subsequently expanded and used in the correction of pathologic cornual and midtubal occlusions and in reversal of sterilization. This approach permitted us to perform tubal anastomosis as opposed to a tubouterine implantation in cases of pathologic cornual occlusion. Such an anastomosis in such cases preserves tubal integrity and thus is a more physiological approach to tubal reconstruction.

Microsurgery, in fact, finds its ultimate application in tubal anastomosis. The use of magnification, microsurgical instruments, and sutures enables the recognition of subtle abnormalities (even in the presence of tubal patency), the excision of abnormal tissues, and the correct alignment of the tubal segments and precise apposition of each layer. Indeed, the application of microsurgery has significantly improved the outcome of such procedures. However, in the treatment of distal tubal occlusion, any improvement attributable to the use of microsurgical techniques has been modest, despite the reduction in postoperative adhesions and improved tubal patency rates.

The introduction of microsurgery into gynecology has yielded benefits much greater than simple improvement in the outcome of certain fertility operations. It created a great awareness of the effects of peritoneal trauma and the resulting postoperative adhesions. It also promoted the use of conservative approaches that are now considered standard care for women undergoing surgical treatment for benign gynecologic disease. These are additional and important reasons to continue to teach reconstructive infertility surgery.

Thus, microsurgery is a surgical philosophy, a delicate surgical approach designed to minimize peritoneal trauma and tissue disruption and to prevent postoperative adhesions while increasing the accuracy of the procedure and improving the outcome.

Microsurgical techniques are equally applicable to both laparotomy and laparoscopic access. We demonstrated the applicability of microsurgical techniques by laparoscopy for adhesiolysis, salpingo-ovariolysis, fimbrioplasty, and salpingostomy as early as the mid-1970s. Microsurgical techniques can be used in all reproductive operations, irrespective of the mode of access. This is especially important today because most such procedures are performed by laparoscopy and minilaparotomy.

The laparoscope provides a degree of magnification. It is also possible to bring the distal end of the laparoscope close to the area of interest and achieve excellent visibility and illumination. There are microsurgical advantages inherent to laparoscopic access. Operating within a closed peritoneal cavity eliminates the need to use packs and prevents the introduction of foreign materials such as lint and talcum powder. The pressure effect of the pneumoperitoneum diminishes venous oozing and permits spontaneous coagulation of minor vessels. It is possible to perform intraoperative irrigation to expose any bleeding vessels and keep tissues moistened. Fine electrodes can also be used to achieve precise electrosurgical hemostasis. Like microsurgery, laparoscopic procedures are performed with few instruments. The instrument manufacturers have at last recognized the need for proper microsurgical instruments for laparoscopy; they are now readily available. We must stress, however, that the large volume of insufflation necessary in operative laparoscopy causes desiccation of the mesothelial cells that line the peritoneum. This phenomenon, which may enhance formation of postoperative adhesions, can be largely prevented by the use of warmed humidified gas, which can be accomplished with the introduction of a special apparatus into the CO₂ line. There is also evidence that CO₂ pneumoperitoneum alters the protective mechanisms of cells against free radicals. This increases with the duration of the pneumoperitoneum, insufflation pressure, and flow rate. This deleterious effect may be partly overcome by frequent irrigation with lactated Ringer solution. Experimental data in animals suggest that the addition of a small percentage of oxygen to the pneumoperitoneum reduces these local effects, as well as the systemic effects of carbonemia and acidosis.

Major Equipment and Surgical Instruments

The major equipment includes an electrosurgical generator suitable for both general and microsurgical work and, depending on the access mode used, either an operating microscope or appropriate laparoscopic equipment.

Most of the good modern electrosurgical generators can be used for both general and microsurgical work. Such generators are now standard equipment in most operating rooms.

When access to the pelvis is achieved by laparotomy or mini-laparotomy, magnification is obtained by the use of an operating microscope or loops. Loops provide low levels of fixed magnification. It is difficult to work with loops that provide magnification greater than 4 times. They are suitable for use only in simple short procedures and are quite helpful when used to divide adhesions or excise endometriotic lesions located deep in the pelvis.

Magnification is best obtained with an operating microscope that provides magnification ranging from 2 times to 40 times; coaxial illumination of a constant visual field enables precise focusing and change of the level of magnification. In gynecologic microsurgery, an objective lens with a focal length of 1.5 times magnification focused on a visual field that is doubled in size provides the best combination of features.
distance of 250 to 300 mm allows for a suitable working distance under the lens. The microscope can be mounted on the floor or ceiling. Focusing, varying the level of magnification, and other functions of the microscope can be manual or motorized. The latter version is preferable because changes can be readily accomplished through controls on a foot pedal while the surgeon’s hands remain in the operative field. Most modern operating microscopes are equipped with beam splitters, which permit the fitting of two pairs of binoculars so that both the surgeon and the assistant can simultaneously view the operative field. A miniature television camera can also be fitted to the same beam splitter, which enables the operating room personnel to follow the surgery on the monitor and allows video recordings of the procedure to be made.

When laparoscopic access is used, a good laparoscope equipped with a high-resolution mini TV camera and monitor is required. The laparoscope does not offer the stereoscopic vision and the excellent depth of field that the operating microscope provides. Nonetheless, first generations of three-dimensional laparoscopic equipment and magnification devices have been produced. Progress is under way.

Good microsurgical instruments are now available from many manufacturers. Their shape is obviously different for open and laparoscopic procedures. However, their functions are similar. The basic microsurgical instruments are few and include plain and toothed platform microforceps, microscissors, microneedle holder, and straight scissors and/or a microblade to transect the tube (Fig. 21.11). The forceps have rounded tips with a shaft designed so that they, like the scissors and needle holder, have good ergonomics and can be used comfortably. Teflon-coated probes with variable rounded tips are used for retraction.

Electromicrosurgery requires the use of a true insulated microelectrode of 100 or 150 microns in diameter with a free pointed conical tip. The microelectrode is connected to the handle of the electrosurgical unit with an adaptor. A rocker switch mounted on the handle allows delivery of current in cutting, coagulating, or blend modes. Irrigation can be performed with an appropriate laparoscopic irrigator. For open procedures, a device with a fingertip control (Gomel irrigator, Fig. 21.12) is commercially available and enables accurate irrigation.

Immediate Preoperative Preparation

Before the induction of anesthesia, the surgeon must ensure that all necessary equipment and instruments are present and in working order. After the induction of anesthesia, the patient’s bladder is catheterized with a Foley catheter, which is connected to continuous drainage. If intraoperative chromopertubation is required, either a pediatric Foley catheter or an appropriate uterine cannula is introduced through the cervix and fixed in
place. The catheter or cannula is connected either directly or by means of an extension tube to a syringe filled with dilute dye solution.

When open surgical access is used, anteverision and elevation of the uterus can be achieved either by selecting a suitable uterine cannula or by packing the vagina. With the latter option, a pediatric Foley catheter should first be placed in the uterine cavity if intraoperative chromatoperturbation is desired.

Surgical Access
As indicated earlier in the text, many reconstructive tubal operations can be performed by laparatomy, minilaparotomy, or laparoscopic access. The selection of the specific access route depends on the nature of the lesion, the type of procedure required, and the skill of the surgeon. The aim is to select the access route that will yield the best outcome for the patient.

Many reconstructive operations, especially those for distal tubal disease, can be efficiently performed by laparoscopic access. Because of the advantages inherent in undertaking such a procedure at the time of the initial diagnostic laparoscopy, it is preferable that a surgeon trained in this type of surgery perform the initial laparoscopy.

Access by Laparoscopy
Once a proper pneumoperitoneum is obtained, the principal trocar and cannula are inserted (usually intravesically), the trocar is removed, and the laparoscope is introduced through the cannula. The details of performing a laparoscopy will not be described in any detail in this chapter. A thorough laparoscopic survey is performed as described earlier in this text, and the nature and extent of the tubal and pelvic lesions is assessed. The information yielded by the prior HSG, complemented by the laparoscopic findings and the status of the other fertility parameters, permits the surgeon to select the therapeutic approach that is best for the patient.

The laparoscopic survey requires the establishment of a secondary portal for the introduction of a probe or other appropriate instrument. This ancillary portal is placed suprapublically in the midline or in one of the lower abdominal quadrants. The undertaking of reconstructive surgery will necessitate the establishment of additional portals of entry. These are placed, depending on the clinical findings and the procedure to be performed, at sites that permit easy access to the operative field.

Abdominal Incision Minilaparotomy
In reconstructive tubal surgery, a transverse suprapubic incision is the type used most often. Since 1985, we have used a small, minilaparotomy, suprapubic transverse or vertical (if a midline or paramedian scar is present) incision to gain access to the pelvis. The length of this minilaparotomy incision is usually 5 to 6 cm. The prior pelvic findings and especially the depth of the patient’s subcutaneous fat and fascia determine the length of the incision. The site of the proposed incision is infiltrated with a long-acting anesthetic agent, such as 0.25% bupivacaine (Marcaine) solution. A transverse suprapubic incision is made and extended down to the fascia. The subcutaneous fat is dissected over the fascia, in the midline upward and downward. The fascia is then incised vertically in the midline. The recti muscles are separated in the midline, and the peritoneum is incised vertically, with the incision curved laterally at the lower end to avoid the bladder. The subcutaneous tissues are reinfiltated with the same solution before closure of the skin incision. Thereafter, a bilateral ilioinguinal nerve block is established. The small size of the incision; the lack of bowel manipulation, along with gentle handling of tissues during the procedure; and the use of local anesthesia reduce postoperative discomfort and analgesia requirements. This approach permits prompt mobilization of the patient and discharge from the hospital or surgical center within 4 to 24 hours. Most of our patients are discharged on the same day. These patients return to normal activity almost as rapidly as those who have had their procedures performed laparoscopically.

It is essential that the surgical personnel thoroughly wash their gloves after they have been put on and again before mak-

ing the peritoneal incision. Once the peritoneal cavity is en-
tered, a wound protector is introduced through the incision, and a small Dennis-Brown retractor is applied. A disposable device, Protractor, combines the functions of wound protector and retractor, providing circumferential retraction with maximal exposure for the incision site. This device is preferable because it is easy to use and enhances access through mini-
laparotomy. Pads soaked in heparinized (5,000 U/L) lactated Ringer solution can be introduced into the pouch of Douglas to further elevate the uterus and isolate the bowel already dis-
placed by a mild (10- to 15-degree) Trendelenburg tilt.

Once the surgical site is well exposed, the operating micro-
scope is positioned. Although the operating microscope can be draped, we have not found this to be necessary, particularly if foot pedals control the microscope. Intraoperative irrigation is performed with heparinized lactated Ringer solution in an intra-
avenous bag that is elevated and connected with intravenous tubing to a Gostel microsurgical irrigator (Fig. 21.12). This enables periodic irrigation of the exposed peritoneal surfaces and ovaries to prevent desiccation and to visualize individual bleeders.

Pelvic Lavage
At the close of a reconstructive procedure, irrespective of the type and the mode of access, the operative site is inspected to ensure that complete hemostasis has been achieved. Any bleed-
ing vessels are electrodesiccated. A thorough pelvic lavage is then performed with the irrigation solution until the fluid re-
 mains clear. Pelvic lavage serves to remove from the peritoneal cavity any blood clots or other debris that may be present.

When laparoscopic access is used for the procedure, under-
water examination of the operative site may be performed. When the irrigation fluid remains clear, the pneumoperitoneum pressure is reduced, and the region is inspected with the distal end of the laparoscope under the surface of the fluid. This per-
mits prompt recognition of any small bleeding vessels, which can be desiccated with use of a microelectrode or microbipolar forceps.

Once the irrigation fluid is completely suctioned out of the pelvis, some investigators leave varying amounts of physio-
logic solution in the peritoneal cavity to reduce postoperative adhesions. We use 200 to 300 mL of lactated Ringer solution. Hysterectomy, which was in vogue for many years, is no longer used. There are promising new products designed to prevent adhe-
sion formation that are easy to apply by both open and lap-
aroscopic access; these are currently undergoing clinical tri-
als. The topic of ancillary measures for adhesion prevention is outside the purview of this chapter and will not be discussed further.
In this chapter, the following procedures will be discussed: salpingo-ovariolysis, fimbrioplasty, salpingostomy, tubotubal anastomosis to repair midtubal disease or to reverse a prior sterilization, tubocornual anastomosis to treat proximal tubal disease, and other procedures performed rarely in unusual circumstances.

The techniques used in these procedures are essentially the same irrespective of the access route. Whereas procedures for distal tubal disease are very amenable to laparoscopic access, anastomatic procedures are technically more difficult to accomplish by this route. Isthmic-isthmic and isthmic-ampullary anastomosis (usually used for sterilization reversal) have been performed with varying degrees of accuracy through laparoscopic access, but accomplishing other types of anastomoses (especially tubocornual) through this mode of access is much more difficult.

With microsurgical procedures, our aim has always been to keep the techniques as simple as possible in order that the results will be reproducible not only by surgical virtuosi but also by all physicians who practice in this field.

Our recent technical modifications, including access through minilaparotomy incision and the use of a Protractor, were the result of the same thought process. Although we remain enthusiastic proponents of laparoscopic access, we do not let this enthusiasm blind us to the possibility that some procedures may still be performed better by improvements in traditional methods.

**SURGICAL TECHNIQUE**

In this chapter, the following procedures will be discussed: salpingo-ovariolysis, fimbrioplasty, salpingostomy, tubotubal anastomosis to repair midtubal disease or to reverse a prior sterilization, tubocornual anastomosis to treat proximal tubal disease, and other procedures performed rarely in unusual circumstances.

The techniques used in these procedures are essentially the same irrespective of the access route. Whereas procedures for distal tubal disease are very amenable to laparoscopic access, anastomatic procedures are technically more difficult to accomplish by this route. Isthmic-isthmic and isthmic-ampullary anastomosis (usually used for sterilization reversal) have been performed with varying degrees of accuracy through laparoscopic access, but accomplishing other types of anastomoses (especially tubocornual) through this mode of access is much more difficult.

With microsurgical procedures, our aim has always been to keep the techniques as simple as possible in order that the results will be reproducible not only by surgical virtuosi but also by all physicians who practice in this field.

Our recent technical modifications, including access through minilaparotomy incision and the use of a Protractor, were the result of the same thought process. Although we remain enthusiastic proponents of laparoscopic access, we do not let this enthusiasm blind us to the possibility that some procedures may still be performed better by improvements in traditional methods.

**Salpingo-Ovariolysis**

Pelvic and periadnexal adhesions usually are the sequelae of PID. These adhesions may be broad or shallow; they are usually not too vascular and extend from one structure to another. In so doing, they tend to leave a space or potential space between the involved structures, an aspect that facilitates adhesiolysis. The space between the involved structures facilitates division. See color version of figure.

In this case, adjacent structures are intimately conglutinated. The adherent area is devoid of the superficial mesothelial layer of peritoneum. Adhesions are often composed of two layers, even though they may initially appear as a single layer. They tend to attach to an organ at two different levels. It is essential to enter the adnexa, making it possible to elevate and bring them closer to the abdominal wall. This move facilitates the remainder of the procedure.

**FIGURE 21.13.** Salpingo-ovariolysis. The space between the two involved structures facilitates division. See color version of figure.

**FIGURE 21.14.** Ovariolysis. Broad adhesions that had already been divided at their distal margins are being excised from the ovary. See color version of figure.
and the adhesion is transected. With open access, placement of a Teflon rod under the incision line enhances exposure. Damage to the peritoneum or ovarian surface is avoided by keeping the transection line 1 mm away from these surfaces. Prominent vessels along the transection line are individually electrodissected.

When a microelectrode is used for this purpose, the electro- surgical unit is put on the blend setting, which on cut mode combines coagulating current with cutting current to provide concurrent hemostasis during the division of adhesions. Pure coagulating current (COAG mode) may be used to obtain hemostasis of individual bleeders, which are exposed under a jet of irrigation fluid. With open access, an elongating adapter may be attached to the handle of the electrosurgical unit to facilitate adhesiolsysis in the deeper parts of the pelvis.

All of the broad adhesions are excised and removed from the pelvis (Fig. 21.14). Shallow adhesions are simply divided. In this case, a small opening is made on the adhesion, through which a fine instrument or Teflon rod is introduced. This permits separation of the adjacent structures and better visualization of the adhesion, which is incised without damaging these structures. The procedure is completed with a thorough pelvic lavage with the irrigation solution mentioned earlier.

The technical principles are identical when laparoscopic access is used for the procedure. In this case, however, because there is no need to lift the adnexa close to the abdominal wall, the salpingo-ovariolysis is commenced with the tube and ovary. Once again, the performance of effective and safe salpingo-ovariolysis requires clear identification of each adhesive layer, which is grasped and retracted, permitting clear identification of the attachments to the organ of interest. The adhesions are incised parallel to the organ of interest and about 1 mm away to prevent damaging its mesothelial envelope (Figs. 21.15 and 21.16). Division is accomplished electrosurgically with a microelectrode or mechanically with the use of proper scissors. We use scissors for laparoscopic salpingo-ovariolysis and electrodissection to secure obvious vessels or bleeders encountered along the incision line. As described earlier, shallow adhesions are simply divided, whereas broad adhesions are excised (by dissecting them free at all points of attachment) and removed through one of the ancillary portals (Fig. 21.16).

Cohesive adhesions require identification of the dissection plane. This is achieved by making a small incision and developing a tissue plane either by spreading the jaws of the scissors, by blunt dissection, or by hydroundissication (injecting irrigation solution into the site under pressure). It is important to abstain from using thermal energy in such cases because of the inherent danger.

It should not be necessary to do a laparotomy solely for the purpose of salpingo-ovariolysis. Our primary approach in such cases has been to perform the procedure by way of laparoscopy, usually at the time of the diagnostic survey.

**Results of Salpingo-Ovariolsysis**

The reported intrauterine pregnancy rates resulting from open microsurgical salpingo-ovariolysis range from 41% to 57%. The rates for live births are 37% to 57%, and the rates for ectopic pregnancies are 5% to 8% of operated patients. In one of these studies, 33 of 63 (52.4%) patients who underwent microsurgical salpingo-ovariolysis achieved intrauterine pregnancies, and there were three (4.8%) ectopic pregnancies at 2-year follow-up. These 63 patients had been randomized to two cutting modalities: electrosurgery (n = 33) and CO2 laser (n = 30). The results were identical in both subgroups. Indeed, there has been no demonstrable improvement in the outcome of such procedures with the use of lasers in both clinical and experimental studies.

