When the tampon does not stain blue with retrograde bladder filling, further dye studies may be done to demonstrate a ureterovaginal fistula. The bladder is emptied and flushed with saline, and 2 cc of sterile methylene blue or indigo carmine is injected intravenously. An alternate method is administration of phenazopyridine hydrochloride orally. One advantage of phenazopyridine is ease of administration. A second is that it stains urine an orange color, which eliminates any confusion with blue in the bladder. With either option, a fresh tampon is inserted and left in place for 15 minutes. If the new tampon is stained, a ureterovaginal fistula is probably present. The vaginal apex is inspected carefully. Leakage of dye from one side of the postoperative vaginal apex strongly suggests the ipsilateral ureter is most likely the site of the fistula, but this is not definitive. An intravenous urogram or retrograde pyelogram is indicated not only to confirm the side of involvement but also the level of the fistula.

Before any attempt at surgical repair, all patients should undergo cystourethroscopy, with careful attention paid to the bladder neck, ureteral orifices, and urethra. The exact location of the fistula in relation to the ureteral orifices, its size, and its possible underlying cause should be determined. Additional fistulous communications need to be excluded to reduce the risk of surgical failure. Larger fistulae may prohibit or cause difficulty in performing liquid-based cystoscopy. In that case, the vaginum may be packed with gauze to limit egress of fluid. Alternatively, the bladder may be allowed to fill with air and dry cystoscopy performed with the patient in a jackknife or knee-chest position. Carbon dioxide also may be used as a distention medium.

The ureteral orifices should be identified and evaluated. Urine fails to spurt through the orifice of a damaged or obstructed ureter. On rare occasions, a compromised ureter continues to spurt urine from the ureteral orifice. Ureterically ligated ureter or damaged kidney, the ureters may look atrophic, and no urine flow is seen. Attempts to pass a ureteral catheter usually fail when the tip reaches the point of obstruction. A retrograde pyelogram sometimes is needed to fully evaluate the ureter. A ureterovaginal fistula usually is visualized with hydronephrosis and hydroureter because stenosis of the ureter occurs at the site of the injury. Scarring at the edges of a VVF in the region of the ureteral orifice also may lead
to ureteral stenosis and proximal dilatation. Further discussion of the differential diagnosis of ureteral fistula is found in Chapter 39.

Although novel radiologic techniques are proving useful in other fields of medicine, their efficacy in the diagnosis of urogenital fistula does not surpass traditional methods. The use of computed tomography (CT) with intravaginal contrast has been reported with limited success. CT may be more helpful in evaluating for coexistent disease involving the upper tracts before surgical correction. Recently, color Doppler ultrasound with contrast media has been described as a diagnostic tool. Sonography was positive in 11 of 12 (92%) patients with VVF. (A jet phenomenon was demonstrated through the bladder wall, in the direction of the vagina, which was distinguishable from ureteral flow.) All patients were known to have fistulae before enrollment into these studies, and specificity of color Doppler for detection of VVF cannot be calculated. In fact, 100% were shown to have a fistula with dye tests. The benefit of color Doppler is that it is easy to learn, noninvasive, results in no radiation exposure, and can evaluate the distance from the fistula to the ureteral orifices. Abulafia and colleagues described the diagnostic use of transperineal ultrasound in a woman who was unable to undergo cystoscopy secondary to urethral obstruction. Currently available ultrasonography and CT are unlikely to replace the traditional diagnostic methods of intravenous urography, retrograde pyelograms, and cystoscopy.

Preoperative urodynamic testing is defended by some authors. Hilton argues for its use before surgical repair of urogenital fistulae to establish the presence of abnormal lower urinary tract function. In his series of the 38 patients, 47% had genuine stress incontinence, 40% showed detrusor instability, and 17% had impaired bladder compliance. The overall incidence of functional abnormality was highest in the patients with urethral or bladder neck fistulae. Most patients became continent after surgical treatment of the fistulae. Those who had urethral or bladder neck fistulae had more residual detrusor instability. Thomas and Williams argue that documenting abnormal urodynamic findings may protect the surgeon medicolegally and prepare patients for a less than perfect outcome. However, for the typical vaginal repair of a posthysterectomy VVF, de novo detrusor instability is rare.

Anatomic Considerations

Posthysterectomy fistulae are usually supratrigonal and medial to both ureteral orifices. Vaginally, this corresponds to the cuff. Fistulae from obstetric causes are typically larger, more distal, and may be associated with urethral injury. Obstetric fistulae have been classified according to their anatomic location in relation to the cervix. They may have a single channel or multiple channels. There may be a single orifice on one side that tracks to multiple orifices on the other side, although this presentation is very unusual (Fig. 39.2). Cystourethroscopy and possible hysteroscopy are absolutely indicated before surgical repair to delineate the anatomy of the fistula or fistulae.

Preoperative Care

Cystitis, vaginitis, and perineal dermatitis should be treated with the appropriate antibiotic. Acute cystitis is uncommon in conjunction with a VVF; therefore, suppressive antibiotic therapy is unnecessary unless upper tract infection is suspected. Perineal care is important and makes the patient more comfortable and tolerant of delayed closure. Frequent pad changes are required to minimize inflammation, edema, and vulvar irritation. Incontinence products are much preferred over menstrual hygiene products because incontinence products are designed for the larger volume associated with drainage of urine and the low viscosity of urine. Zinc oxide ointment or a cream containing lanolin may be especially helpful in the treatment of perineal and vulvar dermatitis. Inventive collection and drainage
systems have been described for this purpose as well. Green and Philips described using dental prosthetic techniques to create a vaginal appliance to control urinary incontinence resulting from a VVF. Another system has been fashioned by gluing a Pezzier catheter to a fitted contraceptive diaphragm with rubber cement (Fig. 39.3). This device traps urine in the vagina and diverts it to a collecting leg bag. It may be worn for the weeks or months before repair is carried out.

Every attempt should be made to divert the urinary stream to protect the perineum and allow the fistula margins to mature. In fact, fistulae <5 mm in greatest dimension may close with catheter drainage alone. In a series of urogenital fistulae referred to a tertiary unit, 7% closed without the need for surgery (Hilton, unpublished data).

Medical therapy as an adjunct to surgery also is important. In the case of the malnourished patient, healing is improved if nutrition needs are optimized and anemia corrected before surgery. Some have described the preoperative use of steroids to reduce tissue inflammation. Despite earlier reports of efficacy, no convincing evidence exists that steroid therapy improves tissue quality before closure or that repair is more likely to be successful. In theory, steroid therapy could even interfere with healing when an early repair is attempted. The authors do not use steroids as an adjunct for these reasons. Estrogen therapy may be used to improve tissue thickness and vascularity provided there are no contraindications. Hyperbaric oxygen has been described as an adjuvant to surgery for radiation-induced fistulae.

Timing of Repair

The timing of repair remains controversial. The traditional belief is to wait a minimum of 3 to 6 months after the inciting event or the last attempt at repair. The delay allows the inflammatory or necrotic fistula margins that are thought to be responsible for surgical failure to resolve and the outcome of cancer therapy to be reevaluated. This interim period of waiting is often very distressing for the patient. O’Conor has said, “A surgeon must stand firm in his conviction that an impatient patient is easier to manage than a surgical failure.” Wein and colleagues have attributed surgical failures to an inadequate delay until repair. Lee and colleagues recommended delaying surgery to increase the success rate of the first attempt at repair. Symmonds recommends generally waiting 3 to 4 months for the tissues to “clean up,” lose their edema, and obtain good vascularity and pliability. In a series from Duke University Medical Center, Berlin and colleagues had a 100% cure rate with an average time to repair of 16 weeks.

Transvaginal repair of VVF within a few weeks of diagnosis was first reported in 1960 by Collins and associates. Patients received 100 mg of cortisone three times daily for 10 to 12 days preoperatively. Of 15 patients without a history of pelvic malignancy or radiation therapy, 13 (87%) had successful repairs. Of 15 patients without a history of pelvic malignancy or radiation therapy, 13 (87%) had successful repairs. In this series, 3 of 5 (60%) patients with cervical cancer and radiation-induced fistulae had recurrences within a brief postoperative period. Eleven years later, these same authors reported a 28% failure rate in a series of patients, all of whom had a transvaginal repair and preoperative steroids within 60 days after diagnosis. The experience with steroids and early closure was again updated in 1984 as O’Quin in an abstract for the Society of Pelvic Surgeons with a series of 54 patients, 11% of whom required a second procedure for successful repair. Persky and associates, also advocates for early repair, reported a series of seven patients who all underwent successful transvesical repair using interposition grafts of peritoneum or omentum within 10 weeks of the antecedent surgery. Cruikshank also had success in 10 of 11
fistulae in his series repaired between 10 and 35 days after a hysterectomy. None of these latter series used preoperative stent therapy. Treatment should be tailored to the individual patient. If the fistula is recognized within the first 88 hours postoperatively, the tissue should be more mobile, have less inflammation, and be amenable to early repair. Fistulectomy arising later usually are considered to be secondary, inflamed, significant, and in a post-irradiation setting. An interval of 3 months from injury to repair in obstetric and surgical fistulae allows inflammation and edema to resolve. As long as 1 year may be required for improvement in the tissues in radiation-induced fistulae before repair; that is, it is difficult to determine accurately when radiation necrosis has run its course. The outcome of prolonged catheterization alone for small fistulae is unpredictable. Large fistulae may be easier to repair once the tract is allowed to scar and edema resolves. On the other hand, the delay of closure may have a significant negative impact on a patient’s quality of life.

The principles outlined for VVF repair also are applicable to urethrovaginal fistulae. Because the urethra has a minimum of redundant tissue with which to work, the tissues must be as near to normal as possible before a repair is undertaken. A delay of several months usually is recommended to allow tissues to completely heal and for inflammation to resolve.

### SURGICAL TECHNIQUE: VESICOVAGINAL FISTULA

Surgery is the mainstay of therapy for urogenital fistulae. Following the tenets of Sims, Symmonds proposed several surgical principles to improve the success rate of fistula repair: (a) wide mobilization of the vaginal epithelium to expose the bladder; (b) excision of all scar tissue, even at the risk of increasing the size of the fistula in an attempt to create a “fresh bladder injury”; (c) infiltration of the vaginal epithelium with saline or a dilution solution of epinephrine (1:200,000) may aid dissection; (d) a tension-free layered closure of the bladder and the vagina; (e) good hemostasis; and (f) bladder drainage postoperatively. These principles are the same for fistulae involving the urethra. Although most authors agree that the best chance at closure of the fistula is the primary attempt, staged procedures have been described. Unfortunately, no controlled trials of route or timing of repair are available to guide management, and the general view is for individualized management.

In most cases, the gynecologic surgeon will favor the vaginal approach, which avoids the potential morbidity associated with abdominal surgery and is believed to provide a quicker recovery and a more cosmetic result. Because it does not require a laparotomy, it is considered to be easier, safer, and more comfortable for the patient. Success rates of 98% and 100% have been reported in two of the larger series. Although an abdominopubic approach has traditionally been favored for larger fistulae, fistula located high on the posterior wall, fistula adherent to the ureters, and concurrent intraabdominal pathology, the usual postsurgical fistula is low in the bladder and easily accessible in the anterior vaginal wall. However, an attempted vaginal repair of a fistula high in an immobile vaginal vault may be limited by visibility and lead to a less than satisfactory result. The abdominal route of repair offers benefit in this circumstance.

The approach of the ureter also may require an abdominal approach to facilitate ureteral reimplantation. Laparoscopy is necessary in fistulae requiring bowel for augmentation cystoplasty. In certain circumstances, a combined vaginal and abdominal approach may be helpful. The authors have described a combined approach to the repair of a large fistula secondary to a vaginal foreign body that involved the trigone.

There is no consensus concerning the need to excise the fistulous tract. Some authors advocate its total removal, whereas others prefer to merely debride the margins, thereby avoiding an increase in the size of the defect and associated morbidity. Elkins and others believe that the vascularization of the bladder provides a ready blood supply to the repaired fistula and advocate the excision of the fistula tract and vaginal cuff scar. This step enables the surgeon to suture viable tissues in every layer to promote wound healing, obviating the need for interpositional flaps or grafts. They reported a 100% cure rate on first attempt. In their series of transvaginal repairs, Raz and associates did not excise the fistula tract in any patient and had no apparent adverse effects. Cruikshank did not excise the tract in a series of 31 patients and had a 100% cure rate. Zacharin warns that excision of the fistula scar markedly increases the risk of operative failure. Elkins and colleagues and Lawson also advised against excising the tract in large obstetric fistulae.

### APPROACH FOR VESICOVAGINAL FISTULA REPAIR

Patient positioning for greater visualization of the fistula edges is a matter of physician preference and some debate. Most prefer lithotomy position for a typical fistula at the vaginal cuff. However, Elkins and others feel that adequate visualization, especially of the proximal urethra and bladder neck, can best be achieved by the knee-chest or Lawson position. Dropping the head of the table and elevating the buttocks may further facilitate exposure. Technical difficulties encountered at surgery are likely to be avoided by optimal exposure and accessibility of the fistula rather than a change in specific instrumentation. Because the vaginal walls normally are very pliable, retraction usually is sufficient for adequate exposure of the fistula. However, a constricted vaginal introitus, scarring of the vagina, a narrow subpubic arch, or a deep and fixed vaginal vault may limit exposure. An epistomy or a Schuchardt’s incision may allow improved access to the cuff in these situations. In current practice, many surgeons hesitate to use these incisions because of the increased morbidity. However, such incisions are invaluable and should be made without hesitation if exposure and accessibility are improved. In addition, the surgery may be facilitated by the placement of stay or traction sutures at the margins of the fistula or gentle traction on a Foley or Fogarty catheter placed through the fistula. These techniques help to identify the fistula’s edges and may bring the tract closer to the surgeon. The Young prostatic retractor may be used in a similar fashion. Infiltration of the vaginal epithelium with saline or a dilution solution of epiinephrine (1:200,000) may aid dissection and decrease oozing. This latter technique is not our current practice for repair of fistulae. The two transvaginal repairs commonly performed are the flap-splitting technique and the Lawce procedure. The flap-splitting technique involves wide mobilization of the vaginal epithelium from the edges of the fistula. Following this, the bladder is closed with a submucosal line of interrupted Lambert sutures, which is followed by a second layer in the muscularis that reduces tension on the previous suture (Fig. 39-4). Trigonal defects should be repaired in a transverse direction. A vertical closure at the trigone may draw the ureters to the midline and lead to kinking or frank obstruction. This

A: Ureters have been catheterized. An incision through the vaginal epithelium is made circumferentially around the fistula. B: The vaginal epithelium is widely mobilized from the bladder. The scarred fistula tract should be excised. C: A continuous (or interrupted) delayed-absorbable suture inverts the mucosa into the bladder. D: A second suture line is placed in the muscularis layer to reinforce the first. Vaginal epithelium is trimmed and approximated.
The need for a cystogram before the vagina 24 hours postoperatively and drain the bladder with methylene blue or indigo carmine. We prefer to leave a pack in surgery by filling the bladder with 200 cc of fluid colored with be watertight. The integrity of the repair may be tested during vaginal tissue.

A pedicled flap of vaginal wall was presented recently as a which may be particularly useful in postradiation or large, traumatic fistulae. The gracilis muscle provides a bulky closure and interference with sexual function should be minimal. Furthermore, vaginal depth expands once the patient resumes intercourse.

Interposition flaps or grafts may be used in large or recurrent fistulae, those involving the urethra or bladder neck, or fistulae requiring additional bulk. Pedicle flaps bring additional blood supply, improve the lymphatic drainage, and distance suture lines. In 1928, Martius first described the use of the labial fat pad as an interposition graft. The vascular supply to the graft informs primarily from the external pudendal artery and superiorly from the external pudendal artery. In mobilizing a labial fat pad pedicle, the surgeon must preserve one of these vascular bundles (Fig. 39.6). Birkhoff and colleagues reported a 100% success rate in six patients with transvaginal repairs of VVF using the Martius technique. In a series mostly of postobstetric repairs, the success rate was 87.5% for simple VVF, 71% for complex VVF, and 80% for fistulae requiring ureteral reimplantation. Ureteral reimplantation, although it makes the operation more complicated and time-consuming, does not seem to significantly worsen the prognosis. Nesrallah and associates reported 100% success in a series of 29 women with VVF, 34% of whom had undergone at least one prior attempt at fistula closure.

Cetin and colleagues described a modification of the O’Conor technique that limits the amount of bladder dissection. A small vertical anterior cystotomy is created to facilitate exposure (Fig. 39.7). Both the bladder and vagina are closed in layers. Stay sutures are placed on either side of the incision to facilitate closure. Advantages include a reduced need for extensive dissection and the ability to tailor the graft to the patient’s anatomy and proximity to the ureteral orifices to the fistula. The repair was accomplished without the need of ureteroneocystostomy, and 90% of the women were cured.

The use of vascularized tissue grafts is helpful in assuring a successful abdominal repair. Omental flaps are excellent in this regard. In fact, one third of omental aprons may reach the deep pelvis without creating a flap. The omentum has a dual blood supply and may be mobilized based on either the right or left gastroepiploic arteries. A large omental flap allows a vagina to be constructed in the abdomen, the ability to elevate the fistula into the surgical field with a vaginal handle, and the ability to perform cystoscopy.

O’Conor and coworkers pioneered an abdominal technique that can be performed extravaginally or intraper vaginally. The bladder is biected, and the posterior wall of the bladder is widely mobilized from the vagina through the vesico vaginal space. The fistula is excised, leaving margins of viable tissue for closure. Stay sutures are placed on either side of the incision to facilitate exposure. The success rate was 87.5% for simple VVF, 71% for complex VVF, and 80% for fistulae requiring ureteral reimplantation. Ureteral reimplantation, although it makes the operation more complicated and time-consuming, does not seem to significantly worsen the prognosis. Nesrallah and associates reported 100% success in a series of 29 women with VVF, 34% of whom had undergone at least one prior attempt at fistula closure.

Cetin and colleagues described a modification of the O’Conor technique that limits the amount of bladder dissection. A small vertical anterior cystotomy is created to facilitate exposure (Fig. 39.7). Both the bladder and vagina are closed in layers. Stay sutures are placed on either side of the incision to facilitate closure. Advantages include a reduced need for extensive dissection and the ability to tailor the graft to the patient’s anatomy and proximity to the ureteral orifices to the fistula. The repair was accomplished without the need of ureteroneocystostomy, and 90% of the women were cured.

B: The vaginal epithelium is mobilized approximately 2 cm from the fistula. C: Delayed-absorbable interrupted mattress sutures are placed parallel to the edge of the fistula tract to invert it into the bladder. D: One or two additional rows of suture approximate the muscularis fascial layer of the bladder. E: The vaginal epithelium is closed transversely with interrupted delayed-absorbable sutures.

Minimally Invasive Management

Minimally invasive approaches center on the use of endoscopy and natural orifice access. Sotelo and associates described laparoscopic repair of VVF in 15 patients who had clear malignant etiologies. All repairs with grafts (12) were successful without regard to etiology, whereas only 16 of 25 (64%) of repairs without grafts were successful. The authors concluded that transabdominal VVF repairs should be performed with an interposition flap regardless of the appearance of healthy surrounding tissues and etiology.
indications for surgical treatment. Hysterectomy was the prior surgery in 14 patients (93%). The technique involved cystoscopy, catheterization of the VVF, laparoscopic cystotomy, dissection of the vesicovaginal space, opening and excising the fistulous tract, cystotomy and colpotomy closure, and use of an interposition graft. None of the cases required conversion to laparotomy. Operative time, hospital stay, and duration of bladder drainage were comparable to open techniques. Only 1 of 14 patients (7%) had a recurrent postoperative fistula. Chibber and colleagues also reported excellent results when the O’Conor technique is performed via the laparoscopic

approach. McKay has described successful repair of VVF using transurethral suture cystorrhaphy. A 5-mm laparoscopic sleeve, for passage of the suture, is inserted alongside a 17F cystourethroscope with a 30-degree lens. Extracorporeal knot tying similar to other endoscopic suturing techniques is used.

Techniques that do not require suture have been used because of the difficulty of extracorporeal knot tying. Successful occlusion of a VVF with fibrin glue was first reported by Petterson and colleagues in 1979. Because the patient also had continuous bladder drainage for 8 weeks, some questioned the etiology of the success. Recently, Sharma and colleagues reported successful treatment of urinary tract fistulas in eight patients who underwent a single endoscopic injection of fibrin glue. Retrograde endoscopic injection of fibrin glue would appear to offer an efficacious alternative to traditional options for small defects and may avoid the morbidity of open surgery. Electrosurgical fulguration of small VVF followed by continuous drainage has been reported to be successful by Stovisky and associates and Falk and Orkin. Recently, Dogra and Nabi described the use of an endoscopic Nd:YAG laser to fulgurate a small 2- to 3-mm posthysterectomy VVF. They refer to the procedure as a “laser welding.” Whether the denuded tract closed spontaneously after the 3-week period of continuous drainage or was truly welded remains a matter of conjecture.
Urethrovaginal Fistula

Damage to the urethra that leads to loss of structural integrity is fortunately uncommon. Parturition, gynecologic surgery, pelvic radiotherapy, pelvic trauma, and sexually transmitted infections that are associated with tissue destruction are common antecedent events. Complications of surgery for urethral diverticulum, cystocele, or urethral hypermobility lead the list and account for more than 90% of urethrovaginal fistulae. Indeed, some 15% to 20% of women who have surgery to remove a suburethral diverticulum develop a fistula. The remainder is preceded by intrapartum obstetric events, especially operative vaginal delivery, pelvic radiotherapy, and traumatic disruption.

A urethrovaginal fistula may present with a variety of symptoms, but new onset urinary incontinence is almost always the trigger for diagnostic evaluation. Fistulae involving the proximal urethra and bladder neck present similarly to VVF. Midurethra fistulae may present with stress incontinence, recurrent cystitis, or no symptoms. Patients with distal fistulae may be asymptomatic or report a spraying urinary stream. The algorithm for evaluation of fistula is similar without regard to its etiology.

Most fistulae are easily seen on physical examination. However, when inspection does not reveal the fistula, additional studies are needed. A double balloon urethrogram may reveal an otherwise undemonstrated fistula by increasing pressure in the urethra and forcing fluid through the opening. Because urethrovaginal fistula may be complex and associated with injuries to bladder and ureters, the integrity of the entire urethral tract must be assessed with radiographic imaging, such as cystogram, voiding cystourethrogram, and intravenous pyelogram. The location of the fistula and its relationship to the urethrovaginal junction is assessed with cystourethroscopy. Knowing the relationship of the fistula to the bladder neck and to the point of maximum urethral pressure will help predict postoperative incontinence.

In general, the surgical principles for repair of VVF also apply to the correction of a urethrovaginal fistula. Likewise, because urethrovaginal fistulae are relatively uncommon, the surgical approach, timing of repair, and postoperative management lack standardization. The repair of a urethrovaginal fistula is more difficult than for simple VVF. Extensive urethral loss and lack of viable tissue may make conventional layered closures impractical, if not impossible. The success rate of urethrovaginal fistula repair is reported to be 73% to 100%.

Urethral reconstruction of a large defect begins by making a U-shaped flap of vaginal epithelium exposing the underside of the trigone and sphincter. The length of the flap roughly approximates the length of a normal urethra. The flap is rotated forward (Fig. 39.8). After the flap of vagina is mobilized, the vaginal incision is extended caudally 6 to 7 mm wider than the urethral defect and for a distance equal to the length of the flap. The vagina is then mobilized laterally.

The original flap is rotated so that the raw edges of the flap may be sutured to the denuded area of the urethral remnant. When this step is completed on both sides, an epithelial-lined conduit is formed that serves as a neourethra. Because the pedicles are relatively long, they are very susceptible to ischemia and subsequent necrosis. Thus, a layer of paravaginal fascia is plicated beneath the new urethra for support and additional blood supply. Two or three deep sutures are placed in the region of the sphincter and, when tied, will tighten the internal orifice. Approximation of the lateral edges of vaginal epithelium buries the newly constructed urethra and completely closes the wound.

Symmonds described another technique for urethral reconstruction in which an incision is made in the anterior vaginal wall and is extended around the margins of the urethral defect. No more than 2 mm of vaginal epithelium remains attached to
FIGURE 39.8. Reconstruction of urethra and repair of sphincter. A: A U-shaped incision is made through the vaginal epithelium. B: The flap is mobilized and rotated over the fistula. Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

buttock have been advocated for especially large defects. The anterior bladder wall can be mobilized via a retropubic approach through the vagina and used to fashion a neourethra. An alternative method is to harvest patch grafts from the detrusor and to use the patch to form a tubular structure. Not enough data is available to prove that one of these techniques has a clear advantage over another. Therefore, use of these grafts is individualized to meet individual patient needs.

When using an abdominal approach, the urethra may be reconstructed using the bladder. Fernandes has reported tubularizing an anterior advancement flap of bladder to reconstruct an entire urethra. Omo-Dare has used patch grafts of bladder mucosa for urethral reconstruction after gonococcal stricture with some success. The use of a tubularized rectus abdominis muscle flap has also been described in a series of refractory urethrovaginal fistula patients, all of whom had undergone at least one unsuccessful repair incorporating a Martius graft.

A pedicle graft may be appropriate to eliminate tissue tension, fill a defect in the vagina, reestablish vascularity, and enhance cosmesis. For the most part, Martius grafts are used for this purpose. The principles are similar to when they are used for VVF.

FIGURE 39.9. Reconstruction of total or partial loss of the urethral floor. A: A line of incision is made along the margins of the roof of the urethra and extended to the bladder base. B: The urethral margins and fascia are mobilized from the vagina to permit tension-free approximation of the urethral mucosa. C: Urethral edges are approximated over a 12F catheter with interrupted delayed-absorbable sutures. Mobilized urethral fascia is sutured on each side of the total length of the urethra. D: The lower strand of each suture is tied beneath the urethral floor, and the upper strands of the two sutures are used to pull the fascia beneath the urethra, where they are tied. (Continued)

Urinary Diversion and Reconstructive Techniques

In irreparable or recurrent urinary tract fistulas and cloacal defects following high-dose irradiation therapy for gynecologic malignancies, urinary diversion is the last resort to achieve a socially acceptable solution. An early technique of urinary diversion was implantation of the ureters into the sigmoid colon. Kidney failure, metabolic and electrolyte disturbance, and increased risk of colon cancer at the site of ureteral anastomosis led to its disfavor. Uretersigmoid implantations are rarely performed in the United States but continue to be used in developing countries. Ureteral implantation into an isolated ileal loop...

The vaginal mucosa between the urethral operative site and the labial graft is resected. G: The skin margins of the labial graft are sutured to the vaginal margins. The labial defect is closed.
POSTOPERATIVE CARE

Postoperative care issues center on urinary drainage and resumption of coitus. Duration of urinary drainage and choice of transurethral or suprapubic routes are determined by the extent of scarring, character, and repair history. In general, the longer the drainage, the less likely the bladder wall is to heal adequately. An adequate time for drainage ranges from 6 to 12 weeks. Transurethral drainage is the preferred method for small fistulae, whereas suprapubic drainage is employed for large, external, and high fistulae. Drainage is continued until there is excellent healing at the repair site, and except for patients with other major surgical procedures or for those with a high incidence of surgical complications, transurethral drainage is preferred.

The role of bladder injury antecedent to fistula formation seems obvious; thus, much of the effort in preventing VVF is directed at reducing the incidence of bladder injury. However, fistulae occur after gynecologic surgery. The risk of bladder injury is substantially higher at laparotomy, especially in the presence of fistulae. The role of bladder injury antecedent to fistula formation is also the subject of much research, and it is clear that interventions designed to minimize bladder injury are essential to the prevention of fistulae. The principles of fistula surgery are well established: visualization of the tract, a tension-free watertight closure, assurance of adequate vascularization, and protection of the ureters. Modern imaging techniques are increasingly being used in novel ways in other fields, but their utility in the detection of urogenital fistulae does not surpass conventional methods for urinary fistulae. Radioimaging—including pyelogram, cystogram, and voiding cystourethrogram—is used to assess the complexity of the fistula and potential involvement of the ureters. Preoperative cystourethroscopy should be used to evaluate the anatomic relationship of the fistula.

Optimal management regarding timing of repair and surgical approach remains undecided. Laparoscopic repair of VVF is a feasible and efficacious minimally invasive alternative for its management. Minimally invasive approaches seem most appropriate for small, uncomplicated fistulae. Obstetric fistulae remain common in developing countries where access to adequate health care is limited, and fistulae in industrialized nations typically occur after gynecologic surgery.

The role of bladder injury antecedent to fistula formation seems obvious; thus, much of the effort in preventing VVF relies on protecting the bladder at the time of surgery or delivery. The risk of bladder injury is substantially higher at laparoscopic surgery and antincontinence surgery. Despite preventive measures and good surgical technique, these injuries result in a significant number of cases where bladder injury is sustained. It is therefore essential to develop and implement strategies to minimize bladder injury in these settings. The principles of fistula surgery are well established: visualization of the tract, a tension-free watertight closure, assurance of adequate vascularization, and protection of the ureters. Modern imaging techniques are increasingly being used in novel ways in other fields, but their utility in the detection of urogenital fistulae does not surpass conventional methods for urinary fistulae. Radioimaging—including pyelogram, cystogram, and voiding cystourethrogram—is used to assess the complexity of the fistula and potential involvement of the ureters. Preoperative cystourethroscopy should be used to evaluate the anatomic relationship of the fistula.
still occur. Even when cystotomy is recognized and repaired, a fistula may arise. Because fistula formation is multifactorial, defining the benefit of individual preventive strategies is virtually impossible.

**BEST SURGICAL PRACTICES**

- Transvaginal repair is the preferred method of repair when available.
- Interposition grafts can be used for tissue bulk and as a source of neovascularity. They may also be used to expand the vagina when caliber or depth is compromised. They may also enhance postoperative continence.
- The abdominal approach should be reserved for situations in which access to the fistula is limited. When the abdominal approach is chosen, the O’Connor technique as modified by Cotin and associates is a technique favored by many surgeons.
- Interposition grafts can be used for tissue bulk and as a source of neovascularity. They may also be used to expand the vagina when caliber or depth is compromised. They may also enhance postoperative continence.
- The abdominal approach should be reserved for situations in which access to the fistula is limited. When the abdominal approach is chosen, the O’Connor technique as modified by Cotin and associates is a technique favored by many surgeons.
- An interposition graft of peritoneum or omentum seems to enhance overall success.

**ACKNOWLEDGMENT**

The authors wish to thank Dr. John Thompson for his enormous contribution to the previous editions of this text.

CHAPTER 40 ■ ANAL INCONTINENCE AND RECTOVAGINAL FISTULAS
MICHAEL P. ARONSON AND RAYMOND A. LEE

DEFINITIONS

Anal incontinence—Involuntary loss through the anus of flatus, liquid, or solid stool that is perceived as a social or hygienic problem.

External anal sphincter—Striated muscle sphincter, under voluntary control, that is responsible for much of the squeeze pressure in the anal canal.

Extra-anal incontinence—Involuntary loss through a fistula of flatus, liquid, or solid stool.

Fecal incontinence—Involuntary loss through the anus of liquid or solid stool only; excludes flatal incontinence.

Internal anal sphincter—Thickened continuation of the circular smooth muscle layer of the bowel, under autonomic control, that is responsible for much of the resting pressure in the anal canal.

Pubococcygeus muscle—Striated muscle medial portion of the levator ani that is responsible for maintaining and increasing the anorectal angle and contributes to the squeeze pressure in the anal canal.

Puborectalis muscle—Thickened continuation of the circular smooth muscle layer of the bowel, under autonomic control, that is responsible for much of the resting pressure in the anal canal.

Puborectal fold—Epithelial lined connection between the rectosigmoid or anal canal and the vagina or perineum.

No symptom of pelvic floor dysfunction is more debilitating or has greater psychosocial impact on a woman than that of anal incontinence. The inability to control solid stool, liquid, or gas can have a devastating effect on a woman’s feelings of self-worth, sexuality, and ability to be an active social participant in her community. The evaluation and treatment of the anal incontinent patient is a challenging but rewarding task because relief of these symptoms can greatly improve the quality of a patient’s life. Because the problem of anal incontinence is multifactorial, the approach to the problem is often multidisciplinary, involving health care providers from gynecology, colorectal surgery, and gastroenterology, as well as nutrition and physical therapy. Anal incontinence is part of a spectrum of disorders of defecatory function that includes constipation, incomplete evacuation of the bowel, urgency, frequency, and painful defecation. Outcomes of treatments should be understood in terms of their impact on a patient’s symptoms and quality of life, not purely on anatomic results.

Although anal incontinence has a major impact on a patient’s quality of life, most individuals are reticent to discuss this symptom with their health care providers. Johanson and Laterry report that more than 50% of women with anal incontinence will never present to a health care provider with their problem. The prevalence of both anal and fecal incontinence is difficult to establish as there has been a lack of uniform definitions used in past studies. The 3rd International Consultation on Incontinence in Monaco in 2004 defined anal incontinence as involuntary loss of flatus, liquid, or solid stool that is perceived as a social or hygienic problem. Fecal incontinence excludes flatal incontinence and represents the loss of liquid or solid stool only. Boreham and colleagues, in a multicenter study of 457 consecutive women presenting for routine general gynecologic care, found anal incontinence in 28.4% with irritable bowel syndrome, constipation, age, and body mass index identified as significant risk factors. In a questionnaire study designed to reflect the age and sex distribution of the adult population of Germany, Giebel and associates found anal incontinence in 19.6% and fecal incontinence in 4.8% (specifically incontinence of solid stool). In a review, Macmillan and colleagues found the prevalence of fecal incontinence to be between 2% and 13% of community-dwelling adults.

There are no data regarding the incidence of anal incontinence in the community-dwelling population, but Chassagne and associates reported on an elderly, long-term-care facility population. They enrolled 1,386 individuals 60 years of age or older who did not have anal incontinence. After 10 months, 20% had developed anal incontinence. They identified five significant risk factors: history of urinary incontinence, neurologic disease, poor mobility, severe cognitive decline, and age older than 70 years.

It is well established that the presence of anal incontinence is associated with the presence of urinary incontinence as well as pelvic organ prolapse. The connective tissue and muscular and neurologic elements of the pelvic floor function in concert with the organs they support as an interdependent unit to provide multiple functions simultaneously. In a cross-sectional community-based study involving 762 randomly selected women age 50 or older, Roberts and colleagues found 15% had anal incontinence, 48% had urinary incontinence, and 9% had both. Viewed another way, 60% of those with anal incontinence had concurrent urinary incontinence. Among patients presenting to a urogynecology clinic for evaluation of urinary incontinence, a high proportion have dual incontinence, defined as concurrent urinary and anal incontinence. Lerner and associates (1999) found 28% of 409 patients in France, and Gordon and colleagues found 28% of 283 consecutive patients in Israel, had dual incontinence. Nichols and coworkers looked at 100 patients with stage II or greater pelvic organ prolapse and/or urinary incontinence. Fifty-four percent had concomitant anal incontinence, and 52% had anal sphincter defects by ultrasound. Clearly because the pelvic floor uses some common elements in maintaining support and continence of feces and urine, it follows that injury to one mechanism could simultaneously affect the other.

An important development has been the beginning of an understanding of the relationship of vaginal birth to the problem
of anal incontinence. In a review, Sultan and associates noted a reported 6.6% to 14% prevalence of anal incontinence in vaginally parous women. In a more recent prospective study of 949 consecutive women delivering vaginally, Eason and colleagues found at 3 months postpartum that 26% percent had anal incontinence and 3% had fecal incontinence. As tools for treatment of this problem have limited success, it becomes apparent that future research should focus on the prevention of childbirth injuries that can contribute to anal incontinence.

In this chapter, we examine the anal continence mechanism in an effort to understand how damage may be sustained. Particular emphasis is placed on the effect of childbirth on the anatomic and neurologic aspects of that mechanism. We then review the evaluation of the anally incontinent patient as well as medical and surgical treatment options. Finally, we consider the etiology, evaluation, and techniques for surgical repair of extraanal incontinence of feces through a rectovaginal fistula.

ANAL CONTINENCE MECHANISM

Normal anal continence requires the coordinated control of the multiple synergistic elements summarized in Table 40.1. An anatomically and neurologically intact anal sphincter complex is necessary to keep the anal canal closed effectively. Intact reflex arcs and anorectal sensation are necessary for the individual to perceive rectal filling and discriminate the nature of rectal contents. Intact motor enervation is essential so that the sphincter mechanism can respond appropriately to the increased need for anal closure such as during straining or coughing. The puborectalis muscle must be capable of reflexive contraction at the moment of need to increase that angle and move rectal contents. The anal sphincter complex and the rectal mucosa must be capable of reflexive contraction at the moment of need to increase that angle and move rectal contents off the sphincter complex into a capacious and distensible rectal reservoir. Lastly, gastro-intestinal considerations such as colonic motility and stool consistency need to be reasonable for maintenance of continence. The complete interrelated mechanisms of defection and anal control are more easily visualized once the principal elements of the anatomy related to continence are delineated.

Anatomy of the Anal Canal and Related Structures

The anal and rectal regions of the lower colon share a common embryologic origin: the posterior portion of the endoderm of the cloaca. During the development of these regions, the terminal end of the alimentary canal is surrounded by muscular sphincters of somatic origin. Thus, the anorectal region is composed of both visceral and somatic components. The visceral components include the rectum, internal anal sphincter, and lining of the upper part of the anal canal. The voluntary or somatic components are the epithelium of the lower part of the anal canal as well as the striated muscles of the floor and the external anal sphincter. The rectal mucosa consists of mucous-secreting columnar goblet cells, which invaginate to form tubular glands. The mucosa is surrounded by a muscularis mucosa and an inner circular layer of smooth muscle. This circular smooth muscle layer thicken distally to become the internal anal sphincter. An outer longitudinal layer of smooth muscle transitions distally into fibrous fascicles that travel between the internal and external anal sphincter and insert into the perianal skin, thus anchoring the sphincter complex and creating the puckering effect seen on clinical examination.

The anal canal in the female is approximately 2.5 to 4 cm in length and normally remains completely collapsed because of the tonic contractions of the sphincters. Posterior to the anal canal is the coccyx, from which it is separated by intervening fibrofatty tissue. The levator ani muscles are posterior to the canal until it opens onto the perineal skin. The levator muscles also separate the lateral boundary of the anal canal from the ischiorectal fossa, through which pass the important nerves, lymphatics, and blood supply of the terminal rectum, anal canal, and perineum. The canal is fused anteriorly with the lower portion of the rectovaginal septum and perineal body (Fig. 40.1).

The lining of the anal canal is nonuniform. The proximal 1 cm is lined by rectal-type columnar mucosa, followed by modified or stratified columnar epithelium for about 1.5 cm. The distal half of the anal canal is lined by squamous epithelium, which is richly supplied by branches of the inferior hemorrhoidal nerves and is exquisitely sensitive. The anal mucosa, like the rectum, is also surrounded by the inner circular layer of smooth muscle, which is in turn surrounded by the outer longitudinal layer. The main blood supply to the rectum and anal canal is from branches of the superior and inferior hemorrhoidal arteries.

The anatomic sphincter mechanism of the anal canal has been a matter of controversy since first described by Galen almost 2,000 years ago. It is most often thought of as consisting of three separate anatomic structures: the internal anal sphincter, the external anal sphincter, and the action of the most medial portion of the levator ani, the puborectalis muscle (Fig. 40.2).

The circular smooth muscle layer of the rectal wall, which is under autonomic control, thickness at the proximal anal canal to form the internal anal sphincter. It can be identified on dissection or at the time of third- or fourth-degree obstetric laceration repair as a thick, fibrous, white layer between the anal mucosa and the external anal sphincter. The internal sphincter accounts for about 70% of the resting tone of the anal canal and is innervated by the autonomic nervous system, providing continuous involuntary muscle tone. The remainder of the resting tone of the anal canal is thought to be provided by the slow twitch fibers of the external sphincter and the hemorrhoidal complexes.

The portions of the anatomic continence mechanism that are under voluntary control are the striated muscles of the external anal sphincter complex and the medial puborectalis portion of the pubococcygeus muscle, which courses behind the rectum in a slinglike fashion. Unlike most other striated muscles, the external anal sphincter and the puborectalis muscle

MECHANISMS OF ANAL CONTINENCE

The portions of the anatomic continence mechanism that are under voluntary control are the striated muscles of the external anal sphincter complex and the medial puborectalis portion of the pubococcygeus muscle, which courses behind the rectum in a slinglike fashion. Unlike most other striated muscles, the external anal sphincter and the puborectalis muscle...
Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas

maintain a constant muscular tone that is directly proportional to the volume of rectal contents. The tone of the puborectalis muscle wrapping around posterior to the junction of the rectum and the anal canal produces what is called the anorectal angle. The fibers of pubococcygeus that do not wrap around go on to form the fibrous anococcygeal raphe, often referred to as the levator plate, which inserts onto the last two segments of the coccyx. Willful contraction of structurally and neurologically intact puborectalis and pubococcygeus muscles, along with the rest of the levator sling, can increase the anorectal angle and support the levator plate and the rectal reservoir above it in a horizontal axis to aid in maintenance of continence.

The external anal sphincter complex is thought by different anatomists to be composed of one, two, or three parts. Most anatomists agree, however, that the entire external anal sphincter complex is enervated by perineal branches of the pudendal nerves emanating from S2–4. Although some authors refer to a three-part sphincter as having superficial, medial, and deep portions (Fig. 40.2), clinically the entire external sphincter responds to the same enervation and functions as a single
Anal Incontinence and Rectovaginal Fistulas

Squeeze pressure
Resting pressure
Rectal pressure

**FIGURE 40.3.** Anal manometry demonstrating pressures in the anal canal. Rectal pressure reflects intraabdominal baseline pressure recorded in the rectal reservoir. Resting pressure essentially reflects the effect of the involuntary, smooth-muscle internal anal sphincter. Squeeze pressure largely reflects the transient contractile effort of the voluntary, striated external anal sphincter.

The subcutaneous part of the external sphincter is small and inserts in the perianal skin. The superficial part is more substantial and is attached posteriorly through the anococcygeal raphe to the coccyx. The deep portion is intimately related to the puborectalis muscle posteriorly, where its fibers loop around the anorectal junction. The external anal sphincter and puborectalis muscle are responsible for most of the voluntary squeeze pressure that is exerted in the anal canal (Fig. 40.3).

To review, the puborectalis muscle originates from the pubic bone on either side of the midline, passes behind the vagina and rectum, and fuses posteriorly behind the anorectal junction to form a U-shaped sling around the rectum. Some fibers interdigitate with the walls of the anal canal (Fig. 40.4). The constant resting tone of the puborectalis muscle pulls the anorectal junction anteriorly to create an approximately 90-degree angle between the rectum and anal canal, thereby maintaining anorectal continence of solid stool by closing the rectal inlet. Both the puborectalis muscle and the external anal sphincter contain a majority of type I (slow-twitch) muscle fibers that are ideally suited to maintaining constant tone over time. Each muscle also contains a smaller portion of type II (fast-twitch) fibers, which allow them to respond quickly during sudden increases in intraabdominal pressure. The external anal sphincter is enervated by branches of the pudendal nerve (S2–4). The puborectalis muscle is enervated directly by the S3–4 pelvic nerves, as well as possibly by collateral branches of the pudendal nerve.

Classically, the female anal sphincter complex has been thought of as forming a broad band of tissue posteriorly but narrowing to a small tubular bundle of tissue anteriorly within the perineal body. In the past, the internal sphincter has most often been portrayed as a minor structure. These concepts came from many centuries of anatomic study of cadavers augmented by observations in the delivery room, at the time of third- and fourth-degree laceration repairs, of the transected ends of the anterior portion retracted into round holes in the perineal body. In the recent past, it has become possible to view this anatomy undisturbed in living, continent, nulliparous subjects with magnetic resonance imaging (MRI). In an early MRI study, Aronson and colleagues found the shape of the combined internal and external anal sphincter complex to be nearly cylindrical as it encircles the anal canal. Measured in the midline, the anterior portion of the anal sphincter complex appeared as a broad band of tissue, not a narrow tube. In this study, 54% of the anterior thickness was smooth muscle of the internal anal sphincter. Subsequent studies, including the cadaver studies of DeLancey et al. (1997), found a similar shape with a substantial contribution from the internal anal sphincter. This substantial anterior anal sphincter length and thickness, as well as the contribution from the internal sphincter, is important to keep in mind during primary repair of obstetric lacerations as well as in surgical

**FIGURE 40.4.** Function of the anal sphincter and puborectalis muscle. A: At rest, the constant tone of the puborectalis muscle pulls the anorectal junction anteriorly to create an approximately 90-degree angle between the rectum and anal canal, closing the rectal inlet and maintaining continence of solid stool. At moments of need, this muscle can be contracted further, increasing the angle and supporting the stool bolus over the levator plate. B: During defecation, the puborectalis muscle relaxes, opening the rectal inlet, while intestinal peristalsis and the voluntary increase in intraabdominal pressure move stool into the anal canal. The anorectal angle is decreased and the stool bolus is lined up over the anal canal.
correction of anal incontinence secondary to a chronic perineal laceration.

The tone of the levator ani muscle is stabilized by the skeletal muscles of the anterior compartment of the urogenital diaphragm, and by the bulbocavernosus and transverse perineum muscles, which have a common insertion into the central perineal body between the anus and vaginal introitus. The perineal body is an important anatomic structure that is closely associated with the external anal sphincter and anal canal, and includes the insertion of two components of the transverse perineal muscles: a superficial and a deep muscle layer, both composed of striated muscle. The central raphé of the perineal body serves as a pivot point giving rise to the transverse perineal muscle, the terminal end of the bulbocavernosus muscles, the external anal sphincter, and, to an extent, the medial aspect of the levator ani or the puborectalis muscle (Fig. 40.1). Trauma or separation of the perineal raphé causes relaxation of the perineal body, which is attached to the external anal sphincter. The resulting alteration of attachment may contribute to loss of control of both liquid stool and gas.

**Physiology of Anal Continence**

Anal continence is dependent on the complex interaction of many physiologic and anatomic factors. Often the focus is on the anatomic and neurologic aspects of continence that obstetricians see damaged in the labor room and attempt to repair. However, many factors essential to continence are actually quite distant from the pelvic floor. They can include problems with stool volume and consistency, colonic transit time, rectal capacity, and rectal distensibility. For example, a severe malabsorption syndrome delivering massive quantities of stool of a liquid consistency that is difficult to manage can overwhelm even a normally adequate continence mechanism. The rectum also needs to be capacious and distensible to serve as a storage vessel so that the timing of defecation may be consciously deferred. A patient with a radiation-damaged and fibrotic rectum may lose that capacity. An individual must also possess adequate mental faculties to recognize the need for evacuation, as well as sufficient mobility to transfer to an appropriate location for willful defecation to remain continent. Although the relative importance of these factors has not been defined, it seems clear that for the normal patient with a normal consistency for willful defecation to remain continent. This theory has been questioned. Defecography studies have not confirmed the relationship of the anorectal angle to anal continence, just as the surgical restoration of the normal anorectal junction angle with a Parks postanal repair, or retrorectal levatorplasty, has not been consistently associated with the return of continence.

For defecation to occur, the puborectalis muscle must voluntarily relax while intestinal peristalsis and a voluntary increase in intraabdominal pressure allow the stool to move downward into the anal canal (Figs. 40.4B and 40.5B). Of note is when denervation of the pelvic floor musculature occurs, the muscles relax, lining up the rectum onto the fattyubic sphincter complex just as during an act of normal defecation. This relationship is unfavorable to continence and may contribute to incontinence, especially in patients with compromised sphincter function.

The internal and external sphincters maintain continence below the level of the puborectalis muscle. As discussed, they are particularly important in the control of liquid stool and gas. At rest, the anal canal is kept closed by the baseline tone of the internal sphincter and the constant tonic activity of the external sphincter. When stool enters the rectum, the rectum accommodates or relaxes, allowing it to hold stool until defecation is socially convenient. Stool in the rectum also triggers relaxation of the internal anal sphincter by the involuntary rectoanal inhibitory reflex before defecation is perceived (Fig. 40.6). This reflex relaxation of the internal sphincter allows the bolus to enter the proximal anal canal where discrimination of the solid, liquid, or gaseous nature of the bolus by the sensory-rich upper anal canal occurs. Subsequently, rectal distension and the presence of stool in the anal canal are consciously perceived. This leads to voluntary contraction or relaxation of the pelvic floor muscles to maintain continence or permit defecation, respectively. These two sensory mechanisms—awareness of the degree of rectal distention and the ability to discriminate the nature of intestinal contents—are crucial to maintenance of continence.

As rectal filling continues, the internal sphincter contracts once again to facilitate anal closure. If defecation or passage
Anal Incontinence and Rectovaginal Fistulas

FIGURE 40.5. A: Lateral defecography of normal continent patient deferring defecation by contracting puborectalis sling, increasing anorectal angle, and exerting squeeze pressure in anal canal. Note how barium bolus is supported over levator plate and away from the fatigable anal sphincter complex. B: Lateral defecography of normal continent patient willfully defecating by relaxing puborectalis sling, decreasing anorectal angle, and decreasing pressure in the anal canal. Note how barium bolus becomes lined up over anal canal.

of gas is inconvenient, the external sphincter and puborectals muscle can be firmly contracted. This helps force rectal contents back into a capacious and distensible rectal reservoir supported over the levator plate. Striated muscle, such as the external sphincter and puborectals, can only be contracted maximally for approximately 1 minute; by the end of 3 minutes, most of the force of contraction is diminished (Fig. 40.7). Injury to the internal sphincter that results in loss of tonicity of the anal canal may permit the involuntary passage of liquid stool and gas. Such an injury is particularly noticeable when the urge to defecate is persistent from a bolus of fecal material in the terminal rectum and when the voluntary contraction of the external sphincter and puborectalis muscle wanes.

FIGURE 40.6. Rectoanal inhibitory reflex. Arrival of stool in the rectum triggers reflex relaxation of the internal anal sphincter, allowing the bolus to enter the proximal anal canal, where discrimination of the solid, liquid, or gaseous nature of the bolus by the sensory-rich upper anal canal occurs.

CAUSES OF ANAL INCONTINENCE

The Effects of Vaginal Birth

Although numerous causes of anal incontinence are summarized in, a major factor is obstetric injury to the pelvic floor in healthy adult women. Vaginal birth may compromise the continence mechanism by direct anatomic injury to the anal sphincters, puborectalis sling, perineal muscles, and perineal fascia. DeLancey and associates (2003) and Dietz and Lanzarone demonstrate—in MRI and ultrasound studies, respectively—significant damage to the puborectalis sling associated with vaginal birth. Kearney and colleagues show an association of these defects with use of forceps (odds ratio [OR] 14.7), anal sphincter rupture (OR 8.1), and use of episiotomy (OR 3.1). Nerve injury may occur in some women as well and play a significant role. These injuries, either separately or in combination, can lead to some degree of anal incontinence. Other risk factors have been also defined. In a study of identical twin sisters, Abramov and associates identify age, menopause, obesity, parity, and stress urinary incontinence as major associated risk factors for anal incontinence.

Third- or fourth-degree obstetrical laceration of the anal sphincter complex is highly associated with subsequent development of anal incontinence. In a population-based, retrospective study at more than 2 million vaginal deliveries, Handa and coworkers found an anal sphincter laceration rate of 5.85% when preterm births, breech deliveries, stillbirths, and multiple gestations were excluded. Numerous case control studies report 6% to 44% of patients, after obstetric injury to the anal sphincter, have some degree of anal incontinence despite immediate surgical repair. Sultan and colleagues (1993) prospectively studied 20 consecutive pregnant women with multiple
modalities and found that although none of the nulliparas entering the study had a sphincter defect before delivery, 35% of primiparous women and 44% of multiparous women who delivered vaginally had an internal and/or external anal sphincter defect present postpartum. They found that anal incontinence in their study population was significantly associated with the presence of a sphincter defect. In a study of 808 vaginally delivered women in Sweden, Zetterstrom and associates found sphincter tears detected at delivery to be associated with nulliparity (OR 9.8), midline episiotomy (OR 5.5), fundal pressure (OR 4.6), postmaturity (OR 2.5), and increased fetal weight (OR 1.3). Of their subjects with primarily repaired sphincters, 54% reported at least “mild” anal incontinence at 5 months, and 41% still had symptoms at 9 months postpartum. In a 10-year follow-up of anal sphincter injuries, Fornell and associates found that subjective and objective anal function after injury deteriorates further over time and with subsequent deliveries. However, Nygaard and colleagues found, in a 30-year retrospective cohort study, that differences in anal incontinence between women with sphincter rupture, those with episiotomy and no rupture, and those who had cesarean delivery decrease with time from delivery to the point of equivalence.

The use of midline episiotomy is associated with anal sphincter rupture. Shiono and associates, using data from the Collaborative Perinatal Project, reported that midline episiotomy was associated with statistically significant 4.2-fold and 12.8-fold increases in the risk of third- and fourth-degree lacerations among primiparous and multiparous women, respectively. Studies by Green and Soohoo, Wilcox and

incontinence (0% vs. 24%), fecal urgency (3.7% vs. 32%), and sphincter with separate repair of the internal sphincter when recently, Fernando and colleagues, in a randomized controlled internal anal sphincter regardless of type of primary repair. Most subjects had a residual full-thickness defect present in their ex-

sphincter defects in study subjects versus controls. Forty percent of their study population demonstrated unsatisfactory outcomes. Poen and colleagues reported on long-term clinical and functional results of standard primary repair of third-degree lacerations. They found significantly diminished squeeze pressures and increased first sensation anal canal of continent subjects. With increasing age, the inter-

ural decline with aging in resting and squeeze pressures in the

nence is now understood to be neurogenic anal inconti-

Other Causes

A promoter of anal incontinence over time is the fact that the normal process of aging results in decreased efficiency of the anal sphincter complex. Hasdem and associates showed a nat-

ural decline with aging in resting and squeeze pressures in the anal canal of continent subjects. With increasing age, the internal sphincter generates a lower resting pressure, and the pro-

portion of fibrous tissue increases. The squeeze pressure able to be exerted by the external sphincter suffers a natural decline as well. Increasing age also is associated with prolonged pu-

dendal nerve terminal motor latencies (PNTMLs) and elevated rectal and anal sensory thresholds. Because of this, many pa-

tients with damaged continence mechanisms may be able to compensate for a period of time, but they go on to decom-

pensate secondary to these age-related changes and become incontinent.

Functional problems of the bowel, such as constipation or diarrhea, can result in incontinence. Chronic constipation with its repeated straining at stool can cause stretch-induced injury to pudendal enervation. Overall, the most common cause of anal incontinence in the elderly, particularly those who are in-

stitutionalized, is fecal impaction. Fecal impaction may cause, rather than prevent, lacerations. Mediolateral episiotomy is associated with third- or fourth-degree lacerations, 47 (92%) were caused by obstetric trauma. Even meticulously repaired lacerations will occasionally com-

pletely break down. This leaves the patient with an open cloacal deformity. Anal incontinence usually is a problem for these pa-

tients until the tissues are healed sufficiently to allow secondary repair. Repairs that appear on the surface to have healed satis-

factorily may have some internal persistent structural defects, such as partial separation of the sphincter muscle fibers, re-

vealed by ultrasound. The clinical significance of these small defects is not clear.

Another potential cause of persistent incontinence, even af-

ter successful anatomic repair of the anal sphincter, is dener-

vation injury to the sphincter muscles. Snooks and colleagues (1984) demonstrated that there is physiologic evidence of den-

ervation of the sphincter in 80% of patients with anal inconti-

nence and an obstetric tear. In women who did not sustain any injury to the external sphincter during delivery, 42% had evi-

dence of denervation. These denervation injuries were strongly associated with a prolonged second stage of labor, forceps de-

livery, and a large fetus, suggesting that the mode of injury of the pelvic nerves may be from stretching of the nerves dur-

ing descent of the pelvic floor, from ischemic injury, or from direct compression of the nerves. Most of these individuals re-

enervate their pelvic floor over the first 6 months postpartum with improvement in their anal function. However, many do not gain full neurologic function. At present, there is no way to predict who will sustain damage or who will regain function. Much of what used to be termed “idiopathic” anal inconti-

nence is now understood to be neurogenic anal incontinence.

anal canal of continent subjects. With increasing age, the inter-

nal decline with aging in resting and squeeze pressures in the

sphincter laceration, Hammerer-Doak and col-

leagues found significantly decreased resting and squeeze pres-

sures in study subjects versus controls. Forty percent of study subjects were found to have sphincter defects present on ultra-

sound despite primary repair, and a trend toward continued ano-

rectal dysfunction was found in the laceration group.

The idea of a different repair using an overlapping tech-

nique for the external anal sphincter with a separate repair of the internal anal sphincter is the subject of some research interest at present. Sultan et al. (1999) published an initial ex-

perience with such a repair in 32 patients performed by two experienced surgeons with the patient moved to a well-lit oper-

ating room and given adequate anesthesia and antibiotics. At follow-up, all had apparent healing, 8% encountered inconti-

nence of flatus, 15% had persistent external sphincter defects on ultrasound, and 44% had persistent internal sphincter de-

fects. Fitzpatrick and associates prospectively randomized 132 primiparas who suffered a third-degree laceration to overlap-

ping versus approximation repair. At 3 months, they found no statistically significant difference in incontinence scores, anal manometry, or endoanal ultrasound. Interestingly, 66% of all subjects had a clinically significant thickness defect present in their ex-

ternal anal sphincter regardless of type of primary repair. Most recently, Fernando and colleagues, in a randomized controlled trial (1999) found unacceptably poor repair of the external anal sphincter with separate repair of the internal sphincter when needed was associated with a significantly lower rate of fecal incontinence (0% vs. 24%), fecal urgency (3.7% vs. 32%), and perineal pain (0% vs. 20%) compared with an end-to-end ap-

proach. In general, most of these studies imply that results of obstetric sphincteric rupture repair may be improved by op-

timizing standard surgical considerations, including lighting, exposure, adequate anesthesia, use of antibiotics, and proper aseptic surgical technique.

On occasion, the rectal mucosal portion of a repair will break down, which can result in rectovaginal fistula. In Hibbard’s series of 24 rectovaginal fistulae and 27 chronic per-

anal lacerations, 47 (92%) were caused by obstetric trauma. Even meticulously repaired lacerations will occasionally com-

pletely break down. This leaves the patient with an open cloacal deformity. Anal incontinence usually is a problem for these pa-

tients until the tissues are healed sufficiently to allow secondary repair. Repairs that appear on the surface to have healed satis-

factorily may have some internal persistent structural defects, such as partial separation of the sphincter muscle fibers, re-

vealed by ultrasound. The clinical significance of these small defects is not clear.

Another potential cause of persistent incontinence, even af-

ter successful anatomic repair of the anal sphincter, is dener-

vation injury to the sphincter muscles. Snooks and colleagues (1984) demonstrated that there is physiologic evidence of den-

ervation of the sphincter in 80% of patients with anal inconti-

nence and an obstetric tear. In women who did not sustain any injury to the external sphincter during delivery, 42% had evi-

dence of denervation. These denervation injuries were strongly associated with a prolonged second stage of labor, forceps de-

livery, and a large fetus, suggesting that the mode of injury of the pelvic nerves may be from stretching of the nerves dur-

ing descent of the pelvic floor, from ischemic injury, or from direct compression of the nerves. Most of these individuals re-

enervate their pelvic floor over the first 6 months postpartum with improvement in their anal function. However, many do not gain full neurologic function. At present, there is no way to predict who will sustain damage or who will regain function. Much of what used to be termed “idiopathic” anal inconti-

nence is now understood to be neurogenic anal incontinence.

A diarrheal state can result in anal incontinence even in a pa-

tient with normal anorectal function, owing to the presence of large quantities of liquid stool that may overwhelm a normally
functional mechanism. Neurologic disorders affecting sphincter control also may result in anal incontinence. Usually, the neurologic defect is widespread, and anal incontinence is but one manifestation.

Traumatic injury, more often a side-straddle injury in young girls, may result in simple or extensive laceration of the perineum. The extent of the injury may be difficult to determine because a patent, febrile, which may indicate chronic hemorrhage and hematoma formation. Examination under anesthesia is advisable so that appropriate repair can be made, looking carefully for lacerations of the anal sphincter and rectum as well as other structures. Hematoma dissection above the levator muscles must be ruled out with pelvic ultrasound and with careful rectovaginal examination under anesthesia. Above the levator muscles, there is nothing to impede the progression of a hematoma until the diaphragm is reached.

Rectal trauma from operative procedures can affect rectal capacity and compromise anal continence or perhaps lead to extramal incontinence through a rectovaginal fistula. Entry into the rectum may occur during posterior colporrhaphy, especially when the anterior rectal wall and posterior vaginal skin are closely adherent with little, if any, intervening connective tissue. Such an enteroctomy should be repaired transversely if longitudinal closure would compromise rectal capacity. A difficult hysterectomy, either abdominal or vaginal, may result in injury to the rectum, especially when dissection behind the cervix is difficult because of dense adhesions, induration tissue from infection, or involvement of the cul-de-sac and anterior rectal wall with endometritis. If the rectal defect does not heal properly or is not closed properly, a high recto-vaginal fistula may develop through the newly closed vaginal apex. Partial excision of anal sphincter and other muscles involved in maintaining anal continence may be required in such cases. Other causes of anal incontinence, as reported by Berek and others, include laceration of the anal sphincter, anal trauma, and radiation injury. Isolated cases have been reported by Berek and others. Injury to the anterior rectal wall may occur during hemorhoidectomy, excision of a Bartholin’s gland, or colotomy for pelvic abscess drainage. Forty to sixty percent of patients with rectal or rectal mucosal prolapse also have some degree of anal incontinence. Although this was originally thought to be secondary to a dilatation effect on the internal anal sphincter, there is often evidence of associated neurovascular damage to the external anal sphincter muscles as well. This has been confirmed by studies demonstrating prolonged PNTMLs in these patients. These individuals may present with a patulous anal sphincter, passive stretching of the puborectalis muscles, and a long history of straining with constipation. The tissue prolapse may be related to prolapsing internal hemorrhoidal tissue, rectal mucosa, or complete (full-thickness) rectal prolapse. Questions such as the frequency of occurrence of the prolapse, association with activity or defecation, estimated distance of the prolapsed tissue from the anus, spontaneous or manual reducibility, and history of incarceration may be helpful in better defining the type of problem. Patients may have relatively occult prolapse of tissue, which can manifest as mucous or brownish staining in the underwear with occasional blood.

On physical examination, it is important to note the following:

Malignant tumors may erode through the tissues between the vagina and the rectum. When a patient with tumor involvement of the rectovaginal wall receives radiation, sloughing of the tumor may result in a rectovaginal fistula. Radiation also may cause a rectovaginal fistula through a retained cervix. Rarely, anal incontinence may be congenital, as seen in one of 5,000 newborn girls who have an imperforate anus with associated fecal incontinence through a congenital rectovaginal or rectoenteric fistula. Total rectal agenesis is rare. Paul and Lloyd reported hindgut duplication with a congenital rectovaginal fistula; however, most anal incontinence is acquired. Finally, although anal incontinence may be termed idiopathic in about 10% of women, the mechanism of incontinence in these women is usually secondary to pelvic floor denervation. In summary, although an intact and functional anal sphincter complex and puborectalis sling are important in the maintenance of anal continence, it must be remembered that a variety of other factors are involved, including intact anorectal sensation and reflexes, rectal capacity and distensibility, reasonable colonic transit time, appropriate stool volume and consistency, and adequate patient mental function and mobility.

**EVALUATION OF ANAL INCONTINENCE**

A careful history and physical examination are vital to eliciting the presence of, delineating the cause of, and guiding the
Patients are reticent to discuss problems of anal incontinence. A survey of 666 patients in a general genecologic outpatient clinic in Switzerland by Faltin and colleagues found that 5.6% had anal incontinence. Of those individuals, only 20% had ever reported this symptom to a health care provider. For this reason, patients should always be asked during a history about specific symptoms of anal incontinence in a nonthreatening way that helps them overcome feelings of embarrassment and invites discussion.

Once a history of defecatory dysfunction is elicited, the examiner should attempt to differentiate true incontinence from other conditions. A symptom diary can be useful both for diagnosis as well as monitoring progress during treatment. Perianal leakage of material other than stool can occur because of prolapsing hemorrhoids, anorectal neoplasms, or sexual or anorectal surgery, number of vaginal deliveries, a history of prolapsed hemorrhoids, anorectal neoplasms, or sexual or anorectal surgery, number of vaginal deliveries, a history of prolonged labor, use of forceps, and significant perineal laceration. (Anal incontinence is rarely the presenting symptom in patients with spinal cord lesions.) Pelvic examination should include a neurologic examination to identify occult neurologic disease. Patients are reticent to discuss problems of anal incontinence. A symptom diary can be useful both for diagnosis as well as monitoring progress during treatment. Perianal leakage of material other than stool can occur because of prolapsing hemorrhoids, anorectal neoplasms, or sexual or anorectal surgery, number of vaginal deliveries, a history of prolonged labor, use of forceps, and significant perineal laceration.

Physical examination should include a general screening neurologic examination to identify occult neurologic disease. (Anal incontinence is rarely the presentating symptom in patients with spinal cord lesions.) Pelvic examination should include a careful inspection of the posterior vaginal wall, perineum, anal sphincter, anal canal, and rectum, including assessment of the patient’s function as well as anatomic. A patulous anus indicates a major loss of sphincter function and can be associated with rectal prolapse. Most obstetric injuries are associated with an anterior segmental defect in the external anal sphincter and may appear as the loss of the perineal body, loss of the corrugated appearance surrounding the anus, or attenuation of the rectovaginal septum. In some instances. In more subtle cases in which the perineal body appears intact but the external sphincter is actually separated, there may be only the dimples of the laterally retracted ends of the anal sphincter muscles apparent. This produces a “divertail” appearance, as described by Toogood and Delaney, in which the normal radial distribution of the anal erases is absent anteriorly but is present laterally and inferiorly. If there is a question as to the presence of a segmental defect, endosonral or transperineal ultrasound can be useful in delineating the anatomy. Next, a screening examination to increase our understanding of anorectal anatomy and function; however, their precise clinical role still remains somewhat unclear. Many of the above studies are most useful in patients with idiopathic anal incontinence or persistent incontinence after a failed surgical repair.

Once the diagnosis is in doubt, the ability to retain an enema argues for the presence of a small fistula orifice. When the fistula is small, it may be localized by the presence of feces in the vagina or by the posterior vaginal walls. The vaginal opening of a fistula may be localized by the presence of fecal material on the perineal skin or by the dark red rectal mucosa seen protruding at the fistulous opening. As the rectum is distended with air by a syringe attached to the Foley catheter with a 10-mL balloon is inserted into the anus while the posterior vaginal wall is painted with a concentrated solution of soap and water, or, alternatively, the vagina can be filled with water. As the rectum is distended with air by a syringe attached to the Foley catheter, the vaginal orifice of the fistula may be localized by the presence of bubbles forming at the fistula site. A small probe may then be passed along the fistula tract. Alternatively, when a rectovaginal fistula is suspected but cannot be identified, radiologic studies such as a vaginogram or fistulogram may identify a fistulous tract. These studies are superior to barium enema for identifying a fistula because they use a thin, water-soluble atmosphere instead of thick barium solution. As such, although fistulae occasionally may be identified by barium enema, the intraluminal pressure of the bowel often is inadequate to force the barium solution.
through a small fistula opening. In addition, the presence of barium in the lower bowel may obscure a fistula tract.

When a rectovaginal fistula is diagnosed, it is important to complete a thorough assessment of the anal sphincter and pelvic floor as well because these patients may have multiple defects. If not properly evaluated preoperatively, the patient may undergo successful repair of her fistula only to become anally incontinent postoperatively. Her compromised sphincter function may have been adequate preoperatively when excess pressure was bypassing the sphincter through the fistula. After her fistula is repaired and the full force of rectal contents is delivered to the sphincter complex, there may not be enough sphincter function to maintain continence. A full treatment of rectovaginal fistula management appears later in this chapter.

A thorough digital rectal examination should be performed. Any rectal mass must be noted and the stool consistency assessed. A gross assessment of the patient’s resting and squeeze pressures within the anal canal and her ability to contract her levator ani muscles should be included. Anal sphincter tone should be evaluated with the patient at rest and during sphincter contraction. An anterior sphincter defect may be easily detectable as the loss of the palpable muscular ring within the perineal body. Even in the absence of external anal sphincter muscle anteriorly, a scarified band of tissue can remain that completes the contractile ring and helps the patient maintain continence. Next, the anorectal axis can be assessed. On rectal examination, the puborectalis muscle is palpable posteriorly at the junction between the rectum and the anal canal. By directing the examining finger posteriorly, the angle between the anus and rectum can be estimated and should approximate 90 degrees in a normal woman. More important, when the patient is asked to squeeze the sphincter, the puborectalis muscle should pull the examiner’s finger anteriorly toward the pubic bone.

The cause of anal incontinence can be identified in most cases by using these guidelines for careful evaluation of the perineum, posterior vaginal wall, pelvic floor muscles, external anal sphincter, and rectum. In the young parous patient, obstetric injury to the anterior anal sphincter complex is most often apparent on physical examination. One exception is the integrity of the internal anal sphincter. It cannot be assessed adequately by physical examination alone, but can be determined by radiologic and physiologic tests. A defect of the internal sphincter can be assumed, however, if there is significant thinning of the rectovaginal septum. In many of these cases, both the internal and external anal sphincters are injured. Certainly, the patient with a cloacal deformity by definition has a segmental defect of both sphincters. From a practical and technical viewpoint, the internal anal sphincter cannot be repaired unless the external sphincter also is repaired. Surgery is rarely effective for an isolated defect of the internal sphincter. When surgical repair of the external anal sphincter is indicated, however, one should consider repairing defects in the internal sphincter as well.

Testing

Clearly, many patients will have a diagnosis and be ready to proceed to treatment after their history and physical examination. For others, the picture will be less clear. There may be questions about a particular patient that thoughtful use of testing can answer. Is a segmental defect present at the internal or external anal sphincter? What is the functional status within the anal canal? Is rectal sensation normal? Is the eversion to the striated musculature of the continent mechanism intact? How does the patient actually defecate: Are rectoceles, enteroceles, or sigmoidoceles interfering? Is intussusception involved? Judicious use of testing based on the information needed to arrive at an accurate diagnosis and to plan successful treatment can be important.

Anal Imaging

Endoanal, transvaginal, and transperineal ultrasound techniques have made it simple and relatively inexpensive to identify defects in both the internal and external anal sphincters. These defects can go clinically unrecognized, but may be amenable to surgical repair. Endoanal endosonography is one radiologic technique for assessing posttraumatic defects of the internal and external anal sphincters. High-resolution images of the separate sphincter muscles are obtained using a rotating endprobe, and anatomic defects can be identified as a loss of continuity of the muscle rings (Fig. 40.8). Several studies have found that anal endosonography correlates well with needle EMG mapping of sphincter defects, manometric mapping of sphincter defects, and intraoperative findings. Ultrasound is less time-consuming than EMG or manometry and much more comfortable for the patient. Other studies have established that transvaginal ultrasound is equally efficacious to endoanal ultrasound in identifying sphincter defects. Peschers and colleagues described normal sphincter and puborectalis anatomy as well as defects in both the internal and external sphincters using coaxial ultrasonography: a conventional 3-MHz convex transducer placed on the perineum. Ultrasound currently is the study of choice for establishing the presence or absence of a segmental anal sphincter defect. The approach chosen—endoanal,

![FIGURE 40.8. Endoanal ultrasound image of an anally incontinent patient with a segmental external anal sphincter defect. Probe, endoanal ultrasound probe; M, anal mucosa; IAS, internal anal sphincter; EAS, external anal sphincter; defect, segmental defect of external anal sphincter. (Photograph courtesy of Justin A. Maykel, MD.)](Image)
Anal manometry provides information regarding function, sensation, compliance, and the presence of intact reflexes within the anal canal and distal rectum. The first part of this test is essentially a pressure profile of the anal canal, providing information on the functional status of the internal and external anal sphincters. Some computer-based, multichannel manometry equipment can provide graphic cross-sectional analysis of the anal canal to help detect the presence of segmental sphincter defects.

The test usually is performed with the patient in the left lateral decubitus position without any special bowel preparation. There are many different protocols for performing anal manometry. Most commonly, a fluid-filled pressure catheter with radial side ports located 90 degrees apart circumferentially is connected to pressure transducers, and a recording device is used to measure the anal canal pressures during rest and during voluntary contraction of the anal sphincter (Fig. 40.9). These pressures may be recorded either as the pressure catheter is slowly pulled through the anal canal—a station pull-through technique—or at static points along the anal canal as the pressure catheter is pulled out in certain increments, usually every 0.5 cm. The average pressure measured at rest in the anal canal to help detect the presence of segmental sphincter defects is the resting pressure, and the highest pressure recorded along the anal canal with the patient at rest is the maximum resting pressure. The increase in pressure over the basal canal pressure initiated by voluntary contraction of the anal sphincter is the squeeze pressure, and the highest such increment is the maximum squeeze pressure. The resting anal canal length is measured from the point at which the anal sphincter pressure continuously exceeds the average intrarectal pressure by 4 mm Hg. The squeeze response is a reflection of the internal anal sphincter function, whereas the squeeze pressure reflects the strength of the external anal sphincter voluntary contraction (Fig. 40.3).

A second part of anal manometry testing is the evaluation of rectal sensation. A balloon is placed in the rectum and incrementally distended. The minimum perceived volume, the volume causing the urge to defecate, and the maximum tolerable volume are recorded. Measurements of pressures within the balloon allow the calculation of rectal compliance. The presence of a reflex rectal contraction after a bolus of air is introduced into the balloon, followed by the return to normal baseline pressures as the rectum accommodates, is noted. Most healthy patients have a minimal perceived volume of about 30 cc and a maximum tolerable volume of about 300 to 350 cc, although this can be highly variable. When the rectal capacity is 200 cc, however, procitosis is often found.

“Normal” range for maximum resting pressure is 40 to 80 cmH2O and for maximum squeeze pressure is 100 to 200 cmH2O; however, there is tremendous overlap in values between patients who are continent and those who are incontinent. As a group, incontinent patients have lower values on anal manometry testing than continent patients, although there is no discriminatory level that can be used to predict incontinence. It has been suggested that patients with a maximum resting pressure of <20 cmH2O and a maximum squeeze pressure of >40 cmH2O are unlikely to be continent. Sentovich and colleagues found decreased resting and squeeze pressures in 97% of patients with a history of anal sphincter injury. Poon and associates found significantly decreased maximum squeeze pressures and also found first sensation of filling to be significantly increased in 40 subjects who had third-degree lacerations primarily repaired with controls. They also found that 35 (88% percent) of these subjects still had sphincter defects present on endoanal ultrasound despite apparently successful healing of their repair. Gearhart and colleagues were unable to demonstrate any single preoperative manometric parameter that was predictive of outcome following sphincteroplasty.

FIGURE 40.9. Anal manometry perfusion catheter. An open-tipped perfusion catheter with radial side ports located every 0.5 cm (arrows) records anorectal pressures. Distention of the balloon at the end of the catheter is used to determine rectal sensory thresholds and to elicit the rectoanal inhibitory reflex.
Pelvic Floor Electromyography

Pelvic floor EMG evaluates the pelvic floor muscles for evidence of nerve injury. The smallest functional neuromuscular unit is the motor unit, and injury to nerves or muscles produces characteristic changes recorded in the motor unit action potentials. Conventional needle EMG involves placing a small needle with a recording electrode into the muscle being studied. The firing pattern of the motor units is assessed as the needle is being inserted, during spontaneous muscle activity, and during maximum voluntary contraction of the muscle. The characteristics of the recordings can then be evaluated. Single-fiber EMG allows the recording of action potentials from individual muscle fibers of a motor unit. When nerve injury occurs, there is often denervation but with a change in fiber density. The denervation is more diffuse and results in less effective muscle contraction than the original active reinnervation. When these studies indicate nerve reinnervation, therefore, it reflects prior nerve damage that has healed. Needle EMG studies also can be used to map specific anatomic defects of the external anal sphincter but, as stated previously, this function currently is more often fulfilled by ultrasound studies.