The preexisting tubal patency and the uncontrolled nature of the salpingo-ovariolysis series reported in the literature may cast doubt on the value of this procedure. The Canadian Infertility Evaluation Study Group addressed this issue by studying treatment-dependent and treatment-independent pregnancies in patients with peritubal disease whose fallopian tubes were not completely occluded. This was a multicenter, controlled, randomized study. The cumulative pregnancy rates were 59% among 69 patients in the group who underwent microsurgical salpingo-ovariolysis and 78% among the 78 control patients who were not treated. This study confirms that pregnancies may occur in a small proportion of women with periadnexal adhesions and patent tubes and proves the therapeutic value of salpingo-ovariolysis in such cases.

In the early stages of development of operative laparoscopy, we demonstrated that laparoscopic salpingo-ovariolysis yields results similar to those obtained by microsurgery. We also stressed the importance of adhering to microsurgical principles in the performance of such procedures by laparoscopic access. We reported later a series of 92 patients who underwent salpingo-ovariolysis by laparoscopy. The duration of involuntary infertility was longer than 20 months for all patients. Peritubal adhesions were severe in 79 patients and moderate in 13. Moreover, the series included only those patients in whom ovum pickup by the tube on the side with lesser disease was deemed impossible or greatly hampered. At the time of the survey, the patients had been monitored postoperatively for a period of 9 months or longer. Of the 92 patients, 57 (62%) achieved at least one intrauterine pregnancy; 54 (59%) had one or more live births, and five (5.4%) had ectopic pregnancies. Ten of the patients who did not get pregnant had a second-look laparoscopy that demonstrated no significant residual adhesive process.

Similar results were corroborated by other centers in Europe and North America. This demonstrates that the results of laparoscopic salpingo-ovariolysis, as expected, depend on the severity of the adhesions. The reported intrauterine pregnancy rates after laparoscopic salpingo-ovariolysis range from 51% to 62%, and ectopic pregnancy rates range from 1% to 8% of operated cases. Although no prospective, randomized trials exist, these results appear similar to those yielded by laparotomy.

**FIGURE 21.15.** Salpingo-ovariolysis by laparoscopic access (same patient as in Figure 21.9). Division of adhesions parallel to the tube. See color version of figure.
Fimbrioplasty

Fimbrioplasty is the reconstruction of the fimbriae or infundibulum in a tube that exhibits fimbrial agglutination or preinfundibular phimosis, and results in partial distal occlusion. Often, the tube and ovary are involved in adhesions, in which case salpingo-ovariolysis must precede the fimbrioplasty. The technique of fimbrioplasty, which will be described further, is the same irrespective of the access route used. Our approach is invariably by laparoscopic access.

Fimbrial phimosis results from the agglutination of the fimbriae. A small opening is usually present at the distal end of the tube unless this opening is covered by fibrous tissue. The latter usually becomes evident when the tube is distended by transcervical chromopertubation. When the opening is covered by fibrous tissue, this tissue must be incised or excised to gain access to the fimbriae. Agglutination of the fimbriae can be corrected simply by introducing a fine forceps (mosquito forceps by laparotomy or a 2-mm grasping or alligator forceps by laparoscopy) with jaws closed through the phimotic fimbrial opening. The jaws of the forceps are opened within the tubal lumen, and the forceps are gently withdrawn with the jaws open. Deagglutination is achieved by repeating this movement a few times, varying the direction in which the jaws of the forceps are opened (Fig. 21.17). When sufficient gentleness is used during this manipulation, bleeding is usually negligible.

When the stenosis is located at the level of the true abdominal tubal ostium, which is located at the apex of the infundibulum, the fimbriae may have a normal appearance. However, when chromopertubation is performed, the ampullary portion of the tube distends before any exit of dye solution. In this instance, it is necessary to place an incision on the antimesosalpingeal border of the tube, which commences at the infundibulum and continues past the stenotic area into the distal ampulla. The tube is stabilized by introducing a thin Teflon probe through the stenotic opening into the distal ampulla, and the incision is made electrosurgically using a microelectrode. This is the approach we generally use. Alternatively, the area can be injected with 1 mL of dilute vasopressin solution (1 IU in 10 mL of normal saline), and the incision made mechanically with microsurgical scissors. Bleeders are desiccated electrosurgically. The edges of the two flaps thus created are folded back either by securing them to the adjacent ampullary serosa with no. 7-0 or 8-0 polyglactin 910 (Vicryl) sutures or by

A: Division of adhesions commences in a well-exposed area. B: Adhesions are stretched and are divided one layer at a time parallel to the organ of interest. electrosurgery (or a defocused CO₂ laser beam), which desiccates the serosal aspect of the flaps, causing them to fold backward (Fig. 21.18).

Results of Fimbrioplasty

Very few investigators have classified fimbrioplasty as an independent procedure. Most include such patients in their salpingostomy series. French and Belgian centers include fimbrioplasty (correction of partial distal tubal occlusion) as stage 1 in their salpingostomy series.

Patton and colleagues, in a series of microsurgical fimbrioplasty procedures in 40 patients, reported total intrauterine and ectopic pregnancy rates of 63% (23 patients) and 5% (2 patients), respectively, after 24 months of follow-up. The outcome of the intrauterine pregnancies and the live birth rates were not provided.

In 1983, Gomel reported 40 such patients, all treated by laparoscopic access. Live births occurred in 19 (48%), and two patients (5%) had tubal gestations. Mettler and associates reported a crude pregnancy rate of 31% among 51 women. The anatomic location and outcome of these pregnancies were not recorded. Dubuisson and colleagues reported 31 such patients. After 18 months of follow-up, eight patients (26.5%) had intrauterine pregnancies, and four (12.9%) had ectopic pregnancies. Donnez and colleagues (1986a), in a series of 100 patients, reported a total pregnancy rate of 61%. The location and outcome of these pregnancies were not recorded. Canis and colleagues included 32 such patients with their salpingostomy patients; 16 (50%) of these achieved intrauterine pregnancies, but the outcome was not reported. Surprisingly, there were no tubal pregnancies.

Laparoscopic and open microsurgical fimbrioplasty appear to be comparable with regard to intrauterine pregnancy rates; however, with the former, the ectopic rate can be up to 14%.

Salpingostomy (Salpingonocostomy)

Salpingostomy, or salpingonocostomy, is the creation of a new stoma in a tube with a completely occluded distal end (hydro-salpinx). Salpingostomy can be terminal, ampullary, or isthmic, depending on the anatomic location at which the new
stoma is fashioned. Isthmic and ampullary salpingostomy are of historic interest, except for the reversal of prior fimbriectomy (Kroener's sterilization), in which ampullary salpingostomy may have a place. We did demonstrate that success with ampullary salpingostomy in such cases is dependent on ampullary length, and suggested that reconstructive surgery should only be undertaken when more than one half of the ampulla is present. This recommendation is corroborated by a recent study, by Tourgeman and colleagues, reporting on 41 women who had fimbriectomy reversal.

Distal tubal occlusion is usually associated with varying degrees of pelvic and periadnexal adhesions that must first be lysed. Thereafter, the distal end of the tube is examined to ensure that it is not adherent to the ovary or other structures. If the distal tube is adherent, it must be dissected free until the tuboovarian ligament is exposed (Fig. 21.19). Only by freeing the tube can the surgeon ensure that the neostomy is being performed at the appropriate site.

Once the salpingo-ovariolysis is completed and the tube is totally freed, it is distended by transcervical chromopertubation. The occluded terminal end of the tube is examined under magnification, which permits recognition of the relatively avascular zones that radiate from a central punctum. The tube is entered at this central point with use of the microelectrode or microsurgical scissors, and the incision is extended toward the ovary over an avascular line (Fig. 21.20). This incision fashions a new fimbria ovarica that maintains the tuboovarian relation. At this point in the procedure, it becomes possible to view the tube from within when placing additional incisions along its circumference to complete the creation of a new stoma. These additional incisions are made between endothelial folds, over avascular areas. In so doing, one avoids cutting through vascular mucosal folds, which will be shaped as fimbriae, and bleeding is minimized as a result. Any bleeding points that occur are exposed under a jet of irrigation fluid and desiccated individually with a microelectrode or microbipolar...
forceps. Once a satisfactory stoma is achieved, the flaps created in the process are everted either by securing them without tension to the ampullary seromuscularis with interrupted no. 8-0 Vicryl sutures (Fig. 21.20) or by desiccating their serosal surface, which causes them to fold backward. Desiccation is achieved either electrosurgically with a ball-shaped electrode and a low power density or with CO₂ laser using a defocused beam. The procedure is concluded with a thorough pelvic lavage, as described earlier in this chapter.

Considering that the results of salpingostomy obtained by laparoscopy approach those obtained by open access, an open salpingostomy should be rarely indicated.

If during the initial diagnostic laparoscopy, the surgeon decides to perform the salpingostomy by open access and if the adnexa are found to be fixed by periadnexal adhesions, these adhesions can be lysed laparoscopically at their distal margins, thus mobilizing the adnexa. Such an undertaking permits the subsequent salpingostomy to be readily performed through a minilaparotomy incision. The same applies to cases of tubo-tubal anastomosis and more complex reconstructive procedures.

Results of Salpingostomy

In the major published series, the live birth rate after microsurgical salpingostomy ranges from 20% to 37%, and the ectopic pregnancy rate ranges from 5% to 18% (Table 21.3). The factors that affect the outcome of salpingostomy were reviewed earlier in this chapter. Work performed in the past 30 years has made it evident that the major determinants of the outcome of salpingostomy are the degree of preexisting tubal damage and the extent and nature of periadnexal adhesions (Figs. 21.21 and 21.22). As stated earlier in this chapter, the reported live birth rate after microsurgical salpingostomy in favorable cases (mild) ranges from 40% to 60%. This rate drops to less than 20% in unfavorable (severe damage) cases.

We reported a series of 90 patients who underwent microsurgical salpingostomy with a minilaparotomy incision. Nineteen (21.1%) were lost to follow-up and were considered failures. Twenty-seven (30%) patients achieved one or more intrauterine pregnancies, and eight (8.9%) had tubal pregnancies. Ectopic gestations occurred in two additional patients who also had intrauterine pregnancies. Twenty-three (25.6%) women were successful in having one or more live births. These 90 patients were assessed with the classification approved by

NS, not stated.

*Follow-up period more than 8 years.
*Follow-up period more than 1 year.
*Twenty-three of these were iterative procedures; only three of these patients (13%) had live births.
*Thirty-seven of these procedures were performed with the carbon dioxide laser.
*Eight of the nine patients had prior salpingostomy by conventional techniques that resulted in mucocclusion.
*Performed with the carbon dioxide laser.
Tubotubal Anastomosis

The term tubotubal anastomosis refers to an anastomosis performed anywhere along the tube either to treat occlusions resulting from disease processes or to reverse a prior sterilization. The procedure used to repair proximal or cornual tubal disease is usually referred to as tubal reversal and will be discussed separately.

Microsurgery finds its ultimate application in tubotubal anastomosis. The precision afforded by this technique allows total excision of occluded or diseased portions, proper alignment, and excellent apposition of each layer of the proximal and distal tubal segments.

Tubotubal anastomosis is performed either to reverse a previous tubal sterilization or to reconstruct the tube after removal of a diseased portion that is often occluded and affects the tube at a site other than the fimbriated end. Depending on the tubal segments that are approximated, tubotubal anastomosis can be intramural-isthmic, intramural-ampullary, isthmic-isthmic, isthmic-ampullary, ampullary-ampullary, or ampullary-infundibular. This section first describes the fundamentals of tubotubal anastomosis and then the technical variations necessary to deal with each specific type of anastomosis.
Basic Principles of Tubotubal Anastomosis

When periadnexal adhesions are present, salpingo-oovariolysis is first completed. When access is achieved through laparotomy or minilaparotomy, the occluded segment is grasped with a strong-toothed forceps to expose the site and facilitate hemostasis.

The principles of tubotubal anastomosis are the same, irrespective of the method used. The proximal tubal segment is detangled transversely by coagulation of the mucosal spatula. The tube is transected, with appropriate scissors, adjacent to the site of occlusion or, in the case of a previous tubal sterilization, near the occluded end. The occluded or impacted segment of the tube is grasped with a strong-toothed forceps to expose the site and facilitate the transection (Fig. 21.23A), which is effected with sharp scissors or a sharp microblade. It is essential to halt the incision at the mesosalpinx, in the immediate periphery of the tubal musculature, to avoid damaging the adjacent vascular arcade. Dye solution can now escape from the transected tubal lumen (Fig. 21.23B).

The occluded tubal segment is excised from the mesosalpinx electrosurgically or with scissors, the line of incision kept close to the tube to avoid damaging the vessels mentioned earlier (Fig. 21.23C). The cut surface is examined under high magnification to ensure that the tube is normal. Healthy tube is devoid of scarring and exhibits normal muscular and vascular architecture together with intact mucosal folds (Fig. 21.23D). Hemostasis is obtained by precise electrodesiccation of the more significant bleeders, which are located between the serosa and musculature. Each is exposed by irrigation and dissected with an insulated microelectrode. If open access is used, gentle compression of the tube between thumb and forefinger facilitates this process. Desiccation of minor bleeders is unnecessary because they stop spontaneously. Desiccation of the tubal epithelium must be avoided to prevent damaging it and adversely affecting future tubal function. Major tubal vessels (such as those composing the vascular arcade) may be divided inadvertently or by necessity. These can be electrodesiccated with monopolar or bipolar current. Overzealous electrodesiccation must be avoided to prevent devitalizing the anastomosis site.

When there is no significant luminal disparity between the two segments, the distal portion is prepared in a similar manner. Before transection, the distal segment is detached by descending hydroperistalsis, which consists of injecting a few milliliters of irrigation fluid or dilute dye solution through the distal tube to identify the distal limit of the occluded portion or, in the case of a prior sterilization, to identify the extremity of the stump. The tubal segments are approximated in two layers. The first of these joins the adventitia and mucous membranes, and the second joins the serosa. We generally use no. 8-0 Vicryl sutures swaged on a 130-micron-shaft, 4- or 5-mm-long, taper-cut needle for tubal anastomosis. The first suture of the inner musculoepithelial layer is always placed at the mesosalpingeal border (6-o’clock position) to ensure proper alignment of the two segments of tube. All of the sutures are placed in a pingeal border (6-o’clock position) to ensure proper alignment of the knots peripherally.

In exceptional circumstances when the distance between the two segments is great, the mesosalpinx adjacent to the cut ends of the two tubal segments can be approximated first, using a single interrupted no. 7-0 or 8-0 suture. This step brings the tubal segments into close proximity; thus, it facilitates placement of the sutures of the inner layer and reduces the tension that would have existed when tying these sutures.

Once the 6-o’clock suture is tied, the placement of three or more additional sutures (depending on the type of anastomosis) is required to appose the inner layer. These additional sutures can be placed by using a single strand of suture as a continuous series of loops, including the muscularis and the epithelium of the two segments (Figs. 21.23E and 21.24). The sutures are tied individually, after the division of the loop between each successive suture (Fig. 21.23F). This approach facilitates and speeds up suture placement. We advise against the use of a suture on the luminal border of the tubal because this does not facilitate the procedure and may traumatize the epithelium. Instead, if necessary, the cut surface may be stained with methylene blue or indigo carmine solution to accentuate the visibility of the individual layers.

After approximation of the inner layer, chromopertubation should demonstrate tubal patency and a watertight anastomotic site (Fig. 21.23G). The serosa is then joined either with interrupted sutures or with two continuous sutures, one that runs anteriorly and the other posteriorly, starting at the time-mesosalpingeal border (12-o’clock). Finally, the defect in the mesosalpinx is repaired (Fig. 21.23H).

Tubotubal Anastomosis to Repair Midtubal Disease

The most common reason to perform a tubotubal anastomosis is reversal of sterilization. Midtubal occlusions resulting from disease processes are rare. Such lesions usually affect the intramural or proximal isthmic segments and require a tubocornual type anastomosis.

The causes of midtubal occlusion include endometriosis and tubal pregnancy, usually undiagnosed or treated by observation. A tubal pregnancy treated medically with methotrexate administration or surgically by linear salpingotomy may result in tubal occlusion at the gestational site. Treatment of tubal pregnancy by segmental excision will leave the tube in two segments, as with tubal sterilization. Rare causes of occlusion include congenital absence of a midtubal segment and tubal ectopic pregnancy at the gestational site. Treatment of tubal pregnancy treated medically with methotrexate administration or surgically by linear salpingotomy may result in tubal occlusion at the gestational site. Treatment of tubal pregnancy by segmental excision will leave the tube in two segments, as with tubal sterilization. Rare causes of occlusion include congenital absence of a midtubal segment and tubal ectopic pregnancy at the gestational site. Treatment of tubal pregnancy treated medically with methotrexate administration or surgically by linear salpingotomy may result in tubal occlusion at the gestational site. Treatment of tubal pregnancy treated medically with methotrexate administration or surgically by linear salpingotomy may result in tubal occlusion at the gestational site. Treatment of tubal pregnancy treated medically with methotrexate administration or surgically by linear salpingotomy may result in tubal occlusion at the gestational site.
FIGURE 21.23. Microsurgical tubotubal anastomosis for reversal of Fallope-ring sterilization. A: The occluded end of the isthmus is grasped, and the tube is transected with scissors. B: Dye solution escapes from the lumen. C: The occluded tubal segment is excised from the mesosalpinx electrosurgically by use of a microelectrode. D: The cut surface of the patent tube is assessed under high magnification. E: Once the 6-o’clock suture is tied, subsequent sutures can be placed with use of a single strand of suture as a continuous series of loops. F: Each suture is tied individually after the division of the loop between successive sutures. G: The apposition of the inner musculoepithelial layer is complete. H: The anastomosis is completed with approximation of the serosa. See color version of figure.

Reconstructive Tubal Surgery

chromoperturbation distends this small segment of isthmus, facilitating identification of its distal margin and its dissection from the uterus. The dissection must be effected carefully to avoid damaging the tube itself and the vessels supplying it. The conservation and appropriate preparation of this segment, even when very small, convert the anastomosis to an isthmic–isthmic type and facilitate the procedure.