Nerve conduction velocities, which are the actual speed of conduction of the action potential along the nerve, are another measure of nerve function. The nerve conduction velocity can be calculated by measuring the nerve latency, which is the delay between the stimulation of the nerve at a specific point and the response in the target muscle supplied by the nerve. Standardized latencies for most peripheral nerves have been established. Evaluation of PNTML, as developed by Snooks and colleagues, is of interest in patients with anal incontinence. The pudendal nerve is stimulated as courses behind the ischial spine into Alcock’s canal, and the time is measured until a response is detected in the external anal sphincter. Prolonged PNTMLs indicate nerve damage; however, this test only reflects the conduction time of the healthiest axon remaining in a nerve. Therefore, normal PNTMLs do not confirm a lack of damage to the whole nerve. The only test that can conduct a response normally. Cheong and colleagues found pudendal neuropathy in 16% (21 bilateral, 15 unilateral) of 223 patients (174 women) presenting with anal incontinence. Osterberg and associates found a correlation between fiber density and clinical and manometric variables in 72 continent patients (63 women), but failed to find a correlation with PNTML. Vaccaro and coworkers found pudendal neuropathy to be an age-related phenomenon in patients with anal incontinence and constipation. A finding of prolonged PNTML may be of clinical significance; however, normal PNTMLs do not exclude the possibility of neurologic damage. Although PNTML testing is in use by many centers, it may lack sensitivity and specificity for detection of external anal sphincter weakness caused by pudendal nerve damage. The American Gastroenterological Association’s (AGA) medical position statement on anorectal testing techniques states that “although interesting from a research point of view, the clinical usefulness of this test is controversial. … The PNTML cannot be recommended for evaluation of patients with anal incontinence.”

Although suggestion of neurologic injury may be identified by careful physical examination, neither ultrasound nor anatomic manometry is helpful in identifying neuropathic patients. Identification of such patients is important. In the presence of neurologic damage, patients are less likely to have a good functional response to operations designed to restore anal incontinence, even when the anatomic result appears completely successful. Knowledge of a patient’s pelvic floor neurologic status can be particularly useful for counseling her on what to expect after surgical repair. Although the presence of pudendal neuropathy implies a poorer prognosis for the potential sphincteroplasty patient, it does not mean that many such patients could not derive significant improvement in their continence. Chen and colleagues found in a small group of patients undergoing sphincteroplasty that, based on continence scores, the one patient with no neuropathy had an excellent result; of seven patients with unilateral pudendal neuropathy, 70% had a good to excellent result and 30% had a fair to poor result; whereas in four patients with bilateral neuropathy, half had a good to excellent result and the other half scored fair to poor.

Defecography

Defecography is a radiologic evaluation of the lower gastrointestinal tract. It was used initially in the evaluation of patients with defecation disorders; but more recently, it has been used as part of the evaluation of anal incontinence. The rectum of the patient is filled with a barium-oatmeal or potato starch paste mixed to a consistency to approximate semisolid stool. The patient then is seated on a special commode chair and asked to defecate during fluoroscopy. Lateral radiographs usually are taken before, during, and after evacuation of the rectum (Fig. 40.3). Alternatively, cinedefecography can be performed, which is a videotaped dynamic fluoroscopic study.

The anorectal angle can be observed, as can the effect of willful contraction of the puborectalis muscle on this angle. It also provides information about rectal emptying and the mobility of the rectal wall. Anatomic abnormalities of the gastrointestinal tract not previously identified, such as intussusception, rectal prolapse, and rectal ulcers, can be detected by defecography. Now it is possible to perform a response in the study known as the anorectal angle measurement. The anorectal angle measurement is more often fulfilled by ultrasound studies. The anorectal angle can be observed, as can the effect of willful contraction of the puborectalis muscle on this angle. It also provides information about rectal emptying and the mobility of the rectal wall. Anatomic abnormalities of the gastrointestinal tract not previously identified, such as intussusception, rectal prolapse, and rectal ulcers, can be detected by defecography. Now it is possible to perform anorectal angle measurement.
sphincter weakness and predict response to biofeedback train-
ing; (e) rectal and anal sensory testing; and (f) testing of rectal
compliance. Procedures of possible value for an individual pa-
tient might include (a) surface EMG for evaluation of sphincter
function and evacuation proctography or (b) cine-dfecography,
when rectal prolapse is suspected. Testing procedures that are
counterintuitive for the clinical evaluation of anal incontinence
are the use of PNTML testing for an assessment of the presense
of pudendal nerve function and (b) MRI, because of its expense.

NONSURGICAL THERAPY OF
ANAL INCONTINENCE

The goal of nonsurgical therapies is to minimize the threat to
continence from intestinal contents by managing stool consis-
tency and maximizing the patient's remaining levator ani and
sphincter function. Because surgical therapy has less than per-
fected outcomes, strong consideration should be given to try-
ing to optimize a patient's function before the decision for
surgery is made. Dietary manipulations and pharmacologic
agents may reduce flatus and liquid stools, and pelvic floor
exercises, biofeedback therapy, and electrical stimulation facil-
itate optimization of anal sphincter and levator ani function.

To reduce the challenge to the sphincter mechanism, all condi-
tions producing diarrheal states, such as inflammatory bowel
disease and malabsorption syndromes, should be treated di-
rectly. For constipated patients, a high-fiber diet and the addi-
tion of an osmotic laxative (e.g., sorbitol) may produce soft,
formed stools that are more easily managed by a compromised
sphincter mechanism. For patients with diarrhea, a low-residue diet
to reduce stool bulk and constipating agents such as loperamide or diphenoxylate with atropine are often
helpful. Patients should avoid foods that cause intestinal hyper-
motility as well as carbonated beverages and foods that tend
to produce flatulence. Many patients learn on their own that consti-
pation helps them with continence and maintain themselves in
a constipated state for many years before presenting to a health
care practitioner. Santoro and associates studied amitriptyline
for both its ability to slow colonic transit time resulting in a
fatter stool that is passed less frequently, as well as improve
pressure dynamics in the rectal reservoir. They found signific-
ant improvement in symptoms as well as manometric param-
eters in the study group. In some patients, a system of planned
defecation with the use of glycerol suppositories or a daily tap
water enema may leave the rectum clean between evacuations
and decrease incontinence episodes. Pelvic floor rehabilitation through physiotherapy with
biofeedback, pelvic floor exercises, and electrical stimulation
may help improve anal sphincter and pelvic floor function.
These techniques are particularly helpful in patients with mild
pelvic floor denervation to maximize the strength and function
of the sphincter mechanism and levator sling. Rehabilitation
techniques may be useful as an initial conservative measure in
patients with recent obstetric trauma and evidence of pelvic
floor nerve injury. Some reenervation tends to occur over the
first 6 months postpartum in these patients. Those who are
not able to willfully contract their pelvic floor muscles imme-
diately postpartum because of transient nerve injury may best
benefit from electrical stimulation techniques. Pelvic floor re-
habilitation may be useful preoperatively to try to maximize
the outcome of a subsequent surgical repair. Patients who are
improved but not totally continent after surgical repair also
may benefit from these techniques to restore their margin of
continence.

Pelvic floor exercises, similar to the Kegel exercises per-
formed to improve urinary incontinence and pelvic support,
may improve the functioning tone of the external anal sphinc-
ter. Biofeedback therapy using an anal balloon or plug electrode
can facilitate the proper muscle contraction by measuring the
strength of the sphincter contraction with (a) the use of bio-
feedback to the patient with a visual demonstration of muscle function. Biofeed-
back therapy also has the advantage of being able to train pa-
tients to perceive decreasing volumes of air in the rectum and
to coordinate this with the contraction of the external anal sphincter. Biofeedback therapy has been reported to improve
anal incontinence in 50% to 90% of patients treated, with
most studies showing improvement in about 80% of patients.
Some effects of biofeedback training may be long lasting in re-
lation to anal incontinence. Eack and associates studied anal
incontinent patients treated with biofeedback versus controls
almost 10 years after treatment ended. They did not find
a lasting difference in prevalence of anal incontinence, but did
find a significant difference in severity of incontinence mea-
sured in number and frequency of incontinent episodes. The
success of biofeedback therapy seems primarily dependent on
the improvement in rectal sensation; manometric studies have
not consistently shown an increase in sphincter pressures af-

ter therapy. Suitable candidates for biofeedback therapy must
have some degree of rectal sensation and be able to contract
the anal sphincter voluntarily.

Transanal electrical stimulation can be used as an adjunct
to pelvic floor exercises in patients who are unable to contract
their pelvic floor muscles or who are unsuccessful with biofeed-
back therapy alone. An anal probe connected to a neuromus-
cular stimulation unit delivers a preset voltage to the external
anal sphincter to induce contraction of the striated sphincter
muscles. This technique causes minimal patient discomfort and
has been associated with a significant increase in the maximum
squeeze pressure following therapy, with subsequent improve-
ment in partial anal incontinence. It has not been successful in
patients with major incontinence of solid stool. Transanal elec-
trical stimulation also is unlikely to be successful in patients
with a severely denervated anal sphincter because of the degree
of irreparable end-organ damage.

SURGICAL THERAPY FOR ANAL
INCONTINENCE

Surgical procedures for anal incontinence are measured by
their impact on an individual's symptoms and quality of life.
 Cure (i.e., total continence of solid, liquid, and gas) is rarely
achieved. Papers that discuss surgical results for anal inconti-

ence procedures most often use significant improvement on an
incontinence scoring system scale as their criterion for success.

Most patients with anal incontinence who see an
obstetrician-gynecologist present with a specific anatomic de-
fect resulting from obstetric or postoperative trauma. These
patients suffer from a long-standing disruption of the perineal
body and anterior anal sphincter complex often called a chronic
perineal laceration (Fig. 40.10). Approaches to the surgical re-
pair of this problem are discussed at length in this chapter.

Treatment of patients with idiopathic, neurogenic, or recur-
rent incontinence without an anatomic defect requires a
specialized care and more advanced procedures. These patients
are most often referred to a colorectal surgeon or proctologist
with a special interest in this area. Although a full discussion of
In most cases of chronic perineal laceration with long-standing disruption of the anterior anal sphincter complex, classic symptoms include the progressive loss of control of gas and feces with a mean follow-up of 3 years. Setti Carraro and associates studied 34 postanal repair patients with a mean follow-up of 6.2 years. They found that only 9 (26%) had continence of solid and liquids and 5 of the 9 still leaked flatus. Recognizing that improvement may be a significant goal, it is important to note that 28 of the 34 subjects assessed their outcome as improved, with the remainder relating no change.

A total pelvic floor repair operation has been proposed that involves a postanal repair, a plication of the levator muscles anterior to the rectum, and a sphincteroplasty. This operation was studied by Deen and colleagues (1993) in a prospective, randomized trial. A total pelvic repair was compared with anterior levator plication plus sphincteroplasty alone as well as with postanal repair alone. They found at 6 and 24 months a significantly better outcome for the total pelvic repair than for either of the other two procedures.

**Chronic Perineal Laceration**

In most cases of chronic perineal laceration with long-standing disruption of the anterior anal sphincter complex, classic symptoms include the progressive loss of control of gas and feces from the anus. The severity of symptoms generally varies with the degree of perineal laceration and sphincter loss. If the puborectalis muscle is left intact and is well innervated and functional, it can provide sufficient muscular contraction to permit control of feces when the patient is constipated or when the stool is of normal consistency. Such patients quickly learn this and maintain a constipated state to decrease their symptoms. If the entire perineal body is disrupted, including the internal and external anal sphincters, and the posterior vaginal wall heals directly to the anterior rectal wall above the hymenal ring, then the patient is said to have a cloacal deformity. The concept was to plicate the levator ani together behind the anorectal junction to increase the anorectal angle and augment what was proposed as a "flap valve" mechanism for continence involving the levator plate. Since that time, the idea of a flap valve mechanism has been discredited. Keighley studied 105 patients who underwent this operation. With a follow-up of at least 6 months, he found that two-thirds had regained continence. Long-term results of the postanal repair have been disappointing. Matsuoka and colleagues found postanal repair successful in 7 of 20 (35%) patients based on a significant decrease in incontinence scores after a mean follow-up of 3 years. Regardless of which surgical approach is chosen, a preoperative mechanical bowel preparation is important. An oral bowel preparation should be given the evening before surgery is scheduled. If such a preparation is given the day of surgery, the patient may still be releasing stool during the operation. Although the patient may be given three doses of oral erythromycin, 500 mg, and neomycin, 1 g, the day before surgery, this may not be necessary in all patients.
To avoid 2 months of uncomfortable symptoms, some surgeons have advocated an earlier repair. The results of early repair of an external sphincter and rectal mucosal laceration or dehiscence were first reported in 1986 by Hauth and associates. Each patient was seen within 10 days of delivery with dehiscence of a repaired fourth-degree laceration. Patients underwent preoperative mechanical bowel preparation on admission, prophylactic antibiotics, and debridement appropriate to the extent of superficial infection and necrosis, and preoperative intravenous antibiotic therapy. A range of 1 to 6 days elapsed to allow preparation of the wound area before a layered closure was performed. The bowel was rested for 10 days after the repair. Seven of eight cases were successfully repaired, with complete healing, normal external sphincter function, and no dyspareunia. Similar good results with early repair of dehiscence of fourth-degree episiotomy in 22 patients were reported by Hankins and colleagues. The average hospital stay for debridement, intravenous antibiotic therapy, and repair was 15 days. Two patients developed postoperative rectovaginal fistula after early repair. Secondary repair in both cases was successful. Good results of early repair of dehiscence after mediolateral episiotomies, as opposed to midline episiotomies, have been reported by Monberg and Hammen.

A number of techniques have been described over the past 100 years for reconstruction of a complete chronic perineal laceration, including (a) the layered method of repair, the Warren flap procedure, and the Noble-Mengert-Fish operation. Today, some form of layered method of repair is performed most often. The internal rectal mucosa is intact and the injury is largely limited to the anal sphincter complex and perineal body, repair consists of anal sphincteroplasty with extensive perineorrhaphy. If the injury extends into the anal canal and involves the anorectal mucosa, this approach would essentially recreate a fresh fourth-degree perineal laceration, which would then be repaired in a standard layered fashion. Therefore, the initial layer of such a repair would include a suture line in the anorectal mucosa. This was a major disadvantage to the layered approach in these patients in the preantibiotic era. Today this does not represent a significant problem, although infectious complications do occur.

The Warren flap method, first described in 1882, avoids a mucosal incision in the anus, provides a pedicle graft of vaginal mucosa for enlargement of the perineal skin, and provides a more cosmetic result to the perineal body. However, the Warren technique offers no particular improvement in the correction of the muscular defect that produced the anal incontinence. The main advantage of the procedure is that a suture line is not created in the anal mucosa. With the Warren technique, the vaginal mucosa is turned backward and used as the new portion of the anterior wall at the end of the anal canal. The anal sphincter is then reaproximated over the inner portion of the vaginal flap, which remains attached to the anal mucosa. The Warren flap procedure is still used, although less frequently than when first described.

The Noble operation, or anal pull-through procedure, as it is more commonly called, also avoids creating a suture line in the anal mucosa. The procedure was described originally in 1902 by Noble, but received little attention until described again independently by Mengert and Fish in 1955. Noble’s original claims for the operation in the surgical era before the availability of antibiotics, blood banks, and modern advances in general anesthesia included (a) elimination of the danger of infection or fecal matter from the rectum in the surgical wound, (b) avoidance of the tediousness of dissecting a vaginal flap, (c) minimal blood loss, and (d) uniformly good results. The most important advantage was the absence of a suture line in the anterior rectal wall. Although performed much less frequently than a layered approach today, interest in this operation remains, particularly for the treatment of rectovaginal fistula. Veronikas and associates reported a 94% anatomic success rate and 77% excellent functional success rate in 34 patients treated with this operation for primary and persistent rectovaginal fistula.

Regardless of which approach is taken to repair a chronic perineal laceration in the patient with anal incontinence, it is the sphincteroplasty itself that is the keystone to the repair. Below we discuss techniques of anal sphincteroplasty as well as approaches to overall repair of a chronic perineal laceration.

The surgeon should keep in mind that the anal sphincteroplasty may be the most important part of the overall repair, especially when transanal incontinence is part of the indication for the operation.

**Anal Incontinence and Rectovaginal Fistulas**

Anal sphincter complex is a surgical challenge to repair because both the internal and external sphincters have a constant tone that begins pulling against the healing area almost immediately. Functional results from this surgery are far from perfect. The overlapping repair was proposed for the external anal sphincter in the hopes that the scarified ends of the torn sphincter would bolster support for the reparative sutures and not allow them to pull through, resulting in a better anatomic result and, in the hope, better functional results. The advantage in terms of outcome seems to favor the overlapping approach over the end-to-end approximation method; however, more data clearly are needed. Many studies of these operations are difficult to evaluate because the criteria for what constitutes success or cure often are poorly defined. Total continence of solid stool, liquid, and gas is not often achieved. Again, improvement in continence and quality of life may represent the best outcome measure.

Blaisdell, in an older report, and Arnaud and associates more recently, reported success rates of approximately 60% using the end-to-end approach. Using the overlapping technique, Stitzer and Thomson reported a 74% success rate in 27 women, most of whom had obstetric sphincter injuries. The continence rates after anal sphincteroplasty appear to diminish with time. Rothbarth and colleagues reported on 39 patients who had obstetric injuries and underwent overlapping sphincteroplasty. Their success rates were 77%, 67%, and 62% at 3, 9, and 12 months, respectively.

Three long-term follow-up studies of the degree and quality of continence after overlapping sphincteroplasties reflect the difficulty of the task at hand. Malouf and associates studied patients with a minimum of 5 years follow-up (median 77 months) and found that 23 of 46 patients (50%) had a successful outcome defined as no further surgery and episodes of urge fecal incontinence occurring once a month or less. Of the 23 patients judged to have a successful outcome, 15 had passive soiling, 17 had fecal urgency, 19 were incontinent of solid and liquid stool, and none were fully continent of stool and flatus. Halverson and Hull found in patients with a median follow-up of...
of more than 5 years that 54% were continent of solid or liquid stool, and 14% remained totally continent. Gutter-ree and colleagues reported on 130 patients with a median follow-up of 10 years. Sixty-one percent continued to have incontinence or required further surgery. Eight patients were totally continent.

The success rates for anal sphincter repair in patients with concurrent pudendal neuropathy are much lower than for those with intact enervation. Gilliland and colleagues looked at a large group of patients who had undergone an overlapping sphincteroplasty with a median follow-up of 2.4 years. They found that 62% of 59 patients with normal pudendal function had a successful outcome, compared with only 17% of the 12 patients with unilateral or bilateral prolonged PNTMs. Karoui and associates found success rates to deteriorate with time and reported that poor results also were associated with the presence of an internal sphincter defect.

The importance of the internal anal sphincter to continence is a subject of recent interest. It has long been known that this structure contributes most of the resting tone in the anal canal and helps to maintain our day-to-day continence. Pur-poseful lateral disruption of the internal sphincter to aid with anal fissure healing has been shown to be associated with the development of at least transient incontinence. Vaizey and as-sociates have identified primary degeneration of the internal sphincter as an independent cause of passive anal incontinence in some women with normal neurologic function and no obstetric trauma. It follows that repair of a disrupted internal sphincter should contribute to continence.

Little attention has been paid in the past to repair of the internal sphincter either at the time of initial obstetric injury or at the time of reconstruction of a long-standing injury. Repair of this smooth muscle structure that is tonically contracting against a closed lumen is a major challenge in the healing phase because it is to actually accomplish in the operating room. Preliminary reports regarding this repair are mixed. Abous-Zed reported on eight patients (two women) who had their ultra-sonically established internal sphincter defects repaired end to end with 2-0 polyglycolic acid sutures. At a median follow-up of 15 months, all were improved, and two achieved full continence. On the other hand, Leros and associates (1997) reported on five patients with persistent incontinence after surgery that affected the internal sphincter. Three patients felt improved, but none were fully continent. All had persistent defects on ultra-sound postoperatively. Three had improvement of their resting pressure, but only one was in the normal range. In a random-ized trial addressing internal sphincter repair during topical pelvic floor repair for anal incontinence, Deen and colleagues (1995) showed no differences in resting and squeeze pressures or in symptom relief.

Layered Method of Repair of Chronic Perineal Laceration

A transverse or crescent perineal incision is used at the junction of the posterior vaginal wall and anal mucosa. The lateral margins of the incision are extended to the region of the peri- neal dimple created by the retracted external sphincter, and a midline incision is made along the lower half of the posterior vaginal wall (Fig. 40.11A). The edges of the vaginal and rectal mucosa are grasped sepa-rately with Allis clamps, and the anterior rectal wall is sepa-rated in the midline from the posterior vaginal wall with careful scissors dissection. The dissection is carried laterally by sharp dissection to the region of the external anal sphincter. The in-ternal anal sphincter, which is the thickened distal conden-sation of the circular smooth muscle layer of the rectum, can be seen between the external anal sphincter and the anorec-tal mucosa as an area of white fibrous tissue (Fig. 40.11B). Meticulous hemostasis and wide mobilization to allow closure without tension are crucial.

A fibrous scar that is retracted lateral to the wall of the anal canal (Fig. 40.11B) often identifies the external sphincter. The exact anatomic margins of the external sphincter frequently are difficult to ascertain. A nerve stimulator can be used to iden-tify contractile skeletal muscle. Alternatively, the Allis clamps containing the ends of the external sphincter can be brought together in the midline and a circumferential sphincter test ed for by inserting a double-glove index finger into the rectum. If necessary, the clamps should be readjusted to incorporate more of the retracted muscle bundles until the constricted effect of the reaproximated sphincter can be demonstrated.

All scar tissue is excised from the margins of the anorec-tal mucosa, and the defect in the anal mucosa is closed using a continuous or interrupted suture of 3-0 delayed-absorbable material. A running suture may have the advantage of distrib-uting tension along the entire suture line and helping prevent a gap in the closure that could occur from ischemia if an inter rupted suture is tied too tight. A submucosally placed suture is ideal. Sometimes this tissue is quite friable, and a full-thickness suturing of the mucosa is the safest method.

After the mucosal margins are approximated, a second sup-porting layer inverts the internal mucosal suture line. This layer often has been thought of as the external anal “perirectal fascia,” but in fact it is the thickened downward continuation of the circular smooth muscle layer of the rectum that is the internal anal sphincter. This appearance of a thick mucosa layer between the anorectal mucosal closure and the external anal sphincter (Fig. 40.11C). Care should be taken in reapproxi-mating this layer over a length of 3 to 5 cm as this muscle is responsible for most of the resting pressure in what is nor-mally a 4-cm high-pressure zone in the anal canal. This layer also serves to umbricate and isolate the mucosal layer and take tension off of it to help it heal and seal against infection.

In an approximation-type external anal sphincteroplasty, the external anal sphincter ends are completely trimmed of scar tissue and united in the midline with interrupted 0 or 2-0 delayed-absorbable sutures. Although some surgeons pre fer a permanent suture, such as a braided silicone-treated polyester, a delayed-absorbable monofilament suture such as poliglecaprone has the advantage of maintaining excellent ten-sile strength for an extended period while avoiding the presence of a permanent foreign body. This becomes particularly impor-tant in the event of wound infection. Four or five sutures are used to approximate the sphincter muscle. These can be placed 1 cm apart, full thickness, with the nondominant index fin ger in the anal canal to aid in acquiring excellent purchase on both ends while assuring no penetration of the anal canal itself.

In an overlapping approach to the external anal sphincter, the scarified ends of the sphincter are important to the repair it-self and are left in place. The concept of the overlapping sphinc-teroplasty is to use the scarred ends of the torn sphincter to help hold the sutures that reconstitute the circumferential sphincter. The ends are widely mobilized with the scar tissue left on. Care should be taken to not dissect beyond the 3- and 9-o’clock posi-tion because the pudendal enervation to the sphincter enters lateral to the external sphincter. Then is brought together over...
FIGURE 40.11. Layered closure of a chronic complete perineal laceration with overlapping sphincteroplasty. A: A transverse incision is made at the junction of the vaginal and rectal mucosa and extended up the midline of the posterior vaginal wall. B: The rectal wall has been separated from the posterior vaginal wall with careful sharp dissection. The ends of the external sphincter have been identified and grasped with Allis clamps. The internal anal sphincter can be seen between the external anal sphincter and the anorectal mucosa as an area of white fibrous tissue. C: The defect in the anal mucosa has been closed with a continuous 3-0 delayed-absorbable suture. The internal anal sphincter then is reapproximated over a length of 3 to 5 cm. This layer also serves to imbricate and isolate the mucosal layer and take tension off of it to help it heal and seal against infection. D: The ends of the external anal sphincter are widely mobilized with the scar tissue left on. Care should be taken not to dissect beyond the 3- and 9-o’clock position as that is where the pudendal innervation to the sphincter enters laterally. The external sphincter then is brought together over the repaired internal sphincter with two rows of two horizontal mattress sutures of delayed-absorbable or permanent suture material. E: After the external sphincter has been repaired, the genital hiatus is narrowed by bringing the puborectalis muscles closer together with interrupted delayed-absorbable sutures placed in the fascia overlying them. F: The bulbocavernosus and superficial transverse perinei muscles have been reattached to the perineal body, and the vaginal mucosa was closed with a continuous locking stitch of 3-0 delayed-absorbable suture that was continued subcuticularly to approximate the perineal skin.
the repaired internal sphincter with two rows of two horizontal mattress sutures of delayed-absorbable or permanent suture material (Fig. 40.11D). An important part of the perineal reconstruction is the restoration of a narrower genital hiatus by bringing the puborectalis muscles closer together. One must remember that the arms of the puborectalis muscle do not normally come in contact with each other between the rectum and the vagina. Overzealous plication of the puborectalis muscle can constrict the vaginal introitus and create posterior tissue banding that can lead to dyspareunia. Dissection should be carried out laterally to the fascia overlying the medial border of the puborectalis muscles, and this fascia should be brought together by a series of interrupted, delayed-absorbable sutures. Each suture should be held tightly and the vagina tested before tying to assure that posterior bands are not formed. If it is, that suture should be removed and another placed. Extending this procedure to the midportion of the vagina can produce excellent anatomic support for the underlying anal canal and rectum (Fig. 40.11E).

Further support and elevation of the perineal body are provided by bringing together the disrupted ends of the superficial transverse perineal muscles and the bulbocavernous muscles. These muscles normally insert on the perineal body and play a part in pelvic floor support. They should be included in perineal reconstruction, including obstetric repair, to restabilize and support the perineal body. After this step, the redundant vaginal mucosa is excised, and the remaining mucosa is approximated in the midline with a continuous 2-0 or 3-0 delayed-absorbable suture. This is followed by a subcuticular closure of the perineal skin (Fig. 40.11F).

In 1937, Miller and Brown proposed making a paradoxic incision in the inferior portion of the anal sphincter at the 5- or 7-o’clock position to relax the tension on the anterior suture line in patients undergoing sphincter repair. The procedure disrupts both the internal and external sphincters and is not without physiologic risk, such as poor healing and scarring of the sphincter with the potential for postoperative anal incontinence of gas and liquid feces. For these reasons, paradoxic incisions are not widely used at the present time. Nevan and Pemberton studied a similar procedure and reported that although lateral internal sphincterotomy done for treatment of a chronic anal fissure led to fissure healing in 96% of 487 patients, anal incontinence was persistent in a small subgroup. Although most of this incontinence was minor and transient, the incontinence was persistent in a small subgroup.

Incomplete perineal repair. Interrupted plication stitches of 2-0 delayed-absorbable sutures are used to advance the fascia and shorten the muscle fibers of the perineal body, which strengthens the external sphincter as well. The margins of the vaginal mucosa and graft are approximated in the midline by a continuous locking stitch of 3-0 delayed-absorbable suture. The tip end of the vaginal mucosal flap should not be trimmed too closely, even though it protrudes somewhat from the repaired perineal body. It retracts as healing occurs (Fig. 40.12E).

### Noble Procedure for Complete Perineal Laceration

The torn perineum, anal, and rectal tissue in patients with a complete perineal laceration form a “butterfly” appearance across the perineum (Fig. 40.13A). The “wings” of the butterfly are the lateral perineal dimples of the retracted ends of the external anal sphincter. The initial incision is outlined around the margins of this area following the margin of the anal mucosa along the anatomic defect in the rectovaginal septum. The perineal skin is left attached and held with Allis clamps to facilitate later dissection of the retracted ends of the external sphincter. A small margin of vaginal mucosa is also left attached to the anal wall for traction because the anal mucosa is so friable. Atraumatic clamps are placed along the margin of the anal canal, and sharp dissection is used to carefully separate the anal wall from the overlying vaginal mucosa. The external anal sphincter remnants should be sharply mobilized and separated from the underlying anal wall (Fig. 40.13B). The vaginal mucosa is widely mobilized from the anal canal and lower rectal wall laterally to the underlying levator muscles and proximally into the middle or upper one third. Adequate mobilization of the anterior anorectal wall allows it to be pulled outside the vagina, which will avoid the formation of an anal orifice without difficulty, thus avoiding su- tures in the anorectal canal.

Once the ends of the external anal sphincter are mobilized to meet in the midline with traction on the Allis clamps, the overlying skin previously left attached is excised, and the suture lines are approximated end to end in the midline (Fig. 40.13C). Alternatively, one could perform an overlapping plication sphincteroplasty as previously described (Fig. 40.11D,E). Several of these sphincteroplasty sutures also should include the muscular layers of the anterior rectal wall to prevent it from retracting inward and to avoid tension on the suture line between the advanced anterior anorectal wall and the perineal skin. The genital hiatus should be narrowed by bringing the puborectalis muscles closer together as previously described (Fig. 40.11D,E). The transverse perineal muscles and the inferior margins of the bulbocavernous muscles then are

### Warren Flap Operation for Complete Third-Degree Tear

An inverted V-shaped incision is made in the posterior vaginal mucosa, outlining the flap that is to be turned down. The lower ends of the incision should be just lateral to the dimples caused by retracted sphincter ends (Fig. 40.12A). The length of the flap should measure a minimum of 3 cm to provide sufficient vaginal mucosa to be incorporated into the anal canal and cover the reconstructed perineal body. Taking care to avoid injuring the bowel wall, the surgeon dissects the flap of mucosa free from the top downward (Fig. 40.12B), stopping short of the margin between the vaginal and anal mucosa. If this margin is perforated, then the blood supply to the mucosal flap is compromised, thereby nullifying the advantage of the flap technique. The properly demar- cated flap allows the areas overlying the sphincter ends to be denuded. The flap is grasped with two mucosal Allis clamps and is turned down to hang over the anus. The external anal sphincter ends are then dissected free, using Allis clamps for traction. An approximation or overlapping-type external anal sphincteroplasty then is performed (Fig. 40.12C). Although an approximation-type sphincteroplasty is pictured, an overlapping procedure as described above could be incorporated into this procedure (Fig. 40.11D,E). The fascia overlying the anodermal aspect of the puborectalis muscles is identified, and this tissue is brought together with a series of interrupted sutures for reinforcement in the manner described for the layered technique, using 0 or 2-0 delayed-absorbable sutures (Fig. 40.12D). Each suture should be tested before tying to assure that the caliber of the vagina is not compromised.

Closure of the vaginal mucosa is carried out as in an ordinary perineal repair. Interrupted plication stitches of 2-0 delayed-absorbable suture are used to advance the fascia and shorten the muscle fibers of the perineal body, which strengthens the external sphincter as well. The margins of the vaginal mucosa and graft are approximated in the midline by a continuous locking stitch of 3-0 delayed-absorbable suture. The tip end of the vaginal mucosal flap should not be trimmed too closely, even though it protrudes somewhat from the repaired perineal body. It retracts as healing occurs (Fig. 40.12E).

---

**Surgery for Corrections of Defects in Pelvic Support and Pelvic Fistulas**

---

The perineum is left attached and held with Allis clamps to facilitate later dissection of the retracted ends of the external sphincter. A small margin of vaginal mucosa is also left attached to the anal wall for traction because the anal mucosa is so friable. Atraumatic clamps are placed along the margin of the anal canal, and sharp dissection is used to carefully separate the anal wall from the overlying vaginal mucosa. The external anal sphincter remnants should be sharply mobilized and separated from the underlying anal wall (Fig. 40.13B). The vaginal mucosa is widely mobilized from the anal canal and lower rectal wall laterally to the underlying levator muscles and proximally into the middle or upper one third. Adequate mobilization of the anterior anorectal wall allows it to be pulled outside the vagina, which will avoid the formation of an anal orifice without difficulty, thus avoiding su- tures in the anorectal canal.

Once the ends of the external anal sphincter are mobilized to meet in the midline with traction on the Allis clamps, the overlying skin previously left attached is excised, and the suture lines are approximated end to end in the midline (Fig. 40.13C). Alternatively, one could perform an overlapping plication sphincteroplasty as previously described (Fig. 40.11D,E). Several of these sphincteroplasty sutures also should include the muscular layers of the anterior rectal wall to prevent it from retracting inward and to avoid tension on the suture line between the advanced anterior anorectal wall and the perineal skin. The genital hiatus should be narrowed by bringing the puborectalis muscles closer together as previously described (Fig. 40.11D,E). The transverse perineal muscles and the inferior margins of the bulbocavernous muscles then are
FIGURE 40.12. Warren flap operation for complete perineal laceration. A: The line of incision outlines the flap of vaginal mucosa. B: The flap is dissected free and turned back. C: The flap is retracted downward. The ends of the sphincter are delivered and are either sutured end to end as pictured or with an overlapping technique as described. D: The external sphincter has been repaired, and the puborectalis muscles are then brought closer together taking care not to create a posterior band of tissue. E: The vaginal incision is closed with a continuous locking stitch that is continued subcuticularly over the perineum. The margins of the vaginal mucosal flap are reapproximated, further reconstituting and supporting the perineal body.

The vaginal mucosa is trimmed, if necessary, and the margins of the posterior vaginal wall are approximated with a continuous locking stitch of 3-0 delayed-absorbable suture. The continuous suture closing the posterior vaginal mucosa is carried over the perineal body as a subcuticular stitch, and the perianal skin then is approximated at the midline. The mobilized anterior wall of the anal canal is drawn outside the reconstructed anal orifice and sutured without tension to the perianal skin (Fig. 40.13E). The excess anal mucosa is trimmed. Care should be taken to remove as little of the distal anal canal as possible because this tissue contains the internal anal sphincter. Vertical mattress sutures of 3-0 delayed-absorbable suture are used to approximate the broad surface of the anal submucosa to the perianal skin. Any residual separation of the margins of the anal mucosa and perianal skin can be approximated with interrupted sutures.

Muscle Transposition, Artificial Sphincters, Diversion, and Other Procedures

The following advanced procedures are largely reserved for patients with difficult anal incontinence problems or multiple operative failures. Muscle transposition procedures exist...
FIGURE 40.13. The Noble operation for complete perineal laceration. A: A “butterfly-shaped” scar is noted across the perineum, where there are torn perineal, anal, and rectal tissues. The ends of the external anal sphincter can be recognized by lateral perineal dimpling. B: The anterior rectal wall is mobilized extensively from the posterior vaginal wall to allow it to be pulled down without tension. The wings of the butterfly are left attached to facilitate dissection of the retracted ends of the sphincter. C: Ends of the anal sphincter are trimmed and sutured together and to the pararectal fascia of the advanced anterior rectal wall. Several delayed-absorbable sutures are used. D: The levator muscles and pararectal fascia are brought closer together in the midline. (Continued)
in which the gracilis muscle, sartorius muscle, or gluteus muscle are swung as flaps to encircle the anal canal. Dynamic muscle plasty procedures involve stimulation of this muscle with an intramuscular neuromuscular stimulator to induce it to contract around the anal canal and occlude it continuously. When the patient wishes to defecate, the pulse generator can be turned off by a magnet. Once defecation is complete, the stimulator can be turned on again by the magnet. In a series of 20 patients reported by Hallan and associates, 12 have a functioning neoanal sphincter. Madoff and colleagues (1999) reported that frequency for 8 to 10 weeks until the transformation from a fast-twitch to a slow-twitch muscle has been achieved. At this point, the frequency of stimulation is increased so that the muscle contracts around the anal canal and occludes it continuously.

There are several classification systems for rectovaginal fistulae. We have favored that of low (vaginal opening near the posterior fourchette), mid (from the level of the cervix to just posterior to the posterior fourchette), and high (the fistula is in the area of the posterior fornix).

**Etiology**

Although there are many different causes of rectovaginal fistulae (Table 40.3), numerous series report that obstetric trauma is the cause for the majority of them. Rectovaginal fistulae usually arise as a complication of a repaired fourth-degree perineal tear. Venkatesh and colleagues reported that even though this sequence of events may be the most common, only 0.1% of vaginal deliveries result in fistula formation. Risk factors for development of a rectovaginal fistula in association with vaginal deliveries include prolonged labor, difficult forceps delivery, shoulder dystocia, and a midline episiotomy.

A rectovaginal fistula may develop as a result of direct surgical injury to the rectum or vagina, ischemia, or postoperative infection. Other less common causes include blunt instrumentation or penetrating trauma caused by an accident.
Occasionally, rectovaginal fistulae follow an infectious process such as a perianal abscess or an infected Bartholin duct cyst abscess. The most common cause of high rectovaginal fistulae is repeated bouts of diverticulitis with abscess formation followed by development of a sigmoidovesical fistula or a combined sigmoidovesicovaginal fistula. Inflammatory bowel disease such as ulcerative colitis or Crohn disease may result in complex rectovaginal fistulae. Crohn disease is a transmural condition that often results in a rectovaginal fistula.

Radiation is a relatively infrequent cause of fistula formation, usually beginning as a proctitis with ulceration and fistula formation followed by a stricture. Fistulae may occur several years after completion of radiation therapy. Primary or metastatic disease in surrounding organs (rectum, cervix, uterus, or vagina) may result in rectovaginal fistulae. Because congenital rectovaginal fistulae is usually managed at a young age and is associated with other anomalies, it is usually not managed by the gynecologic surgeon.

### Clinical Evaluation

The most common symptoms are the passage of flatus and stool into the vagina. The severity of these symptoms may be affected by the size of the fistula and its number. There is usually a foul-smelling vaginal discharge with periodic, uncontrolled escape of gas. Occasionally, the fistula may develop immediately. More commonly, it appears 7 to 10 days after delivery. The breakdown of a primary repair, inadequate repair, or infection at the primary site may explain this delayed presentation. Because of the unpredictable condition and the desire to have more children, the patient may not seek medical attention for some time. Diarrhea, rectal bleeding, mucus discharge, and abdominal pain are caused by the underlying status of the bowel and do not result from the fistula per se. The history frequently suggests the underlying cause of the fistula and may greatly influence the timing and route of repair. On physical examination, the location, size, and number of openings can be identified. The route of the fistula may be outlined by the passage of a thin probe from the vagina through the fistulous tract into the anal or rectal canal. Placing an examining finger in the rectum aids in this process. Contractions of the pubococcygeal and external anal sphincter should be evaluated for competency. The perineal body is examined, and the tissues about the fistula are delineated to gain more insight into the cause of the underlying fistula. A proctosigmoidoscopic examination usually is done to ensure that the mucosa of the intestinal tract is normal.

In patients with a history compatible with a fistula but in whom no fistula opening can be identified, a simple office examination can be helpful. With the patient in a slight Trendelenburg position with a size 20 Foley urinary catheter, a 5-ml balloon is placed in the anal canal. Air is instilled through the catheter while the water-filled or soap-covered vagina is observed for any escape of air bubbles originating from the anal canal. Contrast studies are necessary to define the sigmoidovesical fistula or fistulae associated with primary bowel disease.

### Surgical Management

Numerous operative procedures have been described for repair of rectovaginal fistula, including transvaginal, transanal, and abdominal approaches. Gynecologists usually use a transvaginal approach, whereas colon and rectal surgeons prefer the transanal technique. The determining factors to be considered include the cause of the fistula, its location and accessibility, and the status of the anal sphincter.

The most typical rectovaginal fistula is one following disruption of a primary repair of a fourth-degree laceration. It typically occurs low along the rectovaginal septum just inside the external anal sphincter. Generally, it presents 6 to 10 days after the initial repair with passage of air or stool through the vagina. Venkatesh and colleagues report that approximately 50% of these small fistulae may heal without operative intervention during the first 6 to 8 weeks postpartum.

### Early Repair

As previously mentioned, Hankins and colleagues described early repair of carefully selected rectovaginal fistulae and episiotomy breakdowns using a technique of early return to the operating room for debridement followed by daily cleaning of the wound area. After a 6- to 7-day interval, their patients were returned to the operating room for surgical repair of the fistula. With this approach, successful healing occurred in 90% of their patients. We prefer to wait 8 to 12 weeks to allow the surrounding inflammation to resolve before surgical intervention. Preoperative mechanical bowel preparation should be given. On the morning of operation, tap water enemas can be given until clear.

Appropriate treatment of a rectovaginal fistula requires consideration of the cause and location of the fistula and the condition of the involved tissues. For fistulae located in the lower portion of the anal canal, we prefer to use the lithotomy position to carry out the operative repair. For fistulae at the very apex of the vagina, an abdominal approach generally is required.

### Low Rectovaginal Fistula: Technique of Repair

A transvaginal technique for small rectovaginal fistula repair involves a circular incision about the fistulous opening (Fig. 40.14). With traction on the vaginal wall and countertraction applied to the edge of the fistulous tract, the vagina is separated from the underlying rectal wall with sharp dissection, and this proceeds circumferentially (Fig. 40.15). This wide mobilization permits later approximation of the fresh injury free of tension.
FIGURE 40.14. Small rectovaginal fistula with proposed line of initial incision.

Once the vaginal walls are mobilized from the underlying rectum, the entire fistulous tract is excised to include a small rim of the rectal mucosa (Fig. 40.16), converting the fistula to a fresh injury. With the surgeon’s nondominant index finger lifting and supporting the anterior rectal wall, the initial sutures are placed extramucosally, including a portion of the muscularis and submucosa, with 3-0 delayed-absorbable sutures (Fig. 40.17). We frequently place all sutures throughout the length of the fistula, after which they are individually tied in the order in which they were placed. The initial suture line begins and is extended a full 3 to 8 mm above and below the site of the fistulous tract to assure complete closure. A second layer

FIGURE 40.17. Extramucosal placement of sutures in wall of anterior anal canal.
Surgery for Corrections of Defects inPelvic Support and Pelvic Fistulas

FIGURE 40.18. A: Inversion of initial suture line with approximation of muscularis of the anal canal. This thickened smooth muscle layer is the internal anal sphincter. B: Side view representing closure of the first and second layers in the anal canal.

(Fig. 40.18) begins 5 mm above the previously closed suture line and extends 5 mm distal to the fistulous closure, inverting the initial suture line into the rectum, and no sutures are located within the rectal lumen.

Once the wall of the rectum is reconstructed, the lower portions of the puborectalis muscle and the external anal sphincter are approximated to add a third layer in the closure (Fig. 40.19A), which helps to reconstitute the anterior rectal wall. Care should be taken that approximation is not carried so far superiorly that it results in a transverse bar across the posterior vaginal wall, which may lead to dyspareunia. Once the muscular walls are approximated, the vaginal wall is approximated with 3-0 delayed-absorbable sutures, accurately placed so as to promote primary apposition of the fresh edge of the vaginal wall (Fig. 40.19B).

Occasionally, the fistulous tract is so close to the external anal sphincter that closure is difficult. In this situation, the bridge of skin, sphincter, and perineal body can be divided,
FIGURE 40.21. Mobilization of posterior vagina off anterior anal canal with conversion of rectovaginal fistula to fourth-degree injury.

and the fistula is thus essentially converted to a fourth-degree tear (Fig. 40.20). The fistulous tract is excised, and the posterior vaginal wall is mobilized from the anterior anal wall (Fig. 40.21). The anal canal is then reconstructed with interrupted or running fine delayed-absorbable sutures approximating the mucosa of the anal canal. This initial suture line then is inverted with a second layer of interrupted fine delayed-absorbable sutures approximating the retracted tissues of the internal anal sphincter, resulting in reconstruction of the anal canal (Fig. 40.22). The retracted ends of the external anal sphincter are approximated in the midline in an end-to-end fashion with fine delayed-absorbable sutures (Fig. 40.23). This results in a snug closure that is resistant to the passage of the surgeon’s little finger. Alternatively, at this point one could perform an overlapping sphincteroplasty as described earlier (Fig. 40.11D,E). The perineal body is reconstructed in such a

FIGURE 40.22. Two-layer reconstruction of anal canal.

FIGURE 40.24. Reconstructed perineal body with subcuticular approximation of skin of perineum.
fashion that there is significant support to the reconstructed anal sphincter, and yet entrance to the vagina is not compromised (Fig. 40.24).

Considerable experience exists with the transanal flap approach to rectovaginal fistulae involving the lower portion of the rectovaginal septum. Rothenberger and colleagues reported on a technique that uses an endorectal flap consisting of mucosa, submucosa, and circular muscle fibers. The flap is twice as wide at the base as it is at the apex. They achieved successful repair in 32 of 35 patients with rectovaginal fistulae. Hoexter and associates reported a similar high rate of fistula healing and improvement in anal continence, emphasizing several points for successful repair via endorectal flap: (a) elevating the rectal flap for at least 4 cm to the fistula, (b) excising the fistulous tract, (c) leaving the vaginal wound open for drainage, and (d) using an elliptic flap to avoid devascularization of the flap apex. Others have reported a high degree of efficacy of the endorectal flap for achieving both fistula healing and repair of any associated anal sphincter disruptions.

**Repair of Radiation-Induced Fistula**

Less commonly, a sizable rectovaginal fistula is located high in the posterior vaginal wall, frequently associated with a degree of stricture of the adjacent rectum and significant perirectal fibrosis and scarring. When this occurs, it is almost always after radiation therapy. Successful closure of the fistula requires aggressive excision of the surrounding tissues damaged by radiation. In selected patients, the fistula is best managed with a primary resection and anastomosis of the rectosigmoid through a lower midline incision. However, successful closure can be accomplished vaginally by means of a pedicled bulbocavernous muscle with an overlying labial fat pad (Martius procedure).

Figure 40.25 depicts the usual location of the fistula, high in the posterior vaginal wall. Figure 40.26 outlines the potential sites from which the pedicled bulbocavernous Martius-type flap is obtained. Initially, an incision is made in the vagina to separate the scarred vagina from the underlying anterior wall of the rectum circumferentially. The edge of the scarred vaginal epithelium adjacent to the edge of the rectal mucosa is excised in anticipation of this being the site of the initial suture line approximating the squamous epithelium from the vulvar flap to the rectum in order to fill the defect in the rectum. With a Mayo scissors, a subcutaneous tunnel is made from the labium majus to the fistula under the labium and vaginal mucosa (Fig. 40.27). The free end of the muscle is guided through the subcutaneous tunnel with a single absorbable suture placed along its edge to assist in passage through the tunnel. The
Proposed sites to harvest skin and subcutaneous tissue in preparation to fill hole of rectovaginal fistula.

The rectal defect is such that it cannot be closed primarily. Thus, the edge of the squamous epithelium from the vulvar graft is sutured to the edge of the rectal mucosa with 4-0 delayed-absorbable sutures. Occasionally, a Schuchardt incision is required in the vagina to obtain adequate exposure for the dissection.

The pedicled graft is used to close the fistulous defect, beginning at the 3-o'clock position, in a synchronous fashion such that the entire edge of the fistulous tract is in immediate proximity to the edge of the skin from the vulva (Fig. 40.28). Once in place, the muscle and subcutaneous tissue of the graft are sutured to the surrounding connective tissue.

To provide coverage for the exposed Martius flap, which has been inserted as a plug into the rectum, a similar pedicled graft is developed from the patient’s right side; this is placed so that the skin of the vulva is approximated to the skin of the vagina (Fig. 40.29). The edges are placed such that there is no exposed source for granulation tissue (Fig. 40.30).

A small suction catheter is placed between the two pedicled grafts and brought out through a stab wound lateral to the perineal incision. The vulvar incision is closed in layers, the skin approximated with fine interrupted delayed-absorbable suture.

Sigmoidovaginal Fistula: Sigmoid Resection with Sigmoidorectostomy

Fistulae between the sigmoid colon and vagina occur infrequently, but the overwhelming majority result from diverticulitis of the sigmoid colon (Fig. 40.31) in a patient who has previously had a hysterectomy. Generally, the sequence of events consists of the patient experiencing repeated bouts of acute diverticulitis that finally result in perforation of a diverticulum and abscess formation with a fistulous tract communicating to the vagina. Passage of fecal material or gas through the vagina in the absence of a rectal communication should lead one to suspect a fistula arising from the sigmoid colon or small intestine. A proctoscopic examination should be done, although often it is impossible to visualize the fistulous orifice because of narrowing or fixation resulting from the inflammatory condition. Surgical intervention is indicated for a sigmoidovaginal fistula that is large enough to permit the passage of fecal material. In a few selected patients, a colostomy may be the only treatment, or the fistula may be divided and the sigmoidal defect closed with or without a temporary colostomy. In the overwhelming majority of patients, we prefer a sigmoid resection with primary anastomosis and closure of the opening into the vagina. The need for a temporary protective colostomy is determined on an individual basis.

Hartmann Procedure

Under some circumstances, the infected, inflammatory process is such that the sigmoid mass may be excised, but a primary anastomosis is ill advised. It may be more appropriate to excise the diseased colon, close the fistula in the vagina, leaving the defunctionalized rectal stump in the pelvis for later reanastomosis (Fig. 40.32). Omentum and a suction drain are usually placed over the stump. The distal end of the descending colon is brought out as a colostomy, which is matured at that time. Later, usually after 2 to 3 months, reoperation can be done through the previous incision. Placement of a gauze pack in the vagina and an EEA sizer in the anal stump will help to identify these structures. Once identified, the descending colon is freed from the splenic flexure in a sufficient fashion to permit the primary descending colorectostomy in a noninfected field as a closing step in this two-stage procedure.

The management of the anally incontinent patient is a complex undertaking whether that incontinence is transanal or extrarectal. Preoperative evaluation of the anally incontinent patient is the most important part of any surgical therapy before a decision for surgery is made. Consideration should be given to extensive use of nonsurgical management. Judicious use of preoperative testing can aid in identifying patients most likely to achieve benefit from surgery. Because surgical results in anally incontinent patients are less predictable, it is important to give careful consideration to preoperative counseling regarding expectations and possible outcomes is crucial for the ultimate satisfaction of the patient. Surgery for anal incontinence and rectovaginal fistula repair requires thorough surgical planning, careful attention to detail, and a meticulous operative technique to provide the patient with optimal results.

SUMMARY

The management of the anally incontinent patient is a complex undertaking whether that incontinence is transanal or extrarectal through a rectovaginal fistula. Care must be taken in the assessment and diagnosis of these patients with testing judiciously used where it will provide clinically useful information. Because surgical results in anally incontinent patients are less predictable, it is important to give careful consideration to preoperative counseling regarding expectations and possible outcomes is crucial for the ultimate satisfaction of the patient. Surgery for anal incontinence and rectovaginal fistula repair requires thorough surgical planning, careful attention to detail, and a meticulous operative technique to provide the patient with optimal results.

BEST SURGICAL PRACTICES

Preoperative evaluation of the anally incontinent patient should include a careful assessment of her symptoms and their impact on her quality of life.

A histologic sample is obtained rather than a cytologic sample as with fine-needle aspiration. Cooper’s ligaments—Fibrous septa connecting the skin to the underlying pectoralis fascia. Involvement in a carcinomatous process may lead to contraction of the ligament and result in dimpling of the overlying skin. Cystosarcoma phyllodes—Rare, usually slow-growing circum- scibed or infiltrating fibroepithelial breast tumor that resem- bles a fibroadenoma but may be partly cystic. The stroma is cellular and resembles a fibrosarcoma. The tumor is usually benign, but occasionally may be malignant and metastasize. Cytologic evaluation—Evaluation of a cellular sample for mi- crosopic evaluation to determine the presence or absence of a cancerous condition. Diagnostic mammogram—Imaging in a women with symp- toms, which may include a mammogram, sonogram, and/or examination by a radiologist. Digital mammography—An imaging technique that stores an x-ray image as a computer image rather than on the usual x-ray film. Ductal carcinoma in situ (DCIS)—Histologically variable col- lection of carcinomas of the lactiferous ducts that have not spread beyond the basement membrane but have the potential of becoming invasive and spreading to other tissues. Ductogram (galactogram)—A test used in the evaluation of nipple discharge in which a radioopaque dye is instilled through a fine plastic tube placed into the ductal opening of the nipple, the outline of which is displayed on x-ray. Fibrocystic lesions—Refers to a broad spectrum of heteroge- neous benign histopathologic changes in the breast associated with stromal fibrosis and with variable degrees of intraductal epithelial hyperplasia and sclerosing adenosis. Fine-needle aspiration—Process of obtaining a specimen of cells and tissue for microscopic examination by applying suc- tion through a fine needle (usually 21- to 23-gauge) attached to a syringe. May be therapeutic in drainage of a fluid-filled cyst. Ultrasound guidance may be helpful but is not necessary. A cytologic sample is obtained rather than a histologic sample as through a core biopsy or excisional biopsy. Sometimes called fine-needle aspiration biopsy. Genetic counseling—Guidance provided by a medical professional typically to individuals with an increased risk of harboring genes that may increase their risk for developing cancer or producing an offspring having a genetic disorder. Includes providing information and advice concerning the prob- ability of disease, diagnostic testing, and available options/ treatments. Hormone receptor assay—Evaluation of a breast tumor to determine if it is likely to be affected by/responsive to hor- mones (generally estrogen, progesterone, and human epidermal growth factor 2 [HER2]). Immunohistochemistry (immunocytochemistry)—Use of antibo- dies to detect specific chemical antigens in cells or tissue samples evaluated under the microscope. Intraductal papilloma—Generally benign breast mass that is usually microscopic but may grow to 2 to 3 mm in diameter. The lesion may present with spontaneous unilateral bloody nipple discharge. Lobular carcinoma in situ—Early type of breast cancer devel- oping within the lobules that does not penetrate through the basement membrane. Lumpectomy—Surgical excision of a margin of normal breast tissue (preferably 1–2 cm) surrounding a breast carcinoma usu- ally less than 4 cm in diameter. Often a component of breast-conserving therapy, which may also include removal of axillary lymph nodes and radiation therapy. Macrocalcifications—Large, coarse calcium deposits that are often caused by noncancerous processes/conditions, such as aging of the breast arteries, old injuries, or inflammation. Com- mon in women older than the age of 50. Mammo- lography—Special imaging examination of the breasts using x-ray. Magnetic resonance imaging (MRI)—A noninvasive imaging technique that generates computerized images of internal body tissues and is based on nuclear magnetic resonance of atoms within the body induced by the application of radio waves. A large magnet polarizes hydrogen atoms in the tissues and then monitors the summation of the spinning energies within living cells.
Breast Diseases: Benign and Malignant

IBMROLOGY

The breasts, or mammary glands, begin embryologic differentiation in the fifth or sixth week of fetal development. Two central bands of thickened ectoderm (known as mammary ridges or “milk lines”) develop and extend from the area of the future axilla at the base of the forelimb to the future inguinal region of the hind limb (Fig. 41.1). With normal regression of the ridges (which occurs shortly after the sixth week of fetal development), only one gland persists on each side, at the level of the thorax. This process is similar in both sexes. Accessory mammary glands (polymastia) or accessory nipples (polythelia) may result along the original mammary ridge with failure of normal regression. This minor congenital anomaly may occur in both sexes with an estimated frequency of about 1%.

Ingrowth of the remaining ectoderm into the underlying mesenchyme initiates the development of the primary and secondary bud of the mammary gland. Canalization of these

Mastectomy—Surgical removal of all or part of the breast tissue; may be associated with removal of lymph nodes and muscles. Microcalcifications—Tiny specks of calcium in the breast that may appear alone or in clusters. To judge the likelihood of malignant change, a radiologist uses the shape and appearance of the clusters on mammography. Specks of deodorant may be mistaken for calcifications and thus should not be used before a mammogram.

Modified radical mastectomy—Removal of the breast tissue and only the fascia over the pectoral muscles. Montgomery glands/subareolar—Accessory glands located at the periphery of the areola. They are intermediate glands in between sebaceous glands and true mammary glands, and thus may secrete milk.

Paget disease—Rare breast carcinoma often mistaken for eczema, dermatitis, or mastitis of the nipple. May or may not be associated with an underlying mass lesion.

Partial or segmental mastectomy—A type of surgery that removes only the part of the breast in which the cancer is located and a margin of normal breast tissue surrounding the tumor.

Polymastia—More than two breasts.

Polythelia—More than two nipples.

Positron emission tomography—Highly specialized imaging technique using short-lived radioactive substances with formation of tomographic images by computer analysis of photons detected from annihilation of positrons emitted by radionuclides incorporated into biochemical substances. The scanner uses integrated x-ray and computing equipment.

Prophylactic mastectomy—Procedure performed before any evidence of cancer is found for the purpose of preventing cancer.

Quadrantectomy—Partial mastectomy in which the quarter of the breast that contains a tumor is removed.

Radical mastectomy—En bloc removal of the breast tissue; associated skin, nipple, areola, axillary lymph nodes; and the underlying pectoral muscle and minor muscles.

Screening mammography—Breast imaging based on guidelines to detect cancer early in symptomatic women.

Sentinel lymph node biopsy—Currently considered conventional treatment in certain categories of breast cancer patients for initial evaluation of the axilla. The surgeon uses either blue dye and/or a radioisotope tracer injected into the tumor site at the time of surgery. The first (sentinel) node that picks up the dye is removed and biopsied. If the node is cancer-free, further lymph node evaluation is terminated.

Simple mastectomy—Removal of the breast tissue and associated skin, nipple, and areola, but without removing the underlying muscle or fascial tissue. May be used as a prophylactic procedure. Also called total mastectomy.

Stereotactic needle biopsy—Use of mammogram images taken at two angles to map the exact location of a (usually nonpalpable) mass by computers. The patient lies face down on a table with the breast hanging through an aperture in the table.

Subcutaneous mastectomy—Excision of breast tissue by undermining the skin, thus preserving the cosmetic appearance and form of the nipple, areola, and skin. Appears to have been abandoned as a procedure for prophylactic mastectomy.

Thermography—Imaging technique in which cutaneous temperatures of the breast or infrared radiation from the breast are measured through electronic detectors to diagnose breast disorders.

TNM staging—A system of clinicopathologic evaluation of tumors based on the extent of tumor involvement in the primary site (T), lymph nodes (N), and metastasis (M).

TRAM flap—Muscle flap procedure using the transverse rectus abdominis muscle as a method of breast reconstruction.

Triple test—Not an actual test, but a correlation of the results of the breast physical examination, mammogram, and tissue sampling technique to determine the malignant potential of a lesion. If all agree that the lesion is benign, there is a high likelihood of correlation with a benign result.

Ultrasound (sonography)—Imaging technique that uses high-frequency sound-wave transmission through tissues to outline organs. No radiation is used.

The specialty of obstetrics and gynecology is devoted to the health care of women throughout their lifetime. Concerns about breast health are common to women from puberty to menopause, therefore obstetrician/gynecologists are becoming increasingly involved in not only the detection of breast masses but also the diagnosis, evaluation, and treatment of such lesions. Although the etiology of most breast symptoms is a benign disorder, the fear of cancer is often the motivating factor for women seeking attention. Breast cancer remains the most common cancer in women, with the American Cancer Society (ACS) estimating more than 211,000 cases in the United States in 2005. Although mortality from breast cancer is decreasing, cancer of the breast remains second only to lung cancer in cancer deaths in women, making it an especially dreadful adversary. Advances in treatment modalities, genetic predisposition, and chemoprevention have thrust breast health issues into the forefront of the media and medical technology. The zeal to achieve the ideal cure or prevention strategy persists unabated in the medical profession and remains an ongoing challenge. A thorough understanding of the diagnosis and management of breast disease, as well as an appreciation of contemporary treatment options, are essential for the practicing gynecologist.

The purpose of this chapter is to review breast embryology, anatomy, and pathology and to examine strategies for the diagnostic, management, and treatment of breast conditions. The role of the women's health clinician in breast cancer detection, therapy, assessment of risk factors, genetic testing, and chemoprevention is also discussed. The woman in whom breast cancer develops requires a multidisciplinary team. The gynecologist must be a knowledgeable participant in her treatment plan.
epithelial cords (under the influence of placental sex steroids) during the third trimester marks the development of the lactiferous ductal system. Proliferation of basal mesenchymal cells and smooth muscle development initiates transformation into the fully formed nipple. Failure of elevation of the nipple above the skin level occurs in 2% to 4% of the population, resulting in inverted nipples.

Anatomy

The breast, or mammary gland, is a highly modified sudoriferous gland situated between two layers of superficial fascia on the pectoralis major, serratus anterior, and external oblique muscles. It is bordered by the second rib superiorly, the sternum medially, the sixth intercostal space inferiorly, and the midaxillary line laterally. It is composed of several lobes, with the greatest volume of glandular tissue located in the upper outer quadrant. Fibrous septa, called suspensory or Cooper’s ligaments, interdigitate between the parenchymal tissues to connect the two fascial planes. The ligaments permit mobility of the breast on the anterior thoracic wall while also providing structural support (Fig. 41.2).

The breast lobes are arranged in a radial pattern and contain many lobules. Each lobule consists of 10 to 100 alveoli or tubuloacinar secretory units (Fig. 41.3). Breast cancer is thought to originate in these units, also called terminal duct lobular units. Each lobe terminates in a lactiferous duct, which opens onto the nipple. Beneath the areola, each lactiferous duct features a dilated portion called the lactiferous sinus. Inspissation of material in the lactiferous sinus may account for galactoceles.
Breast Diseases: Benign and Malignant

FIGURE 41.3. Internal structure of the breast. The breast is a large apocrine gland. The secretory parenchyma is composed of lobules containing acini, fat, and fibrous tissue. The ducts drain centrally toward large lacunae located directly beneath the nipple. These act as reservoirs until they receive the impetus for ejection.

The epidermis of the nipple and areola is highly pigmented. Additional increased pigmentation and size of the nipple–areolar complex is noted in pregnancy. The areola contains many sweat, sebaceous, and accessory glands. During pregnancy, accessory glands called Montgomery tubercles become prominent.

The breast tissue is well supplied by an extensive arterial and venous system. The anterior perforating branches of the internal thoracic (internal mammary) artery supplies the medial and central aspect of the breast. The upper outer quadrant is supplied by the lateral thoracic artery, a branch of the axillary artery. The two vessels combined provide the major blood supply to the nipple. Other vessels supplying the breast include the anterior and lateral branches of the intercostals, other branches of the axillary artery (including the pectoral branch of the thoracoacromial artery), and the subcapsular and thoracodorsal arteries.

Venous and lymphatic drainage of the breast follows the course of the superficial and deeper arteries. Principal venous drainage goes to the internal thoracic vein medially, to the axillary vein superolaterally, and by way of the intercostal veins to the vertebral and azygous veins posteriorly. This drainage pathway accounts for the frequent sites of metastases, as breast cancer enters the venous system and metastasizes to the lungs by way of the axillary or intercostal veins or to thoracic, abdominal, and pelvic organs by way of the vertebral vein. Similarly, the primary lymph node drainage is initially into the axillary region, but additional drainage can precede to the infracavicular and mediastinal (parasternal) areas, thus suggesting the need to extend the routine breast examination to the bony borders to ensure adequate coverage of these potential cancer-bearing areas. The lymphatic plexus has deep and superficial drainage pathways. Lymphatic drainage from the deep lesions is directed toward the axilla and the axillary nodes, although all breast quadrants contribute lymph to the medial parasternal lymph nodes. This lymphatic plexus is divided into levels based on their relation to the pectoralis minor muscle. Level I nodes are located lateral to the muscle, and level III nodes are located medially. Level II nodes are located deep or posterior to the pectoralis minor muscle (Fig. 41.4).

LIFE CYCLE CHANGES

The development and physiologic functioning of the breast is orchestrated by the anterior lobe of the pituitary gland and the ovaries. This development is a lifelong process that begins in utero. Transient enlargement of the breast bud and associated milklike nipple secretion (“witches milk”) may occur in both newborn girls and boys as a result of placental transfer of maternal hormones (primarily estrogen). The fluid secretion may appear for a week postpartum, but subsequent involution of the tissue results by the third or fourth week postpartum. Breast development occurs during thelarche, which signifies the beginning of puberty. This stage typically begins between 9 and 10 years of age, but may begin as early as 8 years in some girls, with ethnic and environmental factors accounting for the variation. Before the transformation that occurs at puberty, the function and histology of the human breast is identical in boys and girls. However, at puberty in girls, the rudimentary male ductal system develops as a consequence of estrogen stimulation, and the lobular-alveolar system develops in response to progesterone secretion. The first
visible manifestation of this hormonal response is a symmetric palpable enlargement beneath the nipple. 

Menstruation, pregnancy, and menopause are additional sentinel events in the cycle of breast development. Before the onset of menstruation, breast transformation begins with ductal branching and proliferation of interductal stroma. With each menstrual cycle, ductal proliferation occurs under the influence of estrogen. Proliferation of the terminal duct structure and increased mitotic activity in the basal epithelial cells occur in the secretory phase under the influence of progesterone. Stromal proliferation and edema, in response to the hormonal milieu, accounts for the sense of fullness or tenderness experienced premenstrually. The decrease in hormones that occurs with menstruation signals disappearance of stromal edema, desquamation of epithelial cells, atrophy of intralobular connective tissue, and overall shrinkage in the size of the ducts.

Further maturation of the breast occurs with pregnancy. Significant development of glandular tissues and decrease in the surrounding stroma portends reversal of the stromal glandular relation seen before this stage. After pregnancy, these changes regress but do not return completely to their prepregnancy state. Menopause heralds a further reduction and shrinkage of the ducts, gland buds, and surrounding stroma.

Lactation

Hormonal and structural changes, which prime the breast for future milk production, occur during pregnancy. As previously occurred during puberty, increased estrogen and progesterone secretion in early pregnancy results in ductal development and maturation as well as enlargement of lobular size. During the latter half of pregnancy, glandular epithelium is transformed into secretory epithelium in response to insulin, thyroxine, growth hormone, and corticosteroids. Human placental lactogen and prolactin also play critical roles in breast development during pregnancy. Paradoxically, despite considerable increases in prolactin, its functioning is inhibited at the alveolar level by progesterone. Thus, lactation (the process of mature milk secretion) does not occur until the rapid decline of estrogen and progesterone that occurs with delivery, although colostrum leakage may be seen in the second half of pregnancy.

Stimulation of the afferent neural arc suppresses prolactin inhibitory factor (PIF), allowing release of prolactin-releasing factor (PRF) and further elevation of the prolactin concentration. Breast suckling stimulates the neural arc, as do auditory (infant crying) and visual stimuli. PIF is thought to be dopamine, and PRF is thought to be thyroid-releasing hormone or thyrotropin-releasing hormone. Additionally, stimulation of the neural arc triggers release of oxytocin by involving the paraventricular and supraoptic nuclei of the hypothalamus. Oxytocin release from the posterior pituitary induces contraction of the myoepithelial cells surrounding the nipple ducts, resulting in milk ejection or letdown. Continued suckling induces additional prolactin secretion and replenishment of the milk supply; however, this can be modified by psychological stress, pain, or fatigue, resulting in a decreased milk output. Discontinuation of suckling results in increased levels of PIF, which inhibit prolactin production. Ultimately, lactation ceases, with resultant decrease in size of the alveoli.
Breast Diseases: Benign and Malignant

Table 41.1 lists the basic anatomic structures and the most commonly associated pathologic abnormalities. A brief review of pathology of the breast follows.

### Congenital Anomalies

Congenital abnormalities affecting the breast anlage include amastia, hypertrophy, asymmetry, and congenital inversion of the nipples. Additionally, supernumerary nipples or breasts may be seen—the result of persistence of epidermal thickenings along the milk line.

### Inflammation

Acute mastitis or breast abscesses may develop during nursing or with other dermatologic conditions of the nipples. The breast is vulnerable to bacterial infection from tears or fissures in the nipples. The offending bacterium in puerperal mastitis is most commonly *Staphylococcus aureus* and *Streptococcus*. Treatment includes continued emptying of breast milk, either through nursing or pumping, and use of warm or cold compresses. The most effective broad-spectrum antibiotics are dicloxacillin or a first-generation cephalosporin for 10 days. For those with penicillin allergies, erythromycin may be substituted.

Nonpuerperal mastitis is often associated with a sticky, multicolored discharge and is noted in individuals who are immunocompromised (e.g., diabetic patients), people who have undergone radiation treatment, and those who have an autoimmune disorder. Purulent discharges generally respond to antibiotics, but an abscess requires incision and drainage for complete resolution.

Duct ectasia is characterized by dilation of the ducts, inspissation of breast secretions, and marked periductal and interstitial chronic granulomatous inflammatory reaction. It is often associated with a multicolored, sticky, spontaneous, bilateral nipple discharge coming from multiple ducts. It is most commonly seen in women in the fifth or sixth decade of life; however, the etiology is unknown. Periductal inflammation may result in nipple inversion, areolar thickening, and a breast mass that can mimic a cancer or nonpuerperal abscess. This condition is discussed further under the section on nipple discharge.

Galactocele occurs as a result of overdistention of lactiferous ducts with resultant inspissation of milk. It usually presents as a firm nontender mass in the outer quadrants of the breast, away from the areolar margin.

### Fibrocystic Changes

Fibrocystic change (FCC) of the breast is the most frequently encountered benign breast disorder. It occurs most often in reproductive women between the ages of 30 and 50 years. It also occurs in approximately 10% of women younger than 21 years of age; therefore, breast symptoms in adolescence must not be ignored. Fibrocystic condition does not increase the risk of developing breast cancer, but it does often make the physical examination of the patient more difficult (Fig. 41.5).

In 85% to 90% of cases of significant FCC, breast discomfort is the leading symptom. Women often present with a history of bilateral, menstrually related, painful, tender, and nodular breasts, most often localized to the upper outer quadrants. Typically, the pain is most severe just before menses as a result of the normal physiologic stromal edema and ductal dilation.

The breast is normally an inhomogeneous appendage with uneven distribution of adipose and fibrous tissue. It is estimated that at least 50% of women have palpably irregular breasts. This “normal” anatomic asymmetry leads to physiologic inhomogeneity, irregularity, or lumpiness in some women. Nodularity, particularly as it waxes and wanes during the menstrual

cycle, is a physiologic process. This nodularity and irregularity is often mistaken for a dominant breast mass. Evaluation of FCC, thus, creates a difficult dilemma for physicians. Providers must carefully decide whether their findings represent a dominant mass or an exaggeration of normal breast tissue associated with the “nodularity” of FCC.

Dominant masses may represent a variety of benign and malignant processes, including fibroadenomas, macromas, prominent areas of FCC, fat necrosis, abscesses, or carcinoma. Dominant masses are distinguished by their persistence throughout the menstrual cycle and palpable difference on examination from the surrounding breast parenchyma. Often, evaluation of the contralateral breast assists in determination of whether an anatomic variation is a mass or normal breast tissue. However, any concern should be referred for evaluation, or a repeat examination may be performed after a menstrual cycle to detect persistence. A delay of 1 to 2 months in a reproductive age woman is acceptable; however, a shorter-term follow-up is preferable in a menopausal woman because of the higher frequency of breast cancer in this age group. Breast masses are often easier to appreciate in postmenopausal women because of atrophy of the surrounding nodular glandular elements. A positive mammogram is helpful. Conversely, a negative mammogram does not obviate the need to evaluate a mass by fine-needle aspiration (FNA) or a histologic method of biopsy as there is a 10% to 15% false-negative rate for mammography.

Fibrocystic change is a term proposed by the ACS. The terminology encompasses several histopathologic categories, including macrocyst formation, hyperplasia of ductal epithelium, apocrine metaplasia, papillomatosis, duct ectasia, sclerosing adenosis, and stromal fibrosis, thus leading to significant confusion. Reporting criteria for pathologists may include all or adenosis, and stromal fibrosis, thus leading to significant confusion. Reporting criteria for pathologists may include all or any combination of these terms.

Benign Tumors
Most women discover their own breast masses by chance or by periodic self-breast examination. Two thirds of the masses found during a woman’s reproductive years are benign and include cystic changes, fibroadenomas, and papillomas. However, 50% of the palpable masses in perimenopausal women and the majority of lesions in postmenopausal patients are malignant. Once a lesion has been characterized as a mass or a dominant mass must be differentiated from a cancerous process. A delay of 1 to 2 months in a reproductive age woman is acceptable; however, a shorter-term follow-up is preferable in a menopausal woman because of the higher frequency of breast cancer in this age group. Breast masses are often easier to appreciate in postmenopausal women because of atrophy of the surrounding nodular glandular elements. A positive mammogram is helpful. Conversely, a negative mammogram does not obviate the need to evaluate a mass by fine-needle aspiration (FNA) or a histologic method of biopsy as there is a 10% to 15% false-negative rate for mammography.

Reporting criteria for pathologists may include all or any combination of these terms.

Conversely, mild hyperplasia (which may also be included in the FCC categorization) does not increase a patient’s risk of breast cancer development. Practitioners should attempt to describe exactly what they are feeling rather than use the undefined FCC term in the clinical arena. This term is not clinically meaningful in that it designates a heterogeneous group of processes, some pathologic and some physiologic. Treatment options for FCC-induced mastalgia are discussed later. Table 41.2 summarizes the various FCCs and their relative risks of breast cancer.

| Multiple, and may be associated with a green-brown nipple discharge (although a thorough evaluation of the nipple discharge should occur despite the presumption of its origin). Of course, any dominant mass must be differentiated from a cancerous process. Fibroadenomas are the most common benign tumors of the female breast and represent the most common breast tumor in women younger than 25 years of age. These tumors are often clinically painless, well circumscribed, and freely movable with a rounded configuration. They are usually rubbery or firm, but when calcified, they may present as a stony hard mass. Multiple fibroadenomas may develop simultaneously or successively in one or both breasts in 10% to 15% of cases. Growth of the fibrous stromal and glandular tissue is thought to be the result of an unopposed estrogenic influence on susceptible tissue, aberrations of normal breast development, or the product of hyperplastic processes, rather than a true neoplasm. These tumors often contain estrogen receptors; hence, they may fluctuate in size with the menstrual cycle or increase in size during pregnancy. They routinely involute with menopause. They are uncommonly associated with carcinoma, but, rarely, in situ lobular or ductal carcinomas arise in or involve fibroadenomas (Fig. 41.6). Fibroadenomas infrequently grow to be very large (10–15 cm in diameter). These are called giant fibroadenomas, although most are excised at 2 to 4 cm. When morphologic changes such as leaflike clefts and “slits” are present, these fibroadenomas are called phyllodes tumors (formerly known as...
Breast Diseases: Benign and Malignant

FIGURE 41.6. Histologic section of fibroadenoma with cellular stroma (in a pericanalicular pattern), ducts maintain patency (H&E ×240) (Courtesy of Taalat Tadros, MD, Emory University, School of Medicine, Atlanta, GA.)

FIGURE 41.7. Benign tumors. A: A circumscribed breast tumor from a young patient illustrates fibroadenoma. A mixture of benign epithelial and stromal components is seen. B: Phyllodes tumor of the breast showing a pattern superficially similar to that of (A). It is distinguished by its leaflike pattern of stromal growth in cystic spaces. The stroma is also markedly cellular. This tumor, although structurally benign, is capable of recurrence. (Courtesy of Bhagirath Majmudar, MD, Emory University School of Medicine, Atlanta, GA.)

as cystosarcoma phyllodes). These can be benign or malignant lesions. Histologic examination reveals that these lesions have a more cellular stroma, rarely display a prominent pericanalicular growth pattern, and tend to occur in an older age group (Fig. 41.7).