In the absence of any isthmus (as may be the case subsequent to either a tubal sterilization or excision of an isthmic pregnancy), maintenance of uterine distention by chromoperturbation will indicate the site where the intramural segment should be sought, between the uterine insertion points of the round and ovarian ligaments. Excision of the serosa and underlying scar tissue over the distended area may permit the dye solution to stream out of the intramural segment. In some instances, it is also necessary to dissect the muscularis of this segment from the surrounding uterine muscle for 1 or 2 mm with microscissors or a microelectrode. After this, the tube is transected with microscissors. This process may have to be repeated until the patent tube is reached, at which point dye solution should stream out of the lumen (see Fig. 21.30).

Because of extensive vascularity, dissection in the cornua usually causes significant ooze that hinders visibility. When more than superficial dissection of this region is anticipated, initial infiltration with dilute vasopressin solution (1 U of vasopressin in 10 mL of normal saline) significantly decreases capillary ooze and facilitates the procedure. With use of a 30-gauge needle on a 3-mL syringe, the cornual region of the uterus is injected with 2 mL of this solution in a circular fashion under the serosa 1 cm medial to the uterotubal junction. The resulting vasoconstriction is recognized by serosal blanching.

In this type of anastomosis, there is no significant luminal disparity between the two segments of tube. Hence, the isthmus is simply transected near the occluded end and prepared, as described earlier. A two-layer anastomosis is then performed. Once the inner layer has been joined, the serosa and superficial muscle of the cornual region are approximated to the serosa of the isthmus. The defect under the tube is repaired by suturing the mesosalpinx to the serosa of the lateral edge of the uterus.

Intramural–Ampullary Anastomosis

The salient feature of intramural–ampullary anastomosis is the considerable luminal disparity that exists between the intramural and ampullary segments. The key technical issue lies in the preparation of the occluded proximal end of the ampulla, where an opening into the ampullary lumen, which is not much larger than that of the intramural segment, must be fashioned.

The intramural segment is first prepared as described under intramural–isthmic anastomosis. To identify the occluded end of the ampulla, which may be buried between the leaves of the mesosalpinx, the tube is distended with a few milliliters of dye or irrigation solution introduced through the fimbriated end. Alternatively, a malleable blunt probe can be introduced through the infundibulum and gently threaded toward the occluded end. With the use of microscissors, the serosa over the tip of the ampullary stump is incised in a circular manner. The serosa and any scar tissue under it are then excised to expose the muscularis of the occluded end. The center point of the exposed muscularis is grasped with toothed microforceps, and a small incision is made into the ampullary lumen with the microscissors. This opening is enlarged to correspond in size to the lumen of the proximal tubal segment by excising a tiny circular portion of muscularis and epithelium (Figs. 21.25A and 21.26). The resulting opening is slightly larger than the intramural lumen, but because of the absence of significant disparity, anastomosis of the two segments can be performed as described for isthmic–isthmic anastomosis.

Isthmic–Isthmic Anastomosis

Isthmic–isthmic anastomosis is the simplest type of anastomosis to perform. The lumina are comparable in size. The technique is the same as that described earlier under the basic principles of tubotubal anastomosis.

Isthmic–Ampullary Anastomosis

The salient feature of this type of anastomosis is also the considerable luminal disparity that usually exists between the lumina
of the isthmic and ampullary segments. The isthmic stump is prepared as described under the basic principles of tubotubal anastomosis. In most instances, the occluded end of the ampullary stump will be free, enabling a lumen of appropriate diameter (comparable in size to that of the isthmic segment) to be fashioned, as described under intramural–ampullary anastomosis (Figs. 21.25A and 24.26). A two-layer anastomosis is then performed as described under the basic principles of tubotubal anastomosis (Fig. 21.25B). Although the muscularis of the ampulla is considerably thinner than that of the isthmus, this poses no problem in approximating the epithelium and muscularis of the two segments.

Occasionally, circumstances will not permit the use of the technique described earlier in the preparation of the occluded ampullary end. The ampullary stump may be occluded by a permanent suture or clip, and removal of this suture or clip may lead to the creation of an opening that is much larger than the isthmic lumen and through which lush epithelial folds will prolapse.

If the opening into the ampullary lumen is made significantly larger than that of the isthmic segment (either inadvertently or by necessity), it will be necessary to either enlarge the isthmic lumen or narrow the ampullary lumen. To enlarge the lumen of the isthmic segment, a 2- to 3-mm slit is made with scissors at its antimesosalpingeal border. Partial excision of the corners thus created results in an enlarged oval opening (Fig. 21.27A). To approximate the inner muscular epithelial layer, the 6-o’clock suture is placed first and tied. Five additional sutures are usually required, and these are placed as described earlier. The 12-o’clock suture must incorporate the muscularis and epithelium of the ampulla and the same tissues at the apex of the isthmic slit (Fig. 21.27B). Approximation of the serosa and closure of the defect in the mesosalpinx complete the anastomosis. An alternative approach is to reduce the size of the large ampullary opening. This is achieved by plicating the muscular layer surrounding the opening with interrupted sutures, after which the prolapsing epithelium is invaginated.

Ampullary–Ampullary Anastomosis

The proximal ampullary segment is transected near the occluded end, which is then excised from the mesosalpinx as previously described. An opening that corresponds in size to the lumen of the proximal segment is made in the occluded end of the distal ampullary segment, as described under isthmic–ampullary anastomosis.

In this type of anastomosis, the major difficulty to be overcome is the propensity of the ampullary epithelium to prolapse through the lumen. Although investigators such as Winston have advocated excision of these epithelial fronds, we advise against this approach because there could potentially be

FIGURE 21.26. Preparation of the ampulla in intramural–ampullary or isthmic–ampullary anastomosis. A: The serosa over the tip of the ampullary stump is incised in a circular manner and excised. B: The center point of the exposed muscularis is grasped and a small opening is made into the lumen.
Isthmic–ampullary anastomosis in the presence of a tubal gestation, leaving distally the infundibular segment, which are interrelated factors; the presence of single versus double reconstructed oviducts; the status of the tubes (presence or absence of disease); the extent and nature of adhesions and the presence of other pelvic disease; the age of the patient; the status of other fertility parameters, especially that of the male partner; last, but not least, the surgical technique used. Therefore, the outcome depends on the degree of rigor in selection criteria and the quality of the surgical technique. This is also corroborated by recent reports on sterilization reversal, which include two large series from Korea (Table 21.4). In our experience, in the absence of a male factor, the two most important parameters that predict outcome are the age of the female partner and the length of the reconstructed tube. A reconstructed tubal length of less than 4 cm adversely affects outcome; this likely reflects the loss of ampullary length and consequent loss of oviductal oocyte retention.

Tubotubal anastomosis by laparoscopic access to reconstruct a previous tubal sterilization or a prior segmental excision for tubal pregnancy is being performed in several centers. Whereas some investigators obtain satisfactory outcomes with this approach, others report significantly inferior results in comparison with open access. This is largely due to modification of the recognized microsurgical technique to make the laparoscopic procedure simpler to perform.

The first report on laparoscopic tubotubal anastomosis was a case report; instead of microsurgical suturing for the apposition of the tubal segments, they used a biologic glue over a stent. Pregnancy outcome was not reported. Early reports on tubotubal anastomosis were on small series, performed with simplified techniques, and although most of the cases were simpler forms of sterilization reversal, the results were relatively poor.

Most surgeons who attempted tubotubal anastomosis by laparoscopic access using the microsurgical technique described earlier found that operating times are prolonged. Many attempted to simplify the technique by using glue as described above or using only two sutures for the apposition of the prepared tubal segments, as first reported by Dubuisson and Swolin. In this technique, the first suture (4/0 Vicryl) approximates the mesosalpinx immediately beneath the two segments of tube, and the second (6/0 Vicryl) the tube at 12-o’clock position. The second suture incorporates the serosa and muscularis of the two segments of tube. There are several recent reports in the literature on this technique. There are also publications reporting on the laparoscopic use of a truly microsurgical, two-layer anastomosis technique. One of these is a large series by Yoon and colleagues, from Korea, which includes 202 cases.

The major published series report live birth rates between 40% and 80% after microsurgical tubotubal anastomosis for reversal of sterilization (Table 21.4). The ectopic gestation rates are usually low.

The factors that affect the outcome of such procedures are multiple and include the following: the type of prior sterilization, the site of anastomosis, and the length of the reconstructed tube or tubes, which are interrelated factors; the presence of single versus double reconstructed oviducts; the status of the tubes (presence or absence of disease); the extent and nature of adhesions and the presence of other pelvic disease; the age of the patient; the status of other fertility parameters, especially that of the male partner; last, but not least, the surgical technique used. Therefore, the outcome depends on the degree of rigor in selection criteria and the quality of the surgical technique. There are also publications reporting on the laparoscopic use of a truly microsurgical, two-layer anastomosis technique. One of these is a large series by Yoon and colleagues, from Korea, which includes 202 cases. Fifteen of these were lost to follow-up, and one had no partner. The remaining 186 were monitored for a minimum of 12 months. One hundred fifty-four achieved intrauterine pregnancy, a rate of 77% if we consider, as most series do, the 15 cases lost to follow-up as failures. Ninety-eight were delivered of healthy infants, 25 pregnancies ended in abortion, and 31 patients had ongoing pregnancies at the time of the survey. If all 31 ongoing pregnancies would have resulted in a live birth, the live birth rate in this series would have been 64%. There
were five cases of ectopic pregnancy. These results are not too
dissimilar to those achieved by open access, which supports the
premise that what is important is the technique used and not
the mode of access. Cha and colleagues, also from Korea, fur-
ther support this assumption. In their study, they compare the
fertility outcome in 81 women who had microsurgical rever-
sal of sterilization, 37 by laparoscopic and 44 by open access.
The outcomes, as well as the intrauterine and tubal pregnancy
rates, were similar in both groups (Table 21.4).
Attempts to develop simple techniques that would yield
equivalent results by laparoscopic access continue to be made.
A recent study reports the use of the following laparoscopic
technique for tubal anastomosis: Once the tubal ends to be
anastomosed were prepared, a splint was inserted into the
proximal tube through a “guiding catheter” inserted vaginally.
The splint was then introduced into the distal portion of the
tube through the fimbriated end. The distal portion was aligned
with the proximal segment over the splint. The seromuscularis
of the two segments was fixed at the 3- and 9-o’clock positions
using microclips of 3-mm size. Subsequently, fibrin glue was
applied “on the anastomosis surface.” The splint was taped ex-
teriorly to the Foley catheter and removed 4 hours after the end
of the procedure. Although they report similar results for both
the laparoscopic group and a control group (selected from pa-
tients whose procedure was performed through a Pfannenstiel
incision), it is surprising that in the control group the cumula-
tive rate of ongoing pregnancy at 3 years was only 52% and in
the laparoscopic group only 45%. This is despite the fact that

*Resurvey of 1980 series; follow-up period more than 18 months.
Follow-up period more than 18 months.
Follow-up period more than 4 years.
Follow-up period more than 1 year.
Follow-up period more than 3.5 years.
Follow-up period more than 2 years. There were eight ongoing pregnancies in addition to the live births.
Follow-up period more than 5 years. There were 31 ongoing pregnancies in addition to the live births.
Tubal anastomosis performed with single-suture technique.
Tubal anastomosis performed by using two-layer microsurgical technique.
There were 31 ongoing pregnancies in addition to the live births.
A screening laparoscopy was performed, and only those having a distal tubal segment of 4 cm and a proximal segment of 3 cm were included.
Comparative study with cases performed with open access.
in the latter group, more than 90% of the sterilizations had been performed by clips or silastic rings, and their average age was only 34.9 years.

Robotic-assisted tubal anastomosis has been explored by several groups. The largest series reported a similar pregnancy rate for robotically assisted surgery as compared to mini laparotomy; however, the cost and surgical time for robotically assisted tubal anastomosis was greater.

Using metaanalysis, Watson and colleagues examined the number of randomized controlled trials and the use of historical control groups. However, as expected, the use of magnification during sterilization reversal as well as during adhesiolysis and salpingostomy led to higher pregnancy and lower ectopic rates.

Microsurgical robotic-assisted reversal of sterilization produces excellent results that are principally dependent on the status and the length of the reconstructed tube. All of the published series report a varying but usually low pregnancy ratio for robotically assisted surgery as compared to mini laparotomy, however the cost and surgical time for robotically assisted tubal anastomosis was greater.

The selection of treatment must be individualized according to the investigative findings, the wishes of the couple, and the results achieved by the center in the latter group, more than 90% of the sterilizations had been performed by clips or silastic rings, and their average age was only 34.9 years.

tying this initial suture would make placement of the subsequent sutures difficult if not impossible. In such cases, the subsequent sutures are placed with use of a continuous strand of suture, as described earlier (Fig. 21.30). This approach facilitates suture placement and prevents the individual sutures from becoming tangled. Three additional sutures, placed at cardinal points, are usually sufficient to join the inner layer. If the cornual crater is deep and the placement of sutures is difficult, this task can be facilitated by making a coronal incision on the uterus, above the cornual crater. The edges of this incision must be approximated at the end of the procedure.

If the distance between the two segments of tube is significant or if there is undue tension, it is necessary to hold the distal tubal segment close to the intramural segment while tying the sutures. Alternatively, a single no. 7-0 Vicryl suture is passed through the mesosalpinx below the cut end of the distal segment of tube and then through the border of the uterus immediately beneath the cornual crater. The suture is tied first. Then the loop between each succeeding suture is divided and tied in turn. After approximation of the first layer, the seromuscularis of the uterus is joined to the serosa of the tube with no. 8-0 sutures. The defect under the tube is closed by approximating the mesosalpinx to the lateral edge of the uterus (Fig. 21.30F, G).

Compared with tubouterine implantation, microsurgical tubocornual anastomosis offers several advantages: it largely maintains the integrity of the uterine cornua; preserves a longer tube; obviates the need for a cesarean section, except for obstetric reasons; and yields better results.
Results of Tubocornual Anastomosis

Microsurgical tubocornual anastomosis for the treatment of occlusive cornual disease yields fairly good results in centers experienced with this procedure. The published series report live birth rates between 33% and 56% and ectopic pregnancy rates between 5% and 7% (Table 21.5). This table makes it clearly evident that there has been a paucity of reports regarding this procedure for more than a decade.

Rare Procedures and Technically Difficult Cases

Rare circumstances may be encountered that are amenable to microsurgical correction. Some of these circumstances are discussed in this section.

The technical difficulty of a procedure must be differentiated from the prognosis that the procedure offers. Furthermore, difficulty is a relative term because what is common-place work for some may be difficult or even impossible for others to achieve. From the patient's standpoint, what is important is the prognosis—the yield associated with the surgical procedure. Furthermore, the prognosis is not necessarily inversely proportional to the difficulty of the procedure. For example, microsurgical tubocornual anastomosis to treat occlusive cornual lesions is one of the technically more difficult reconstructive tubal operations. However, centers experienced in this procedure achieve excellent results. An even more technically difficult operation is tuboovarian transposition.

Tuboovarian Transposition

In the case of a unicornuate uterus without an ipsilateral tube and ovary, the contralateral tube and ovary, if present, may be transposed while preserving their vascular pedicle. We performed such a procedure in a woman with a single left unicornuate uterus whose ipsilateral tube and ovary were removed subsequent to a left tubal pregnancy. On the right side, placed high on the pelvic sidewall, were an ovary and a short oviduct, composed of infundibulum and ampulla (Fig. 21.31A).

The ovary was mobilized further to achieve the proper spatial relation with the fimbrial extremity of the tube (Fig. 21.31D). In the third postoperative cycle, the patient was successful in achieving an intrauterine pregnancy, which resulted in a normal live birth. She has since had two more children.

Correction of Bipolar Tubal Disease

The results associated with surgical correction of bipolar (both proximal and distal) tubal occlusion are dismal. A report from the Mayo Clinic included 31 such patients: bipolar tubal occlusion of both tubes (n = 13) or their only remaining tube (n = 5); bilateral distal and unilateral proximal occlusion (n = 7); and bilateral proximal and unilateral distal occlusion (n = 6). Despite a mean follow-up period of more than 3 years, pregnancies occurred in only three patients. Furthermore, two of these were ectopic, and one was a spontaneous abortion.

Anastomosis of Contralateral Tubal Segments

A patient may have a healthy proximal segment of tube on one side, whereas on the opposite side, an ampullary–infundibular segment exists. In such a circumstance, microsurgical reconstruction of one functional tube can be achieved by anastomosis of the contralateral tubal segments behind the uterus, maintaining the physiologic relation between the tubal infundibulum and ovary. In the presence of both ovaries, the uterovarian ligaments are first approximated with interrupted, nonabsorbable no. 4-0 or 5-0 nylon sutures. This brings the ovaries together and helps reduce tension in achieving the subsequent tubal anastomosis (Fig. 21.32). Successful delivery after such a procedure has been reported.

Approximation of the Fimbriated End of the Oviduct to the Contralateral Ovary

When a single ovary exists on the side opposite the patient's only tube, simple approximation of the fimbriated extremity of the tube to the ovary may be possible. The ovary is mobilized, and the mesovarium is fixed to the posterior surface of the uterus with nonabsorbable sutures. The contralateral oviduct is mobilized, and its mesosalpinx is sutured to the posterior aspect of the uterus. The nonabsorbable sutures are placed on the mesosalpinx about 1 cm from the tube. This will effectively place the infundibulum in close proximity to the ovary. Alternatively, the ovary can be transposed to the contralateral side with its vascular pedicle kept intact.

Iterative Reconstructive Surgery

Except in rare circumstances, there are no data to support the undertaking of an iterative surgical procedure when a prior reconstructive operation has failed.