Management of fibroadenomas is varied. The key to management in all clinical situations is individualization. In women younger than 25 years who have fibroadenomas diagnosed by concurred physical examination, sonography, and FNA (“modified” triple test), the risk of missing breast cancer is 1 in 429 to 1 in 700. This risk remains very low in women younger than 35 years who also have the battery of tests. Fibroadenomas do not regress spontaneously and tend to enlarge with time. Because of the low probability of cancer, conservation is particularly acceptable in women younger than age 25 years if the fibroadenoma is small, not increasing in size, or is not psychologically disturbing. Mammography is an integral part of the evaluation in women older than 30 years (or younger depending on risk factors and clinical suspicion). Lesions greater than 2 to 3 cm should probably be evaluated for excision.

Some authors promote excision of all fibroadenomas, regardless of histology. Clearly, if the FNA cytology reveals atypia or hyperplasia, excisional biopsy should be performed. Small, asymptomatic, mammographically detected fibroadenomas proven by FNA or core biopsy may be watched depending on clinical duration and patient risk factors. Although fibroadenomas may be suspected on the basis of their clinical presentation, a final diagnosis cannot be made without histologic or cytologic confirmation.

Intraductal papilloma and breast cancer are discussed later in this chapter.

COMMON BREAST SYMPTOMS

Mastalgia

Pain is a common and enigmatic condition experienced by 70% of women younger than 55 years and accounting for nearly 50% of breast related visits to the physician’s office. Research into the treatment of breast pain is difficult to interpret as a result of the heterogeneous nature of the pain, the fact that symptoms generally resolve spontaneously within a short time, and because typically, one fifth of patients respond to placebo. Because of the subjective nature of the problem and difficulty in quantification, it was often ignored as a psychoneurotic disorder, although nearly 10% of breast cancer patients have pain as the initial presenting symptom (yet breast pain alone is rarely a presenting symptom of cancer). The histopathologic correlation and optimal treatment of mastalgia are still inadequately defined.

Breast pain may be divided into cyclic, noncyclic, and extramammary categories. A careful history should include the use of pain charts (particularly in patients with persistent or recalcitrant symptoms), documenting exactly when pain occurs during the month and the exact nature of the discomfort. The Cardiff Breast Pain Chart, visual analog scales, and the McGill Pain Questionnaire are frequently used to quantify pain. In addition, a thorough physical examination and radiologic procedures (when appropriate) can assist in distinguishing these three groups. Delineation is important as presenting symptoms, spontaneous remission rates, and likelihood of response to treatment differs for these categories.
Cyclic breast pain usually starts during the luteal phase of the menstrual cycle and may crescendo until the onset of menses, when it disappears. Conversely, some pain may be present at low levels during the entire cycle with premenstrual intensification of symptoms. Cyclic mastalgia typically involves bilateral upper quadrants of the breast diffusely, but may be more severe in one breast than the other and is often attributed to FCG. Therefore, although there is some evidence that this could be related to a decreased progesterone:estrogen ratio during the luteal phase of the menstrual cycle, increased levels of saturated fats, reduced proportions of essential fatty acids, or an unusually high reactive state in the body’s regulation of normal cyclic prolactin release. Because so many women experience asymmetric discomfort, it is unlikely that the sole basis of the monthly pain is hormonal or dietary.

Although mastalgia may be the presenting symptom, most patients are concerned with the possibility of cancer. Therefore, for the majority of patients without a dominant mass, reassurance is often sufficient without the need for medical intervention. Appropriate assessment should be performed, which may include examination, sonography, mammography (depending on age and risk factors), pregnancy testing, and/or frequent follow-up.

Those with severe and protracted symptoms that blanket everyday life and interfere with normal enjoyment and disrupting daily routine, merit treatment. One study showed that mastalgia hampers sexual activity in 48% of women, physical recreation in 37%, social endeavors in 12%, sleep in 10%, and work/school activity in 6%. Thus, breast pain affects not only the individual sufferer but the patient's family and society at large.

Numerous nonpharmacologic methods have been proposed, which include massage, exercise, relaxation training, acupuncture, increasing soy or iodine intake, decreasing methylxanthine intake (coffee, tea, chocolate, cola beverages), promoting weight loss (low-fat diet), and taking diuretics (on the hypothesis that fluid retention is the basis of the problem), but scientific support for these methods is lacking or inconsistent. However, given the well-documented health benefits of caffeine avoidance and weight loss, as well as its low cost, few side effects, health care practitioners may want to suggest these measures, especially in those with symptomatic disease and moderate to high intake of caffeine. Anecdotal evidence exists for the use of gingster tea, vitamin A, vitamin B complex, and a supportive brassiere, but the extent of which these methods are effective is unclear, and placebo-controlled trials have not confirmed these results. Depending on severity, acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) may be helpful. Additionally, topical NSAIDs have shown some effectiveness.

Several hormonal methods for treatment of cyclic breast pain have been advocated. No regimen is 100% effective, and some have a significant placebo response rate. Currently, danazol, an antigonadotropin, is considered the most efficacious (response rates near 75%–92%) and is the only medication approved by the Food and Drug Administration (FDA) for this purpose. However, nearly 30% of patients experience the adrenergic side effects of hirsutism, deepening voice, and amenorrhea, thereby limiting its widespread acceptance. Thus, it is not routinely recommended as a first-line therapy and should be reserved for patients whose pain is strongly affecting their life. This prospective trial, with eventual tapering to lower dose or alternate-day administration. Many patients may not experience relief until 400 mg/day is given. Recommendations on the length of treatment vary from 2 to 6 months. Upon discontinuation, the dose should be tapered to prevent rapid withdrawal. As with all hormonal medication, discontinuation may cause resumption of symptoms.

Because doses less than 400 mg/day do not ensure inhibition of ovulation, an effective method of mechanical/barrier contraception (as it may interfere with oral contraception) should be given to avert possible teratogenic effects of the drug. If the drug phase-only used (200 mg/day) is an alternative treatment regimen that appears to be highly effective for the relief of premenstrual mastalgia. This regimen is associated with few side effects, but further study is necessary to ascertain whether such a regimen avoids potential adverse effects on lipid status. Bromocriptine (Parlodol, Sandoz) is an ergotalkaloid that acts as a dopaminergic agonist on the hypothalamic-pituitary axis and has been effective for mastalgia in 40% to 88% of patients. The dosage of bromocriptine is similar to that discussed earlier in the section on nipple discharge. However, one third of patients experience side effects, and 30% relapse once treatment is discontinued. Side effects may be minimized with use of an incremental dosing regimen, with stepwise increases during a period of 2 weeks. Medication is usually discontinued after 2 months to review symptoms.

Evening primrose oil (EPO) (gamma-linolenic acid) is advocated by many as initial therapy for breast pain. At 3 to 4 g/day, EPO has been noted to have an overall useful response rate of 44% to 97% in some groups of women. Side effects were found in 2% to 12%, but all were insignificant. Yet a randomized, double-blind trial comparing EPO and fish oil showed no difference in response rate; thus, data are conflicting. Gamma-linolenic acid is a precursor of the unsaturated fatty acids and is essential for the production of beneficial prostaglandins in the body. Several hypotheses have been espoused to explain the effects, including modification of prostaglandins. These have include fluidity technical, changes in associated receptors, changes in the inositol cycle, or diminishing response of the breasts to cyclic hormone activity. Yet, the delayed effectiveness (4 months) and the potential gastrointestinal and abortifacient side effects suggest caution in its use, especially in women desiring pregnancy. Most physicians must be cognizant that herbal agents and nutritional supplements are not standardized or monitored for adulteration, and potential interaction with other medications must be considered. Oral contraceptive pills (OCPs) may be a good option for patients seeking birth control in addition to relief of breast symptoms. Earlier studies (which used pills containing significantly higher progestrone contents) indicate that mastalgia was suppressed in 70% to 90% of patients who used the medication for 3 to 6 months. Maximum effects were noted after 2 years of use, but significant decreases in symptoms were noted after 1 year of use. Symptoms recur in up to 40% of patients when the high-dose OCP is discontinued. There is limited research on the effectiveness of the new low-dose formulations of OCPs in the treatment of mastalgia. However, in a recent study by Leonardi, 60% of patients with chronic mastalgia showed a reduction or improvement in symptoms while taking a low-dose formulation for 3 months. This study did not have a placebo group for comparison. The effectiveness appears to be due to the reduced ovarian estradiol production and the alteration of breast estrogen receptors caused by the progestin component of the pill. Although the older formulations appear to have some benefit, the new low-dose estrogen, patches, and the phased estrogen and progesterone dosage medications should be evaluated in a prospective trial to determine effectiveness in the treatment of severe mastalgia. Topical, oral, and parenteral progestogens have also been studied for treatment of breast pain with variable results.
Tamoxifen (20 mg/day) has also been successful in the treatment of mastalgia. It has been heralded as the most effective and least toxic agent for the treatment of severe chronic breast pain. In one study comparing tamoxifen, danazol, and placebo, tamoxifen had the greatest pain relief score, with nearly 75% of those receiving tamoxifen having significant pain relief compared with 65% with danazol and 38% with placebo. Twelve months after treatment, 37% of the danazol-treated patients and none of the placebo-treated patients. Lower dosages (10 mg/day) appear to have significantly fewer side effects and to be as effective in pain control as the higher dosages (20 mg/day). The metabolic effects on bone, mineral metabolism, and lipid profile were insignificant after 3 months of treatment. The effectiveness appears to be due to a reduction in nuclear volume and mitotic activity of the epithelium even when administered only in the luteal phase. However, lack of evidence of the long-term consequences of treatment (particularly deep venous thrombosis and endometrial adenocarcinoma) portends caution in implementation of its use in benign breast disease. Toremifene citrate, a new member of the family of selective estrogen receptor modulators (SERMs), has been shown to have a better safety profile than tamoxifen, as well as efficacy in treatment of mastalgia in a double-blind, randomized, placebo controlled study. Adverse events were similar to that in the placebo group, except vaginal discharge was increased in this short-term study.

Vitamin E at dosages of 600 to 1,200 international units (IU)/day has been associated with a 41% response rate. However, lower dosages have usually been recommended. The mechanism of action is unknown but is proposed to include its potential to alter steroidal hormone production (dehydroepiandrosterone or progesterone), to correct abnormal serum lipid distribution, and to function as an antioxidant (which appears to neutralize free radicals, thereby preventing cell damage and subsequent malignant transformation). Data are inconsistent regarding vitamin E and cardiovascular risk. Recent epidemiologic data indicate an inverse association between cardiovascular risk and vitamin E intake, but other studies indicate benefit for vitamin E in prevention of heart disease, cancer, and dementia. Two randomized controlled trials in women older than 45 years (using 600 IU/every other day) and in elderly patients with cardiovascular disease or diabetes (using 400 IU/day) have shown no benefit in prevention of major cardiovascular events or cancer. Germane to this discussion was the discovery that vitamin E slightly increased the risk of heart failure (5.8% compared with 4.2% hospitalizations for heart failure) at a dosage of 400 IU/day in elderly patients with chronic disease. Thus, researchers are now recommending that vitamin E doses be limited to less than 400 IU/day. Although myocardial infarction prevention is likely not a role for vitamin E, there is strong evidence from other studies that moderately high doses may have other important health roles, including delaying the onset of macular degeneration (a major cause of early blindness) and boosting the immune system in the elderly. Moreover, it is currently being studied by the National Institutes of Health (NIH) in 35,000 men in the Selenium and Vitamin E Cancer Prevention Trial (SELECT) for the prevention of prostate cancer at dosages of 400 IU.

Danazol is an androgen antagonist that moderately high doses may have other important health roles, including its potential to alter steroidal hormone production (dehydroepiandrosterone or progesterone), to correct abnormal serum lipid distribution, and to function as an antioxidant (which appears to neutralize free radicals, thereby preventing cell damage and subsequent malignant transformation). Data are inconsistent regarding vitamin E and cardiovascular risk. Recent epidemiologic data indicate an inverse association between cardiovascular risk and vitamin E intake, but other studies indicate benefit for vitamin E in prevention of heart disease, cancer, and dementia. Nipple Discharge

Any breast symptom has the potential for creating an enormous amount of anxiety for patients. Nipple discharge is the third most common reason for women to consult their physicians regarding a breast problem and is responsible for 7% of breast operations. Reports of nipple discharge not only account for 3% to 6% of office visits for women with breast symptoms, but also occur in 10% to 50% of women with benign breast disease and in 10% to 13% of women with breast cancer. Almost one half of women in their reproductive years can manually express one or more drops of nonpathologic liquid from the breast; conversely, spontaneous discharge from the nipples is uncommon. The practice of squeezing the nipple either during breast self-examination (BSE), clinical breast examination (CBE), or sexual and physical activity can elicit fluid from women of all ages and is thus divisive. This outcome is the basis for suggesting that one should not attempt to elicit nipple discharge during an examination of an asymptomatic patient because pathologic discharge is likely to occur spontaneously without nipple manipulation. However, if nipple discharge is a symptom, the breast examination must include “milking” of the breast toward the nipple to delineate the exact ductal source of the problem.

Galactorrhea

Secretions from the breast may be divided into milky (galactorrhea) and nonmilky discharge with physiologic and pathologic etiologies in each category. Other investigators classify secretion from the nipples according to color, cellularity, and biology. Galactorrhea, which is the nonprofuse secretory secretion of breast milk, must be separated from other types of nipple discharge. This may be done by viewing a sample, under low-power magnification, for multiple fat droplets of various sizes. If the secretion does not contain fat droplets, it is not (by definition) galactorrhea and must be evaluated by other criteria. Galactorrhea usually results in bilateral nipple discharge from multiple ducts and is unassociated with a mass. On the contrary, pathologic sources of nipple discharge may be characterized by unilateral discharge from a single duct with an associated mass in some cases. Also, nipple discharge in women older than 30 years is of concern. Pathologic sources of galactorrhea include medications, hypothalamic lesions or dysfunction, thyroid disorders, Forbes-Albright syndrome, chest lesion (chest trauma, burns, herpes zoster, lung cancer), renal disease, pituitary prolactin-secreting tumors, and nonpituitary prolactin-producing tumors (lung, kidney, craniopharyngioma).

Although many hormones are involved in normal lactation and galactorrhea, prolactin is the most significant. Prolactin was isolated in 1971 and is secreted by the anterior pituitary, the chorion of pregnancy, and by decidual and endometrial tissue. Prolactin (like luteinizing hormone) is secreted in a pulsatile fashion throughout the day with a circadian rhythm. Normal values generally range between 0 and 20 ng/mL.

The most common cause of physiologic nipple discharge is pregnancy, when prolactin values increase to 100 to 200 ng/mL as early as the 10th week of gestation. Lactation does not occur until after delivery because the peripheral action of prolactin is inhibited by estrogen and progesterone. During the process of suckling, prolactin increases to 300 to 600 ng/mL. After 6 months postpartum, there is no longer an increase from baseline associated with suckling. Therefore, amenorrhea, galactorrhea, or hyperprolactinemia more than 6 months after delivery is not physiologic. Any duration of galactorrhea demands evaluation in a nulliparous woman and, if at least 12 months have elapsed since the last pregnancy or weaning, in a parous woman.

The differential diagnosis of galactorrhea (excluding physiologic lactation) is a complex clinical challenge resulting from multiple factors involved in the control of prolactin release. A thorough and detailed history and physical examination are necessary to discern the cause. Prolactin itself, PIP, and PRPs are the major substances involved in prolactin homeostasis. Thus, the pathologic cause of nipple discharge can be easily comprehended with an awareness of the release—inhibition pathway.

To be significant, a discharge should be spontaneous, persistent, and nonlactational. The most common source of galactorrhea is consumed medication; thus, a thorough review of the patient’s medication list is an essential element of the initial evaluation. Tranquilizers and antidepressant medications block the dopamine receptor, whereas amphetamines, such as reserpine and methylphenidate (Ritalin), inhibit the synthesis of dopamine. Opiates (including heroin), amphetamines, marijuana, phenoxybenzamine, and anesthesia suppress dopamine levels.

Nonmilky Nipple Discharge

Nonmilky nipple discharge is often divided into bloody and nonbloody categories (with physical and pathologic causes in each). Tests such as hemoccult or urine dipstick may be helpful to discover occult blood in the secreted fluid, but results should be scrutinized in the face of severe inflammation, which may lead to false-positive results. Additionally, although breast cancer may be associated with a watery or serous discharge; hence, nipple discharge in postpartum women who use the medication. However, its use in women who are not recently pregnant or lactating continues to be recommended. Treatment begins with 1.25 mg orally twice daily and is increased to 2.5 mg orally twice daily once the patient is able to tolerate the side effects. Primary care providers should be made aware of any government, manufacturer, or health advocate updates on the use of this drug.

of nipple discharge rests on its frequency of association with cancer or precancerous mastopathy. Bloody nipple discharge may be seen during the third trimester of pregnancy and while breast feeding is becoming established. It typically subsides within 2 months. Evaluation with cytology is often unproductive. However, discharge lasting more than 2 months, associated with a mass, deriving from a specific ductal source, or having a distinct color or consistency, may be elicited immediately after pregnancy in the absence of significant breast pathology. The phenomenon is likely due to the development of delicate, easily traumatized capillary networks within the ducts. If a breast mass is not found by physical examination or sonography, regular follow-up should be continued because the condition usually disappears shortly after delivery. If a mass is present, FNA or CNB should be performed.

Physical examination, mammography, or galactography and sonography may be used to delineate the exact nature, location, and extent of the lesion preoperatively. Galactography involves cannulation of the discharge-producing duct with a small catheter or needle and injection of a water-soluble contrast agent in the duct. Ductal-oriented sonography uses modern high-resolution techniques to visualize the mammary ducts in detail. These procedures may be complementary in that cases of ducal abnormalities have been missed by sonography yet visualized by galactography. However, researchers caution that modern galactography has a high false-negative rate, so it does not reliably exclude intraductal pathology and is, therefore, not a substitute for surgery in patients with pathologic discharge. Ultrasound may be used in pregnancy to delineate a mass. However, if there is a high suspicion for cancer, a shielded mammogram should be ordered.

Fiberoptic ductoscopy is an emerging technique allowing direct visualization of the ductal system of the breast through nipple orifice exploration. When this procedure was applied to women with nipple discharge, an 83% positive predictive value was noted. The positive predictive value was increased to 86% with the addition of ductal washings to obtain exfoliated cells for evaluation at the time of the ductoscopy. MRI has also been shown to be of diagnostic value, but it is not as informative as regular galactography. Both modalities may offer safe alternatives for identification of malignancy. However, subsequent breast surgery in the treatment of nipple discharge may be required. If imaging studies were unable to preoperatively identify the specific ductal source of nipple discharge, surgical exploration may be required. Skin hooks are used to lift the skin flaps for easier visualization and exploration. The affected duct is identified, and excised. Hemostasis and closure techniques are similar.

method of collecting ductal epithelial cells for cytologic evaluation currently under investigation at several institutions. In a clinical trial of 507 high-risk women, cells collected through ductal lavage were shown to detect the presence of precancerous and cancerous changes in 20% of the women. The presence of these changes correlated with a fivefold to 18-fold increase in the risk of developing breast cancer, depending on family history and the patient’s risk determined by the Gail model. However, sensitivity in detection of invasive and in situ breast carcinoma is low and thus the initial fervor over this procedure is waning except when used for pretreatment analysis. Ductal lavage may not only be a helpful adjunct to determine which high-risk women require closer, more active management, but it may also be used to track cell status in particular ducts over time. Additionally, proteomic analysis of ductal lavage fluid may provide answers regarding tumor markers or patient response to treatments.

Breast cancer is known to develop over time and to present nearly 6 years before earliest detection on mammography. Availability of this technique is termed to provide practitioners with a tool to detect precancerous and cancerous breast cells before they become palpable cancers that can be imaged, thus allowing closer surveillance, surgical intervention, or chemoprevention. Investigational protocol eligibility often includes (i) women with a prior history of breast cancer; (ii) women at high risk for development of breast cancer as defined by Gail Index score, family history, BRCA mutation, or atypical hyperplasia; and (iii) those with persistent or bloody nipple discharge. Incorporation of ductal lavage into an examination of nipple discharge should not replace other standard evaluations. In studies combining CBE, mammography, MRI, and ductal lavage, ductal lavage was noted to detect atypia in an individual with a normal MRI and mammogram. However, additional research is needed to determine the role, sensitivity, and specificity of this method. Additionally, the significance of detection of high-risk lesions in decreasing breast cancer morbidity must be ascertained.

Ductal lavage involves placing a special suction cup over the nipple and applying negative pressure to collect the nipple aspirate fluid (NAF) (Fig. 41.9). A microcatheter is then inserted through the nipple orifice, into the identified fluid-yielding ducts. After saline injection, the ductal fluid is withdrawn and sent for cytologic analysis. In preliminary trials, 79% of subjects yielded NAF, although this rate may be influenced by race and age. In women older than 50 years, African American, Mexican American, and Asian women typically yielded less NAF. The phase of the menstrual cycle, a history of pregnancy, or use of OCPS did not significantly affect the availability of NAF. Hormone replacement therapy (HRT) in postmenopausal women tended to increase the amount of NAF obtained.

**DIAGNOSIS**

Breast cancer accounts for 30% of all cancers in women and 15% of deaths from cancer. Although more than 40% of cases of breast cancer are continuing to decline, incidence rates among certain subgroups (Asian Pacific Islander women) are increasing. Gynecologists are in a crucial position for coordination of ongoing medical care for patients with breast problems. Breast symptoms are appropriately detected by a breast-oriented, physical examination, cytology studies, and imaging techniques. If the diagnosis is in doubt, open surgical biopsy provides the definitive histologic diagnosis.
Breast Diseases: Benign and Malignant

History

A thorough history is a vital aspect of the initial evaluation. However, breast cancer cannot be excluded by any single fact within the patient’s history; rather, the history focuses attention on additional information. The practitioner should obtain detailed information about the patient’s symptom and other pertinent related positive and negative symptoms. The information necessary to assess breast health includes age, menstrual, gynecologic, sexual, reproductive, and lactation history, and any family history of breast or ovarian disorders (including age at onset/diagnosis). Because of recent advances in genetic etiologies, be sure to include cancer assessment of the maternal and paternal family history. In addition, a total body review of systems (e.g., headache, blurred vision for macroadenomas) should be focused on the patient’s symptom. Of vital importance are the following:

- Menopause status
- Timing and specific nature of symptoms
- Cyclic changes
- Onset, duration, and growth pattern of any masses
- Presence of pain
- Attempted and successful relief measures
- Alleviating and aggravating factors
- Use of HRT or OCPs
- Presence or absence of risk factors for breast cancer

All previous breast diagnostic and surgical procedures should be documented. Past medical and surgical history, as well as current medications and social history (including smoking, alcohol, and educational level), should also be reviewed.

Because most breast symptoms in reproductive-aged women are due to a benign cause, reassurance may be an important aspect in reducing anxiety. However, the practitioner should notify the patient of any concerns regarding the history and examination to ensure that the patient understands the significance of follow-up and does not misconstrue the practitioner’s reassurance to mean the diagnostic workup is completed.

Self-Breast Examination

Mammography remains the gold standard for early detection of breast carcinoma, but this technique is not 100% effective. CBE and BSE are important facets of a breast screening program. Controversy exists regarding the utility of routine BSE for increasing the rate of breast cancer detection. Studies yield conflicting results. The research has been hampered by differing BSE education strategies, schedules of performance, and control groups. Although the results are often incongruous, some authors have found a 34% reduction in nodal involvement and increased survival in women performing BSE compared with women who do not. In addition, 70% to 90% of masses are first detected by the women themselves. In a randomized trial in Russia, more cancers were found in the instruction group than in the control group (RR 1.24, 95% CI 1.09–1.41), whereas this was not the case in Shanghai. Conversely, a study from Shanghai of more than 250,000 women, who were randomized to no instruction or to intensive BSE instruction, failed to demonstrate any difference in the number of cancers detected or in the stage or size at which they were found (RR 0.97, 95% CI 0.88–1.06). No reduction in mortality was seen, but more than twice as many benign lesions were found in the
self-examination group. Yet, these trials review BSE instruction, not the practice of BSE, as this information could not be reliably obtained from self-report. Accordingly, promotion of BSE as a single screening method is often not recommended. These findings require assessment, but to negate BSE as an important component of overall personal health care seems inappropriate if there is any possibility that it will affect the survival rate in women. In breast disease, wherein early detection is so clearly related to improved survival, the value of these relatively simple, economical, and minimally inconvenient techniques cannot be overemphasized. With this in mind, the American College of Obstetricians and Gynecologists (ACOG) and the ACS continue to recommend BSE be performed monthly beginning at age 20.

Clearly, discussion of BSE must include the benefits and limitations for the individual patient incorporating personal risk factors. Effective instruction of patients in the technique of BSE incorporates description of the procedure while the patient views the health care provider's performance of the examination. Additionally, having the patient reiterate her understanding of what has been taught and then demonstrating her mastery of the technique using manufactured breast models further solidifies compliance. The patient should understand the significance of breast inspection in various positions as well as the utility of breast palpation in the standing as well as supine positions. The circular method of breast palpation is routinely the easiest to master, although for patients with pendulous breasts, positional changes to ensure positioning of the breast tissue on the chest wall must be emphasized. The best time to perform the examination is usually the week after the menses, although menopausal women should pick a convenient time of the month, such as their birth date or the first of each month. After hysterectomy, patients with continued estrogenic support for the ovaries should observe for breast fullness or tenderness. Breast examination should then be performed 7 to 10 days after maximal breast symptoms.

Clinical Breast Examination

As with BSE, the utility of routine CBE in asymptomatic women has been questioned. Query into its reliability and efficacy has been propagated; however, there is greater scientific support for CBE. The Canadian Health Insurance Plan noted a 70% reduction in mortality from breast cancer as a result of physical examination. Although inferior to mammography, CBE has a sensitivity of 57% to 70% in detecting breast cancer. In addition, the ACS recommends annual CBE of women age 40 years and older and CBE every 3 years for women ages 20 to 39. Strategies to improve a practitioner's ability to detect a mass include increasing the time devoted to the examination, using a technique with variable degrees of pressure, and developing a systematic, consistent search mode. The size of the lesion, of course, is also correlated with the practitioner's ability to detect the mass.

To capture any benefit from early detection, CBE should be a routine part of the examination of gynecologic and obstetric patients. Obstetrician/gynecologists should not abdicate their responsibilities by relying on previous examinations performed by other specialists. Breast Diseases: Benign and Malignant

FIGURE 41.10. (1) Examination of the breasts begins with inspection. The patient is disrobed to the waist and comfortably seated facing the examiner. Asymmetry, prominent veins, and skin changes may be signs of disease. (2) The patient raises her arms above her head, thereby altering the position of the breasts. Immobility or abnormal cutaneous attachments may become evident. (3) Inward pressure on the hips tenses the pectoralis major muscle. Abnormal attachments to its overlying fascia and skin can produce retraction or dimpling of the skin. (4) Supraclavicular lymph nodes are examined by palpation. (5) The deltopectoral triangle is palpated for evidence of infraclavicular nodal enlargement. (6) Each axilla is examined for nodal enlargement. Proper placement of the examiner’s hands and of the patient’s arm is important. (7) Thorough palpatory examination of the entire breast for masses is performed with the patient in the supine position. A fine rotational movement of the hands is useful to appreciate the consistency of the underlying tissues. The examiner should check for nipple discharge by compressing the ducts in a clockwise manner toward the nipple. (From Scott JR, Diltsa PJ, Hammond CB, et al. Danforth’s obstetrics and gynecology, 7th ed. Philadelphia: JB Lippincott, 1994:700.)
A nipple discharge. Each quadrant of the breast is "milked" and impede any discharge from coming to the surface. Using squeezing the nipple may actually obstruct the ductal orifice relate this information to the practitioner, particularly if they symptoms. Patients often have such symptoms but forget to excessive breast manipulation can lead to a nipple discharge. Many practitioners use two hands to perform the breast examination, although a thorough and systematic use of a single hand is satisfactory. Use of the two-handed method uses the second hand to follow behind in the same pattern as the initial hand, thus providing dual evaluations of each area. The Mammocare method of breast examination uses a single hand for palpation in the vertical-strip pattern. If the patient presents with breast symptoms, it is advisable to palpate the unaffected breast first to develop a “tactile baseline” with which to compare the involved breast and prevent omission of lesions in the unaffected breast. Palpation should extend beyond the actual breast tissue to encompass the supraclevicular and infraclevicular lymph nodes, the area adjacent to the sternum, approximately 1 to 2 cm below the inframammary ridge, and the axillary tail of Spence. The examination encompasses these areas to ensure nodal involvement is discernible. Routine evaluation of the nipple for nipple discharge is controversial, and some authors do not recommend this as a routine portion of the breast examination in women without symptoms. It is well known that excessive breast manipulation can lead to a nipple discharge. If one does exclude this as a routine part of the examination, a detailed history should be obtained to rule out any nipple symptoms. Patients often have such symptoms but forget to relate this information to the practitioner, particularly if they have experienced the symptoms for an extended period of time. Squeezing the nipple may actually obstruct the ductal orifice and impede any discharge from coming to the surface. Using a milking technique improves the examiner’s ability to elicit a nipple discharge. Each quadrant of the breast is “milked" by sliding the fingers from the outer quadrant in a clockwise fashion toward the nipple and documenting the location of any fluid accumulation.

Regardless of the pattern of breast examination used, the importance of using a consistent and methodical pattern of evaluation and allowing sufficient time for a thorough assessment should not be underemphasized as factors that increase detection capabilities. As stated, the evidence supporting the value of CBE as a method of reducing breast cancer mortality is limited and mostly inferential, as there is no definitive prospective randomized controlled trial evidence from which to draw conclusions. Thus, current recommendations rely on existing evidence and expert opinion.

In this increasingly litigious society, breast assessment demands careful documentation of the history, examination, and disposition of the case. A clear and legible note should record all findings from the breast examination noting texture, size, consistency, and a detailed description (including diagrams) of abnormal and suspicious features, as well as the plan of action for follow-up. Although positive or abnormal findings are very important, it is important to list negative findings in the medical record as well.

**Mammography**

The etiology of breast cancer remains an enigma; therefore, the major opportunity to alter the natural course of the disease is provided by diagnosing the disease at an early stage, when the prognosis for cure is excellent. Mammography is the most effective screening method for detection of nonpalpable and minimally invasive breast cancer. Studies assessing the value of mammography as a screening tool in the detection of breast cancer are inconsistent. Although estimates vary, it has been suggested that a lesion must be 1.0 to 2.0 cm before it may be palpated. A breast carcinoma grows for 6 to 8 years before reaching a diameter of 1 cm. In slightly less than another year, the carcinoma reaches 2 cm in diameter. It is estimated that, on the average, a mammogram detects a breast cancer 2 years before it is palpable.

Routinely, a false-negative rate of 10% to 15% is quoted; therefore, a normal mammographic examination does not rule out the presence of breast cancer (Table 41.3). Thus, a palpable mass requires further evaluation despite a “negative” mammographic examination. Dense parenchymal tissue is the principal cause of false-negative mammograms. Other sources of error include misjudging a well-circumscribed carcinoma for a benign mass, misconstruing malignant calcifications for benign aberrations, not recognizing the indirect signs of malignancy such as asymmetry, and faulty radiographic technique.
Guidelines promulgated by the American College of Radiology Mammography Accreditation Program have significantly reduced this latter problem. In some studies, HRT reduced the sensitivity of mammographic screening and may undermine the capacity of population-based mammographic screening programs to achieve their potential mortality benefit. For instance, in one research paper, among women who were diagnosed with cancer in the 2-year mammography screening interval, HRT users were more likely to have a false-negative result than nonusers (OR, 1.60; 95% CI, 1.04–2.21). However, among women who did not have cancer diagnosed in the interval, HRT users were more likely to have a false-positive result (adjusted OR, 1.12; CI, 1.05–1.19).

It is important to forewarn patients that adequate breast compression is essential to improved radiographic technique and to deliver a high-quality mammogram. Compression holds the breast motionless, decreasing artifact; separates tissues to disclose small lesions; improves image quality by decreasing radiation scatter; and reduces the radiation dose by decreasing breast thickness. Widespread use of this imaging test, in conjunction with improved treatment, may be responsible for the recent decline in number of deaths from breast cancer. Not only does mammographic imaging enable the detection of nonpalpable breast cancer, but early detection also permits breast conservation surgery (BCS).

Detection Demonstration Project, sponsored by the ACS and the National Cancer Institute (NCI), indicates an even lower average midbreast dose of 0.08 rads. To put radiation risk in perspective, data presented by the National Council on Radiation Protection illustrate that mammographic examination of the breast motionless, decreasing artifact; separates tissues to disclose small lesions; improves image quality by decreasing radiation scatter; and reduces the radiation dose by decreasing breast thickness. Widespread use of this imaging test, in conjunction with improved treatment, may be responsible for the recent decline in number of deaths from breast cancer. Not only does mammographic imaging enable the detection of nonpalpable breast cancer, but early detection also permits breast conservation surgery (BCS).

TABLE 41.3

REASONS FOR FALSE-NEGATIVE MAMMOGRAMS

- Failure to image the region of interest
- Poor image quality
- Errors of perception
- Breast cancer indistinguishable from normal breast tissue

Mammography serves multiple purposes in the evaluation of women’s breast health. It is important to forewarn patients that adequate breast compression is essential to improved radiographic technique and to deliver a high-quality mammogram. Compression holds the breast motionless, decreasing artifact; separates tissues to disclose small lesions; improves image quality by decreasing radiation scatter; and reduces the radiation dose by decreasing breast thickness. Widespread use of this imaging test, in conjunction with improved treatment, may be responsible for the recent decline in number of deaths from breast cancer. Not only does mammographic imaging enable the detection of nonpalpable breast cancer, but early detection also permits breast conservation surgery (BCS).

In detection of breast cancer, there are several mammographic characteristics of malignancy, which include the presence of a mass, architectural distortion, asymmetrical density, and microcalcifications. Malignant lesions generally display more of these pathognomonic mammographic appearances than do benign lesions, but benign lesions may have similar features. Calcification in the breast can be benign or malignant. Round, smooth calcium deposits of uniform size generally tend to be associated with benign processes, whereas branching and polymorphic calcifications suggest the possibility of malignancy. The presence of clusters of microcalcifications in a small geographic area is also a suspicious finding. Microcalcifications play an important role in the early detection of breast cancer. However, calcifications occur in fewer than half of nonpalpable cases, and fewer than half of these calcified lesions demonstrate the classic appearances suggestive of malignancy. The calcifications of FCCs often mimic those of malignancy, leading to unavoidable false-positive mammograms. Calcificlike deposits in the skin secondary to tattoos, deodorants, ointments, or sebaceous gland secretions can also be mistaken for malignancy. Therefore, clustered microcalcifications are a sensitive but not a specific sign of malignancy.

The radiation risks associated with x-ray mammography are considered negligible. Contemporary ionizing radiation units, specifically designed for breast imaging, use the most advanced technology to obtain images of the highest quality with a considerable decrease in radiation dose to probably less than 0.2 to 0.3 rads (2–3 cGy). Information from the Breast Cancer Detection Demonstration Project, sponsored by the ACS and the National Cancer Institute (NCI), indicates an even lower average midbreast dose of 0.08 rads. To put radiation risk in perspective, data presented by the National Council on Radiation Protection illustrate that mammographic examination of the breast motionless, decreasing artifact; separates tissues to disclose small lesions; improves image quality by decreasing radiation scatter; and reduces the radiation dose by decreasing breast thickness. Widespread use of this imaging test, in conjunction with improved treatment, may be responsible for the recent decline in number of deaths from breast cancer. Not only does mammographic imaging enable the detection of nonpalpable breast cancer, but early detection also permits breast conservation surgery (BCS).
100,000 women at age 45 years would theoretically result in the eventual loss of one life.

Screening Guidelines

Mammography has been shown in randomized trials to reduce breast cancer mortality by as much as 23%. Survival from breast cancer is influenced by tumor size, degree of invasion, and lymph node status at the time of diagnosis. The advantage of early detection and diagnosis is reduced mortality because of smaller-sized cancers, more localized lesions with a lower percent of positive nodes, and increased feasibility of RCS. Clearly this fundamental tenet accentuates the importance of compliance with radiologic screening programs and knowledge of guidelines.

Women who have less than a high school education, who are a minority, who are uninsured, who do not speak English as their primary language, and who are socioeconomically disadvantaged are less likely to report having had a mammogram. According to data from the National Health Interview Survey, fewer than 60% of women age 50 years and older and 45% of women age 70 years and older reported having had a mammogram in the preceding 1 to 2 years. Only 38% of women aged 50 years and older with low income and 42% of those with less than a high school education had a recent mammogram. Clearly, efforts to increase screening should specifically target older women and socioeconomically disadvantaged women, who are at the highest risk for underutilization of mammograms.

Randomized controlled trials (RCTs) have demonstrated a decreased mortality rate in women who received mammography at age 50 to 69. However, a metaanalysis by Olsen and Gotzsche demonstrated no reduction of breast cancer mortality when incorporating only two of the existing RCTs of screening mammographies—indicating that the then additional five trials had serious methodological flaws and excluded their results. Yet, a review specifically of the Health Insurance Plan of Greater New York (HIP) screening trials and both Canadian National Breast Screening Studies (CNBSS1 and CNBSS2) documented improved mortality in screen-detected cancers compared with those detected symptomatically. In the HIP trial, 76% of screen-detected cancers were stage I, compared with 51% of interval/incident cancers (cancers detected within less than 1 year or more than 1 year after the last negative screen) and 49% of cancers in the control (no screening mammography). Those unscreened and women who failed to attend their screenings had the highest percentage of stage II/IV cancers (34% and 22%, respectively). Likewise, in the CNBSS 1, 55% of screen-detected cancers, 40% of interval/incident cancers, and 47% of cancers in the control group were stage I. In CNBSS 2, 62% of screen-detected cancers, 44% of interval/incident cancers, and 47% of cancers in the control group were stage I. Although adjusted for lead-time bias, tumor sizes were smaller in the screening groups, and there were significantly higher proportions of negative lymph nodes among women with screen-detected cancers. The survival advantage seems to arise from the mammogram’s tendency to detect less aggressive, more slow-growing, and thus less biologically lethal tumors than those discovered symptomatically. However, despite this benefit, fewer than 40%, even among this age group of women, had had a mammogram in the past year.

The controversy regarding screening in women younger than 50 years of age is multifaceted. Reduction of mortality rates as a result of screening is a subject of debate, the cost-effectiveness when compared with that in older women is unknown, and, finally, the frequency of screening intervals has become a point of disagreement among the committees that issue imaging guidelines. Authors have argued that mammograms performed in women younger than 50 years are not useful because younger women have more radiographically dense breast tissue that obscures abnormalities (Fig. 41.13). Some investigators have advocated yearly mammograms for all women 40 to 49 years old because breast cancer is often more aggressive and faster growing in younger women. The benefit of mammography in women age 40 to 49 years is less clear than for those age 50 and older. However, with mounting years of follow-up, evidence of a benefit for women in their 40s has increased, and studies show that regular mammograms reduce the death rate from breast cancer in this age group by about 17% to 23%. However, some trials with significant numbers still fail to show benefit in this age group. Nevertheless, NCI and the U.S. Preventive Services Task Force recommend screening with mammography beginning at age 40 in women of average risk for breast cancer. ACOG and the ACS continue to recommend offering screening mammography for women 40 to 49 years of age and annually for women older than 50 years. (Tables 41.4 and 41.5). Women who are at higher-than-average risk of breast cancer should seek expert medical advice about earlier screening and the frequency of screening (Table 41.6).

Although there are insufficient data regarding women age...

Many exciting developments are occurring in breast imaging. Although mammography still remains the gold standard for breast cancer screening and diagnosis, it often cannot differentiate benign from malignant disease and is less accurate in patients with dense glandular breasts, with diffuse involvement of the breast with tumor, and in those taking HRT. Ten percent to 20% of breast cancers detectable by physical examination are not visible radiographically. Furthermore, of the women who are referred for biopsy based on mammographic findings, only 20% to 40% of lesions actually prove to be malignant. Clearly, there is room for improvement in both breast cancer detection and lesion characterization.

Digital mammography (DM) is a rapidly evolving technology offering improved efficiency of absorption of x-ray photons, as well as greater contrast resolution, especially in dense breast tissue. Systems are based on the absorption of x-rays by a phosphor material with subsequent conversion of the absorbed energy to electronic charge. The charge signal is then digitized and stored as a matrix in computer memory to represent the image.

The recently reported DMIST trial (Digital Mammographic Imaging Screening Trial) evaluated 49,528 asymptomatic women in the United States and Canada with both digital and film mammography. The overall diagnostic accuracy of digital and film mammography was similar for screen detection of breast cancer, but DM was more accurate in women younger than age 50 years, women with radiographically dense breasts, and pre- or perimenopausal women. Additional data indicate digital systems may be superior to conventional film-screen mammography in detection of microcalcifications which are the earliest evidence of minimal breast cancer. Other studies have shown inferior sensitivity of DM compared with conventional film screen mammography but significantly lowered recall rates.

DM offers further technologic advancements. Computer-aided diagnosis (CAD) is the detection of a potential abnormality by means of computer analysis of the mammogram; that is, a second reading by a computer. Information of this kind can be supplied to radiologists to help improve their diagnostic performance. Several investigators have demonstrated improved radiologist performance in lesion detection and characterization when a CAD system is used. The CAD enhancement of radiologist performance in lesion detection and characterization.

Digital mammography (DM) appears highly promising; however, further clinical studies are needed to evaluate the relative efficacy of different CAD methods. Moreover, the medicolegal status of CAD is uncertain at present and needs to be clarified.

Because digital images can be readily transmitted electronically for remote interpretation and consultation, DM holds the promise of telemammography. DM also allows for stereoradiography or stereomammography, in which two images of the breast are taken at slightly different angles and later “fused” to provide greater perception of the relative depths of structures within the image. Additionally, DM can be used to combine several single images into a three-dimensional image called tomosynthesis. Both techniques have been proposed as solutions to the problem of false-negative conventional...
screen-film mammography due to masking from overlying structures, particularly in very dense breast tissue. During tomosynthesis, multiple images are acquired as the x-ray tube rotates in an arc above the breast and detector. By manipulating the digital image, any plane in the breast can be easily displayed. Preliminary data have shown breast tomosynthesis to be equivalent or superior to conventional diagnostic mammography in small numbers of women. Ultimately such systems may substantially improve diagnostic accuracy. A multicenter validation study is planned.

Dual-energy mammography is another technology that becomes practical once the image is digitized. This technique provides another approach to the problem of overlapping breast tissue masking lesion detection. With this method, two exposures of the breast are made at substantially different x-ray spectra. Weighted subtraction of one image from the other provides additional information about breast tissue composition. Specifically, it may render calcifications more obvious in dense breast tissue.

DM offers other benefits, including diagnostic signs that are identical for interpretation of screen-film mammography and DM, which could facilitate the transition from one system to the other. Another variation, mammography, may be helpful in identifying drug-resistant tumors before therapy. Although DM may reduce some costs by eliminating film and film-processing chemicals, decreasing film storage space, and reducing film library staff, immediate cost savings are unlikely. Substantial capital equipment costs are necessary in that the DM systems cost four to five times that of conventional mammography units.

Major technical challenges remain, and further clinical studies are necessary to determine the actual clinical value of this modality as a probable adjunct to conventional mammography, particularly in the area of dense breast tissue. Moreover, measuring cost-effectiveness of this evolving technology and the effect of the density of the tissue. The cyst shows the typical characteristics of transmission, homogeneous internal features without “debris,” and smooth margins. The compressibility of the cyst can be seen in the second ultrasound screen.

Unfortunately, breast ultrasound in its current state is extremely inefficient in detecting malignancy and is thus not suitable as a method of breast cancer screening (Fig. 41.16). In one study, only 44% of the mammographically detected nonpalpable lesions and 37% of the cancers could be visualized by high-frequency ultrasound. Ultrasound also has a low capacity for detecting small lesions or small aggregate groups of calcifications, which may be evidence of early breast carcinoma. However, newer sonographic techniques of spatial compound imaging, tissue harmonics imaging, and three-dimensional imaging in breast disorders do not appear to offer improved accuracy or diagnostic value over current methods. Because breast cancer control can be achieved only by early diagnosis of minimal breast cancer, diagnostic ultrasound can be a helpful aid to screening mammography.

Ultrasound imaging of the breast has been an extremely valuable addition to the breast-imaging armamentarium. Ultrasound is currently used to assist in differentiation of benign and malignant lesions, to distinguish cystic from solid masses (95% accuracy, 96.9% sensitivity, and 98.4% specificity), and to guide aspirations and biopsies in mammographically detected nonpalpable lesions, thus likely preventing unnecessary open biopsies (Fig. 41.14). Moreover, this technique is useful in intraoperative surgical margin evaluation and staging of breast cancer. The rate of inadequate samples in ultrasound-guided FNA was 0% for malignant lesions and 28.4% for benign (95% accuracy, 96.9% sensitivity, and 98.4% specificity), and to guide aspirations and biopsies in mammographically detected nonpalpable lesions (95% accuracy, 96.9% sensitivity, and 98.4% specificity), and to guide aspirations and biopsies in mammographically detected nonpalpable lesions, thus likely preventing unnecessary open biopsies (Fig. 41.14). Moreover, this technique is useful in intraoperative surgical margin evaluation and staging of breast cancer. The rate of inadequate samples in ultrasound-guided FNA was 0% for malignant lesions and 28.4% for benign (95% accuracy, 96.9% sensitivity, and 98.4% specificity), and to guide aspirations and biopsies in mammographically detected nonpalpable lesions.

In younger women, sonography has evolved into a highly specialized imaging technique useful as primary imaging modality in this population, as well as in pregnant and lactating women. An ultrasonically detected cyst in a young woman may allow deference of mammography and prevent unnecessary x-ray exposure. However, a normal sonogram at any age should not prevent further evaluation of an abnormal physical finding. Conversely, if a nonpalpable solid mass is detected by sonography but is not clearly seen on a mammogram, biopsy or needle localization must be performed during real-time sono graphic imaging (Fig. 41.15). The benefits of this diagnostic technique include the absence of radiation, noninvasive technique, lack of morbidity, and ease of repeated examinations.

Unfortunately, breast ultrasound in its current state is extremely inefficient in detecting malignancy and is thus not suitable as a method of breast cancer screening (Fig. 41.16). In one study, only 44% of the mammographically detected nonpalpable lesions and 37% of the cancers could be visualized by high-frequency ultrasound. Ultrasound also has a low capacity for detecting small lesions or small aggregate groups of calcifications, which may be evidence of early breast carcinoma. However, newer sonographic techniques of spatial compound imaging, tissue harmonics imaging, and three-dimensional imaging in breast disorders do not appear to offer improved accuracy or diagnostic value over current methods. Because breast cancer control can be achieved only by early diagnosis of minimal breast cancer, diagnostic ultrasound can be a helpful aid to screening mammography.

In younger women, sonography has evolved into a highly specialized imaging technique useful as primary imaging modality in this population, as well as in pregnant and lactating women. An ultrasonically detected cyst in a young woman may allow deference of mammography and prevent unnecessary x-ray exposure. However, a normal sonogram at any age should not prevent further evaluation of an abnormal physical finding. Conversely, if a nonpalpable solid mass is detected by sonography but is not clearly seen on a mammogram, biopsy or needle localization must be performed during real-time sono graphic imaging (Fig. 41.15). The benefits of this diagnostic technique include the absence of radiation, noninvasive technique, lack of morbidity, and ease of repeated examinations.

Unfortunately, breast ultrasound in its current state is extremely inefficient in detecting malignancy and is thus not suitable as a method of breast cancer screening (Fig. 41.16). In one study, only 44% of the mammographically detected nonpalpable lesions and 37% of the cancers could be visualized by high-frequency ultrasound. Ultrasound also has a low capacity for detecting small lesions or small aggregate groups of calcifications, which may be evidence of early breast carcinoma. However, newer sonographic techniques of spatial compound imaging, tissue harmonics imaging, and three-dimensional imaging in breast disorders do not appear to offer improved accuracy or diagnostic value over current methods. Because breast cancer control can be achieved only by early diagnosis of minimal breast cancer, diagnostic ultrasound can be a helpful aid to screening mammography.
of development is incapable of accomplishing this task. However, there is renewed interest in evaluating ultrasound as a potential adjunctive screening tool in women with radiographically dense breasts when the detection benefit of supplemental sonography increased with increasing grades of breast density. Moreover, some authors consider ultrasound significantly better than mammography for detecting invasive breast cancer, especially in certain subpopulations. False-positives appear to be increased; thus, minimizing unnecessary patient anxiety and costs are critical goals of any new screening procedure. Authors caution use of screening sonography only for practitioners experienced in breast sonography, with comprehensive discussion with the patient to consider the risk of a false-positive examination and understanding that early detection may or may not be of benefit to her if a cancer is found. As an RCT with mortality as an end point may be unethical, weighing potential risks and benefits with each patient is vital.

Blood flow in malignant breast lesions is considerably increased because of vascular proliferation. Doppler flow ultrasonography can detect increased blood flow and has the potential to distinguish benign from malignant lesions. As a rule, malignant lesions produce Doppler signals of higher frequency and amplitude during continuous flow through diastole. Presently, Doppler flow analysis is not sensitive enough to be used as a tool for distinguishing malignant from benign tissue, but it offers potential for advancement in the field.

### Magnetic Resonance Imaging

MRI is emerging as perhaps the most promising imaging modality as an adjunct for breast cancer detection to date (Fig. 41.17). Interventional MRI machines have produced unique opportunities for image-guided surgery. MRI has excellent sensitivity in demonstrating invasive breast cancer that is both mammographically and clinically occult, especially in dense breast tissue, but it has a low specificity (ranging from only 37% to 97%). Moreover, its sensitivity in noninvasive lesions, such as ductal carcinoma in situ, has been reported as low as 40%, possibly secondary to more variable angiogenesis in these lesions. Nevertheless, contrast-enhanced MRI may be useful in monitoring chemotherapeutic responses in breast cancer, in the preoperative evaluation of patients being considered for BCS, and intraoperatively to define the margins of the lesion and ensure complete excision. Published results, although from studies with relatively small numbers of patients and small numbers of cancers, have shown robust data for screening women at high risk for breast cancer based on genetic mutation or strong family history of breast cancer. The Magnetic Resonance Imaging for Breast Screening (MARIBS) researchers reported MRI to be nearly twice as sensitive as mammography for detecting breast cancers in this subgroup of patients. In total, MRI detected 77% of cancers, and mammography detected 40%. Combined, the two methods produced a sensitivity of 94%, yet 25% of cancers in younger women and 10% in older women were missed. Studies combining MRI with mammography, ultrasound, and CBE have also shown improved detection of cancers with MRI (77% vs. 36%, 33%, and 9.1%, respectively). Combined, the modalities had a sensitivity of 93% versus 45% for mammography and CBE combined.

This imaging modality has considerable benefits, including absence of ionizing radiation and lack of known radiobiologic hazards, but it is time-consuming and expensive, and it lacks sufficient resolution for the identification of small lesions. It is also especially deficient in detecting the aggregates of small calcifications that may be evidence of early carcinoma, and it possesses significant overlap in contrast enhancement kinetic and morphologic features of benign and malignant lesions, which severely limits its usefulness as a screening method. MRI, though, seems to be the most accurate method for detection of breast implant integrity. Although MRI screening appears to be feasible in the high-risk populations, further clinical investigation is needed to address the issue of cost-effectiveness and to define the technical requirements for optimal imaging, interpretation criteria, and clinical indications for which MRI should be used as an adjunct to conventional imaging methods.

### Positron Emission Tomography

Onologic breast imaging using positron emission tomography (PET) scanning is a noninvasive nuclear medicine imaging modality rapidly gaining acceptance. Fluorodeoxyglucose is the most commonly used agent, which is a short-lived...
FNA or fine-needle aspiration biopsy was first reported by Martin and Ellis at Sloan-Kettering Cancer Center in 1930 and is now an established diagnostic method in evaluation of palpable breast lesions. In response to the increasing frequency with which women are consulting their obstetrician-gynecologists about concerns related to their breasts, the American Board of Obstetrics and Gynecology (ABOG) has promulgated specific educational requirements for resident training in the various aspects of diagnosing and treating breast disease. Technical proficiency in this procedure is essential for the proper evaluation, treatment, and further definition of a palpable lesion.

FNA is recognized as highly accurate and cost-effective when used in conjunction with clinical examination and imaging as part of the triple test. The “triple test” consists of tissue sampling, mammography, and CBE. If all components of the triple test are benign-negative, the chance of breast cancer is low (0.7%). Yet, if each aspect is suggestive of cancer, the risk of breast cancer is very high (99%). Alone, FNA is relatively accurate but has a false-negative rate as high as 20%. The false-negative rate is highest in detection of lobular carcinoma and carcinoma in situ. However, FNA has a sensitivity of 96% and specificity of 98% (similar to core biopsy), as well as a 99% positive predictive value and 94% negative predictive value and an overall efficacy of 97%.

FNA provides a cytologic rather than histologic sample for review. Thus, limitations include inability to distinguish invasive from in situ carcinoma. Use of FNA or core needle biopsy as the initial diagnostic testing remains controversial and is left to the clinician. However, FNA has multiple advantages (Table 41.7) over excisional biopsy and is helpful in confirming the clinical impression of both benign and malignant breast disease. Nevertheless, a negative cytologic report, as with a negative mammographic report, must not be relied on to rule out malignancy in a clinically suspicious lesion and thus should not preclude further evaluation. Any clinically suspicious mass in a patient with negative FNA findings requires additional evaluation, including core biopsy or excisional biopsy, or other methods of detection should be performed. If breast cancer or a specific benign condition (e.g., apocrine metaplasia or fibroadenoma) is not detected by FNA (or is inconsistent with the triple test), core biopsy or excisional biopsy is warranted. A positive finding of malignant cells eliminates further evaluation and allows early selection of appropriate therapy before further surgical intervention. When cyst aspiration is performed, the fluid may be discarded if it is clear (transparent and not bloody) and the mass disappears. If the cyst aspirate is bloody or the mass does not disappear, the patient should be considered a candidate for excisional biopsy. Additionally, if the cyst recurs after aspiration, excisional biopsy is warranted.

The recommendations of the National Cancer Institute Consensus Conference include use of FNA for sufficiently defined palpable breast masses of clinical or patient concern, persistent or suspicious masses in patients with increased family risk factors, evaluation of nonpalpable mammographically suspicious breast lesions, or low risk for malignancy lesions when recommended follow-up with imaging is not feasible or accepted by the patient. FNA should not be used for investigation of microcalcifications but may be used under ultrasound or stereotactic guidance to investigate densities presumed to be nonmalignant. Doubtful densities are best assessed by core biopsy.

FNA is an easily mastered technique, but the adequacy of specimens is improved with experience and training (Fig. 41.18). Procedure risks include infection, bleeding, and bruising at the site. Because the chest wall is immediately beneath the site, pneumothorax has been listed as a potential complication. The small size of the needle and the mass is stabilized over a rib during the procedure significantly decreases this complication.

After the procedure is explained to the patient and consent has been obtained, the skin is cleansed. The lesion is identified and stabilized, preferably over a rib, between the fingers of the nondominant hand (Fig. 41.19). The instrument table should be prepared for easy access because the nondominant hand should not be removed (once it has been placed alongside the mass) until the procedure is completed (Table 41.8). Stabilization of the hand throughout the procedure prevents frequent “loss” of the mass and repeated attempts to locate the targeted structure.

If anesthesia is desired, a small wheal is placed in the skin over the mass, assuring excess local anesthesia does not obscure the mass. A 21- to 23-gauge needle with a clear hub attached to a 10- to 20-ml syringe is then inserted into the central portion of the mass. Increasing the needle gauge does not necessarily increase the sample size. In fact, the larger the needle, the more blood aspirated, and the greater the likelihood of hematoma formation. A pistol-grip holder may also be used, as the mechanics of hand motion are often easier with the holder. Mastery of both techniques (with the holder and without) is recommended because not all institutions have this equipment. If a holder is not used, two fingers are placed under the piston of the syringe, and the thumb is used against the body of the syringe to pull the piston toward the hub, applying negative pressure. With use of the holder, the grips of the holder are pulled together to apply negative pressure.

The lesion is sampled by moving the needle up and down within the mass several times. Several passes should be made into every portion of the mass to prevent false-negative samples. If the lesion is cystic, liquid material is seen in the hub of the needle and possibly the body of the syringe. With a solid mass, one may not see evidence of cellular material in the hub.

After complete sampling along each axis of the mass, suction is released and the needle is removed from the lesion. Releasing the suction before removing the needle is a critical aspect of this procedure. Continued negative pressure upon removing the needle (without release of suction) results in aspiration of the specimen into the body of the syringe, from which it is difficult to retrieve. Once the needle is removed, pressure is applied to the puncture site (by an assistant or the patient). Significant bleeding from the site of the needle puncture is often characteristic of carcinoma or an inflammatory lesion, although benign conditions and bleeding diathesis may also result in this complication. The patient usually does not require any dressing or bandage on completion of the procedure.

The material should be expelled onto a glass slide (frosted ends facing up toward the practitioner) with the needle bevel facing down to prevent scatter of the specimen (Figs. 41.20–41.23). To release additional sample, the needle is detached, air is drawn into the syringe, the needle is reattached, and further expulsive efforts are accomplished. The “detach, draw air, and reattach” portion is repeated until all the cellular material has been expelled.

Complete aspiration of a cystic mass should always be attempted because at follow-up it will be difficult to determine whether the fluid has reaccumulated or is a remnant from the prior procedure. This becomes important, because reaccumulated fluid in a cyst should be referred for excisional biopsy (Table 41.9).

Cells air dry quickly, so it is crucial that immediate fixation with 95% ethanol or a spray fixative occur after smearing. The examiner must provide the cytopathologist with an accurate clinical history, including age, clinical examination, and whether the patient is pregnant or lactating, because this information is crucial in interpretation of the sample. Figures 41.24 through 41.26 demonstrate examples of FNA cytology. With adequate sampling, HER2/neu, estrogen, and progesterone receptor status may be determined. FNA can produce bleeding into the breast tissue and a hematoma formation beneath the surface, which can complicate mammographic interpretation. For this reason, mammograms (and probably ultrasounds) should be performed either before the FNA procedure or at least 2 weeks afterward.

Random periareolar fine-needle aspiration (RFNA), a modification of FNA, has been espoused as a risk assessment technique to determine an individual’s risk for development of breast cancer and as a tool to measure response to preventive measures. It has also been shown to be effective in evaluating breast lesions for high-risk tumor markers. Trials are under way comparing RFNA and ductal lavage; however, there are currently insufficient data to recommend either method as an independent screening modality or in combination with screening mammography.

Core Needle Breast Biopsy

It is estimated that approximately 1 million breast biopsies are performed yearly to diagnose approximately 200,000 breast cancers. Percutaneous core needle biopsy (CNB) may spare many of these women the need for more deforming, invasive, and expensive surgical procedures. With this procedure, a histopathologic diagnosis may be obtained compared with cytologic evaluation with FNA. Studies indicate a high degree of accuracy (98% positive predictive value and 80% negative predictive value), sensitivity of 89%, and specificity of 100% in confirming malignant invasion. False-negative results may occur, but false-positive results are rare except with radial scars. Increasing the number of core specimens by taking samples...
Technique of fine-needle aspiration—slide preparation. The slide is fixed as rapidly as possible to avoid air drying. Usu-
ally, two to three slides can be made from one fine-needle aspiration attempt. The technique chosen for slide preparation depends on the desire of the pathologist from several locations in the lesion may increase the representa-
tiveness of the specimens.

CNB may be performed under tactile, stereotactic, or ultra-
sound guidance. Less tissue is removed during CNB compared
with excisional biopsy, resulting in no deformity in the breast and minimal to no scarring on subsequent mammograms. An-
other advantage is the ability to distinguish between invasive
and intraductal carcinoma (unlike FNA). Because special train-
ing is not required to interpret the histologic material obtained
from CNB, this obviates the need for the special skills of a cy-
topathologist needed for FNA. One disadvantage of CNB is
that local anesthesia is needed because of the large size of the
needle (generally 8- to 18-gauge).

This biopsy procedure is often used in the assessment of
BL-RADS category 4 lesions (Table 41.10). If core biopsy of
a category 4 lesion yields a benign diagnosis concordant with
the imaging characteristics, the woman is usually spared the
diagnostic surgical biopsy. Although most often performed
for nonpalpable lesions, percutaneous imaging-guided core
biopsy can also be helpful in the evaluation of palpable breast
masses, particularly for those that are deep, mobile, or vaguely
palpable.

Stereotactic CNB requires dedicated equipment but may be
helpful in evaluating suspicious mammographic findings, par-
ticularly in nonpalpable lesions. Ultrasound-guided CNB has
several advantages, including real-time visualization of the nee-
dle, lack of ionizing radiation, accessibility to all parts of the
breast and axilla, multipurpose use of equipment, and lower
cost. However, it is limited in detection of lesions less than 1
cm and has decreased sensitivity in detection of microcalcifica-
tions. Vacuum-assisted and MammoToMte devices may improve
tissue sampling by obtaining larger and more intact samples.

The choice depends on several factors, including equipment
availability, lesion visibility and accessibility, and preferences
of the radiologist and the patient.

After administration of local anesthesia, the area is cleaned.

As the core needle is introduced into the mass, the tissue in-
side the core of the needle is cut from the surrounding tissue
as the outer sheath is advanced. After removal of the sheath
and core needle, a pressure dressing is applied. This proce-
dure may obviate the need for needle localization surgical
biopsy, and studies indicate similar sensitivity and lower cost.
The histologic core specimen may be used to determine hor-
monal receptor status and to study other tumor markers using
immunohistochemistry.

Open Surgical Biopsy

Open surgical biopsy includes excisional and incisional tech-
niques. Incisional biopsy is a diagnostic procedure reserved for
masses that are too large to be completely excised. There are
currently few indications for the use of incisional biopsy be-
cause FNA and CNB usually provide sufficient tissue to make
diagnosis with less morbidity and lower cost. Conversely, ex-
cisional biopsy refers to the removal of all gross evidence of
disease, usually with a small rim of normal breast tissue, and
is the definitive procedure for some benign breast masses. Ex-
cisional biopsy is usually an outpatient procedure performed
under local anesthesia with intravenous sedation as needed.

Some authors recommend beginning the procedure by
marking the incisional site with the patient in the sitting po-

tion. Conversely, others recommend locating the lesion with the
patient in the same position in which the surgery is to be
performed. This marking should be performed before injec-
tion of any anesthetic because the anesthetic may obliterate
the outlines of the mass. Circumareolar incisions are the most
ideal cosmetically and heal well. They are attempted for most
benign masses despite having to tunnel a short distance to reach
the lesion. This should not be done with suspected malignant
lesions to prevent the spread of tumor cells along the tunnel,
thus prohibiting breast-conserving therapy in the future. On the
other hand, Langer or curvilinear lines (following the anatomic
skin lines) may be used depending on the location of the lesion.
Langer’s lines may be defined by gently pinching the skin over
the mass and noting the outline. Radial incisions are made over
the axilla and inframammary portions of the breast but are ill-
advised in the upper portions of the breast because of possi-
ble contracture and asymmetric cosmetic result. It is important

sharp dissection is used to develop the skin flaps to
achieve better exposure. Blunt dissection increases adhesions
and inflammation. The edges of the incision are retracted with
skin hooks. Instruments that will crush the tissue are never used
so as to prevent cutting the tumor into smaller pieces, thus mak-
ing excision more difficult, or to prevent tumor seeding. The
mass may be gently grasped with suture for traction while exci-
sion is performed with sharp dissection. Cautery should be
used only for hemostasis, not for excision of the mass, because
heat may distort estrogen and progesterone receptor evaluation
and margin delineation. If malignancy is suspected, the biopsy
specimen should include a margin of normal tissue around the
mass. Furthermore, estrogen and progesterone receptor sta-
rus and human epidermal growth factor receptor 2 protein
(HER2/neu) evaluation is critical. Ideally, the pathology de-
partment should receive the specimen on ice, because room
temperature (heat) can damage the estrogen and progesterone
receptors.
Closure of the defect left by the excised mass (dead space) is
discouraged because of the increased risk of infection from su-
ture placement and the potential for skin distortion. If a large
defect is obtained, a minimum number of sutures should be used,
and drainage of the site bears additional significance. A
subcuticular closure with 4-0 or 5-0 absorbable material us-
ing Steri-Strips is generally performed. Alternatively, nonab-
sorbable suture can be used and removed 1 or 2 weeks post-
operatively. To prevent hematoma formation, a snugly placed
elastic dressing is applied for 24 to 48 hours. A bra should then
be worn continuously for 3 to 7 days to minimize the risk of
bleeding and discomfort. The patient should avoid heavy lifting
with the affected arm and strenuous activity for 3 to 7 days.
Needle localization excisional biopsy is performed for sus-
picious nonpalpable abnormalities seen on mammography. In
the radiology suite, under local anesthesia, the lesion is iden-
tified by fluoroscopy, and a needle is placed near it. A hooked
wire is inserted through the needle and located just beneath
the lesion. After the needle is removed, the wire is stabilized
on the skin, and the patient is transported to the operat-
ing suite for surgical excision. Incisions similar to those used
for excisional biopsy are made, and the suspected abnormal-
ity and the wire are excised. Radiographic studies are per-
formed on the specimen to ensure that the lesion originally
noted on mammography has been excised in its entirety. This
procedure can be done under local anesthesia in an outpa-
tient setting. The complications are similar to those of exci-
sional biopsies, including bleeding, hematoma formation, and
infection (cellulitis, abscess). Improvements in CNB (either
stereotactic or ultrasound-guided) has made this procedure less
necessary.

BREAST CANCER

The risk of breast cancer has reached epidemic proportions, affecting one in eight women who live to the age of 85 years. Its incidence is more that two times that of all female pelvic cancers combined, and it is probably the most feared disease by women today. The increasing lifetime risk for development of breast cancer may be attributed to early detection of prevalent cases, primarily because of the increased use of mammographic screening, and lower mortality that is due to causes other than breast cancer. A millennium of scientific inquiry, theoretical investigation, and systematic experimentation has only now begun to provide the medical profession with prevention strategies for women at high risk.

Thus, breast cancer remains a leading cause of cancer-related mortality, with estimates that more than 40,000 women will die of this disease. Men are not immune; 1,500 new cases of male breast cancer were expected to be diagnosed in 2005. There is good news, though, in that the incidence rates appear to have leveled off in the 1990s after increasing about 4% per year in the 1980s. Additionally, mortality rates have declined since 1992, with the largest decreases noted in younger women (both black and white).

Epidemiology of Breast Cancer

The etiology of breast cancer is multifactorial and, although numerous risk factors have been identified, they only account for 21% of the risk of breast cancer in women age 30 to
Related Surgery

FIGURE 41.27. Technique of excisional biopsy. A: For cosmetic reasons, circumareolar incisions are preferable when the lesion is thought to be within 2 or 3 cm of the areola. Not more than one half of the areolar margin should be incised. A curved incision parallel to the areola is made over lesions further out from the center. When malignant disease is strongly suspected, the surgeon should attempt to avoid the probable path of the subsequent mastectomy incision. B: An intradermal wheal is raised along the path of the proposed incision using 1% lidocaine and a hypodermic (no. 25) needle. From the wheal, deeper injections of anesthetic are made around the circumference of the lesion and beneath it. C: The incision is carried down through the dense subcutaneous tissue and into the lobule containing the lesion. Self-retaining retractors are helpful when an assistant is not available. D: If the lesion is small or easily mobilized, it should be sharply dissected and excised with a thin margin of adjacent tissue. E: The lobular defect is sutured with fine absorbable suture material if the closure places no tension on the overlying skin. Bleeding is controlled with absorbable ligatures or electrocoagulation. Absolute hemostasis is essential. F: The skin is closed with interrupted 4-0 or 5-0 silk or nylon sutures. Drainage is seldom necessary. A pressure dressing for 24 to 48 hours is desirable if a significant amount of dead space has been left behind.

54 years and only 29% in women age 55 to 84 years. Furthermore, nearly three fourths of women with breast cancer have no identifiable risk factors other than sex and age; thus, all women should be considered at risk. Previously identified risk factors for breast cancer include increasing age, nulliparity, delayed childbirth (childbirth before age 18 years portends one third the risk of breast cancer than in a woman delivering at age 35 years), personal or family history of breast cancer, benign proliferative breast disease, obesity in postmenopausal women, a long menstrual history (menarche before age 12 and late menopause), and higher education and socioeconomic status. Lactation has been shown in observational studies to decrease the risk of breast cancer. Other factors—such as fat intake, previous abortions, smoking, prior placental weight, and alcohol intake—have all been suggested to contribute to breast cancer risks, but the associations either show no effect or remain inconclusive, inconsistent, and controversial.

Family History

Family history is the most widely recognized breast cancer risk factor. First-degree female relatives of women with breast carcinoma have two to three times the general population risk of developing the disease. The risk increases even more if the affected relative was premenopausal with bilateral breast disease on diagnosis (eightfold increased risk) compared with a postmenopausal affected relative with only unilateral disease (onethird to twofold increased risk). Centers for Disease
30% to 60%. It is estimated, based on data from families linked to 90%, whereas the risk of ovarian cancer was approximately breast cancer in families with BRCA1 was approximately 80% breast cancer.

p53 mutations, Hras, ataxia-telangiectasia, and as yet unde-served for research settings and is not yet suited for wide-scale ing must be made after a thorough and informed discussion and employment discrimination—the decision to undergo test-ing up a quandary for women at risk for inherited forms of available DNA-based carrier detection became available, open-ethic Breast cancer incidence and mortality rates vary among racial and ethnic groups. For all ages combined, white women are more likely to develop breast cancer, yet African-American women are more likely to die of breast cancer. Native Ameri-cans have the lowest incidence of breast cancer, nearly one third the risk of white women. In addition, Native American and Asian women have approximately one third the mortality of African-American women. Although Hispanic women appear to have a lower incidence of breast cancer (compared with Cau-casian women), some studies have shown a greater proportion of this ethnic group to be less than 50 years of age at diagno-sis, to present with larger tumors, and to have a greater likeli-hood of being estrogen receptor (ER) negative (when compared with Caucasian women). Individuals of Ashkenazi Jewish an-cesty have a higher likelihood of harboring one of the founder mutations of BRCA1 and -2 when combined with other risk fac-tors.

Genetic Predisposition and Hereditary Breast Cancer

The past decade has witnessed an explosion of knowledge in the field of cancer genetics and inherited susceptibility to cancer syndromes. It has been estimated that approximately 5% to 10% of breast cancers are inherited in an autosomal dom-inant pattern. Breast cancer susceptibility genes, BRCA1 and BRCA2, were discovered in the early 1990s and mapped to chromosome 17q and 13q, respectively. In 1996, commercially available DNA-based carrier detection became available, open-ing up a quandary for women at risk for inherited forms of breast cancer. Because these tests are expensive, often diffi-cult to interpret, and documented to have a significant psych-ologic impact for both positive and negative test results— as well as placing healthy individuals at risk for insurance and employment discrimination—the decision to undergo test-ing must be made after a thorough and informed discussion between the physician and the patient. Thus, testing is re-served for research settings and is not yet suited for wide-scale screening.

The only currently known BRCA genes are BRCA1 and BRCA2, thus the discussion herein is based only on these muta-tions. There are more than 1,000 different mutations in BRCA1 and -2. BRCA1 mutation is believed to account for nearly half of all inherited breast cancer cases and nearly 90% of the hered-ity ovarian cancer cases. Similarly, BRCA2 mutations are re-sponsible for approximately 10% of familial breast cancer and 5% to 10% of familial ovarian cancer. Li-Fraumeni syndrome, p53 mutations, Hras, ataxia-telangiectasia, and as yet unde-tected genes appear to account for the other cases of inherited breast cancer.

Initial studies suggest that the lifetime risk of developing breast cancer in families with BRCA1 was approximately 80% to 90%, whereas the risk of ovarian cancer was approximately 30% to 60%. It is estimated, based on data from families linked to BRCA1, that 50% of female mutation carriers will develop breast cancer by age 50 years (compared with 1.7% in the general population) and 85% by age 70 years (compared with 11% in the general population at age 70 years). Pedigree analysis in BRCA2 carriers has identified a similar risk of development of female breast cancer to that seen with BRCA1 mutations. However, the risk of ovarian cancer for carriers of BRCA2 mutations is only 10%. Based on these data, the overall lifetime risk of developing breast or ovarian cancer is nearly 100%. Population-based studies (versus studies based on spe-cific families), however, suggest that the actual overall lifetime cancer risk of mutation carriers is closer to 36% for breast cancer and 16% for ovarian cancer. It is unclear whether these inconsistent results are related to the populations tested, to the size of the studies, or, perhaps, to differences in penetrance between different mutations. Further longitudinal studies may resolve this question.

BRCA mutation carriers not only have an increased overall risk of developing cancer, but commonly have a younger age at onset and a greater probability of second tumors. Accordingly, although the inherited mutations account for only 3% to 10% of all breast cancers, they account for nearly 25% of breast cancer cases diagnosed before the age of 30.

Not only are the BRCA genes associated with increased risk of female malignancies, they have also been shown to be a marker for hereditary cancer syndromes in men. Male breast cancer is much more common in BRCA2 families than in the general population. Five to fifteen percent of male breast can-cer is associated with BRCA2 mutations, with recent data in-dicating an association with BRCA1 mutations as well. Male carriers of BRCA2 mutations have a 6% lifetime risk for the de-velopment of breast cancer compared with 0.1% in the general population.

In addition, other malignancies are increased in BRCA2 carriers, such as laryngeal, prostate, gallbladder, stomach, melanoma, primary peritoneal, and pancreatic cancer. Hence, the BRCA mutation may be transferred to a woman through a male relative. However, a male carrier of a BRCA1 mutation is much more likely to be cancer free than is a woman who car-rries the same mutation. And, although a family history of breast cancer places a mutation carrier at increased risk not only for breast cancer but also for ovarian cancer, her brother will be at similarly increased risk for prostate cancer. It is therefore im-portant to elicit a history of all related malignancies, not just a family history of breast and ovarian cancer. Patients are often unaware that the risk of transmission of a BRCA mutation is equally high from the paternal side and do not volunteer infor-mation about cancers from that side. Episodites of malignancies from both sides of the families must be elicited, including age at onset, bilaterality, and history of multiple primary cancers in an individual in the family.

BRCA1 and BRCA2 are believed to tumor suppressor genes. Inactivation of tumor suppressor genes is almost a uni-versal step in the development of a wide range of cancers in humans and experimental animals. In individuals who are not genetically at increased risk for cancer, environmental muta-genesis with time can result in inactivation of both gene copies. In individuals who have inherited a mutation in one of these tumor suppressor genes, the probability of acquiring additional mutations to produce cancer is significantly increased.

Histologic differences in the hereditary breast cancers com-pared with the sporadic cancers may account for the earlier pre-sentation of cancer in mutation carriers. It has been reported that BRCA1-associated breast cancers are characterized by higher-grade medullary features, overexpression of p53, aneu-ploidy, and high proliferation index relative to sporadic breast
cancers. Essinger and colleagues noted that 19% of BRCA1 cancers were of the mediulary variety, as compared with none in the sporadic cases, suggesting that mediulary cancer alone may be an indication for susceptibility testing. Additionally, BRCA1-associated cancers are ER negative 65% to 80% of the time, compared with a rate of 25% to 35% in sporadic cancers. In contrast, the excess of ER-negative tumors is not demonstrated in the BRCA2-associated cancers. Moreover, the clinicopathologic characteristics of BRCA2-associated cancers are similar to sporadic breast cancers with the suggestion of higher grades. However, a number of studies have found no differences between prognosis in BRCA-associated cancers and sporadic cancers. Thus, the issue remains unresolved and suggests the need for longitudinal studies to ferret out this needed information.