Rare exceptions include cases of tubotubal anastomosis that failed for purely technical reasons, in which sufficient lengths of healthy tube is available for reconstruction. In such instances,
Figure 21.30. Microsurgical tubal cornual anastomosis for proximal tubal disease. A: The tube is transected at the uterotubal function (UTF). Commencing at the UTF, serial cuts are made on the isthmus until patent and normal tube is identified. B: The intramural tube is dissected electrosurgically by using a microelectrode, from the surrounding uterine muscle, 1 to 2 mm at a time, and (C and D) transected until patent and normal tube is reached. E: The first anastomotic suture of the inner musculoepithelial layer is placed at the 6-o’clock position. F: After the opposition of the inner layer, the seromuscularis of the uterus is joined to the serosa of the tube. G: The mesosalpinx is joined to the lateral aspect of the uterus.

an iterative microsurgical anastomosis may be undertaken if tubal cannulation fails to restore patency. Tubal cannulation, performed at the time of the postoperative control HSG that demonstrates an obstruction at the anastomosis site, may prove beneficial in a small percentage of cases by breaking down synechiae or dislodging debris that may be present at this site. Iterative surgery yields a modest success rate if the initial procedure was performed with the use of conventional techniques. However, the success rate of iterative procedures is disappointing when they are undertaken after a failed microsurgical intervention.

Most of the available data on iterative surgery concern salpingostomy. Of the 119 such cases reported in the literature, 18 (15.2%) achieved live births, six had spontaneous abortions, and seven (5.9%) had ectopic gestations. All of these 119 patients had their first procedure performed by conventional techniques and their second intervention performed by microsurgery.

The first report on laparoscopic salpingostomy by Gomel (1997) included, except for one case, iterative procedures on patients who had previously undergone surgery with conventional techniques and their second intervention performed by microsurgery. The conception rate after iterative microsurgical fertility-promoting procedures is significantly lower than that obtained with primary microsurgical interventions. Thie and colleagues reported a conception rate of 51% after various primary microsurgical procedures in 161 patients. This rate was only 18% at 3-year follow-up in a similar group of 21 patients who had microsurgery after a failed primary operation performed by conventional techniques.

The preceding data strongly suggest that iterative surgery may be indicated in selected, rare instances and that most of these patients may be better served with IVF.

Observations on Current Practice

The enormous progress in IVF and ART in the past 20 years has been accompanied with the industrialization of this technology and its services all over the world. In parallel fashion, there has been a significant decline in the practice and teaching of reconstructive surgery. There is a paucity of publications on this subject. IVF is offered now, as a primary treatment option, in most cases of tubal factor infertility. These changes have occurred despite the greater acceptance of laparoscopic access to perform many of the reconstructive tubal operations and the use of minilaparotomy incision for more complex anastomotic procedures, which represents a major progress in gynecologic surgery. These changes have occurred despite the satisfactory results yielded by reconstructive surgery in appropriately selected cases and despite the fact that surgery offers the couple the opportunity to attempt a pregnancy over a long period of time and to conceive more than once.

The evidence suggests that surgery should retain its place in the treatment of tubal infertility. Preservation of the place of surgery will require a concerted effort on the part of the teaching institutions. Surgery and ART are complementary approaches that can be used singly or in combination to improve the outlook of couples suffering from tubal infertility. In the preface of the book Microsurgery in Female Infertility, published in early 1983, Gomel wrote:

This manuscript has been completed during a time of rapid change and expansion with the understanding that it represents not an end point but merely an accounting at a given point in time. Further developments are also occurring in the area of IVF and embryo transfer (IVF & ET), which will undoubtedly produce improved results. Nonetheless, I do not consider the techniques of microsurgery on the one hand and IVF & ET on the other as competitive; on the contrary, I see them as complementary, enabling us to achieve a greater success rate among those patients presenting with complex fertility problems.

This statement is still valid today.

BEST SURGICAL PRACTICES

- In most instances, tubal infertility can be managed through surgery and/or ART. Each approach has unique advantages and disadvantages and can be used in isolation or in combination to improve the outlook of couples suffering from tubal infertility.
- Periodic adhesions, coexisting with other types of tubal disease or in isolation, can affect fertility by encapsulating the tube preventing ovum pickup or by distorting the spatial relation between the tube and ovary. Open or preferably
In select cases of proximal tubal occlusion, selective salpingostomy for fimbrial phimosis and salpingostomy for distal tubal occlusion results in the accumulation of fluid within the tube, which is called hydrosalpinx. Hydrosalpinx is a condition that can affect the results of IVF treatment. They should be removed, proximally occluded, or drained surgically through the creation of a neosalpingostomy before IVF.

Intrauterine pregnancies rates of approximately 50% to 60% is best treated by microsurgical tubocornual anastomosis.

Thoughtful surgical technique minimizing tissue damage is the hallmark of fertility-promoting tubal reconstructive surgery and is independent of the route of access but dependent on the skill and dedication of the surgeon.

CHAPTER 22 ■ ENDOMETRIOSIS

JOHN S. HESLA AND JOHN A. ROCK

DEFINITIONS

Adenomyoma—A manifestation of adenomyosis characterized as localized, encapsulated disease of the uterine wall, as compared with the more common diffuse pattern of extension of endometrial glands and stroma in the myometrium.

Adenomyosis—Heterotopic endometrial glands and stroma located deep within the myometrium, with glandular extension below the endometrial-myometrial interface of at least 2.5 mm.

American Society for Reproductive Medicine (ASRM) Classification of Endometriosis—A scoring system to quantify the location and extent of endometriosis with a scalar rather than numeric terminology. This documentation has been proposed to allow direct comparison of patient responses to medical and surgical treatments and to identify factors predictive of disease outcome.

Atypical peritoneal implants of endometriosis—Lesions of varying appearance, including vesicles, flat plaques, raised blebs, polyposid structures, areas of fibrosis and adhesion, formation, and peritoneal defects. May be clear, yellow, brown, blue, or black in color, as compared with the readily recognized red or gray implants.

Cancer antigen-125 (CA-125)—A high-molecular-weight glycoprotein expressed on the cell surface of some derivatives of embryonic coelomic epithelium. CA-125 is often elevated in cases of mild-severe endometriosis, as well as other conditions, including acute pelvic inflammatory disease, adenomyosis, uterine leiomyoma, menorrhagia, pregnancy, epithelial ovarian cancer, pancreatitis, and chronic liver disease.

Endometrioma—A solitary, nonneoplastic mass containing endometrial tissue and blood.

Endometriosis—The presence and growth of functioning endometrial tissue containing glandular and stromal elements in places other than the uterus that often results in severe pain and infertility.

Hydrodissection—Forceful injection of physiologic irrigant through a small defect created in the surfaces to be separated, such as the peritoneum from the retroperitoneal tissue. This may aid in establishment of the plane of dissection.

Presacral neurectomy—Division of the superior hypogastric plexus, useful as an adjunctive procedure to eliminate the uterine component of dysmenorrhea. Proposed by John Sampson as a mechanism for the origin of endometriosis in many women.

Uterine nerve ablation—Division of the uterovaginal ligaments at a point approximately 1.5 cm distal to the cervix to interrupt many sensory nerve fibers of the cervix and uterine corpus. Has been proposed to alleviate severe dysmenorrhea.

Uterine suspension—Surgical technique of elevation of the adnexa to reduce adhesion formation at denuded peritoneal surfaces of the posterior cul-de-sac, uterine serosa, and broad ligament.

Endometriosis is a clinical and pathologic entity initially described by von Rokitansky in 1860 that is characterized by the presence of tissue resembling functioning endometrial glands and stroma outside the uterine cavity. These ectopic implants can be located throughout the pelvic cavity, including the ovaries, uterine ligaments, rectovaginal septum, parietal peritoneum, intestinal serosa, and appendix. Less common sites of involvement include the cervix, hernial sacs, the umbilicus, laparotomy and episiotomy scars, and the pleural and pericardial cavities (Fig. 22.1).

Although endometriosis has been extensively investigated over the past century, it remains an enigmatic disease process. The association between endometriosis and infertility is still undefined, and there are scant data to support the many hormonal and surgical therapies that have been proposed. In addition, the often subtle and varied appearances of endometriosis can make recognition and surgical staging difficult, thereby casting doubt on the utility of the classification systems that have been developed. Nevertheless, the findings of well-designed clinical trials and recent studies that have elucidated the pathogenesis of endometriosis have enabled a more rational approach to the medical and surgical management of this disease.

PREVALENCE

The estimated prevalence of endometriosis among population groups varies depending on the presenting symptoms. One to seven percent of asymptomatic women undergoing tubal ligation are diagnosed with the disease at laparoscopy; this range may approximate the prevalence in the general population. Among women with pelvic pain, the prevalence of endometriosis ranges from about 5% to 21%, and the disease has been diagnosed in 40% to 52% of women with severe dysmenorrhea. Cramer and colleagues, in a multicenter study, diagnosed endometriosis in 17% of women with primary infertility, and in other series the prevalence varied from about 9% to 30%, Verkauf prospectively identified endometriosis in 38.5% of infertile women and 5.2% of fertile women. Other studies have confirmed the odds that infertile women are seven to 10 times more likely to have endometriosis than their fertile counterparts. However, any postmenarchal woman is at risk, because endometriotic implants have been identified in postmenopausal women, in women with primary amenorrhea secondary to mullerian anomalies, and in 69.6% of teenagers who underwent diagnostic laparoscopy for chronic pelvic pain.
Several investigators have reported the possibility of a familial tendency to endometriosis. No studies have confirmed a human lymphocyte antigen linkage for the disease, a polygenic, multifactorial mode of inheritance has been suggested. Simpson and colleagues reported a 6.9% occurrence rate in first-degree female relatives, which compared with 1% for the non-blood-related control group.

**HISTOGENESIS**

The mechanism by which endometriosis develops is unknown, although there has been much discussion as to its origin (Table 22.1). A complete understanding of the histogenesis of the aberrant endometrial cells has been compromised because of the variations of disease presentation. Four major theories have been proposed:

1. The reflux and direct implantation theory suggests that viable endometrial cells reflux through the fallopian tubes during menstruation and implant on surrounding pelvic structures.
2. The coelomic metaplasia theory suggests that the multipotential cells of the coelomic epithelium may be stimulated to transform into endometrial-like cells.
3. The vascular dissemination theory suggests that endometrial cells enter the uterine vasculature or lymphatic system at menstruation and are transported to distant sites.
4. The autoimmune disease theory suggests that endometriosis is a disorder of immune surveillance that allows ectopic endometrial implants to grow.

**Reflex and Direct Implantation Theory**

John Sampson first postulated that endometriosis arose from retrograde flow of fragments of endometrial tissue through the oviducts and into the peritoneal cavity. Much evidence validates this theory. The anatomical distribution of endometriosis as noted at laparoscopy is consistent with a reflux pattern of development; the most common sites of disease in the infertile woman are the ovary and uterosacral ligament, followed by the posterior uterus, posterior cul-de-sac, and posterior broad ligament. Endometriosis developed in monkeys when the uterus was surgically inverted to cause menstruation to occur intraperitoneally. Exposure of abraded peritoneum to endometrial cells has resulted in the growth of endometriotic implants in rabbits and rats. Endometriosis has developed in laparotomy, episiotomy, and cesarean section scars after...
surgical entrance into the endometrial cavity, and anomalies of the Mullerian tract are associated with an increased occurrence of endometriosis. Endometriosis is a common finding in women with stenosis of the external cervical os (Barbieri, 1998). Epidemiologic data suggest that women who menstruate more frequently, more heavily, or for a longer duration have an increased likelihood of disease development.

Peritoneal implants of endometriosis and the presence of endometriomas are more common on the left side of the pelvis as compared with the right (Vercellini et al., 2004). The position of the sigmoid colon creates a sequestered macroenvironment around the left adnexa, which facilitates implantation of endometrial cells regurgitated through the left tube. The large intestine does not provide the right hemipelvis with this anatomical shelter, because the ecameciises more cranial in position.

Focal endometriosis has been identified in 16% to 63% of proximal tubal segments after cautery or Pomeroy tubal sterilization, perhaps as a consequence of recurrent bathing of the healing terminal area with menstrual products. Nevertheless, bloody peritoneal fluid has been observed in 90% of women with patent fallopian tubes undergoing laparoscopy during the perimenstrual time period, a figure much greater than the estimated 2% to 5% prevalence of symptomatic endometriomas in women of reproductive age. Additionally, peritoneal implants have been identified in women who had a prior tubal ligation procedure and were undergoing laparoscopy for the evaluation of pelvic pain. Hence, other factors evidently are present to promote the ectopic implantation.

Coelomic Metaplasia Theory

The germinal epithelium of the ovary, endometrium, and peritoneum all originate from the same totipotent coelomic epithelium. The metaplasia theory postulates that these totipotential cells are transformed by repeated exposure to hormonal or infectious stimuli. This may explain the development of endometriomas in unusual locations and in the odd cases of male patients in whom endometriosis develops after orchectomy, orchietomy, or prolonged treatment with estrogen.

Reports of endometriomas in women with primary amenorrhea and an absence of functioning uterine endometrium and of endometriosis identified in mature teratomas also lend support to the metaplasia theory.

Vascular Dissemination Theory

Endometrial cells can be transported to extrauterine sites by blood vessels or the lymphatic system or by contamination of the pelvis or abdominal wall incision if the uterine cavity is surgically entered. Retroperitoneal endometriosis is hypothesized to arise from lymph vascular spread; 29% of patients with pelvic endometriosis documented on autopsy had pelvic lymph nodes that contained endometriosis. Theories of vascular dissemination help explain how endometriosis can develop in the lung or pericardium.

Autoimmune Disease Theory

Alterations in cellular immunity can facilitate the successful implantation of translocated endometrial cells. Compared with control subjects, monkeys with spontaneous endometriosis had both a lowered cell-mediated response to autologous endometrial tissue, as determined by skin testing, and a decreased in vitro blastogenesis response. Similar studies performed in women demonstrated that lymphocytes obtained from control patients were significantly more efficient in cytolyis of isolated endometrial stromal cells than were lymphocytes obtained from patients with endometriosis. This decreased cytotoxic response to endometrial cells may be due to a defect in natural killer cell activity, such as a decreased lytic effect toward stroma that allows immunologic escape of endometriotic fragments. In addition, there may be an increased resistance of endometrium in women with endometriosis to natural killer cytotoxicity.

Promoting Factors

Clinical and laboratory studies support the concept that endometriosis is an estrogen-dependent condition. Estradiol concentrations greater than approximately 60 pg/mL have been identified as necessary for proliferation of endometriotic lesions. Nevertheless, estrogen and progesterone receptors are found in much lower concentrations in endometriotic tissue than in normal endometrium; such endometriotic tissue also frequently fails to show cyclic variations of development in response to hormonal changes. Early data from primate studies suggested that endometriosis required no steroidal supplementation to become initially established, but later studies demonstrated that chronic exposure to ovarian steroids is necessary for the survival of these experimentally induced endometrial plaques.

Growth factors can originate from the peritoneal environment to stimulate endometrial development. Platelet-derived growth factor, a macrophage secretory product, enhanced endometrial stromal cell proliferation in a dose-dependent manner. Similarly, macrophage-conditioned media promoted mouse endometrial stromal cell proliferation in vitro, and this activation was enhanced with the addition of estrogen. Increased concentrations of macrophage-derived growth factors, including vascular endothelial growth factor, have been identified in the peritoneal fluid of women with endometriosis. This suggests that changes in the vascular permeability and angiogenesis play an important role in the pathophysiology of this disease.

Molecular alterations in steroidogenic enzyme function have been implicated in the pathogenesis of endometriosis. Endometrial tissue from patients with endometriosis expresses aromatase P-450, whereas endometrium from control women without identifiable endometriosis does not. The presence of aromatase within endometriosis results in higher local production of estrogen necessary to support the growth and metabolic activity of the lesion.

Menstrual effluent contains factors that induce alterations in the peritoneal mesothelium, facilitating adhesion of endometrial cells. Attachment of endometrial cells is enhanced by induction of adhesion molecules and their receptors and the overexpression of matrix metalloproteinases and plasminogen activators. These factors ensure local destruction of the extra cellular matrix. Suppression of matrix metalloproteinase production by progesterone decreased ectopic implantation of endometrium in the nude mouse, implicating these proteases in the pathogenesis of endometriosis.

In summary, no single theory explains all cases of endometriosis, although the direct implantation mechanism seems the likely cause for most disease locations. Immunologic factors, inducing substances, or other mediators may explain the development of endometriomas in more distant sites.
NATURAL HISTORY

The natural history of endometriosis is not clearly understood. The disease appears to progress in most untreated patients, although spontaneous regression can occur in as many as 58% of milder cases. Surgical and medical therapies may promote a temporal regression but may not effectively eliminate microscopic, retroperitoneal, and hormonally resistant disease. Dziewulski and Cohen described persistent disease in 15% of patients treated with danazol, and Henzl and associates noted a progression of disease during the course of treatment in 4% to 8% of patients receiving danazol or an analog of gonadotropin-releasing hormone (GnRH). When conservative surgery was combined with danazol or GnRH agonist therapy, the overall recurrence rate at 36 months was between 13.5% and 33%.

The effect of pregnancy on the clinical course of endometriosis is uncertain. Although Sampson proposed that pregnancy induces involution of implants, other authors recently described a variable response of endometriosis to pregnancy. It is possible that endometriosis becomes temporarily suppressed during pregnancy. McArthur and Ulfelder analyzed the clinical effect of pregnancy on endometriosis in 24 patients. They found that the behavior of endometriosis during the gravid state was extremely variable and that the regression of disease appeared to be due to decreased tissue responsiveness to hormonal stimulation rather than to actual necrosis of the lesions. More patients in their series experienced disease persistence than permanent regression. Monkey studies have confirmed these findings; the response of endometrial implants to pregnancy varied from total regression to significant progression. Approximately 2% to 4% of early postmenopausal women suffer from endometriosis. These cases are usually associated with exogenous intake of estrogens or tamoxifen. Nevertheless, there are reports of symptomatic endometriosis in women older than 60 years of age who have not received steroid replacement therapy. Such cases presumably are secondary to the responsiveness of the residual lesions to low levels of estrogens that arise from peripheral conversion of ovarian and adrenal androgens.

PATHOPHYSIOLOGY

Gross Appearance

Signs of endometriosis may be evident on physical examination. Endometriosis can form tender nodules on the uterus or ovaries, or hemorrhagic streaks that are readily palpable. It may infiltrate the deepest portion of the pouch of Douglas and cause pain with defecation and, rarely, cyclic rectal bleeding. Lesions of endometriosis have been identified in the umbilicus, in the vulva, and in epistaxis scars. Complete uterine obstruction has been reported. This can be temporarily reversed with the administration of GnRH agonists, progestogens, and danazol. Diaphragmatic involvement can lead to chronic, recurrent pneumothorax at the time of menstruation. Lesions have been identified in the upper and lower extremities, the pericardium, and the lung.

The gross appearance of endometriosis is extremely variable. On entering the abdomen, the surgeon may find a small, adherent nodule on one or both sides of the pelvis, usually attached to the posterior cul-de-sac and posterior surface of the uterus. Frequently, release of ovarian adhesions to mobilize the adnexa results in an egress of chocolate-colored or dark red fluid that is highly suggestive of endometriosis. Examination of the ovary may disclose a cyst that is rarely larger than 10 cm and has a dark, hemorrhagic lining. Endometromas develop over a time span of a few months as a result of extensive intra-cystic hemorrhage. Reddish blue, fibrous areas that represent small islands of endometriosis may be present on the ovarian cortex. Peritoneal implants vary in appearance from black, puckered lesions surrounded by a variable extent of reactive mesothelium to red polypoid material, to clear vesicles. Other appearances include yellow-brown peritoneal discoloration, white plaques, or scarring. The strong inflammatory stimulus of superficial lesions of endometriosis may promote fibrosis and invagination of adjacent peritoneal surfaces.

The fallopian tube is usually nonobstructed and free of gross disease, although peritoneal adhesions can extend to adjacent structures, particularly in patients with extensive disease. Deeply infiltrating endometriotic nodules extend more than 5 mm beneath the peritoneum and may involve the ureteral ligaments, bladder, ureters, or vagina. The depth of invasion has been correlated with pain symptomatology. Endometrial invasion of the rectal or sigmoidal wall can simulate malignancy or produce complete obstruction.

Microscopic Appearance

The essential diagnostic criterion is the presence of endometrial tissue, both stroma and glandular elements. This aberrant tissue resembles the uterine mucosa both histologically and physiologically. Secretory change and decidualization are seen in response to hormone influences in the luteal phase, and estrogen stimulates proliferation of the ectopic implants. Nevertheless, these functional changes are less uniform for implants than for the uterine mucosa.

The ultrastructural features of endometriosis are consistent with an incomplete response to the hormonal milieu. Endometriotic implants contain lower concentrations of progesterone and estrogen receptors than do corresponding normal endometrium, so the histologic response to progesterone is less profound. Gould and colleagues reported that the nucleus of endometriotic stromal cells had a marked degree of estrogen binding throughout the menstrual cycle, whereas stromal binding sites in the uterine endometrium were present only during the proliferative phase and not the secretory phase of the cycle. The differing responses of the two tissue types to steroid hormones were reflected by the modulation of estrogen binding and changes in glandular histology. Estrogen receptors did not undergo downregulation during the luteal phase of the cycle in endometriotic tissue, despite an increase in endogenous progesterone concentration. Alterations in the quantity, activation, or function of the progesterone receptor may be responsible for this lack of change in estradiol receptors, the abnormal response of the ectopic endometrium to progesterone, and the failure of hormonal therapy in some patients.

Because of the pressure of retained blood in the cyst cavities of endometriomas, a large concentration of endotheial leukocytes heavily laden with hemosiderin (pseudoxanthoma cells) may be found, and the glandular lining may be nearly absent and replaced by reactive connective tissue elements. Biopsy may fail to yield histologic proof of the endometrial glands and stroma in about one third of all cases of typical clinical endometriosis, even if many tissue sections are analyzed. The “chocolate cyst” description of the ovary is used synonymously with endometriotic cyst or endometrioma. Nevertheless, other types of ovarian cysts may have a similar fluid content, including the hemorrhagic follicle, corpus luteum, or...

*Two patients had two different histologic patterns.

Clinical Characteristics

The clinical features of endometriosis are varied, and the presentation depends on the site of growth and the severity of disease. The classic triad of dysmenorrhea, dyspareunia, and infertility has been described as characteristic of the disease (Table 22.3). Nevertheless, patients with extensive endometriosis may be clinically symptom free, and women with only minimal involvement may manifest disabling pelvic pain. Dysmenorrhea is a common symptom that most likely is associated with endometriosis if it develops after age 20 years, is progressive, and is not well relieved by nonsteroidal antiinflammatory agents or oral contraceptives. Spasmodic pain beginning before the onset of menstrual bleeding is another common symptom of patients with endometriosis. When the rectovaginal septum or uterosacral region is involved, the pain is often referred to the rectum or lower sacral and coccygeal regions because of premenstrual and menstrual swelling of ectopic implants. Dyschezia and constipation may be present. Dyspareunia is common, especially in cases of uterosacral or vaginal infiltration, fixed retroversion of the uterus, or ovarian fixation by adhesions. Again, there is no absolute correlation between the amount of visible endometriosis as seen at surgery and the extent of symptoms; minor disease involvement may result in severe pain, whereas massive areas of superficial endometriosis may cause no discomfort.

Other presenting symptoms can include signs of urinary tract involvement, such as hematuria or ureteral obstruction, unusual abdominal or adrenal masses, cyclic scintia, catamenial pneumothorax or hemoptysis, and swollen and painful scars. Premenstrual spotting can occur for 3 to 7 days before the start of menses; this is a poorly recognized but relatively consistent sign of endometriosis. An endometrioma can leak, causing considerable pain, or it can rupture and produce a clinical picture much like that seen with a ruptured ectopic pregnancy or acute appendicitis. Nearly 10% of patients with
had more, yet smaller, follicles and lower preovulatory estradiol. Coworkers reported that women with minimal endometriosis showed advanced disease, many investigators have attempted to identify specific possible mechanisms by which endometriosis causes infertility. Endometriosis presents with acute symptoms that require exploration for diagnosis and treatment. Approximately 20% to 40% of women with endometriosis are infertile. When extensive pelvic scarring or large endometriomas are present in the patient with endometriosis, the associated infertility can be clearly attributed to anatomic distortion. However, the pathophysiology of infertility in patients with less advanced disease is more controversial. Endometriotic implants within the fallopian tube or ovary may promote a local inflammatory response that has a direct, deleterious effect on tubal function (Table 22.4). Oocyte pickup by the fallopian tube may be prevented despite the normal process of oocyte maturation and ovulation. Endometriosis and especially adenomyosis is associated with impeded hyperperistalsis and dysperistalsis uterotubal transport capacity. Chronic salpingitis was detected in 29 of 87 (33%) fallopian tubes of patients undergoing laparotomy for ovarian endometriosis; tubal obstruction was demonstrated in only one of these cases, although adhesions were present in 24%. Endometriosis has been identified in the resected segments of fallopian tubes in women undergoing tubal-cornual anastomosis for proximal tubal obstruction when there was no evidence of implants elsewhere in the pelvis. Others have reported a correlation between tubal endometriosis and chronic salpingitis in similar cases, although this finding has not been uniform. Altered folliculogenesis or ovulation has been described in endometriotic patients who have undergone serial sonogram studies. An abnormal follicular growth rate and total growth period may disturb the normal synchronization of oocyte maturation, uterine receptivity, and ovulation. Tummon and coworkers reported that women with minimal endometriosis had more, yet smaller, follicles and lower preovulatory estradiol levels at the time of midcycle luteinizing hormone (LH) surge. Luteinized unruptured follicle syndrome, a condition of normal ovulatory hormone secretion and luteinization of the follicle without the expected occurrence of ovulation, has been reported to be more common in patients with endometriosis. Mio and colleagues performed transvaginal ultrasound at least every other day from cycle day 8 through the third day after human chorionic gonadotropin (HCG) administration on 47 patients with endometriosis, predominantly minimal and mild, and 28 control patients with male factor infertility. LUF syndrome was diagnosed in 20 of 81 (24.7%) monitored cycles in endometriosis patients and in only 3 of 44 (6.8%) monitored cycles in control patients, a difference that achieved statistical significance. Schenken and associates also noted an increased rate of LUF and associated luteal phase deficiency in monkeys with surgically induced moderate to severe endometriosis. An absence of sonographic evidence of midcycle follicular collapse in patients with mild endometriosis has ranged from 4% to 35% in the literature. Luteal phase function has been evaluated by endometrial biopsy and peripheral progesterone concentrations. There is insufficient evidence to conclusively link endometriosis with a deficiency of corpus luteum activity, although some studies have suggested the existence of a shortened luteal phase, delayed increase in progesterone secretion after ovulation, decreased progesterone secretion in the late luteal phase, and lowered serum estradiol levels during the early follicular phase. The effect of endometriosis on fertilization and preimplantation development is widely debated. Peritoneal fluid from patients with endometriosis had a deleterious effect on sperm-oocyte interaction in homologous mouse and hamster fertilization assays. In vitro studies involving human zona pellucida confirmed an adverse effect of peritoneal fluid on sperm binding in this patient population, although others reported that peritoneal fluid from women with low-stage endometriosis had no detrimental effect on sperm motility characteristics. Peritoneal fluid from women with moderate and severe endometriosis caused declines in sperm motility and velocity. Exposure of two-cell mouse embryos to the peritoneal fluid or serum of patients with endometriosis has resulted in a decreased rate of cleavage and development to the blastocyst and hatching stages as compared with control nondiagnostic specimens. However, this association was not verified by similar studies of mouse embryo development and apoptosis. Integrins are ubiquitous cell adhesion molecules that undergo dynamic alterations during the normal menstrual cycle in the human endometrium. The α5β3 vitronectin receptor integrin is normally expressed in endometrium during the peri-implantation period; such expression may be lost in women with mild endometriosis, which may affect uterine receptivity. A high frequency of spontaneous abortions in infertile women with endometriosis has been reported, although the relation was questioned because of potential control group bias. Naples and coworkers found that patients with endometriosis who refused treatment had the same abortion rate before and after diagnosis (26% and 25.5%). Studies of the last decade with appropriate control groups have demonstrated no substantial increase in the incidence of spontaneous abortion in women with endometriosis.

**Mechanisms Influencing Symptoms**

Because of the uncertain mechanisms causing infertility and pelvic pain in patients with minimal and mild endometriosis, many investigators have attempted to identify specific

endometriosis present with acute symptoms that require exploration for diagnosis and treatment. Approximately 20% to 40% of women with endometriosis are infertile. When extensive pelvic scarring or large endometriomas are present in the patient with endometriosis, the associated infertility can be clearly attributed to anatomic distortion. However, the pathophysiology of infertility in patients with less advanced disease is more controversial. Endometriotic implants within the fallopian tube or ovary may promote a local inflammatory response that has a direct, deleterious effect on tubal function (Table 22.4). Oocyte pickup by the fallopian tube may be prevented despite the normal process of oocyte maturation and ovulation. Endometriosis and especially adenomyosis is associated with impeded hyperperistalsis and dysperistalsis uterotubal transport capacity. alterations in the peritoneal environment that would explain these symptoms. Significant increases or decreases in peritoneal fluid volume that are due to increased production by the ovaries, altered mesothelial permeability, or increases in the colloid osmotic pressure have been hypothesized to inhibit ovum capture by the fallopian tube or to adversely affect tubal transport. Koninckx and associates reported elevations in peritoneal fluid fluid in patients with mild and moderate endometriosis. The quantity of fluid was comparable to that in control subjects during the remainder of the follicular phase. These authors described reduced volumes in the early luteal phase, which directly contrasts with findings reported by Osk and colleagues. Rock and associates evaluated patients during cycle days 8 through 12 and measured no difference in fluid volumes in patients with endometriosis compared with that in control subjects. Similar findings were noted by Rezaei and associates. Hence, it appears unlikely that fluid volume alone plays a role in the establishment of infertility.

Peritoneal fluid from patients with minimal and mild endometriosis has been shown to increase macrophage proliferation in vitro. In addition, several studies have described increases in total macrophage number in the peritoneal fluid of patients with endometriosis. Hill and coworkers measured significant elevations in total leukocytes, macrophages, helper T cells, lymphocytes, and natural killer cells in women with stages I and II endometriosis. Activated macrophages may affect the reproductive process by altering sperm motility, fibrin ovum capture, sperm-oocyte interaction, and early embryonic growth. Increased sperm phagocytosis by macrophages has been demonstrated by in vivo animal and in vitro human studies. Sugianami and Yano have demonstrated the presence of an ovum capture inhibitor in peritoneal fluid from patients with endometriosis, which reduces fibrinial activity for ovum capture in vitro. This molecule may prevent contact between the fibrinial cells and cumulus-oophorus.

Prostaglandins, interleukins, and other substances produced by macrophages may be harmful to reproduction. Falah and colleagues demonstrated that interleukin-1 was present in the peritoneal fluid of almost all patients with endometriosis, but not in the fertile control group. Interleukins have been shown to adversely affect mouse embryo growth in vitro. In addition, interleukin-1 stimulates fibroblast proliferation, collagen deposition, and fibrinogen formation; hence, elevated concentrations of such cytokines may account for the development of fibrosis and adhesions in advanced stages of endometriosis. Interleukin-6 secretion in vitro is upregulated in ectopic and eutopic endometrial stromal cells from women with endometriosis. Nevertheless, not all studies have confirmed the existence of a difference in interleukin activity between endometriosis patients and control groups. Decreased plasmaglandin activator activity in endometriotic implants may also be a cause for increased adhesion formation.

Bleeding from ectopic endometrial implants may promote the formation of free oxygen radicals. The iron in hemoglobin may be the catalyst of free radical reactions. Free radicals may damage proteins, carbohydrates, nucleotides, and lipids, resulting in tissue damage and de novo adhesions. Peritoneal fluid from patients with endometriosis has been hypothesized to interfere with ovulation, to alter tubal motility such that the embryos may arrive in the uterus at a suboptimal time for implantation, or to diminish corpus luteum function. Drake and associates measured the metabolites PGI2, 6-kET, and thromboxane A2 in peritoneal fluid and noted a 10-fold increase in these levels in patients with endometriosis. Ylikorkala and colleagues confirmed these observations, although the increase in prostanooids metabolites in the patients with endometriosis was less than twice that of the controls. When cycle stage was experimentally controlled, Rock and coworkers, Rezaei and associates, and others failed to demonstrate a significant change in prostaglandin levels in peritoneal fluid from patients with endometriosis as compared with control groups. In addition, prostaglandin concentrations did not vary between the follicular and luteal phase in either endometriotic patients or controls. Variations in collection of samples during the menstrual cycle, selection of control groups, and collection techniques have compromised the interpretation of data regarding the relative importance of prostanooid content in peritoneal fluid in the studies that have been published on this topic.

Alterations in the systemic immune response of endometriosis patients may influence fecundity. Cellular and humoral abnormalities have been reported in the peripheral blood and peritoneal fluid of women with endometriosis. Translocated endometrial cells may implant only in patients with an inherent defect in cell-mediated immunity. Functional changes in monocytes and macrophages, natural killer cells, cytotoxic T lymphocytes, and B cells suggest decreased surveillance, recognition, and destruction of misplaced endometrial cells and possible facilitation of their implantation. The endometrial proteins of menstrual fluid may be recognized by foreign to the host and trigger an autoimmune response. This host reaction can be variable, thus explaining why some women with a weak autoimmune response and varying extent of disease can conceive with no difficulty. Other investigators have confirmed a high prevalence of autoantibodies against endometrial and ovarian tissues in the sera and cervical and vaginal secretions of women with endometriosis.

Non-specific polyclonal B-cell activation has been postulated to exist in endometriosis, but there is a lack of substantive data to demonstrate that this association contributes significantly to endometriosis-associated subfertility. Dioxin, a pollutant that is known to decrease cell-mediated cytotoxicity by reducing the number of helper T cells, has been suggested as a causative factor in the high incidence of endometriosis in developed countries. Heilier and associates documented an increase in dioxin-like compounds in the serum of women with peritoneal endometriosis and deep endometriotic (adenomyotic) nodules. Moreover, a dose-dependent relationship existed between dioxin exposure and the subsequent development and severity of endometriosis in the rhesus monkey after a latent period of more than 5 years.

Nevertheless, other studies have suggested that endometriosis may not promote immunologic alterations in the pelvis. In a retrospective analysis of the cell count and volume of peritoneal fluid in 135 infertile women with endometriosis, Haney and colleagues found a negative correlation between total cell numbers and extent of disease and no significant correlation between fluid volume and extent of disease. Similarly, in the rabbit model of endometriosis, there was no difference in peritoneal fluid volume, macrophage numbers, or macrophage activation in treated versus control animals.

Hence, the exact cause-and-effect relation between endometriosis and infertility in the absence of a distortion in pelvic anatomy remains unknown. In a recent study using an adhesion-free rabbit model of endometriosis, peritoneal implants did not adversely affect the number of corpora lutea, the mean recovery rate of implantation, tubal transport, embryonic development and cleavage, or nidation index. Similarly, Mahmoud and Templeton were unable to detect differences in hormonal patterns of the menstrual cycle, follicular growth, preovulatory peritoneal fluid volume and sex steroid concentration, rate of LH, oocyte maturation, fertilization rate, or...
cleavage rate between patients with minimal and mild endometriosis and control women.

Little is known about the mechanisms by which endometriosis induces pain symptoms. Dyspareunia may be related to stimulation of pain fibers by stretching of scarred, inelastic tissue or by direct pressure on nodules of endometriosis embedded in fibrotic tissue. Endometriosis implants secrete inflammatory substances such as prostaglandins, cytokines, and growth factors that initiate the sequence of events that result in the development of pain. Moreover, the extravasated debris and blood from endometriotic implants may stimulate an inflammatory reaction within the peritoneal cavity with production of the aforementioned substances.

**DIAGNOSIS**

**Symptoms**

Dysmenorrhea, dyspareunia, and pelvic, back, and rectal pain—the more common symptoms of endometriosis—have been assumed to be caused by endometrial implants. However, the development of such symptoms is not diagnostic of the disease state. In one random survey of women in the general population, more than 60% reported dyspareunia at some point in their lives, and 33% had persistent discomfort. The prevalence of laparoscopically diagnosed endometriosis in patients with chronic pelvic pain has ranged from 4% to 52% in published series. The age of peak diagnosis of endometriosis based on presenting symptom is pelvic pain, age 15 to 24 years; infertility, age 25 to 34 years; and dysfunctional uterine bleeding, age 35 to 44 years (Leibson et al.).