The frequency of a BRCA1 mutation in the general population is estimated to be 1 in 500 to 1 in 1,000 (with BRCA2 mutations occurring somewhat less), although it appears to be higher in certain ethnic groups, such as Ashkenazi Jews, in whom it is estimated to be 1%. In the Ashkenazi Jewish population (of eastern or central European origin), three different founder mutations have been identified: 185delAG and 5382insC in BRCA1 and 6174delT in BRCA2. Estimates indicate that 1 in 40 Ashkenazi individuals carry one of these founder mutations, and they are responsible for 25% of the early-onset breast cancer in this population. Current investigations indicate the estimated gene frequency in the general population may be artificially high because of ascertainment bias in the initial studies of high-risk families.

Testing for BRCA1 and BRCA2

Our knowledge regarding BRCA mutations is far from complete, and many incongruencies form the basis of our present information. The decision to proceed with genetic testing for BRCA1 or BRCA2 mutations is complex. Considerable caution must be used in counseling patients because definitive data are limited. Therefore, genetic counseling is an essential element of breast cancer susceptibility testing. The ability to reassure those with negative tests is limited by the possible existence of other—as yet undiscovered—genes. Nonpenetrance of the gene may make pedigree interpretation difficult in that absence of cancer in a parent cannot necessarily be interpreted to mean that the children are not at risk. A history of multiple affected first-degree relatives, bilateral disease, early or premenopausal age at onset, male breast cancer, and a family history of both ovarian and breast cancer increases the probability of having an inherited predisposition to breast cancer.

It is preferable to test an affected family member to document the particular familial BRCA1 or BRCA2 mutation. A negative result in the proband is most meaningful in a situation in which the family member has previously tested positive. In the absence of the detectable mutation in the proband, the patient may be reassured that she does not have the high risk of cancer seen in her family. She should be counseled, however, that she still has a baseline risk of cancer seen in the general population (one in eight for women who live to age 85 years) and that she should continue usual care, such as mammography and breast examination. On the other hand, if the family member with cancer has not or cannot be tested, the interpretation of the result is more problematic. Either (i) a BRCA mutation is present but was not detected by the test (possibly because of the testing modality or polymorphisms); (ii) a BRCA mutation is present in the family but was not inherited by the proband; (iii) there is no BRCA mutation, but another gene mutation exists (as yet unidentified or related to a regulatory gene); or (iv) the proband does not have inherited breast cancer predisposition, nor do other family members. In the last case, again, the woman still has a risk equal to the general population for sporadic forms of breast cancer. One study showed that one third of mutations detected involved deletions that are not currently detectable. Moreover, the summary, present techniques do not identify all disease-causing mutations, and patients need to be informed of the limitations of the present technology.

Hormonal Replacement Therapy

No issue related to breast cancer risk has been fraught with as much controversy as has the use of exogenous hormones. The extensive research conducted to answer this question has expanded the debate rather than resolved it. Currently, nearly 42 million American women are postmenopausal, and this number is predicted to increase to 62 million by 2020. Before the Women's Health Initiative study, nearly 40% of postmenopausal women in the United States used HRT; thus, the association of breast cancer with the use of HRT received considerable attention in the medical and lay press.

Initial case control studies did not find an increased risk of breast cancer associated with the use of HRT, but these studies were limited by statistical power and methodological problems. A review of the epidemiologic studies on postmenopausal hormone therapy and the risk of breast cancer also failed to provide definitive evidence regarding this issue because results are inconsistent. The Nurses Health Study (69,586 participants) and the Collaborative Group on Hormonal Factors in Breast Cancer refute previous data and indicate that current users of HRT have a relative risk of 1.33 of developing breast cancer but note no increased risk with past use. The sheer number of participants warrants giving great credibility to these findings. In addition, four subsequent metaanalyses note a slight increased risk in long-term users of HRT (>15 years), although here also there are conflicting results, affected by dosage and duration of HRT use. In contrast, the Four State Case Control Study and the Iowa Women's Health Study showed no change in the risk of breast cancer diagnosis with long-term current use. Note that metaanalyses have the same flaws in methodology and bias as the initial epidemiologic studies on which they are based. Pooling several groups of data does not remove this problem; thus, this information should be viewed with caution. Nevertheless, the trend propels one to consider these findings when making recommendations to patients.

The Women's Health Initiative was a randomized primary prevention trial and persists as pivotal study of this decade. There were 16,608 postmenopausal women aged 50 to 79 with intact uterus at baseline recruited. After slightly more than 5 years of follow-up, the risk of coronary heart disease (CHD) (nonfatal myocardial infarction and CHD death) increased by 29%, breast cancer by 26%, and stroke by 41%, and the risk of pulmonary embolism doubled. Conversely, the risks of hip fractures and colorectal cancer were decreased by more than 30%. Absolute excess risks per 10,000 person years attributable to estrogen plus progestin were seven more CHD events, eight more strokes, eight more pulmonary embolisms, and eight more invasive breast cancers, whereas absolute risk reductions per 10,000 person years were six fewer colorectal cancers and five fewer hip fractures. Based on this
information, the combined arm of the study was halted; how-
ever, the estrogen-only arm continued, showing no increased risk of breast cancer. Recalling these data is difficult. Many have criticized this study, as the age of initiation of HRT use was greater than generally used, body mass index (BMI) stratifi-
cation showed greater risk in obese women, and more than half of the women had other risk factors for cardiac disease, includ-
ing smoking, diabetes, hypertension, hypercholesterolemia, or prior coronary event. Many have speculated that because the study closed after an average 5 years of follow-up, possibly the detected breast cancers were present before patient accrual into the study. Detailed discussions with patients regarding this information is overall reassuring.

On the other hand, additional data are being compiled showing benefits to HRT when breast cancer is diagnosed. Survival data indicate that the risk of mortality from breast cancer was decreased among women who were using HRT at the time of diagnosis compared with age-matched nonusers. HRT user-associated cancers were more likely to be less ad-
vanced clinically and more likely to be ER positive. Possibly this information supports the idea that the increased risk of breast cancer diagnosis among users of HRT may result from detection bias, wherein participants were more likely to see a physician regularly and have regular breast examination and mammography.

In summary, studies occurring over the preceding 25 years contain conflicting information regarding HRT use in post-
menopausal women. Sufficient evidence exists to indicate an increased risk of breast cancer associated with postmenopausal estrogen use. Patients must consider this possibility in their in-
formed decision making. In addition, the role these agents may play in the development of cancers in genetically predisposed women has to be evaluated. Although HRT use can improve the overall health of women with a genetic risk, it should not be initiated solely for the purpose of prevention of CHD events and should be used for the shortest duration possible for ame-
lioration of menopausal symptoms.

**Oral Contraceptive Medications**

OCPs are used by nearly 11 million women worldwide and are the second most popular contraceptive method available (surpassed only by female sterilization). Since its approval by the FDA in 1960, OCPs have become one of the most exten-
sively studied medications ever prescribed. Recent studies re-
lating OCPs to breast cancer have yielded conflicting results, thus the issue continues to be controversial. Interestingly, OCPs have been shown to decrease the risk of ovarian cancer. This creates a quandary for their use in BRCA mutation carriers, who are at increased risk for both breast and ovarian cancer.

Case control studies, including the Cancer and Steroid Horm-
One Study, initially showed no overall association between OCP use and the development of breast cancer. However, the enrollees were not representative of the current OCP user who is younger, uses OCPs for longer duration, and delays initial versus subsequent pregnancies. Reanalysis of the data shows a correlation between certain subgroups and an increased risk of development of breast cancer, specifically among women using OCPs before their first full-term pregnancy, women age 25 to 34, and long-term users. By age 50 years, the cumulative risk is the same in users and nonusers, and there is no evidence of increased overall breast cancer risk, even with prolonged dura-
tion of use. Although incongruous, it may be that estrogen in OCPs stimulates breast cancer, promotes its growth, and makes it detectable, so that it is more likely to be diagnosed while the OCP user is younger, yet without conferring an increase in over-
all lifetime risk. Another possibility is that the increased risk seen in these analyses represents detection bias—that is, women taking OCPs are more likely to have breast examinations and thus are more likely to have the diagnosis made while they are younger. Furthermore, the Nurses Health Study, a prospective cohort study of more than 100,000 female nurses in the United States, showed no increased risk of breast cancer or breast can-
cer mortality in past users of OCPs. In a metaanalysis of 54 studies, a relative risk of 1.24 was associated with current use of OCPs (p = 0.001). The risk was elevated for 10 years after use of oral contraceptives was discontinued but was not influ-
ce the general history of breast cancer, which contrasts with the 2000 study mentioned below. In many of these studies, the increased risk was noted only in women taking OCPs before 1975 when formulations were likely to contain higher dosages of estrogen and progestrogens than that in OCPs today.

Studies specifically of women at high risk for breast can-
cer have also generated contradictory results. In women with a family history of breast cancer and OCP use, a 1989 study by Mutry (with more than 4,500 women) showed no association with subsequent development of breast cancer. Conversely, a study published in 2000 involving 426 families (3,300 women with a positive family history for breast or ovarian cancer) revealed a threefold increased risk of development of breast can-
cer in those with a family history compared with those with-
out such history who also used OCPs. However, other authors believe the strength of the study and indicate they would con-
tinue to support use of low-dose formulations in women with a family history of breast cancer unless the cancer history was compelling.

Additionally, Narod and colleagues showed that OCP use may provide a reduction in the risk of ovarian cancer specifi-
cally in women harboring BRCA1 and -2 mutations. Marckbanks and associates showed that neither use of OCPs nor the initiation of OCP use at a young age was associated with an increased risk of breast cancer in women with a family history of breast cancer.

The purported associations must be placed in perspective, though. It is evident that case control studies have inferior methodological strength compared with the gold standard of RCTs. The conclusions may be imprecise because of the low numbers of participants in some studies. Also, studies have not included current low-dose formulations in wide-scale, but have been based on previous high-dose OCPs, which clearly may confer higher risk. Finally, studies often include women with a family history of both ovarian and breast cancer, whereas there is evidence that OCPs actually decrease the risk of ovarian and endometrial cancer in the general population.

Overall, it appears that long-term use of OCPs is associ-
ated with a modest increase in the risk of early-onset breast cancer in the general population and a decrease in the risk of ovarian cancer (at least 50% reduction in an unselected pop-
ulation of women). As patients carrying the BRCA1 gene have a 50% to 80% lifetime risk of developing breast cancer and a 25% to 45% lifetime risk of ovarian cancer, OCP use may create a quandary. Narod and associates found an increased risk of early-onset breast cancer among BRCA1 mutation car-
ers who first used OCPs before 1975, who used them before age 30, or who used them for 5 or more years. OCP use did not appear to be associated with the risk of breast cancer in BRCA2 carriers, although data for this group were limited. However, the same authors also found a reduced risk of ovarian cancer in both BRCA1 and BRCA2 mutation carriers. The author suggests that OCP use after age 30 is not likely to increase the risk of breast cancer among BRCA1 carriers.
Mammographic Breast Density

Assessing the impact of breast density on breast cancer risk is hampered by data comparisons derived by applying differing mammographic screening intervals and by improvements in radiographic technology that may hinder our ability to accurately analyze and generalize the information. Nonetheless, women with greater mammographic density have been reported to have a four- to sixfold increased risk of breast cancer. This relationship has also been shown in differing ethnic groups. Increased density impairs the detection of breast masses, increases interval cancers, and produces false-positive recalls with the associated patient psychological stress and elevated costs of care. The likelihood of dense breasts increases with nulliparity, older age at first birth, and current use of postmenopausal hormone therapy (about 23% of women taking combined HRT have increased density in their breast tissue) and decreases with advancing age and increasing body weight. The correlation with nulliparity supports the assertion that early pregnancy produces structural change in the breast tissue that persists throughout life and is associated with resistance to proliferation.

Moreover, hormonal agents associated with increased breast cancer risk (estrogen and progesterin) likewise increase breast density, whereas hormonal agents that decrease risk (tamoxifen and raloxifene) likewise decrease breast density. The breast is rapidly responsive either to initiation or discontinuation of hormones, with increases in mammographic density noted largely within the first year and decrease in density occurring in as little as 2 weeks after withdrawal. In postmenopausal women on HRT (especially continuous combined as opposed to sequential regimens), many studies have indicated a 5% to 20% decreased mammographic sensitivity in hormone users with dense breasts. Yet current evidence does not explain whether the increased density associated with hormone therapy specifically changes an individual's risk of breast cancer development. In an effort to influence a woman's risk of developing breast cancer, anticancer, breast cancer, and ovarian cancer. As these women are at risk for breast and ovarian cancer, incorporating their information into the ROCA (risk of ovarian cancer algorithm) model may be helpful, with initial studies showing specificity of 99% and positive predictive value of 19%. Counseling must stress that these figures are estimates and not absolute risks, and thus balance the magnitude of risk for the individual patient.

Breast Cancer Risk Reduction

Several algorithms have been developed to estimate a woman's risk of developing breast cancer, with the best known of these being the Gail and Claus models. The Gail Model Risk Assessment Tool (Fig. 41.28) incorporates the patient's race, current age, age at menarche and first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and histology (as modified) results in generating an estimate of breast cancer risk. Limitations of this model include inclusion of only first-degree relatives, lack of information on the age at menarche or Ashkanazi Jewish background and lack of inclusion of a history of ovarian cancer. Conversely, the Claus model, using fewer categories, incorporates maternal and paternal breast cancer family history, first- and second-degree relatives, and the relative's age at cancer diagnosis. Although helpful in diagnosing, models are often inappropriate to the proband. In particular, the Gail model cannot be used for women younger than 35 years of age and is less accurate in women who do not obtain annual mammograms. Moreover, studies have shown that the Gail model underestimates risk in women with a personal history of breast cancer and those who are BRCA positive. Concordance of the two models is only fair, but only the Gail model has been clinically validated.

The BRCAPRO model developed by Parmigiani and colleagues, provides estimates of the likelihood of harboring the BRCA mutation. This model incorporates information regarding relatives diagnosed with early-onset breast cancer, male breast cancer, and ovarian cancer. As these women are at risk for breast and ovarian cancer, incorporating their information into the ROCA (risk of ovarian cancer algorithm) model may be helpful, with initial studies showing specificity of 99% and positive predictive value of 19%. Counseling must stress that these figures are estimates and not absolute risks, and thus balance the magnitude of risk for the individual patient.

Increased Surveillance

In a consensus statement by the Cancer Genetics Study Consortium (CGSC), it is recommended that carriers of BRCA mutations have vigilant surveillance through monthly self-examination beginning in early adulthood (18–21 years), annual or semiannual CBE, and annual mammography starting at age 25 to 30 years. The benefit of close follow-up alone for women at increased risk of breast cancer include increased cancer surveillance, chemoprevention, lifestyle modifications, and prophylactic (or risk-reducing) surgeries (mastectomy and/or oophorectomy).

Risk reduction options in women at increased risk for breast cancer include increased cancer surveillance, chemoprevention, lifestyle modifications, and prophylactic (or risk-reducing) surgeries (mastectomy and/or oophorectomy).

the current screening modalities of CA125 and transvaginal ultrasonography can be effectively used for widespread disease screening; these currently available screening tests may be applicable to patients at risk for hereditary ovarian cancer syndromes with appropriate counseling.

Chemoprevention

Chemoprevention became an option for risk reduction based on information from the Breast Cancer Prevention Trial (BCPT), which was launched in 1992. This clinical trial (NSABP P-1) randomized 13,207 healthy women at increased risk for breast cancer (based on Family History) to either placebo or tamoxifen 20 mg/day. The short-term risk of invasive breast cancer was reduced by 43% and that of noninvasive cancer reduced by 37%, particularly in women with a history of atypical hyperplasia (p<0.00001). Tamoxifen significantly reduced the rate of ER-positive tumors but had no effect on ER-negative tumors. However, as anticipated from the experience of women taking tamoxifen for breast cancer treatment, the drug was associated with an increased risk of thromboembolic disease, endometrial cancer, and cataracts. However, a decreased rate of fractures was noted. The earlier results of this trial prompted approval of tamoxifen by the FDA for use in the reduction of breast cancer incidence in 1998, despite two other negative trials from Europe. Several factors may account for the discrepancy, including dissimilar inclusion criteria, the length of treatment, and the length of follow-up.

The International Breast Intervention Study (IBIS I) closely replicated the findings of the BCPT. In this trial, nearly 7,200 women aged 35 to 70 were randomized to receive tamoxifen or placebo. Women enrolled had a fourfold increased risk of breast cancer compared with the general population, in most cases based on family history. A 32% reduction was noted in the group receiving tamoxifen. It is unclear how effective tamoxifen is in reducing breast cancer risk in women with hereditary breast cancer. Because the majority of cancers in BRCA1 mutation carriers are ER negative, one would not expect tamoxifen to be effective. However, BRCA2 carriers often have ER-positive tumors and thus are more likely to be responsive to tamoxifen chemoprophylaxis. Conversely, bilateral oophorectomy (which also affects the estrogenic effects on breast and endometrial tissue and estrogenic effects on bone, lipid metabolism, and blood clotting. Raloxifene binds to estrogen receptors to competitively block estrogen-induced DNA transcription in the breast and endometrium. Because raloxifene does not increase the risk of endometrial cancer as seen with tamoxifen, it is particularly attractive as a preventive strategy in reducing the incidence of breast cancer. Raloxifene is being studied in the second NSABP prevention trial, the STAR (Study of Tamoxifen and Raloxifene) trial. This trial enrolled 6,139 postmenopausal women at increased risk for breast cancer (based on Family History) in the first year. The study is designed to determine whether raloxifene (60 mg/day) is as effective as tamoxifen in reducing breast cancer risk. The results of this trial should be available in 2006. Results from the multicenter, randomized, double-blind Multiple Outcomes of Raloxifene Evaluation (MORE) trial revealed a 76% decreased risk of breast cancer among postmenopausal women with osteoporosis during 3 years of treatment with raloxifene; however, no objective tumor response was noted in patients with metastatic breast cancer in a phase II clinical trial. The trial was not accrued with breast cancer as a primary end point; thus, additional information is necessary to determine the possible benefits of this SERM over tamoxifen.

Many clinical trials are ongoing to determine additional effective options in the arena of chemoprevention. Based on benefits over tamoxifen noted in early breast cancer patients, aromatase inhibitors are being reviewed. Moreover, interest in using suppressants of prostaglandin synthesis has been stimulated by epidemiological observations that the use of aspirin and other NSAIDs is associated with a reduced incidence of breast cancer by nearly 30%. In preclinical models, COX-2 inhibitors reduced the incidence and growth of ER-positive tumors. Moreover, an additive effect with aromatase inhibitors in preventing tumor growth was also seen. NSAIDs function through inhibition of the cyclooxygenase enzyme (COX). The COX-2 enzyme is induced in both in situ and invasive breast cancers resulting in overexpression. COX-2 catalyzes the conversion of arachidonic acid to prostaglandin E2. This prostaglandin in turn up-regulates a number of intracellular growth pathways, resulting in increased angiogenesis, induction of aromatase activity, cell growth, and division. It is postulated that inhibition of COX-2 may have a general anti-cancer effect via decreased blood vessel formation, decreased cell growth, and enhanced apoptosis, as has been seen in mammary carcinogenesis in rats. It remains to be seen if these findings can be extrapolated to humans, possibly resulting in modulation of a critical step in the initiation and promotion as well as progression of breast cancer. Moreover, the finding of a fourfold increased risk of breast cancer reduction, however, are recent concerns regarding cardiovascular risks associated with this class of medications. Two randomized trials have yielded conflicting results. Born out of the premise that much of the gastrointestinal toxicity appeared to be related to COX-2 (which predominates in the gastric mucosa and yields protective prostaglandins), pharmaceutical efforts were redirected toward development of a COX-2 inhibitor as an antiinflammatory agent without gastrointestinal toxicity. The Vioxx Gastrointestinal Outcomes Research Study (VIGOR: 8,076 patients) showed the relative risk of developing a cardiovascular event was nearly twofold greater in the COX-2 inhibitor rofecoxib compared with naproxen. The Celecoxib Long-term Arthritis Safety Study (CLASS; 8,059 patients) revealed no significant difference in cardiovascular event rates between celecoxib and NSAIDs. Of note, the annualized myocardial infarction rates for COX-2 inhibitors in both trials were significantly higher than that in the placebo group of a recent metaanalysis of prevention trials. Additional data reported at the European Congress on Rheumatology about a cohort of 651,000 adult patients featuring nearly 2.4 million patient years of follow-up support the notion that non-COX-2 inhibitor NSAIDs may have equivalent effectiveness in causing myocardial infarction as compared with COX-2 inhibitors (except rofecoxib, which has a higher rate than other noncoxibs). Thus, the available data raise a cautionary flag about the risk of cardiovascular events with COX-2 inhibitors and have prompted a black box warning by the FDA. Many ongoing prevention trials involving COX-2 inhibitors have consequently been placed on hold, and additional trials may have difficulty accruing additional patients. Accordingly, additional trials using COX-2 inhibitors may be difficult to attain, although further analysis of prospective data is needed to
characterize the magnitude of cardiovascular risk and breast cancer risk reduction. Trials such as PRECISION (Prospective Randomized Evaluation of C efcoxib Integrated Safety vs. Ibuprofen or Naproxen) was recently opened to evaluate this issue with the anticipated accrual of 20,000 patients. Results are expected in 2009.

Lipophilic statins (atorvastatin, simvastatin, lovastatin), which more readily permeate cell and nuclear membranes (which in theory should enhance full expression of the statins’ pleiotropic benefits), have been shown to reduce the likelihood of developing ER-negative breast cancer. Mouse studies, which laid the groundwork for these studies, also showed that lipophilic statins conferred protection against ER-negative murine breast carcinoma. Based on these encouraging results and the statins’ remarkably good safety profile, studies are developing to review these statins’ role in breast cancer prevention.

**Lifestyle Modification**

Although heredity may be the strongest risk for development of breast and ovarian cancer syndromes, reproductive risk factors may be modifiable. Early age of first live birth and increased parity appear to lower the risk of breast cancer development. Use of fertility drugs and ovulation induction may need to be reevaluated. OCP use appears to increase the risk of breast cancer but decreases the risk of ovarian cancer. Modification of diet, alcohol consumption, exercise, or lactation is unlikely to have profound alterations, especially on genetically determined breast cancer risk. There are few prospective, randomized controlled trials that directly address breast cancer risk modification in women with hereditary breast cancer syndromes.

**Prophylactic Surgeries**

Prophylactic oophorectomy and mastectomy are attempts to remove at-risk healthy tissue before the onset of cancer. However, neither approach removes all the risk. Furthermore, there are a number of traditional risk factors that play a role in the onset of carcinogenesis, but for BRCA1 and BRCA2 mutation carriers, these remain unknown.

Even though these women’s greatest concern may be breast cancer, gynecologists should advise that they are also at risk for ovarian cancer and can substantially reduce risk by undergoing risk-reduction surgery. Analysis of case control data from women with a BRCA1 and BRCA2 mutation carriers, these remain unknown. Initially, subcutaneous mastectomy was performed wherein breast tissue is removed with preservation of the nipple-areolar complex; however, subsequent cases of breast cancer development were noted. This procedure has been largely abandoned because only 90% to 95% of the breast parenchyma is removed. Residual ductal tissue remains adherent to the undersurface of the nipple-areolar complex, and nipple sensation is not preserved. Conversely, simple or total mastectomy (skin-sparing removal of the breast tissue) has supplanted the subcutaneous procedure, because the cosmetic result after this procedure is excellent. Total mastectomy reduces the amount of breast tissue remaining postoperatively; however, cases of breast cancer after this procedure have been reported.

Although there is limited data regarding the efficacy of prophylactic surgery, statistical models suggest that certain women at high risk for development of breast or ovarian cancer may gain 2.9 to 5.3 years of life expectancy by undergoing prophylactic mastectomies as well as 0.3 to 1.7 years in life expectancy with prophylactic oophorectomy. To place this gain in perspective, studies of mammography in normal risk women have life expectancy gains of less than 0.7 years. Whereas prophylactic surgery is not a panacea for women with a genetic predisposition for cancer, identification of the women at high risk and counseling of her options is an important aspect of her care. Prophylactic surgery may be a reasonable approach for women at substantially high risk for breast cancer who are willing to accept its irreversible consequence.

### Related Surgery

Partly as a result of widespread adherence to mammographic screening, breast cancer is being detected at earlier stages.
TABLE 41.11
STAGING FOR BREAST CARCINOMA

DEFINITIONS:
PRIMARY TUMOR (T)
Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1 cm increment.

T1 Tumor 2 cm or less in greatest dimension
T1mic Microinvasion 0.1 cm or less in greatest dimension
T1a Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T1b More than 0.5 cm but not more than 1 cm in greatest dimension
T1c More than 1 cm but not more than 2 cm in greatest dimension
T2 Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3 Tumor more than 5 cm in greatest dimension
T4 Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a Extension to chest wall, not including pectoralis muscle
T4b Edema (including peau d’orange) or ulceration of the skin of breast, or satellite skin nodules confined to the same breast
T4c Both T4a and T4b
T4d Inflammatory carcinoma

Nearly 64% of white women and 53% of African-American women are presenting with localized disease. A critical aspect of breast cancer treatment is full knowledge of the extent of disease and microscopic features that contribute to the determination of the stage of disease, assist in the estimation of the risk of recurrence, and yield information predictive of tumor response. Breast cancer is staged clinically according to tumor size, regional lymph node involvement, and distant metastasis (TNM classification) (Table 41.11). The American Joint Committee on Cancer staging was modified in 2003 to incorporate a reclassification of nodal status by the number of involved lymph nodes and use of sentinel lymph node biopsy, distinguishing between micrometastases and isolated tumor cells on the basis of size and histologic evidence of malignant activity and change in staging if clavicular or internal mammary nodes are involved. These changes dramatically affect stage-specific survival.

Complete staging includes a thorough history, physical examination, bilateral mammography (ultrasound as necessary), pretreatment chest radiograph, and routine blood studies,

**Clinical:**
- Regional lymph nodes cannot be assessed (e.g., previously removed)
- No regional lymph node metastasis
- Metastases to movable ipsilateral axillary lymph node(s)
- Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent* ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
- Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
- Metastasis only in clinically apparent* ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
- Metastasis in ipsilateral infracavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent* ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis, or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
- Metastasis in ipsilateral infraclavicular lymph node(s)
- Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
- Metastasis in ipsilateral supraclavicular lymph node(s)

**Pathologic (pN)a:**
- Regional lymph nodes cannot be assessed (e.g., previously removed, or not removed for pathologic study)
- No regional lymph node metastasis histologically, no additional examination for isolated tumor cells (ITC)
- No regional lymph node metastasis histologically, negative IHC
- No regional lymph node metastasis histologically, positive IHC, no IHC cluster greater than 0.2 mm
- No regional lymph node metastasis histologically, negative molecular findings (RT•PCR)b

*Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.

**Isolated tumor cells (ITC):**
- Defined as single tumor cells or small cell clusters not greater than 0.2 mm, usually detected only by immunohistochemical (IHC) or molecular methods but which may be verified on H&E stains. ITCs do not usually show evidence of malignant activity, e.g., proliferation or stromal reaction.

Including hematologic and liver panels, pathology slides should be reviewed, and of course ER, PR, and HER2 status should be determined. Breast MRI may be considered for BCS for preoperative evaluation of the extent of disease and detection of mammographically occult disease in the breast; however, decision making should include tissue sampling of suspicious areas. Routine bone scan is not cost-effective in that only 0.6% of asymptomatic patients have a positive bone scan. However, bone scans may be helpful if patients experience localized symptoms, elevated alkaline phosphatase, or otherwise are at increased risk for metastasis. In addition, abdominal imaging is optional in early-stage disease but may be helpful if elevated alkaline phosphatase, abnormal liver function tests, or advanced disease (stage III or above) is present. Mammography is essential to adequate staging, even in the most obvious cases. Synchronous cancer is present in 4% to 5% of patients, and multicentric disease may be discovered in the involved breast. Furthermore, the clinical nodal status is often incorrect, with a false-positive and false-negative rate of approximately 25%. The pathologic stage of the primary lesion...

---

Based on histologic examination at the time of surgery is the main determinant of actuarial survival of the patient. Staging is reflective of 5-year survival rates. The 5-year survival rate for localized breast cancer has increased from 72% in the 1940s to nearly 98%. If the cancer has spread regionally, however, the survival rate is 81%. There is a significant decrease in survival to 26% for women with distant spread. African-American women have a lower overall 5-year survival rate compared with Caucasian women (76.7% vs. 90.3%), This is surmised to be reflective of fewer presenting with early-stage disease or premature termination of chemotherapy. A better understanding of the determinants of suboptimal

treatment may lead to interventions that can reduce racial disparities and improve breast cancer outcomes for all women (Fig. 41.29).

Pathology

Cancers of the mammary gland comprise a histologically heterogeneous group of tumors. More than 90% of breast cancers arise with the ducts. Infiltrating or invasive ductal carcinoma (IDC) is by far the most common histologic pattern of breast cancer seen, constituting 68% of cases (Fig. 41.30). Infiltrating lobular carcinoma (ILC) is the second most frequent cancer of the breast at 6.3% incidence. Other histologic subtypes include medullary carcinoma (2.8%), mucinous adenocarcinoma (2.2%), comedocarcinoma (1.4%), and Paget disease (1.1%). Papillary carcinoma, tubular adenocarcinoma, and inflammatory carcinoma each have an incidence of less than 1%. Inflammatory carcinoma is by far the most aggressive of the histologic types and has the poorest 5-year rate of 18%.

Terminology, however, has been confusing in that nearly three fourths of infiltrating carcinomas of the breast have been included in the imprecise category of infiltrating ductal or adenocarcinoma, not otherwise specified. Much of the terminology of breast cancer is divided into lobular and ductal, based principally on historical perspectives. Initially, early classifications used the term lobular to refer to lobular carcinoma in situ, and those without a lobular pattern were referred to as ductal; hence, the term ductal has no specific meaning. In fact, the majority of breast cancers originate in the terminal duct lobular unit, but these terms have impelling familiarity and are thus the basis of much of the scientific literature. Some authors promote the histologic classification that recognized special types of mammary carcinoma defined in terms of specific histologic criteria (lobular, tubular, medullary, and...
mucinous carcinomas). Because of its familiarity and to judge against current literature, the earlier terminology is used herein.

IDC accounts for the majority of breast cancers. These lesions usually present as stony hard masses resulting from the density of the fibrous tissue stroma. Tumors on average are approximately 2 cm and rarely exceed 4 to 5 cm. These are more often detected by mammography because of their increased frequency of calcifications compared with ILC. Additionally, this variant commonly metastasizes to the axillary lymph nodes.

Fleshy tumors are characteristic of medullary carcinoma, which can measure up to 5 to 10 cm in diameter. The histopathologic appearance exhibits a predominance of syncytial cells, lymphocytic infiltrate, and a lack of microglandular structure (Fig. 41.31). As a group, these tumors tend to have a better prognosis than the other IDC variants.

Colloid carcinoma appears as a large, slow-growing, gelatinous mass usually found in older women. Pathologic review of the specimen reveals large lakes of mucin and isolated tumor groupings (Fig. 41.32).

Paget disease is another form of IDC that originates in the excretory ducts of the breast. Involvement of the nipple-areolar complex may result in a firm consistency of the nipple, inflammation, ulceration, edema, and “weeping” of the skin. Characteristic Paget cells appear in the epidermis as large anaplastic cells surrounded by a clear halo. Paget may present solely with skin changes and the absence of an underlying mass. Thus, any nipple rash or skin changes that do not resolve with symptomatic treatment in a few weeks should be evaluated with dermatologic punch biopsy.

Finally, ILC arises from the terminal ductules of the breast and tends to be multifocal within the same breast as well as frequently bilateral. Involvement of the contralateral breast occurs in 20% of cases. Histologically, loosely, dispersed single-cell columns form strands of infiltrating tumor cells (Fig. 41.33).

In situ or noninvasive histologic variants of breast cancer also exist. Coincident with the widespread use of screening...
mammography, there has been a shift in the stage at presentation of breast cancer toward earlier-stage disease, particularly for ductal carcinoma in situ (DCIS) (Fig. 41.34). Data from Surveillance, Epidemiology, and End Results (SEER) shows nearly 300% change in incidence of DCIS in women age 50 years and older and greater than 100% increase in the incidence of stage I disease in the same group. The percentage of change was more pronounced in African-American women than in white women. DCIS is a nonobligatory precursor to IDC with variable rates of progression, depending on histology, size, and margin status. DCIS refers to lesions with proliferation of malignant cells within the ductal system of the breast but without invasion of the stromal tissue (basement membrane). This category represents 20% of all newly diagnosed breast cancers with a 20-year survival rate of 97%. In at least 90% of patients, the diagnosis is made with mammography. Only about 10% of patients have a palpable mass. Because of the controversy as to the potential for progression of DCIS to IDC, optimal management is one of the biggest challenges in breast disease faced by clinicians. Although DCIS is a preinvasive form of breast cancer and is not life threatening, treatment options may include lumpectomy, mastectomy, radiotherapy, and/or tamoxifen. Current treatment modalities may be overly aggressive because many cases of DCIS may not recur or progress to invasive cancer. Conservative contemporary treatments include lumpectomy with breast irradiation, generally excluding axillary lymph node dissection. Evidence is accumulating that DCIS <2 cm may not require irradiation. However, sentinel lymph node biopsy may be useful in evaluating large or high-grade lesions because of the increased risk of undetected micrometastasis. Historically, multicentricity was used to justify mastectomy for DCIS. In the literature, estimates of multicentricity in DCIS range widely, from 2% to 78% depending on the definition and mode of detection. Until we are better able to identify those patients at low risk for progression, it is unlikely that current treatment will change. Genomics holds great promise in this regard, yet prospective studies with long-term follow-up will be needed before treatment can be personalized for individual subsets.

Lobular carcinoma in situ (LCIS) refers to proliferation of cells within the breast lobules. LCIS is considered a predictive marker of future cancer rather than a cancer precursor. It is usually found incidentally by microscopy at the time of breast biopsy performed for another indication and does not present characteristic clinical or mammographic findings. It is typically multicentric and has a sevenfold to 10-fold increased risk of subsequent invasive breast cancer, which is typically ductal carcinoma. Studies of women with LCIS managed with biopsy alone demonstrate a risk of cancer development of approximately 1% per year.

Breast cancer may present with a firm consistency, fixed position (lack of mobility), dimpling or retraction of the overlying skin, nipple retraction, and irregular shape. Peau d’orange skin changes are associated with obstruction of the lymphatics and associated edema. This characteristic feature is not always associated with breast cancer and may be seen with mastitis. IDC frequently metastasizes to bone, lung, liver, or brain, whereas ILC more often metastasizes to meningeal serosal surfaces. On the other hand, inflammatory cancer causes extensive swelling, redness, and tenderness, which is often mistaken for a hematoma or abscess.

In general, breast cancer is slightly more common in the left breast than in the right. In most women, the left breast is slightly larger than the right. The upper outer quadrant is
The first recorded operative treatment for breast cancer was in the Greco-Roman period 220 B.C. by a Greek physician named Leonides. A century ago, William Halsted published his first paper on the radical mastectomy for the control of breast cancer. This procedure was very extensive, including removal of the breast tissue en bloc, pectoralis muscles, and axillary lymph nodes to achieve superior local and regional control of disease in that day. It remained the gold standard until the 1970s, when the trend in surgery for breast cancer has been to use more limited procedures. Taking into account comorbidities and the patient’s preferences, treatment may involve lumpectomy (local removal of the tumor); mastectomy (surgical removal of all the breast tissue); sentinel lymph node biopsy and/or axillary lymphadenectomy; radiation therapy; chemotherapy; or hormone therapy based on the stage and histology of the tumor, completeness of removal (i.e., status of the margins of the surgical specimen), and prognostic factors, including lymph node involvement, tumor size and grade, hormone receptor status, HER2-neu status, and S-phase fraction.

Currently, long-term updates of original prospective clinical trials have confirmed that BCS, which includes lumpectomy, postoperative radiation therapy, and surgical axillary staging (when appropriate), is the appropriate primary therapy for most women with stage I and II breast cancer. The largest of the BCS trials, NSABP B-06, reviewed women over 15 years and proved the equivalence of the treatments. Other studies have shown congruent results demonstrating no statistically significant differences between rates of local and regional recurrences, distant metastasis, and overall survival between mastectomy and BCS with early-stage disease. Tumor recurrence is 40% with BCS but is decreased to 10% with the addition of radiation therapy, which is similar to treatment with modified radical mastectomy. The appropriate candidate for mastectomy is primarily the patient in whom it is evident that BCS will not control the primary tumor. Cosmetic factors are important, but the primary concern is adequate removal of the primary tumor with pathologically negative margins. One other concern with respect to BCS is the necessity for radiation therapy and continued intense surveillance. For this reason, patients with certain medical conditions, such as active or preexisting collagen vascular disease, may not be candidates for BCS, because these patients have been shown to have poor tolerance to radiation in the breast and chest wall areas (Tables 41.12 and 41.13). Complete axillary dissection continues to assume a position of diminishing importance in the treatment of breast carcinoma but remains controversial. As the role for systemic therapy even in patients with negative nodes expands, some investigators have stated that not all patients require an axillary dissection, but 30% of patients with no palpable lymph nodes (clinically negative axilla) have been found to have histologically positive lymph nodes. Because axillary nodal status is the best established indicator of their risk for systemic relapse, the potential of the more limited sentinel lymph node evaluation is evident (discussed below).

For patients with negative axillary involvement, the tumor size and histologic grade are the most useful prognostic factors. Among patients with invasive tumors of less than 1 cm in greatest diameter, the 5-year disease-free survival rate is more than 90%. Expression of the estrogen receptor or the progesterone receptor is associated with a better prognosis, primarily attributable to the responsiveness of these tumors to antihormone therapies, for example, tamoxifen and aromatase inhibitors. HER2 amplification has been associated with a poor prognosis; however, the role of HER2-neu as a prognostic factor remains controversial. The role of HER2 as a predictor of response to chemotherapy is discussed in the section on tumor-specific therapies. There is no clear evidence to suggest that women with breast cancer associated with a BRCA1 or BRCA2 mutation should be managed differently from those with sporadic cancers. BCS remains the standard of care for women with early-stage sporadic breast cancer and is routinely offered to mutation carriers who have been diagnosed with breast cancer; BRCA mutation carriers are at increased risk for contralateral breast cancers; this risk may be as high as 60%. Thus, questions exist regarding optimal surgical management. Researchers question whether these patients may benefit from an ipsilateral mastectomy on the affected breast and contralateral prophylactic mastectomy on the unaffected breast. Thus, advance knowledge of one’s BRCA status may be important in determining surgical options.