Some authorities have suggested that the symptoms may be dependent on the location of the implants, the presence of adhesions, distortion of ovarian anatomy by endometriosis, and involvement of other organs, such as the ureter or rectum. However, Fedele and colleagues found no significant association between the American Fertility Society (AFS; now known as the American Society for Reproductive Medicine) classification of disease stage and the presence and severity of dysmenorrhea, pelvic pain, and dyspareunia in a prospective study of 160 women. The pain profiles of the patients with ovarian lesions were similar to those of the patients with peritoneal or ovarian and peritoneal disease. Conversely, in a later study by the same group, ovarian endometriomas were the only lesions significantly associated with severe dysmenorrhea and pelvic pain in infertile women.

Koninckx and coworkers demonstrated that the presence of pelvic pain did not correlate with the total area of endometriosis, type of lesion, or volume of disease. The only significant discriminator proved to be the depth of infiltration; endometriotic lesions greater than 1 cm in depth were associated with severe dysmenorrhea and pelvic pain in infertile women.

Pain symptoms generally correlate with fluctuations in steroid hormone concentrations. In response to cyclic stimulation by ovarian estradiol and progesterone, endometriotic lesions undergo epithelial and stromal proliferation, variable secretory changes, stromal pseudodecidual reaction, and periodic regression in a manner more disorganized than, yet similar to, that of normal endometrium. Surgical castration and ovarian hormonal suppressive therapy result in diminution of pain in most patients.

**Physical Findings**

Bimanual pelvic examination may reveal tender uterosacral ligaments, cul-de-sac nodularity, induration of the rectovaginal septum, fixed retroversion of the uterus, adnexal masses, and generalized or localized pelvic tenderness. The adherent tube and ovary may constitute a tender, irregular mass that is similar in characteristics to the mass palpated in cases of chronic salpingitis-oophoritis. Uterosacral nodules occasionally reach 1 cm or more in size. Lesions implanted in the retrocervical area or rectovaginal wall are frequently more easily felt than seen and can be missed if the physical examination is omitted.
false-positive results because of the neovascularity of benign
dimensional sonography and CA-125, but this yields many
creases the sensitivity and negative predictive values of two-
tion of resistance indices in the vessels of adnexal masses in-
not reliable as a screening test. Doppler sonographic evalua-
tive to identify lesser stages of endometriosis and is therefore
studies, however, suggest that CA-125 is not sufficiently sensi-
dometriotic cysts and deep endometriosis. The results of most
14 (PP14) have been related specifically to the presence of en-
antigen.

A perceptible, painful swelling of the implant before and at
menstruation remains a classic and reliable clinical sign of ac-
tive rectovaginal or retrocervical endometriosis.
Cancer antigen-125 (CA-125), a high-molecular-weight gly-
coprotein expressed on the cell surface of some derivatives
of embryonic coelomic epithelium, is often elevated toward the
end of the luteal phase and during menstruation in pa-
tients with AFS stages II to IV endometriosis. Barberi and col-
leagues reported that a value higher than 35 U/mL had a posi-
tive predictive value of 0.58 and a negative predictive value of
0.96 in establishing the presence of endometriosis. Many other
conditions have been associated with an elevated CA-125 con-
centration, including acute pelvic inflammatory disease, ade-
omyosis, uterine leiomyoma, menstruation, pregnancy, ep-
ithelial ovarian cancer, pancreatitis, and chronic liver disease.
Pittaway reported that 80% of women with pelvic pain and en-
dometriosis had a CA-125 titer greater than 16 U/mL, whereas
Pittaway reported that 80% of women with pelvic pain and en-
dometriosis had a CA-125 titer greater than 16 U/mL, whereas
only 6% of patients with pelvic pain and without endometrio-
sis had an increased serum concentration of this cell-surface
antigen.
Increased concentrations of CA-125 and placental protein
14 (PP14) have been related specifically to the presence of en-
dometriotic cysts and deep endometriosis. The results of most
studies, however, suggest that CA-125 is not sufficiently sensi-
tive to identify lesser stages of endometriosis and is therefore
not reliable as a screening test. Doppler sonographic evalua-
tion of resistance indices in the vessels of adnexal masses in-
creases the sensitivity and negative predictive values of two-
dimensional sonography and CA-125, but this yields many
false-positive results because of the neovascularity of bengi
tumors. Magnetic resonance imaging (MRI) may be helpful in assessing deep pelvic and extrapelvic endometriosis (Table 22.5).

**Visual Findings**

The patient with unexplained lower abdominal pain or a pre-
sentation suggesting endometriosis requires laparoscopy for
definitive diagnosis. Ultrasonography and other noninvasive
procedures cannot provide the specific information needed to
diagnose or classify the extent or severity of disease. For
proper laparoscopic evaluation, a double puncture technique
is essential. The ancillary probe or forceps placed through the
lower abdominal sheath permits mobilization of the tubes and
ovaries. A methodical regimented approach should be used to
thoroughly inspect the lateral side walls, all ovarian sur-
taces, both sides of the broad ligaments, the bladder and bowel
serosa, and the inferior aspects of the cul-de-sac. Uterine ma-
nipulation with a cannula fixed to the cervix facilitates eval-
uation of the uterosacral ligaments and rectal serosa. Photog-
raphy and video recording are useful for documentation of
findings.
Awareness of the wide range of visual appearances of en-
dometriosis is necessary for accurate diagnosis and appropri-
sate surgical therapy of the disease. Although darkly pigmented
lesions are readily recognizable and are considered a classic
presentation of endometriosis, less discernible yet common
forms of implants were described as early as the 1920s, when
Sampson noted “red raspberries, purple raspberries, blueber-
ries, blebs, and peritoneal pockets.” The black or blue pack-
ered “powder-burn” implant is a late consequence of cyclic
growth and regression of the lesion, to the point that bleeding
and hemosiderin staining of the tissue have occurred. Biopsy
of such areas reveals inactive endometrial glands and fibrous
stroma.
Distinctive morphologic variations include vesicles, flat
plaques, raised lesions, polyposid structures, areas of fibrosis
and adhesion formation, and peritoneal defects (Table 22.6).
Yellow, brown, blue, or black coloration is proportional to the
amount of hemosiderin deposition. Red polyoid lesions share
the closest histologic characteristics with native endometrium
and are thought to have the greatest metabolic activity, as is sug-
gested by their high concentrations of prostaglandin metaboli-
tes. Biopsy of unpigmented implants (i.e., implants that are
the same color as adjacent peritoneum) may reveal active en-
dometriotic glands and stroma. White lesions are predom-
antly fibromuscular scarring with scattered glandular and
stromal elements, and brown lesions are mainly hemosiderin
deposits. Peritoneal defects and subovarian adhesions contain

</table>
endometriosis in 40% to 70% of cases. Because other peritoneal lesions share morphologic features similar to those of endometriosis, the differential diagnosis is broad and includes old suture locations, epithelial malignancies, hemangiomia, inflammatory reaction to infection or oil-based hysterosalpinogram dye, and carbon deposition from laser surgery. Rec-tovaginal endometrotic lesions consist of smooth muscle with a loose fibrous stroma and variable hemosiderin deposits. They share similar characteristics to adenomyomas.

Small endometrotic lesions become more visible during the premenstrual and menstrual phases of the cycle, because during this time microfoci of peritoneal disease become congested with blood and debris. In addition, vascular dilatation, superficial hemorrhage, and ecchymosis formation cause accentuation of the more typical features of endometriosis. Performance of laparoscopy at a time when ovarian steroideogenesis is suppressed by medications such as GnRH analogs or progestogens may lead to inaccuracies in the assessment of extent of disease. Jansen and Russell reported the presence of nonpigmented lesions in 38% of their 202 patients with biopsy-proven endometriosis; 15% had only nonpigmented implants. Most areas of pigmented endometriosis are surrounded by nonpigmented endometriosis. These subtle lesions may represent the first stage of development of peritoneal disease. Recognition of nonpigmented endometriosis may be enhanced by "painting" the peritoneum with the patient's blood or by filling the pelvis with irrigation fluid and submerging the laparoscope to appreciate the three-dimensional configuration of clear lesions. Subtle lesions are likely to originate from microscopic glands; they appear and disappear like blebs on the peritoneal surface. With progressive fibrosis, these implants become the classic pigmented, scarred lesions, and finally, when fibrosis replaces the stroma, they appear as white, inactive disease.

The ability to detect subtle lesions of endometriosis increases with the experience of the surgeon and is reinforced by histologic confirmation. Although depth perception is impaired when the monocular lens of the laparoscope is used to view the pelvic cavity, the magnification ability of this lens when closely approximated to the peritoneum may allow identification of subtle surface irregularities present in occult disease. Magnification up to 10× power can be obtained with the laparoscope, depending on the working distance. Microscopic implants of endometriosis not visible even with 10× magnification have been documented by scanning electron microscopy in peritoneal biopsies of patients with unexplained infertility who had no evidence of disease at the time of laparoscopy. A scanning electron microscopic study of samples of supposedly normal tissue from endometriosis patients has documented the presence of endometriotic foci in 25% of cases. Lesions as small as 200 μm have been identified through this technique. Hence, surgical treatment of all visible disease is more accurately described as cytoreductive rather than ablative.

An ovarian endometriotic cyst is usually formed by an inversion of the ovarian cortex. The frontal surface of the ovary in the proximities to folium is the most common site for the invagi-nation process to occur. Adhesions are common from the ovary to the fossa ovarica or to the posterior leaf of the parametrium. Recognition of deep ovarian endometriosis is necessary for correct surgical staging. Small endometromas were diagnosed in 48% of infertile women with mildly enlarged ovaries (3.5 to 5 cm in diameter) when the ovaries were punctured with a 16-gauge needle. The ovarian surfaces were without gross disease in 20% of cases. Preoperative sono graphic evaluation is a useful screening test for the presence of small endometrotic cysts; their identification may affect the disease categorization to which the patient is assigned. Sonographic patterns may indicate purely cystic features, cystic features with few septations or minimal debris, complex combinations of cystic and solid elements, and largely solid features. Most recently, fat-saturated MRI has been shown to be an acceptable tool for detecting endometromas larger than 4 mm in diameter. Deep ovarian endometriosis is frequently associated with the presence of intestinal or more extensive pelvic disease.

Vercellini and colleagues studied the visual diagnostic parameters of ovarian endometromas at laparotomy in 245 women with ovarian cysts. The gross characteristics that established the diagnosis included a size smaller than 12 cm in diameter; adhesions to the pelvic sidewall, to the posterior broad ligament, or to both; the presence of endometrotic les-sions; superficial endometriosis with adjacent puckering on the surface of the ovary; and tarry, thick, chocolate-colored fluid content. These criteria yielded a specificity of 97%, a sensitivity of 95%, and an accuracy of 96%.

An adnexal mass in a patient with known pelvic endometriosis cannot be assumed to be an endometriotic cyst of the ovary. Ovarian malignancy must remain in the differential diagnosis; the size of the mass has been correlated with malignancy. In a study of 180 women, 1% of masses smaller than 5 cm, 11% of masses between 5 and 10 cm, and 72% of masses larger than 10 cm were malignant. Most of these malignant tu-mors were adenocarcinoma.

The rules that apply to the management of all women in whom an adnexal mass develops also apply to patients with endometriosis with an adnexal mass. Among women of reproductive age, unilateral adnexal masses that are cystic and unilocular with regular borders on ultrasound examination are likely to be benign, whereas masses with solid areas, septa, papillations, or irregular borders have a greater likelihood of being malignant. Endometromas vary in their appearance but usually have regular borders. As endometriosis enlarges, these internal echoes unless fresh hemorrhage is present. Sensitivity and specificity of transvaginal ultrasound have been reported by Eskenazi and colleagues to be 84% to 100% and 90% to 100%, respectively.

The depth of peritoneal infiltration by endometriosis cannot be evaluated by inspection alone. Deep endometriosis, which is almost exclusively localized to the posterior cul-de-sac and the urovesical ligaments, is better detected by palpation and becomes even more apparent during excision. Deep endometriosis has been recognized to become smaller with increasing depth, although in some women, the largest volume is hidden under an adhesion involving the bowel or is buried in the rectovaginal septum. Diagnosis is enhanced if clinical exam-iinations are performed during menstruation in women with chronic pelvic pain, severe dysmenorrhea, or deep dyspareunia. In most cases, a nodule is more palpable at this time.

Koninckx and Martin have described three types of infiltrat-ing endometriosis. Type I is characterized by a large pelvic area of typical or subtle lesions surrounded by white scarlike tissue. During excision, deep disease becomes obvious and grows progressively smaller with deeper sectioning of tissue (like a cone). Type II is formed by retraction of the bowel and is recognized clinically as a small classic lesion associated with retraction. In some women, no implant is visible, but retraction is associ-ated with the retraction. Excision usually reveals the presence of a nodule. Type III is nodular endometriosis of the recto-
CLASSIFICATIONS

Many endometriosis classification systems have been introduced to allow direct comparison of patient responses to medical and surgical treatments and to identify factors predictive of disease outcome. No system has yet been devised that is entirely satisfactory. AFS (renamed the American Society for Reproductive Medicine) organized a panel of experts in 1979 to develop a classification system that might serve as a basis for evaluating various therapies. The committee devised an innovative scheme based on the natural progression of the disease. Three anatomic areas—the peritoneum, ovary, and fallopian tube—were examined for the presence of endometriosis or adhesions, with allowances made for unilateral involvement. However, the system was not weighted for depth of infiltration of peritoneal implants. A point system instead assigned values to each area of disease involvement based on the presumption that implant area and adhesion characteristics were most often associated with disease prognosis. The stage of disease was determined by the cumulative score of the assigned points. This classification system was criticized for its arbitrary division of endometriosis into categories that did not necessarily reflect the true relative risk of disease sequelae, pain, and infertility.

The AFS classification was revised in 1985 to provide a more standard assessment of endometriosis for correlation of surgical treatment with distribution and severity of implants (Table 22.7). The point range of mild disease was expanded, and greater weight was given to deep endometriosis, dense adhesions, and cul-de-sac obliteration by adhesive disease. Although the revised staging system appropriately acknowledges the importance of adhesive disease and endometriomas, most women with extensive peritoneal disease in the absence of ovarian involvement, particularly deeply invasive implants, receive a very low score on laparoscopic inspection of the lesion.

This revised AFS classification has been widely used by investigators to categorize disease states. Nevertheless, direct comparison of treatment outcome is compromised by inconsistencies in the application of the staging criteria and by the great variations in medical and surgical therapeutic options being applied in the management of endometriosis. Evaluation of the extent of disease by laparoscopy may be limited by a lack of recognition of atypical implants, particularly if the patient is hypoestrogenic as a result of recent discontinuation of medical therapy for endometriosis. Furthermore, the divisions between stages of endometriosis remained arbitrary, the point score for ovarian involvement was weighted too heavily, and the classification scheme did not address disease involving the fallopian tubes, intestines, or urinary tract. Also, there were no parameters to indicate the present activity and state of evolution of the disease.

The Endometriosis Classification Subcommittee of the American Society for Reproductive Medicine (ASRM) released new recommendations in 1996 for the documentation of the extent and location of disease. One concern over the reproducibility of the scoring system was directed at the variability in assessing ovarian endometriosis and cul-de-sac obliteration. The subcommittee indicated that an endometriotic cyst should be confirmed by histology or by the presence of the following features: (i) cyst diameter less than 12 cm; (ii) adhesion to pelvic organs.

\*Determination of the stage of endometrial involvement is based on a weighted point system. The following categories have been established: stage I (minimal disease) 1–5 points; stage II (mild disease) 6–15 points; stage III (moderate disease) 16–40 points; stage IV (severe disease) >40 points.

If the fimbriated end of the fallopian tub is completely enclosed, change the point assignment to 16.
and sequelae. The potential benefits of cytoreductive therapeutic treatment of minimal or mild endometriosis in the patients bearing lesions that may be inhibiting ovulation or tubal function. Nevertheless, patients who have pelvic pain or dysmenorrhea in association with typical endometriotic lesions as compared with normal endometrium. Limited knowledge of the specific pathophysiologic alterations by which endometriosis can cause these symptoms has so far prevented any precise categorization of disease based on response to conventional therapies for these symptoms.

**THERAPIES**

Although women with endometriosis can present with a range of symptoms, therapy is usually initiated for the correction of pain, infertility, or a persistent pelvic mass. Pain and infertility may be present concurrently, whereas, many women with endometriosis-associated infertility have relatively little or no discomfort. Treatment options vary depending on the clinical history and findings at the time of surgery.

**Expectant Management**

Treatment of mild and moderate endometriosis with hormonal preparations may not offer any advantage over expectant management in promoting conception. In studies by Seeholz and colleagues, Hull and associates, and Telimaa, patients assigned to expectant management conceived either earlier than the medically treated group, and the cumulative pregnancy rate was not higher for women receiving progesterone or danazol. This lack of enhancement of fecundity may be related to the lower number of estrogen, progesterone, and androgen receptors in endometriotic lesions as compared with normal endometrium. Nevertheless, patients who have pelvic pain or dysmenorrhea and minimal or mild disease do benefit from hormonal therapy. The age of the patient and the duration of her infertility are important factors to consider in determining the appropriate therapy for the symptomatic individual. Laparoscopic laser ablation of milder stages of endometriosis appears to lessen the interval to conception. Although the cumulative pregnancy rate may not be greater than that of women managed expectantly, surgical therapy for more advanced disease results in a higher pregnancy rate than does expectant management or hormonal treatment, partly because of correction of mechanical factors that may be inhibiting ovulation or tubal function. There is no direct evidence to support the contention that surgical treatment of minimal or mild endometriosis in the asymptomatic patient will inhibit progression and sequelae. The potential benefits of cytoreductive therapy must be weighed against the risk of adhesion formation through surgical devitalization of peritoneal surfaces.

**Medical Treatment**

Mild pain symptoms associated with endometriosis may be effectively treated with nonsteroidal antiinflammatory oral contraceptives (Fig. 22.3). Additional endocrinologic therapies include progestogens, GnRH agonists, and danazol. These agents have similar degrees of efficacy in the relief of pain symptoms; side effects vary depending on their mechanism of action. At restoration of ovulation and of physiological levels of estrogen, both estrogenic and progestational endometrium resume metabolic activity. Therefore, medical therapy is symptomatic rather than curative, and most patients experience pain relapse at suspension of treatment.

**Progestogens**

By inhibiting the pituitary release of LH, progestogens suppress ovarian steroidogenesis and promote endometrial glandular atrophy, apoptosis, and extensive decidual transformation of the stroma.

Progestogens oppose the growth-promoting effects of estrogen on the endometrial tissue by altering the clearance of the nuclear estrogen receptor and inducing 17β-hydroxysteroid dehydrogenase, which converts estradiol to the weaker estrone. Moreover, by eliminating cyclic bleeding and suppressing uterine contractility, progestogens prevent reflex menstruation, a potential stimulus for continued endometriosis development. Progestogens may prevent implantation and growth of regurgitated endometrium by inhibiting the expression of matrix metalloproteinases and plasminogen activators. Moreover, progestogens have antiinflammatory properties.

Luciano and colleagues administered medroxyprogesterone acetate, 30 mg daily for 4 months, to symptomatic women with moderate to severe endometriosis. Improvement of pain, pelvic nodularity, and tenderness on examination occurred in 80% of patients. Twenty percent of women experienced breaks through bleeding, and an additional 10% reported persistent cyclic bleeding. Minor weight gain, edema, and increased irritability were other described side effects, which were generally well tolerated. A lower daily dose of 30 mg may provide equivalent relief of symptoms. Berggren and Theorell administered this dose to patients for 6 months and found a similar improvement in quality-of-life scores as that achieved with the GnRH agonist nafarelin. Compared with the cost of GnRH agonists and danazol, which are the other commonly prescribed agents, the low cost of the medroxyprogesterone acetate is a notable advantage.

Norethindrone acetate has been shown to be effective in achieving amenorrhea and controlling disease symptoms. When used to treat moderate or severe pelvic pain after unsuccessful conservative surgery for symptomatic rectovaginal endometriosis, a dose of 3.5 mg per day for 12 months resulted in a 73% satisfaction rate (33/45). Vercellini and colleagues (2005) reported a substantial reduction in dysmenorrhea, deep dyspareunia, nonmenstrual pelvic pain, and dyschezia scores. Low-dose norethindrone acetate could be considered an effective, tolerable, and inexpensive first-choice medical alternative to repeat surgery in those with recurrent pain.

A similar response rate can be obtained with megestrol acetate. Doses of 40 mg per day for up to 24 months resulted in significant relief of dysmenorrhea, noncyclic pelvic pain, and dyspareunia in 86% of subjects. Parenteral depot medroxyprogesterone acetate has also been used to produce long periods of amenorrhea and elicit...
direct progestational changes of the endometrial tissue. A regimen of 150 mg intramuscularly every 3 months for 1 year has been used to manage endometriosis patients with moderate to severe pelvic pain. Twenty-nine of 40 subjects (72.5%) were satisfied with their pain relief after 1 year of therapy. An alternative regimen is 104 mg subcutaneously every 3 months. Frequent breakthrough bleeding can be troublesome to correct. The rate of recurrence of symptomatic endometriosis after progestogen therapy appears to be related to the length of follow-up. Riva and colleagues reported an 18% rate after an average of 11 months, whereas Bloshassi and Boyce described a 42% recurrence rate during a 2-year interval after discontinuation of medication.

Cyclic administration of low-dose oral contraceptive pills may result in relief of pelvic pain, particularly cramping associated with menstruation. This line of therapy should be considered for the woman with mild symptoms who is not attempting to conceive. Long-term continuous oral contraceptive use has been proposed for women with symptomatic endometriosis and menstruation-related pain who have failed a cyclic pill regimen. With such a regimen, the endometrium remains thin on sonogram studies, and endometriotic plaques subjected to a progestin-dominant pill are less active, usually less painful, and will undergo apoptosis. Low-dose (20 to 35 mg ethinyl estradiol) combination oral contraceptives may be given daily for 6 to 9 months without break to relieve pain or more severe dysmenorrhea. The dose may be increased to two or more tablets per day for several days to alleviate episodes of breakthrough bleeding. Eighty percent (40/50) were satisfied or very satisfied with continuous use of an oral contraceptive containing ethinyl estradiol (0.02 mg) and desogestrel (0.15 mg) for 2 years, and 96% experienced pain relief, although spotting and breakthrough bleeding were frequent side effects (Vercellini et al., 2003).
The levonorgestrel intrauterine device (IUD) has proven effective in relieving pelvic pain symptoms caused by peritoneal and rectovaginal endometriosis and in reducing the risk of recurrence of dysmenorrhea after conservative surgery. In a study by Lockhart and colleagues, an improvement in symptoms was observed in 96% throughout the 36 months of use, with only 11% experiencing pain symptoms at 18 months. The progestogen released by the IUD creates a hypoestrogenic, antiestrogenic, and antiprogestational action on endometrial implants and creates a hypoestrogenic state and increases bone mineral density over baseline. The clinical trials described a concomitant increase in low-density lipoprotein (LDL) cholesterol; the alteration in the ratio of HDL to LDL cholest erol may be an unacceptable risk to some patients. Because danazol is metabolized by the liver, modest elevations in serum glutamic oxaloacetic transaminase and serum glutamate pyruvate transaminase may arise. Reported idiosyncratic drug reactions include gastrointestinal disturbances, weakness, dizziness, skin rash, headaches, and muscle cramps. Both positive and negative effects occur in as many as 85% of patients, and at least 10% of women receiving danazol discontinue pharmacologic treatment because the adverse effects are intolerable. Combining danazol therapy with aerobic exercise appears to reduce the incidence of many of these adverse effects. Preliminary data from trials using danazol vaginal rings suggest that this route of administration may result in symptomatic improvement of pain while avoiding the androgenic side effects of the oral administration.

Because of the potential androgenic action of this hormone on the developing fetus, the patient must not be pregnant when initiating therapy. Barrier contraception has been recommended for the entire course of treatment to eliminate the possibility of conception, although high doses of danazol usually cause anovulation.

The amenorrhea induced by danazol has been found to benefit patients with dysmenorrhea, dyspareunia, and cyclic pelvic pain associated with endometriosis. Young and Blackmore reviewed the effects of different dosages of danazol with respect to relief of symptoms in 452 patients. At a dose of 800 mg, 95% of patients noted relief of dysmenorrhea, and 89% reported relief of pelvic pain. At a dose of 400 mg, posttherapeutic relief was reduced by 10%. Moore and associates reported that pain associated with minimal and moderate pelvic endometriosis appeared to respond well to doses of danazol of 400 mg or less per day, whereas severe endometriosis was best treated with doses greater than 400 mg per day. A 6-year prospective study that evaluated the effectiveness of danazol at two doses (400 mg and 800 mg) in carefully classified patients concluded that there was no difference in side effects between the two doses and that gross resolutions of disease at second-look laparoscopy were similar. However, ovarian endometriosis greater than 1 cm did not respond as well to either dose of danazol as did peritoneal or ovarian disease less than 1 cm.

Recurrent of symptoms within 4 to 12 months of discontinuation of danazol therapy approached 50% in most studies. Poles and Hammond found that pain recurred in 38% of patients after a mean of 8.9 months; active disease was found within 1 year in 51% of women. Lower daily doses of medication or courses of treatment less than 4 months in duration may result in a shorter symptom-free interval. Clinical trials designed to assess the efficacy of medical therapy for minimal, mild, and moderately severe stages of disease refute the notion that danazol may enhance conception. Furthermore, conception is delayed while the patient is receiving danazol.

Gonadotropin-Releasing Hormone Agonists

GnRH agonists are available for use in the treatment of estrogen-dependent diseases such as endometriosis. Some of the more frequently studied analogs include leuprolide, nafarelin, buserelin, and goserelin. Alteration of the amino acid at position 6 and ethylamine replacement of the C-terminal amino acid of the native decapptide hormone results in a GnRH agonist with increased resistance to lysosomal degradation. Pituitary receptor binding is enhanced, resulting in a decline in the number of receptors available for further occupancy. Continued administration of the GnRH agonist leads to a desensitization of the pituitary gonadotropin receptor and a reversible downregulation of the pituitary-ovarian axis. Ovarian estrogen secretion may reach castrate levels.

The initial response to GnRH agonist administration is a markedly increased secretion of pituitary stores of follicle-stimulating hormone (FSH) and LH. If therapy is begun in the follicular phase of the menstrual cycle, the developing follicle may respond to the flare in circulating gonadotropin levels with a rapid increase in estradiol production. Estradiol levels may...

ضردة in mean pain scores and essentially no change in compact bone
density in most patients when nafarelin was readministered for
in the rat model. A maximal effect was measured after 4 weeks
excretion and radiologic evidence of loss of bone mineral
density. CEDars and co-workers reported a diminution in the
side effects mentioned earlier when medroxyprogesterone ac-
etate was administered at a dose of 20 to 30 mg per day
during the 6-month course of agonist therapy; however, la-
paroscopic evaluation after completion of therapy failed to re-
veal any improvement or suppression of active endometrio-
sis with the combination regimen, and the regimen failed to
significantly reduce symptoms of the disease. Dyspareunia
Response to therapy may be dependent on route of adminis-
tration. Donnez and colleagues reported that buserelin admin-
istration by a long-acting subcutaneous implant led to a greater
reduction in endometriosis score, mitotic index, and endome-
trial stromal cell infiltration compared to an intranasal form. This
may have been due to a greater consistency in hormonal release
by the injected preparation.

As occurs with danazol and progestogen regimens, symp-
toms recur at variable periods after discontinuation of GnRH
analog therapy. Subjective return of pain occurred in 57% of
patients within 6 months of discontinuing leuprolide, although
37% with moderate or severe pelvic pain at baseline were still
improved at 1 year. Fransson and colleagues noted a lasting
and significant amelioration of dysmenorrhea and dyspareu-
nya 6 months after completion of treatment; however, scores
for chronic pelvic pain had nearly reached their pretreatment
level once this time had elapsed. Patients with a higher disease
stage at the onset are more likely to experience recurrence and
to experience it earlier than patients with minimal disease. One
treatment option for such patients may be a second 3-month
course of GnRH analog. Hentil reported a significant decrease
in mean pain scores and essentially no change in compact bone
density in most patients when nafarelin was readministered for
3 months after a treatment-free interval of 6 months or more.

The effect of GnRH analog on endometriosis-associated in-
Fertility is difficult to assess because of a lack of an expectant
management control group in most clinical studies. The pre-
liminary pregnancy rates, which range from 0% to 60%, are
defined from trials that do categorize response based on stage
of disease.

Most of the side effects associated with GnRH analog therapy
are related to hypoestrogenism. Hot flashes are com-
mon and can lead to sleep disturbances and chronic fatigue
in extreme cases. Vaginal dryness, superficial dyspareunia,
headaches, and depression have been reported. In general, these
adverse effects are better tolerated than those experienced with
danazol use. In addition, there are no undesirable changes in
HDL, LDL, or total cholesterol throughout the prolonged pe-
riod of hypoestrogenism induced by GnRH analog, unlike the
change accompanying GnRH agonist therapy. A decline in trabecular bone mineral content and an increase in
urinary calcium excretion to menopausal levels occur dur-
ing the course of GnRH analog therapy in about two thirds of
patients. Quantitated computed tomographic studies con-
sistently show significant loss of trabecular bone of the ver-
tebrae and hip with GnRH analog exposure. Restoration of
normal estrogen production after cessation of therapy appears
to at least partially reverse these bone changes. In a study of
the GnRH agonist goserelin, an 8.2% decline in density of the
lumbar spine was measured after completion of 6 months of
treatment; this improved to a mean loss of 3.4% at 6 months
postcessation. Others found no significant change from base-
line after a 6-month course of GnRH analog when bone density
was assessed 6 months after treatment.

Concomitant administration of a progestogen during the
course of GnRH analog therapy has been examined to ame-
liorate vasomotor symptoms and retard both urinary calcium
excretion and radiologic evidence of loss of bone mineral
density. CEDars and co-workers reported a diminution in the
side effects mentioned earlier when medroxyprogesterone ac-
etate was administered at a dose of 20 to 30 mg per day
during the 6-month course of agonist therapy; however, la-
paroscopic evaluation after completion of therapy failed to re-
veal any improvement or suppression of active endometrio-
sis with the combination regimen, and the regimen failed to
significantly reduce symptoms of the disease. Dyspareunia
Response to therapy may be dependent on route of adminis-

Conservative Surgery

Surgery is indicated for correction of pain, infertility, or other symptoms in patients with extensive pelvic endometriosis, or when hormonal manipulation fails to adequately diminish pain symptoms in women with lesser stages of disease. Surgery is successful in relieving pain in a very high percentage of cases and offers a better prognosis for pregnancy than does endocrine therapy in many cases of advanced disease.

The surgeon who has mastered the specialized techniques of operative laparoscopy can treat a wide range of pathologic findings at the time of diagnosis. Therapeutic planning depends on many factors, including the age of the patient, her desire for fertility or pain relief, the duration and intensity of her symptoms, the extent of disease, and previous treatments that have been undertaken. Preoperative rectoscopy-sigmoidoscopy and intravenous pyelography are recommended in patients with symptoms suggestive of deeply invasive endometriosis of the posterior cul-de-sac and rectovaginal septum. MRI may also be helpful in predicting the extension of disease (Table 22.5).

The decision of whether to perform surgical resection of endometriosis through the laparoscope or open abdomen is not entirely dependent on the stage of disease encountered. Laparoscopy can be considered for all cases unless there is difficulty in establishing the appropriate tissue planes of dissection or unless improved access is necessary for traumatic manipulation of the involved organs. Specific endoscopic procedures include ablation of endometriotic implants, adhesiolyysis, ovarian cystectomy, oophorectomy, and salpingectomy. Although the results and complications are similar, the cost savings with respect to decreased hospital expenses and loss of work time favor laparoscopy over laparotomy when other factors regarding risks and outcome are equal. Laparoscopy provides superior visualization of the posterior cul-de-sac and allows a high degree of magnification of peritoneal surfaces, which aids in the identification of subtle disease.

Conservative resection of disease by laparotomy is most valuable in cases of extensive, dense pelvic adhesions or endometriosis greater than 5 cm in diameter. In addition, deep involvement of the rectovaginal septum with fibrotic extension into the perirectal fossa, invasion of the bowel muscularis, and endometriotic infiltration in the region of the uterine vessels and ureter are generally best approached through the open abdomen for all but advanced endoscopic surgeons. The objective of the laparotomy procedure is complete excision of all endometriotic and associated adhesive disease to restore normal functional anatomy of the reproductive tract. The usual surgical approach is through a transverse suprapubic incision. The Maylard incision provides adequate exposure for presacral neurectomy and reconstructive surgery of ovarian endometriomas of almost any size.

Principles of Microsurgery

Microsurgical technique, or the philosophy of gentle manipulation of tissue in an attempt to avoid trauma, is the major tenet of pelvic reconstruction. The inflammation, trauma, coagulation, and foreign materials associated with conventional microsurgical technique lead to tissue ischemia and adhesion formation because of local failure of the intrinsic peritoneal fibrinolytic system. Adhesion formation can be reduced by the application of loupes magnification or use of the operating microscope, reconstruction with fine, nonreactive sutures, precise hemostasis, and frequent irrigation of tissues with warmed lactated Ringer solution. Nevertheless, there are no definitive data to suggest that use of the particularly costly ancillary laser and the operating microscope has appreciably improved the reproductive prognosis in the surgical management of endometriosis through laparotomy. The magnification provided by laparoscopy in a closed surgical field matches these microsurgical principles.

Several basic techniques are available for the endoscopic ablation of endometriosis, including excision, coagulation, and vaporization. Coagulation can be achieved by monopolar or bipolar cautery, thermocoagulation, or, in some circumstances, laser, depending on the wavelength of energy applied. The extent of tissue penetration in electrocautery is related to the power and type of current, the duration of application, and the size of the electrode. Less tissue damage is achieved with bipolar than with monopolar cautery. The carbon dioxide (CO₂) laser is more precise than the fiber lasers, although CO₂ laser energy is strongly absorbed by water molecules and is rendered ineffective in the presence of blood. Metaculosa technique that maintains serosal integrity may reduce the incidence of de novo adhesion formation.

Sites of Conservative Surgery

Peritoneum. Small lesions of superficial peritoneal endometriosis less than 5 mm in diameter are easily treated with laser or bipolar coagulation while under a constant stream of irrigation. Deep lesions or more extensive peritoneal disease must be excised with a tissue margin of at least 2 to 4 mm, because, as noted previously, microscopic lesions are commonly present in tissue adjacent to visible implants (Figs. 22.4, A). Ablation of deep disease by monopolar microdiathermy or CO₂ laser vaporization rather than excision of the disease may result in inadequate resection and a greater amount of ischemic damage to the tissue, heightening the propensity toward adhesion formation. Immobilizing adhesions can be merely divided during the preparatory phase of the procedure; precise excision is more easily accomplished after the involved organs are freed. Before dissection of the pelvic sidewall, the ureter must be identified and isolated; it is frequently displaced from its normal location by endometriotic adhesive disease. A Lucite, Teflon, or laparoscopic titanium probe can be used to isolate adhesions and protect adjacent structures during separation of the tissue planes. Suture placement can lead to foreign body reaction, tissue anoxia, and fibrosis and should therefore be avoided. Covering hemostatic, deperitonealized surfaces with an absorbable, oxidized, regenerated cellulose barrier (Interceed) significantly reduces the incidence, extent, and severity of postsurgical pelvic adhesions, even in patients with severe endometriosis. Alternatively, application of the Gore-Tex surgical membrane has been shown to result in a statistical reduction in adhesion score; this barrier can be removed at the time of a second-look laparoscopic procedure if its presence would impair tubovarian function.

Estimations of the depth of endometrial implants at the time of laparoscopic resection relate well with histologic measurements. Superficial implants can be destroyed by bipolar cauterization; however, 25% of patients have lesions greater than 5 mm in depth. Deep (<5 mm) and juxtadeep (<10 mm) lesions represent an active form of the disease and occur almost exclusively in patients who report pain. The superficial action of nonvaporizing modalities such as bipolar or thermal coagulation is
not sufficient for deep disease. The diagnosis of retroperitoneal endometriosis is suggested by preoperative digital rectovaginal palpation and laparoscopic blunt probe palpation. The depth of infiltration of deep lesions appears to correlate poorly with the visible surface area of involvement. The laparoscopic treatment of deep disease is often complicated by the proximity of implants to vital structures such as the ureter, bladder, and vessels (Table 22.8).

Laparoscopic forceps are used to elevate and isolate the tissue to be excised. Instruments should be placed with care, because surgical manipulation of tissue that will not be resected may result in de novo adhesion formation. The diseased peritoneum may also be separated from underlying tissue by the technique of hydrolaparoscopy, which forcefully injects physiologic irrigant retroperitoneally through a small defect created in the peritoneum (Fig. 22.5). This retroperitoneal placement of fluid acts to dissipate CO2 laser energy and, in so doing, promotes safer dissection or vaporization of the peritoneal surface.

Coagulation or vaporization of disease in the ovarian fossa or near the uterosacral ligament should be undertaken only after clear identification of the ureter. Uterine manipulation with a Valtchev retractor may be used while treating lesions of the posterior cul-de-sac.

It is difficult to evaluate the depth of tissue damage with electrocauterization; however, laser vaporization allows visualization of the three-dimensional boundaries of every lesion. The laser beam should be applied until the bubbling of retroperitoneal areolar tissue is noted. The zone of thermal necrosis is minimal with the CO2 laser, particularly when applied in the superpulse mode. In the region of the ureter, urinary bladder, colon, or large blood vessels, a single or repeat pulse mode of 0.05 to 0.1 second allows a depth of penetration of 100 to 200 μm. Irrigation of the pelvis washes off debris and carbon deposition and better exposes the base of the site of laser impact. A 2- to 4-mm clear margin is desired around each lesion treated. Excision of the involved peritoneum is superior to vaporization of implants when the extent of tissue penetration cannot be recognized.

Dissection of retroperitoneal disease can be facilitated by placing a bougie probe in the rectum and a sponge forceps in the vagina (Fig. 22.6). Traction in either direction opens the rectovaginal and perirectal spaces. Initial dissection of the

USL = uterosacral ligament.

Electrosurgery should be avoided when extensive dissection is performed because it may be associated with widespread thermal damage and difficulty in recognizing tissue planes. Superficial invasion of the muscularis of bowel or bladder can be treated with laser vaporization or endocoagulation because of the precision and lack of penetration of these energy sources. Anterior cul-de-sac treatment should be accompanied by continuous bladder drainage.

Tubal endometriosis may distort the normal anatomic relationship of the distal tube to the ovary and in severe cases may cause complete fimbrial obstruction. Short pulses of CO₂ laser may be used to vaporize lesions while minimizing thermal damage. Endoscopic adhesiolysis of the distal tube may be accomplished with fine scissors or careful application of...

laser. Unipolar electrocautery should not be used on this tissue.

Defects in the parietal peritoneal surface are frequently associated with endometriosis and are most commonly found in the posterior cul-de-sac region. These defects should be explored and ablated even if they appear grossly normal because of the frequency of microscopic disease.

Ovary. Superficial endometriosis of the ovary usually presents as small, dark, punctate lesions located on and immediately beneath the cortical surface. This disease can be readily treated with laser or bipolar forceps under constant irrigation. Occasionally, however, the small, visible lesion may be merely the tip of a large endometrical cyst. If there is any doubt, the implant should be excised and the ovary explored to determine the extent of disease. Care should be taken to minimize thermal injury to surrounding ovarian tissue. This is particularly important near the fimbria ovarica, because postoperative adhesion formation could compromise distal tubal function. Inability to elevate the ovary is usually a sign of adhesions and endometriotic implants of the interlateral surface of the ovary and the peritoneum of the ovarian fossa. Excising the fibrotic pelvic sidewall and/or uterosacral ligament lesions to which the ovary was attached will reduce disease recurrence.

Reconstruction by laparotomy. Extensive ovarian endometriosis is often associated with peri ovarian and peritubal adhesions. These adhesions may become apparent while manipulating the ovary to visualize the lateral surface adjacent to the broad ligament. Filmy adhesions are elevated with delicate tissue forceps and can be resected with fine-needle cautery, a scalpel, or the laser. Care must be taken to maintain the integrity of the ovarian capsule. After the appropriate adhesiolysis is accomplished, the posterior cul-de-sac is packed with moist, lint-free packs, and a silicon surgical platform can be placed to stabilize the adnexa. The ovary should be carefully examined for extent of disease involvement before creation of the initial incision. Peritoneal spillage of the contents of the endometrioma can be avoided by placement of a lint-free pack around the platform.

The cortical incision should be made in a way that will preserve the normal anatomic relations of the ovary with the uteroovarian ligament and fimbria ovarica (Fig. 22.8). This is best accomplished by making a shallow longitudinal incision over the endometrioma with the monopolar microneedle.
FIGURE 22.7. A: Deep laparoscopic dissection of the rectovaginal space, in combination with colpotomy, for the excision of a large endometriotic nodule of the rectovaginal septum. B: Initial laparoscopic dissection of nodule. C: Completion of dissection by way of colpotomy incision. D: Vaginal suture placement to reapproximate the rectovaginal septal defect.

Endometriosis

The ovary is reconstructed by placing one or two pursestring sutures of 4-0 or 5-0 polyglactin, polyglycolic acid, or polidioxanone to eliminate the dead space and maximize hemostasis. This may be followed by placement of a running subcortical 5-0 suture of the same delayed-absorbable material (Fig. 22.8), if necessary. In some circumstances, less tissue distortion can be achieved by placing a deep layer of interrupted mattress sutures followed by additional layers of running sutures (Fig. 22.8). Suture on or extruding through the surface should be strictly avoided because of its adhesiogenic properties.

After the ovary has been carefully approximated, the posterior surfaces of the uterus and broad ligament are inspected for hemostasis wherever the ovary was previously adhered. Micro bipolar cauterization may be necessary. Placement of an adhesion barrier is useful in separating raw peritoneal surfaces during the healing process.

Endoscopic therapy of ovarian endometriosis. Surgical treatment of endometriosis less than 4 to 5 cm in diameter can be accomplished with relative ease. However, endoscopic resection of larger lesions may be compromised by the presence of dense, cohesive adhesions and by difficulties removing the entire cyst wall because of the inability to find the plane of attachment of the fibrotic endometrioma to the ovarian cortex.

The endometrioma can be excised in an intact or ruptured state during the laparoscopic procedure. In either case, the technique is initiated by longitudinally incising the cortex overlying the cyst after achieving full mobilization of the ovary by adhesiolysis. The incision is generally made along the inferior pole on the opposite side to the hilus in such a manner as to preserve the apposition of healthy ovarian tissue to the fimbria. The cyst contents are immediately drained with the suction cannula, and the cavity is irrigated and inspected for papillary structures or other suspicious features. Often, the cyst ruptures during dissection of adhesions that bind the ovary to the pelvic sidewall. Under this circumstance, the plane of dissection between the cyst wall and the ovarian cortex can be established after identifying the site of rupture. The opening can be extended with the use of the needle electrode or laser.
FIGURE 22.8. Excision of ovarian endometrioma through laparotomy. A: The ovarian cortex is gently incised so that the endometrial cyst is not entered. The incision is made along the longitudinal axis of the ovary. B: The endometrioma is then peeled out with the blunt knife handle. C and D: The ovarian defect is closed with two layers of pursestring sutures of 4-0 or 5-0 absorbable, nonreactive material. E: In the case of a deep defect, a more superficial running suture may be necessary before the cortical edges are approximated with 3-0 nonreactive, delayed-absorbable sutures.

With larger endometriomas, the normal ovarian cortex is stabilized with atraumatic forceps, and the cyst wall is grasped with biopsy forceps and stripped from the bed of normal ovarian tissue (Fig. 22.9). The dissection may be facilitated by removing a small circular rim of tissue around the adhesion site to begin the stripping procedure in a clearer field, where the endometrioma wall is less adhered to healthy ovarian tissue (Muzii et al., 2005). Judicious use of the needle electrode or hydrodissection may facilitate separation of the tissue planes. Remaining fragments of the cyst wall should be vaporized with laser or fulgurated by electrocautery. Hemostasis can be achieved with bipolar cautery. An alternative technique involves sharp and blunt dissection to remove the cyst in an intact state. Hydrodissection is particularly useful with this approach. The cyst contents are carefully drained in a plastic laparoscopy pouch to facilitate clean removal from the peritoneal cavity. Very small endometriomas less than 1 to 2 cm in size may be effectively treated by electrocoagulation of the mucosal lining. Because carbon dioxide laser is absorbed by fluid, complete ablation of the cyst wall with this energy source may be compromised in an environment rich in blood and hemosiderin.

The ovarian defect is usually left to heal spontaneously. Ischemia associated with suture placement can provoke adhesion formation after laparoscopic ovarian reconstruction. Low-power continuous carbon dioxide laser or bipolar coagulation can be applied to the inside wall of the redundant ovarian capsule to cause an inversion of the incised cortex. Most authors have reported excellent results with this no-suture technique. Under the rare circumstances of persistent bleeding or poor apposition of ovarian tissue, the cortex may be reapproriuminated with sutures. If fine absorbable suture is used, the knot should be placed internally to minimize the possibility of it becoming a nidus for adhesion formation. The high incidence of adhesion formation after surgery for endometriosis, particularly at the site of the ovary or where dense adhesions were divided, underscores the importance of optimizing surgical techniques to potentially reduce adhesion formation. Extensive cauterization of ovarian tissue can lead to a rise in FSH levels postoperatively and should be avoided. Post-surgical ovarian failure after laparoscopic excision of bilateral endometriomas is a rare but possible complication. There were three cases of premature ovarian failure among 126 patients who underwent laparoscopic excision of bilateral endometriomas in a recent series by Busacca and colleagues.
FIGURE 22.9. Laparoscopic ovarian cystectomy after fenestration of the cyst. A: The cut edges of the ovarian cortex and cyst wall are held and teased apart. B: The cyst wall can be stripped off by twisting it around the grasping forceps. Hydrodissection may be helpful. C: Large defects can be closed with laparoscopic suturing. Most incisions are left to heal by second intention.

Endometriosis corresponding to a rate of 2.4%. This may be caused by irreversible trauma to ovarian vasculature by electrocoagulation, excessive removal of ovarian tissue, and an autoimmune reaction caused by a severe, local inflammatory process.

Fayez and Vogel prospectively evaluated four laparoscopic methods for the treatment of endometriomas. Patients were treated postoperatively with danazol and underwent a second-look laparoscopy 8 weeks after their initial surgery. Complete excision with scissors successfully eliminated recurrence of the cysts, but adnexal adhesions had developed postoperatively in all cases. Mere incision and drainage of the cyst contents, followed by stripping or CO₂ laser vaporization of the lining, resulted in adhesion formation in only 23% to 37% of cases, but endometrioma cysts recurred in 21% to 22%. Other authors have used the potassium-titanyl-phosphate (KTP) laser to photocoagulate or remove the cyst lining of large endometriomas and have reported a very low rate of recurrence at 6 months after the procedure.

In a prospective study by Beretta and colleagues, patients were randomly allocated at the time of laparoscopy to undergo either cystectomy or drainage of the endometrioma and bipolar coagulation of the inner lining. No preoperative or postoperative adjunctive medical therapies were administered. The excision technique resulted in a lower 24-month cumulative recurrence rate of dysmenorrhea, deep dyspareunia, and non-menstrual pelvic pain. The median interval between the operation and the recurrence of moderate to severe pelvic pain was longer in the cystectomy group (19 months) versus the drainage and coagulation group (9.5 months). In addition, the 24-month cumulative pregnancy rate was statistically significantly higher in the former group than in the latter group (66.7% versus 23.5%, respectively).

In a recent prospective, randomized clinical trial by Alborzi and associates, the rate of recurrence of pelvic pain and dysmenorrhea over a 2-year postoperative period was significantly less for those who underwent cystectomy (15.8%) as compared
with those undergoing fenestration and coagulation (56.7%). Moreover, the rate of reoperation was 5.8% in the former group and 22.5% in the latter group. The cumulative pregnancy rate was significantly higher in the cystectomy group (59.4%) than in fenestration/coagulation group (23.3%) at 1-year follow-up.

If there is evidence of functional destruction of the ovary or if the patient has chronic, incapacitating pelvic pain secondary to ovarian endometriosis and does not plan to become pregnant in the future, appropriate therapy may consist of oophorectomy. The infundibulopelvic and uteroovarian ligaments can be ligated with an endoloop ligature, bipolar coagulation, the harmonic scalpel, or surgical staples before excision of the structure. The ovary is retrieved by morcellation, mini-laparotomy, or posterior colpotomy. This type of surgery must be performed carefully when adnexal adhesions are present to avoid ovarian remnant syndrome.

Intestines. Intestinal involvement has been estimated to occur in 3% to 15% of women with endometriosis and in up to 50% of patients with severe disease. The most common areas of intestinal involvement are the rectum and rectosigmoid colon, followed by the sigmoid colon, cecum, terminal ileum, proximal colon, and appendix. The incidence of appendiceal endometriosis has been estimated at approximately 0.8% of all appendectomies; 3% to 5% of patients with endometriosis have appendiceal involvement.

Symptoms that should arouse suspicion of colonic involvement include constipation alternating with diarrhea, rectal pain, tenesmus, dyspareunia, and dysmenorrhea. Cyclic rectal bleeding is seen in as many as one third of women with rectosigmoid involvement, but the mucosa is rarely invaded. Small intestine disease accounts for up to 16% of gastrointestinal involvement and most often involves the terminal ileum. The most common symptom associated with disease in this location is midabdominal cramping pain. Ten percent of small bowel involvement presents with obstruction requiring surgery. The more common large bowel disease results in clinical obstruction in only 1% of cases.

The differential diagnosis of intestinal endometriosis includes primary carcinoma, metastatic carcinoma, diverticulitis, inflammatory bowel disease, irritable bowel syndrome, pelvic inflammatory disease, radiation colitis, and ischemic stricture. Endometrial adenocarcinomas have been reported in the colon and rectum but are exceedingly rare in comparison with the relatively large numbers of patients with colorectal endometriosis. Preoperative or intraoperative rigid sigmoidoscopy may be helpful in ruling out primary colorectal malignancy. An intact mucosa effectively rules out primary colorectal malignancy. The greatest chance of diagnosing colorectal endometriosis occurs when the examination is performed at the time of menopause. Although endometriosis rarely invades the intestinal mucosa, mucosal distortion is possible secondary to fibrosis of the submucosa.

Pelvic and rectal pain is the major symptom that leads to colorectal resection in patients with advanced endometriosis. Bowel resection should be undertaken in the symptomatic patient or when there is a suspicion of malignancy; however, the frequency of such indications is small. In a series authored by Prystowsky and colleagues of 1,573 consecutive patients, only 11 women (0.7%) required bowel resection. Resection is usually undertaken for lesions producing partial or complete obstruction because most of these lesions are fibrotic and unresponsive to hormonal manipulation. Recommended approaches for less extensive lesions include CO2 laser vaporization of superficial serosal disease of the rectum or large intestine, excision without entering the mucosa, and oophorectomy or hormonal suppression. A harmonic scalpel may be used laparoscopically to shave an endometriotic nodule in the perirectal fascia. Although oophorectomy can cause regression of the endometrial nodule, large implants of the bowel can scar and ultimately lead to obstruction. The use of electrocautery or fiber lasers should be avoided because of their greater risk of causing transmural thermal damage.

A full mechanical and antibiotic bowel preparation is carried out preoperatively. In cases of large lesions that encroach on the mucosa, full-thickness excision of involved bowel can be undertaken either by disk excision of small, isolated lesions or by segmental resection for larger lesions. The anastomosis can be hand sewn with a continuous single layer of absorbable monofilament suture or created with surgical staples; however, patients with cul-de-sac disease must be in the lithotomy position to allow transanal placement of the stapler. These procedures have been performed by or with the assistance of general surgeons.

Appendectomy should be considered when there is physical evidence of peritonitis, when implants are large and active, when associated adhesive disease to adjacent bowel may result in partial or complete angulation and obstruction, or when the benign nature of the lesion is in doubt. Spontaneous perforation of the appendix that is due to endometriotic involvement is very rare. The technique of incidental endoscopic appendectomy is similar to that performed through laparotomy, although the stump need not be buried in the cecum. The tip of the appendix is grasped and elevated. The appendicular vessels are bipolar cauterized or occluded with surgical clips near the base of the appendix before being excised. Two loop ligatures are placed immediately next to each other at the base, and a third endoloop is then secured approximately 5 mm distal to the first two. The appendix can be transected between the second and third ligature and placed in a surgical pouch for safe retrieval from the abdominal cavity. Judicious application of bipolar cautery at the stump sterilizes the raw surface of the pedicle without causing damage to the adjacent cecum.

Coronado and colleagues reported a complete relief of pelvic symptoms in 49% and an improvement in 39% of patients who underwent full-thickness resection of the colon. Thirty-nine patients in the series achieved a term pregnancy. In a later series by the same colorectal surgeons of 130 patients who underwent aggressive, conservative surgical management for advanced disease, the operative procedures performed included low anterior resection with anastomosis to the extraperitoneal rectum (n = 109), sigmoid resection (n = 10), disk excision of the rectum (n = 7), discectomy resection (n = 2), and small bowel resection (n = 2). Twenty-four of 49 patients (49%) who attempted to conceive delivered a viable child.

Urinary Tract. Endometriosis involving the urinary tract is relatively rare. The spectrum of disease severity varies from incidental findings at laparoscopy, laparotomy, or cystoscopy to more significantly associated hematuria, flank pain, hydronephrosis, and ureteral obstruction. Bladder and ureteral involvement represent 83% and 15% of cases, respectively. Cystoscopy and intravenous urographic studies are helpful in documenting the extent of disease. Vesical endometriosis can be treated by hormonal suppressive therapy or partial cystectomy. These nodular lesions develop within the muscularis and...
are typically seen with partial or complete obliteration of the anterior cul-de-sac. Conservative surgical treatment of bladder endometriosis is effective in ensuring long-term relief in most cases of endometriosis affecting the vesical dome, whereas success, and discorrientions involving the nodule may lie too deep for detection of any color change through the skin. If the nodule is superficial, cyclic bleeding or ulceration may be apparent.