Ablative procedures can be performed in the office or ambulatory surgical setting and may offer patients an alternative to surgical excision. Ablative techniques were initially used on metastatic hepatic tumors with success; thus, similar technology is now being applied to the treatment of breast disease. Ablative therapy uses radiofrequency, cryoablation, laser, microwave, and focused ultrasound in clinical protocols as a minimally invasive treatment modality for small malignant and benign breast tumors. Data are available that demonstrate...
variable success in tissue destruction using different modalities. Long-term follow up data regarding local effects on the breast tissue or recurrence rates of cancer are not available, and local breast changes may pose a diagnostic dilemma in future trials to distinguish recurrent cancer from scar or fat necrosis.

Sentinel Lymph Node Biopsy

The status of axillary nodes is one of the most well-established prognostic indicators for systemic relapse used to select patient subgroups for adjuvant chemotherapy. Patients with involvement of the lymph nodes have a 60% to 70% risk for relapse within 5 years, whereas 70% to 80% of patients with negative nodes are cured by local therapy. Yet currently, there is no evidence that axillary lymph node dissection (ALND) improves survival, thus diminishing its importance. ALND, however, is an effective staging procedure and may be essential for local control of disease in the axilla. In general, the standard treatment of the axilla involves level I and level II axillary lymph nodes. This is extended to level III only if gross disease is apparent for treatment of stages I, IIA, and IIB cancer.

The prior standard of care for surgical management of invasive disease was complete excision of the tumor by either mastectomy or lumpectomy followed by ALND. Based on information gathered from treatment of melanomas, it was established that the first lymph node (the sentinel node) to receive drainage from the primary tumor can be used to predict the presence or absence of tumor in the remainder of the lymph nodes. Published and unpublished results in breast carcinoma surgery support the same concept for axillary node breast metastases. Intraoperative lymphatic mapping and sentinel lymph node biopsy (SLNB) has emerged as an alternative to routine ALND in clinically node-negative early breast cancer and represents a major new opportunity obviating the need for more invasive surgical management of many tumors. Lymphatic mapping with selective lymphadenectomy is an attractive approach in breast cancer patients because it may lead to a substantial reduction in the need for axillary node dissection without compromising survival and regional control and without loss of prognostic staging information, thus translating into a significant reduction in patient morbidity and medical expenses. SLNB is highly accurate and sensitive in patients with small tumors, and no false-negative SLNB has been reported for a breast cancer smaller than 1.0 to 1.5 cm, resulting in a negative predictive value of 100%. In the future, axillary dissection might be avoided in patients who have no metastatic involvement of the sentinel lymph node; however, if the sentinel lymph node cannot be identified or is positive for metastasis, a formal ALND should be performed (or in some cases, axillary radiation therapy administered).

The surgeon can use two techniques to find the node. The technique of intraoperative sentinel lymph node mapping was pioneered by Giuliano and is performed using a blue dye injected peritumorally, which stains the lymphatic duct (Fig. 41.35). After 5 minutes, blue dye can be visualized traversing afferent lymphatics and collecting in a sentinel lymph node through an axillary incision at the tumor site. There is a 93.5% success rate in identifying an axillary node as the sentinel node. The false-negative rate has been 0%. Alternatively,
a lymph node-seeking radioactive tracer ($^{99m}$Tc) migrates from the tumor site (when injected into the breast parenchyma) to the sentinel node and enables its retrieval with the use of a gamma detection probe. Blue dye and lymphoscintigraphy are complementary techniques, and optimal localization is achieved when the two methods are used together. Several authors have achieved greater than 95% success rate and quote a sensitivity of 98% for sentinel node localization.

Other variations of the procedure have been espoused, including the addition of ultrasound to the protocol and endoscopic axillary node dissection in conjunction with BCS. RT should begin as soon as the wounds of surgery are healed and may be given concurrently with certain chemotherapy regimens. It is generally agreed that the breast should be treated with 180 to 200 cGy/day for 4.5 to 5.5 weeks for a total of 4,500 to 5,000 cGy. This course can be supplemented by a boost of 1,000 to 1,600 cGy over 1 to 2 weeks, although this is controversial. A total dose in excess of 5,000 cGy results in fibrosis, retraction, and an unacceptable cosmetic result. Consequently, conventional postoperative whole breast irradiation (WBI) increases the length and complexity of breast cancer treatment and can be inconvenient or prohibitive for patients who are elderly, working, or lack access to a radiation therapy facility. The vast majority of ipsilateral breast cancer recurrences are located within the tumor bed and adjacent breast tissue; therefore, the need for elective irradiation of the whole breast is uncertain, and partial breast irradiation is a biologically plausible concept. Novel approaches to RT are being explored to reduce the volume of tissues irradiated and decrease the time required for delivery. Partial breast irradiation (PBI) may improve the documented underutilization of BCS by allowing RT to be completed in 4 or 5 days, rather than 6 to 7 weeks, eliminating the acute and chronic toxicities associated with WBI, improving cosmesis, and conferring societal economic benefits. This accelerated course of treatment can also eliminate concerns about the sequencing of adjuvant radiation and chemotherapy. A matched-pair analysis has demonstrated comparable outcomes for women treated with PBI or WBI. Sev- eral phase III clinical trials evaluating these issues are ongoing worldwide. Criteria currently include women with breast cancers up to 3 cm and DCIS using 10 fractions over 5 days. Before PBI can be routinely incorporated into clinical practice, appropriate patient selection, optimal fractionation schedules, and PBI techniques must be determined, as well as establish- ment of long-term efficacy, rates of locoregional recurrence, survival rates, cosmesis, and patient satisfaction. Options for PBI currently include intrasternal catheter brachytherapy and balloon-based intracavitary brachytherapy (MammoSite, Al- pharate, GA). Additional trials are focusing on intraoperative radiation therapy, three-dimensional conformal RT, and other novel techniques.

Radiation

The role of radiation therapy (RT) in breast cancer treatment has been more clearly defined in the last 2 decades. RT may be applied to invasive or noninvasive disease. It is a standard component of BCS and has been shown to be of benefit post- mastectomy in patients with large tumor burdens or more than four positive lymph nodes.

Recent results from an Intergroup study found lower rates of recurrence in the radiation arm but no differences in survival or disease-free survival in a group of women with early-stage breast cancer older than age 70 when randomized to receive whole breast irradiation plus tamoxifen or tamoxifen alone. Thus, women older than 70 with early-stage ER-positive disease and negative lymph nodes may be treated without breast irradiation in conjunction with BCS. RT should begin as soon as the wounds of surgery are healed and may be given concurrently with certain chemotherapy regimens. It is generally agreed that the breast should be treated with 180 to 200 cGy/day for 4.5 to 5.5 weeks for a total of 4,500 to 5,000 cGy. This course can be supplemented by a boost of 1,000 to 1,600 cGy over 1 to 2 weeks, although this is controversial. A total dose in excess of 5,000 cGy results in fibrosis, retraction, and an unacceptable cosmetic result. Consequently, conventional postoperative whole breast irradiation (WBI) increases the length and complexity of breast cancer treatment and can be inconvenient or prohibitive for patients who are elderly, working, or lack access to a radiation therapy facility. The vast majority of ipsilateral breast cancer recurrences are located within the tumor bed and adjacent breast tissue; therefore, the need for elective irradiation of the whole breast is uncertain, and partial breast irradiation is a biologically plausible concept. Novel approaches to RT are being explored to reduce the volume of tissues irradiated and decrease the time required for delivery. Partial breast irradiation (PBI) may improve the documented underutilization of BCS by allowing RT to be completed in 4 or 5 days, rather than 6 to 7 weeks, eliminating the acute and chronic toxicities associated with WBI, improving cosmesis, and conferring societal economic benefits. This accelerated course of treatment can also eliminate concerns about the sequencing of adjuvant radiation and chemotherapy. A matched-pair analysis has demonstrated comparable outcomes for women treated with PBI or WBI. Several phase III clinical trials evaluating these issues are ongoing worldwide. Criteria currently include women with breast cancers up to 3 cm and DCIS using 10 fractions over 5 days. Before PBI can be routinely incorporated into clinical practice, appropriate patient selection, optimal fractionation schedules, and PBI techniques must be determined, as well as establishment of long-term efficacy, rates of locoregional recurrence, survival rates, cosmesis, and patient satisfaction. Options for PBI currently include intrasternal catheter brachytherapy and balloon-based intracavitary brachytherapy (MammoSite, Alpharate, GA). Additional trials are focusing on intraoperative radiation therapy, three-dimensional conformal RT, and other novel techniques.

Radiation is also useful in the palliative treatment of bone pain in advanced metastatic disease. Complications of radia- tion therapy include fatigue and development of dry skin, erythema or tanning, edema, and muscle stiffness within the tissues encompassed by the RT field. After completion of the irradiation treatment, most patients recover their nor- mal skin color and texture within a few weeks, but edema can take much longer to resolve. Late complications from RT are unusual, including a very low incidence of rib fracture, radia- tion pneumonitis, brachyphlebopathy, and pericarditis in cases of left-sided lesions. In the overwhelming majority of cases, a return to normal is the rule.

Systemic Therapy

Therapeutic options for patients with noninvasive or invasive breast cancer are complex and varied. Use of additional sys- temic therapy is based on the patient’s likelihood of recurrence and predicted response to hormonal or chemotherapy. This can be estimated with use of an online model, ADJUVANTON- LINE!. In addition, newer molecular techniques, including pro- toxic and genomic analysis, are being developed that may add greater specificity to treatment decisions.

Cytotoxic Chemotherapy

Neoadjuvant (preoperative) chemotherapy is increasingly used, presumably associated with eradication of micrometastatic dis- ease, and has shown comparable efficacy compared with post- operative (adjuvant) chemotherapy in the NSABP B-18 trial demonstrating similar disease-free and overall survival rates in patients with stage I and II operable breast cancer. In this trial, use of standard chemotherapy regimens including doxorubicin (Adriamycin) and cyclophosphamide (AC) demonstrated success in decreasing the tumor size, thus permitting less extensive surgical options. The addition of four cycles of docetaxel signifi- cantly increased clinical and pathologic response rates for operable breast cancer. Neoadjuvant therapy may also be used in large (≤3 cm) and locally advanced breast cancer (T1, T2, T3, N2) to increase the likelihood of successful BCS.

A number of combination chemotherapy regimens are appropriate to consider when adjuvant cytotoxic chemother- apy is warranted. These regimens include 5-fluorouracil, doxor- ubicin, and cyclophosphamide (FAC/CAF) or cyclophos- phamide, epirubicin, and fluorouracil (CEF); doxorubicin or epirubicin and cyclophosphamide (AC/EC); AC (or dose dense ATC). Differing combinations of the above regimens have also been studied with success. Recent studies document sub- stantial improvement in outcome with the incorporation of trastuzumab in the adjuvant setting of HER2/neu overexpres- sion (discussed below). Omitting cyclophosphamide from any combination obviates the long-term risk for acute leukemia and substantially reduces the severity of alopecia and myelosup- pression; thus, it is a better tolerated regimen. Fifty percent to 80% of women have an objective response to FAC, and 40% to 60% have an objective response to CMF (cyclophosphamide, methotrexate, and fluorouracil). Studies of CMF chemotherapy versus no chemotherapy have shown disease-free and over- all survival advantages with CMF chemotherapy. Regimens containing anthracyclines (doxorubicin or epirubicin) were
superior to CMF in the Early Breast Cancer Trialists’ Collaborative Group overview. These chemotherapy regimens may cause short-term complications, including nausea, vomiting, myelosuppression, alopecia, and weight gain. Use of anthracycline-based chemotherapy has the long-term risks of chemotherapy-induced ovarian ablation (70%), cardiac dysfunction, premature menopause, and secondary malignancies. Node-negative patients may benefit from the addition of paclitaxel to the AC regimen; therefore, until other studies are analyzed, treating node-positive patients with four cycles of AC (or CAF) followed by four cycles of paclitaxel is reasonable.

Common toxicities include nausea, vomiting, alopecia, fatigue, mucositis, weight gain, premature menopause, neutropathy (taxanes), and myalgias (taxanes). Less common toxicities include febrile neutropenia (common with TAC), thrombosis, hemorrhagic complications, cardiomyopathy (anthracyclines), and secondary leukemia.

Adjuvant therapy has also been proven to have added benefit for node-negative patients with breast cancer. Zambetti and colleagues found adjuvant chemotherapies increase disease-free survival in 85% of patients compared with 42% of untreated control subjects. Similar values have been verified in other studies. The goal is to determine which node-negative patients are at high risk for recurrence to avoid further unnecessary treatment in patients already cured of their disease.

Several prognostic factors are currently used to predict risk of relapse or death from breast cancer. The strongest are patient age, conoid, the number of involved lymph nodes, tumor diameter, grade, and receptor status. Other less well-established prognostic factors include S-phase fraction (an indicator of proliferative capacity), HER2/neu overexpression, histology, nuclear grade, and DNA aneuploidy. The innovative technique of DNA microarray is poised to revolutionize the treatment of breast cancer. Subclassification systems of breast cancer subtypes have been developed by gene expression profile. In retrospective analysis, these subtypes have shown differing relapse-free and overall survival, thus permitting both prognostic and predictive functions. Additionally, a multigene assay using reverse transcription polymerase chain reaction on RNA isolated from paraffin-embedded tissue was able to identify prognostic subsets and to predict responsiveness to both tamoxifen and CMF or methotrexate/5-fluorouracil/leucovorin chemotherapy.

Thus, node-negative women with moderately or poorly differentiated invasive tumors of larger than 1 cm and negative hormone receptors should be offered chemotherapy. Because the risk for node-negative patients with well-differentiated tumors of less than 1 cm in size is 10% or less, adjuvant chemotherapy is not recommended. In addition to chemotherapies, patients who are premenopausal (or younger than 50 years of age) with negative nodes and ER-positive tumors should be considered for a 5-year course of tamoxifen because even in node-negative patients, 30% of patients have a relapse in 5 years. The treatment of postmenopausal patients with negative nodes and hormone receptor-positive tumors is evolving. Randomized clinical trials showed that chemotherapy plus tamoxifen yields better survival rates than tamoxifen alone, but the absolute benefit is small and the use of chemotherapy in this setting should be individualized. Recent data on trends in breast cancer treatment indicates an increasing proportion of women receiving both chemotherapy and tamoxifen with ER-positive tumors and positive lymph node status as recommended by evidence-based guidelines from the National Breast Cancer. However, use of concurrent therapy remained relatively low among women aged 65 and older, who were more likely to receive tamoxifen only. The international consensus panel recommends hormonal therapy as the treatment of choice for ER-positive women with limited disease regardless of menopausal status, tumor size, or axillary involvement, especially for patients who are asymptomatic or are of advanced age. Hormone receptor status determines the likelihood that a patient will respond to hormonal therapy, with 75% to 80% of patients with estrogen receptor/progesterone receptor–positive tumors showing an objective response. Even patients with ER-negative and HER2/neu–positive tumors had a 10% objective response rate.

**Hormonal Therapy**

Breast cancers are often exquisitely sensitive to endocrine manipulation, thus laying the foundation for the success of antiestrogens in the fight against cancer. Endocrine therapies have been a critical factor in the dramatic decline in mortality from this disease in both the United Kingdom and the United States. Since the introduction of tamoxifen in the 1970s, endocrine therapy for breast cancer has enjoyed a remarkable renaissance with the generation of data touting the benefits of aromatase inhibitors in hormone responsive breast cancer treatment as well.

**Selective Estrogen Receptor Modulators**

Tamoxifen citrate has been shown to be of immense significance in the battle against breast cancer. Tamoxifen has demonstrated benefit when used alone or in combination with chemotherapy in the treatment of advanced breast cancer and has proven efficacy in reducing tumor recurrence, prolonging disease-free survival, and lowering the incidence of contralateral second primary breast cancer by nearly 40% when administered as postoperative adjuvant therapy in stages I and II disease. The improved effectiveness of tamoxifen in this setting prompted its use in the preventive setting in the NSABP P-1 and BCPT trials (discussed earlier under “Chemoprevention”). Although relatively well tolerated compared with cytotoxic chemotherapy, tamoxifen is beset with side effects, particularly hot flashes (30%), vaginal discharge, vaginal bleeding, endometrial cancer, and thromboembolic events. However, it has been suggested that for every endometrial cancer death, 80 breast cancer deaths have been averted with the use of tamoxifen.

SERMs were first evaluated in the 1960s as nonsteroidal antiestrogens. This group of drugs showed potent antifertility activity in rats, but paradoxically proved to be an inducer of ovulation in subfertile women. Tamoxifen is a SERM that remains a vital part of the regimen for ovulation induction. Further studies was commenced based on the compound’s multifaceted actions on different types of receptors. Ancillary studies in this group of drugs focused on treatments for advanced breast cancer; however, only tamoxifen was investigated further because of its high potency, efficacy, and modest side effects.

The strategic application of these medications was first noted in long-term adjuvant treatment of node-positive and node-negative, ER-positive breast cancers. Tamoxifen decreases the serum levels of total cholesterol by 13% and those of low-density lipoprotein cholesterol by 19%. Therefore, tamoxifen has the added benefit of maintaining bone density and reducing the risk of myocardial infarction in postmenopausal women. Thus, despite known benefits of aromatase inhibitors, tamoxifen may remain the standard in patients with osteopenia or osteoporosis.

Several new SERMs are under investigation.Raloxifene has shown benefit for breast cancer prevention in postmenopausal women with osteoporosis; clinical trials are ongoing. Farenolone (Fareston) has shown efficacy similar to...
tamoxifen and may be a reasonable first-line alternative. Because of substantial cross-resistance between toremifene and tamoxifen, there is no role in patients who have tumors resis-
tant to tamoxifen. Drolidoxifene and idoxifene have had mini-
mal evaluation but show binding affinity to ER-positive breast cancers and response rates of 0% to 70%.

Aromatase Inhibitors
Aromatase inhibitors (AIs)—generally anastrozole, letrozole, and exemestane—have made an exciting contribution to the management of hormone-responsive breast cancer. A plethora of studies has shown the superiority of AIs over tamoxifen in postmenopausal patients with ER-positive tumors. Current therapy in these patients may include tamoxifen for 5 years, AI for 5 years, combination of tamoxifen and AI for 5 years, and addition of AI for 5 years at the end of the tamoxifen treatment.

AIs function through inhibition of aromatization, thus blocking the enzyme that catalyzes the final and rate-limiting step in the synthesis of estrogens. Currently, studies are noting benefit primarily in postmenopausal women in whom produc-
tion of aromatase in nonovarian tissues in the periphery (such as adipose tissue, adrenal gland, and muscle) are the dominant sources of estrogen. Now in their third generation, AIs (specifi-
cally anastrozole) have proven superior to tamoxifen in a RCT (ATAC—Arimidex, tamoxifen, alone or in combination trial) of treatment of 9,366 postmenopausal women with localized breast cancer with respect to disease-free survival, time to re-
currence, incidence of contralateral breast primary tumors as first events, and a number of important tolerability parame-
ters. Additionally, fewer patient withdrawals from the study occurred with anastrozole than with tamoxifen as anastrozole was associated with fewer side effects than tamoxifen, partic-
ularly in relation to hot flashes, vaginal bleeding, endometrial cancer, and vagemal discharge. Yet arthralgias and fractures were increased.

Anastrozole now offers a choice for postmenopausal patients with hormone-responsive tumors, although longer follow-up will enable a more definitive benefit/risk assessment. Further-
more, AIs are being studied in premenopausal patients and in the chemoprevention setting.

An additional RCT comparing letrozole to placebo in 5,187 postmenopausal women with hormone-sensitive early-stage breast cancer after 5 years with tamoxifen showed improved disease-free survival and decreased recurrences in the letrozole group compared with placebo. Before this finding, there was no additional standard treatment after the tamoxifen therapy to prevent recurrences. A recent update of the trial indicates substantial clinical benefit even following a 1- to 5-year hia-
sus after 5 years of adjuvant tamoxifen in disease-free survival, distant disease-free survival, and overall survival. Furthermore, switching to anastrozole or exemestane in the middle of the standard 5-year tamoxifen treatment has also shown improved disease-free survival over continuation of tamoxifen. Thus, women’s health practitioners must become knowledgeable re-
garding current patterns of breast cancer treatment and have a thorough discussion with their medical oncologists, thereby referring women appropriately (who may have missed or been reluctant to continue oncologic care but still follow for gy-
ecologic care) for additional care. Researchers are following these women to ascertain long-term effects on bones and lipids.

Current evidence is inconclusive regarding the use of bisphos-
phonates to prevent or for loss in patients taking AIs, although studies are under way to evaluate this possibility.

Letrozole has also shown effectiveness in ovulation induc-
tion and is one of the only safe options for breast cancer patients wishing to undergo in vitro fertilization and ovarian stimula-
tion to freeze embryos before their cancer therapy. Although the product’s label has always stated a contraindication in pre-
menopausal women because of “the potential for maternal and fetal toxicity,” many intraterrorine mammary sthenm inons have replaced the standard clomiphene citrate with letrozole because of its superior pregnancy success rates and ability to decrease gonadotropin requirements. However, a small, un-
published Canadian study presented at the conjoint annual meeting of the American Society for Reproductive Medicine and the Canadian Fertility and Andrology Society warned that the drug may be associated with congenital anomalies, which prompted the pharmaceutical company to send letters to health care professionals regarding this information. However, many fertility experts suggest caution in interpreting the results, as a higher-than-normal dose of letrozole was used (5 mg rather than 2.5 mg) and may portend the dubious consequences.

Additional Treatments
Ovarian ablation has been shown to reduce the risk of tu-
mor recurrence and death in women younger than 50 years, at least in the absence of adjuvant chemotherapy. The combi-
nation of oophorectomy and chemotherapy was as effective as either treatment alone in premenopausal women, but the inva-
sive nature of surgical feminine castration has limited its use in the United States. In addition, tamoxifen is effective in pre-
menopausal women, and no randomized trial has shown the superiority of oophorectomy over tamoxifen.

Luteinizing hormone-releasing hormone analogs are an al-
ternative to oophorectomy. These agents induce a “chemi-
cal castration” and are effective for premenopausal patients with metastatic breast cancer, and have been shown to improve the overall response in women with tumors with high levels of the HER2 protein when adminis-
terated. These tumors tend to grow faster and are gener-
ally more likely to recur than tumors that do not produce HER2. Trastuzumab (Herceptin) is an FDA-approved mono-
clonal immunoglobulin G1 antibody that inhibits human ep-
dermal growth factor receptor 2 (HER2) with high affinity for the HER2/neu receptor and has been shown to be a po-
tent weapon against the recurrence of cancer cells that amplify HER2. Trastuzumab significantly inhibits the growth of breast tumors with high levels of the HER2 protein when adminis-
terated alone or in combination with paclitaxel or carboplatin and has been shown to improve the overall response in women with metastatic breast cancer. A recent clinical trial evaluated these tumors using doxorubicin, cyclophosphamide followed by paclitaxel versus doxorubicin, cyclophosphamide followed by paclitaxel and estramustine. Those patients receiving trastuzumab in combination with standard combination chemotherapy had a 32% statistically
significant reduction in disease recurrence and 33% reduction in mortality compared with patients treated with chemother-
apy alone. Overexpression of this gene product also predicts resistance to tamoxifen therapy. Currently, trastuzumab pro-
longs survival in metastatic breast cancer patients whose tu-
mors overexpress the HER2/neu protein. Its effect on ovarian cancer is investigational at present.

Trastuzumab has side effects, apart from cardiac toxicity in patients concurrently receiving anthracyclines. Thus, careful cardiac monitoring is required in these patients to detect reduction in left ventricular ejection fraction as congestive heart failure rates ranged from 0.5% to 4.1% in sev-
eral trials. It is thus reasonable for trastuzumab to become a treatment option in early or metastatic breast cancer. Sev-
eral institutions routinely incorporate HER2/neu status test-
ing into the assessment of all patients with invasive breast dis-
ease. Additional approaches are being investigated as possible therapeutic strategies targeting HER2, including growth in-
hibitory antibodies, which can be used alone or in combination with standard chemotherapeutics; receptor inhibitors, devel-
oped to block receptor activity because phosphorylation is the key event leading to activation and initiation of the signaling pathway; and active immunotherapy, because the HER2 on-
crop protein is immunogenic in some breast carcinoma patients. Unanswered questions include the appropriate duration and dose of therapy, and whether cardiotoxicity is reversible, espe-
cially if doxorubicin is not used.

CARE FOR BREAST CANCER SURVIVORS

Follow-Up

The risk of recurrent disease in the contralateral breast is estimated at 10% for patients with in situ carcinoma and 5% to 10% with invasive cancer. In addition, patients receiving definitive treatment for breast cancer have a 16% risk at 3 years of developing a second primary site of cancer, including the contralateral breast, ovaries, endometrium, and large intest-
tine. Thus, recommended breast cancer surveillance guidelines include a thorough history and physical examination every 3 to 6 months for 5 years, every 6 to 12 months for 2 years, then an-
ually. A review of systems should elicit symptoms in the breast and at those sites where recurrences frequently occur, such as nodal disease, lung, bone, liver, adrenal gland, and ovary. A focused history should include information on weight loss, local or distant skin changes (radiation effects or breast skin changes—spinalateral and contralateral), mental status changes, headache or sensory deficits, pleuritic chest pain, shortness of breath, bone pain, changes in bowel function and melena or blood in the stool, and abnormal rectal or vaginal secretions. Physical examination should incorporate an evaluation of the remaining breast tissue and lymph node-bearing areas, range of motion of the upper extremity, and increasing arm girth, which may indicate onset of lymphedema or axillary recurrence. Ex-
aminations of the chest and abdomen are performed to search for evidence of pleural effusions or hepatomegaly. A mamo-
gram, pelvic examination, and Pap test should be performed annually. Routine radiological studies (bone scan, CT, chest x-
ray) or laboratory testing (liver function tests, complete blood count, tumor markers) is recommended except based on symptomatology in that no survival advantage is conferred by detecting asymptomatic disease; however, institutional policies may differ. Many surgeons continue to recommend yearly com-
plete blood counts and chemistry panels as well as chest radio-
graph despite evidence of specificity in detection of metastatic disease. One series indicated less than 18% specificity for rou-
tine testing.

Those with initial advanced disease should have regularly scheduled visits at 3-month intervals for their lifetime. Others recommend visits every 3 months for 3 to 5 years, then every 6 months thereafter for patients with advanced disease.

Women with DCIS require physical examination every 6 months for 3 years and then annually, as well as yearly diag-

nostic mammography.

Hormone Replacement Therapy

As more breast cancers are detected at an earlier stage, result-
ing in increased survival, there is a wealth of attention directed toward use of HRT in breast cancer survivors. Many authors sanction use of HRT for menopausal breast cancer survivors who are disease-free and have symptomatic estrogen deficiency, especially after the first 2 years when the risk of recurrence is decreased. Furthermore, patients with localized nodal-negative breast cancers who are at low risk for recurrent disease may be excellent candidates for long-term replacement. ACOG rec-
ommends HRT use with a treatment plan that includes dietary control, exercise, smoking cessation, reduction of alcohol con-
sumption, and weight reduction when appropriate. Women with unexplained vaginal bleeding, acute vascular thrombosis, or significant liver function impairment would remain ineligible for use. All women should be carefully and completely coun-
seled regarding the potential, albeit unproven, risks of disease recurrence.

Gabapentin has also been shown in a randomized double-
blind placebo-controlled trial of 420 women to control hot flashes in cancer patients at 900 mg/day, demonstrating greater reduction in the posttreatment hot flash severity score compared with placebo and lower doses of gabapentin (Neu-
rontin). Gabapentin is approved for the treatment of epilptic seizures but often used for treatment of migraine headaches, restless legs syndrome, and bipolar disorder. Additionally, ven-
lafaxine appears to be an effective treatment for hot flashes.

Pregnancy after Treatment for Breast Cancer

Although oncologists generally caution patients to avoid preg-
nancy until 2 years after completing treatment for breast can-
cer, several investigators have not shown any adverse effects or decreased survival for women who become pregnant after can-
cer therapy. Moreover, although lactation is decreased in the treated breast, radiation therapy appears to have no effect on the contralateral breast. Increased rates of stillbirth, preterm birth, and low birth weight portend a suboptimal intrauterine environment, but the infants are otherwise unaffected.

BREAST CANCER AND PREGNANCY

Breast cancer is estimated to occur in 1 in 3,000 to 1 in 10,000 and have an incidence of 0.2% to 3.8% of pregnan-
cies. Pregnancy-associated breast cancer is defined as that oc-
curring during pregnancy or within 1 year after delivery. Breast cancer diagnosed in pregnancy has an overall inferior prog-
nosis as it tends to be diagnosed at a more advanced stage;
The evaluation, diagnosis, and treatment of a breast mass in a pregnant patient is unchanged from their nonpregnant counterparts. The conventional diagnostic modalities may be performed—including FNA, ultrasonography, CNB under local anesthesia, or excisional biopsy under local or general anesthesia—without adverse sequela. However, additional false-negative FNA results may occur as a function of the increased cellularity and frequent mitoses that can occur normally during gestation. Core biopsies are more accurate, but milk fistulas—a complication seen in surgical biopsies—have been reported. The finding of a thickness or a possible mass usually requires a short interval follow-up and examination because of the effect of the required adjunctive radiation on the fetus. The survival risk to the mother prompted by delaying radiation therapy until after delivery is not known. In the first trimester, particularly during fetal organogenesis, both irradiation and chemotherapy—especially with folate antagonists—are contraindicated. There are scattered case reports of normal, well babies both in all of these treatment circumstances, but the risks to the fetus are significant. Concerns continue to be raised about the future neurologic development and potential subsequent increased risk for childhood cancers among these newborns exposed to radiation; reliable long-term data are unavailable. Thus individualized counseling should be provided in a compassionate, caring forum considering the patients psychosocial situation, anxieties, and future expectations. If the diagnosis is made during the third trimester, the patient may elect to be observed until delivery, when prompt treatment as pregnancy advances could actually be obscured by the normal changes in pregnancy and represent an ongoing developing breast carcinoma. For this reason, ultrasound may be used to evaluate an area that is “negative” on examination but was previously thought to harbor a mass lesion. Breast ultrasonography during pregnancy is safe and helpful in differentiating between cystic and solid masses. However, ultrasound is less specific in distinguishing benign solid masses from malignant masses. Conversely, MRI has been used in pregnancy and seems safe for fetuses because it does not expose them to ionizing radiation, although the safety committee indicates that the safety during pregnancy has not been proven. Recent reports on its use for fetal imaging in prenatal diagnosis contain limited follow-up of the infants, but no untoward effects have been reported. MRI may be particularly useful for the diagnosis of confirmation of bone, liver, or even brain metastases in the staging of patients, although head CT scans with abdominal shielding yield only small amounts of fetal exposure.

Any dominant mass should be evaluated as it would be in the nonpregnant patient to prevent diagnostic delay. Screening mammmography may be deferred to limit fetal exposure but should be obtained without hesitation if the lesion requires additional evaluation. Radiation exposure to the fetus during mammography is estimated at less than 10 mrad, depending on the gestational age, with increasing dose as the gravid fundus grows closer to the targeted breast tissue. The risk for teratogenicity in subsequent fetal development may discourage the institution of therapy for cancer in pregnant women; however, established surgical and adjunctive therapies should be undertaken. Therapeutic termination does not appear to affect the survival in early-stage breast carcinoma and is therefore not advocated. Indeed, the possibility of a detrimental effect on survival has been suggested. Modified radical mastectomy is the optimal treatment for local management of stage I and II. BCS is contraindicated in the first and second trimester because of the effect of the required adjunctive radiation on the fetus. The survival risk to the mother prompted by delaying radiation therapy until after delivery is not known. In the first trimester, particularly during fetal organogenesis, both irradiation and chemotherapy—especially with folate antagonists—are contraindicated. There are scattered case reports of normal, well babies both in all of these treatment circumstances, but the risks to the fetus are significant. dysfunction). Chemotherapy administration during the first trimester is associated with an increased incidence of stillbirths and congenital malformations. The risk of fetal malformation when chemotherapy is instituted in the first trimester is 12% compared with no increased risk with chemotherapeutic administration in the second and third trimester.

Staging procedures for breast cancer are often considered inappropriate in the gravid patient, but there are no contraindications for chest radiography performed with abdominal and pelvic shielding. In late pregnancy, the fetal shield may obscure the lower lung parenchyma; however, exposing the third-trimester fetus to chest radiography presents no great concern. Alkaline phosphatase is elevated in normal pregnancy, making its use in evaluation of bone metastasis ineflectual. Conventional radiography, excluding the pelvis and abdomen (e.g., skull and long bones), can be performed. No adequate substitute for bone scanning exists, although articles have promoted certain modifications of the bone-scanning technique for pregnant patients. Because the incidence of bone metastasis is very low in stage I and II disease, bone scanning can usually be avoided. On the other hand, in clinical stage III disease, in which the possibility of bone metastasis is increased, treatment methods differ and may weigh in favor of provision of the test.

Whereas other human malignancies—including melanoma, hematopoietic malignancies, hepatoma, and chorio- carcinoma—have been reported to cause fetal metastases, breast cancer has not. On the contrary, placental metastases from breast cancer and other solid tumors have been reported. Because half of these patients did not have visible lesions, microscopic examination of the placenta is warranted.

Rarely, breast fibroadenomas may infarct during pregnancy. These cases warrant close microscopic review because they may mimic carcinomas.

**RISK MANAGEMENT AND PROFESSIONAL LIABILITY**

Associated with the increased involvement in evaluation of diseases of the breast comes attached potential liability. Although medicolegal concerns for abortion providers are minimal, instances of abortion, including therapeutic abortion, must be cognizant of the legal environment. The special challenge of these cases derives from the emotionally charged nature of the cancer diagnosis, combined with high expectations in the current capability of breast cancer screening and treatment outcomes. In this litigious society, nearly 80% of board-certified obstetricians/gynecologists in the United States have been sued for alleged malpractice. The most recent ACOG Professional Liability survey listed failure to diagnose breast cancer as the second leading primary allegation in claims against gynecologists (second only to surgical injury). Specifically, failure to diagnose breast cancer accounted for 33% of these claims, with failure to diagnose cervical (7.4%) and ovarian cancers (7.3%) running a far second and third. According to the Physician's Insurers Association of America, failure to diagnose cancer is the second most expensive condition to indemnify with an average payment of $212,896.

Health care providers encounter a wide variety of legal issues with regard to patients with breast disorders, including liability for alleged misdiagnosis, delayed diagnosis of breast cancer, failure to obtain informed consent, and improper treatment of breast disease. Controversial issues related to medical malpractice often affect the care of breast disorders. For example, many state legislatures have mandated informed consent requirements for those treating patients with breast cancer. Finally, legislation and litigation regarding insurance coverage for mammography screening, managed care policies, and new breast cancer treatments are becoming increasingly common. The idea that physicians would not be brought into suits against Health Maintenance Organizations (HMO) and pharmaceutical companies has drastically changed, with more private doctors becoming involved in lawsuits against corporate entities.

Analysis of the paid malpractice claims revealed women who were relatively young for the diagnosis of breast cancer (60% were younger than 50 years of age) and a high occurrence of false-negative mammogram results (nearly 80% of the claims had negative orequivocal mammogram results) were overrepresented. The average length of diagnostic delay was 14 months, with the average malpractice award or settlement increasing with longer periods of delay. The average indemnity payment increased by 36%. Interestingly, radiologists have surpassed gynecologists as the most frequently sued practitioner for delayed diagnosis, accounting for 24% of claims (gynecologists accounted for 23%). Specifically, this is a significant change from the previous study, wherein gynecologists accounted for 38% of the claims and radiologists for 11%. In 1995, family practitioners accounted for 17%, surgical specialties for 14%, internal medicine for 4%, and pathologists for 2%.

Historically, U.S. jurisdictions used a “but for” test to establish legal, or proximate, causation. Causation in legal terminology signifies that the practitioner’s action (e.g., delayed diagnosis) must have an association with the resultant injury (development of breast cancer) that is sufficiently close to hold the practitioner liable for damages. Under the “but for” test, malpractice damages are not awarded unless a better outcome was probable, better than even, or more likely than not, absent the actions of the practitioner. Under this test, only actions that possibly or with a likelihood of 50% or greater result in the alleged injury are deemed sufficient to make the practitioner liable for damages.

Historically, the “but for” standard was the most frequently used test of causation; however, this standard has been replaced in most states by causation theories that allow recovery in circumstances in which the probability that the negligent action led to patient injury is less than 50%. For instance, the “substantial factor” test permits recovery when the negligent behavior is a substantial factor in producing injury, even if the plaintiff’s chance at a better outcome absent the actions of the practitioner was less than 50-50. A distinct, but related, alternative causation standard is the “loss of a chance” theory. Many states have adopted this theory as a standard. In those jurisdictions, a physician may be held liable for actions that deny the patient some chance or prospect of a better outcome. For instance, a delayed diagnosis that reduced a patient’s chance of survival from 39% to 24% would preclude a verdict in favor of the physician in a “loss of a chance” state. Recovery would not be possible in a jurisdiction that followed the traditional “but for” causation analysis, in which, as in this scenario, there was less than a probable impact on outcome. Hence, the particular causation standard that a jurisdiction follows can have an enormous impact on the outcome of a medical malpractice liability case.

Medical malpractice cases based on delayed diagnosis are usually barred after the statute of limitations has run except under the Continuance Treatment Doctrine. Here the statute of limitations is tolled until the end of a course of treatment when the course of treatment, which includes the wrongful acts or omissions, has run continuously and is related to the same original condition or symptom. The purpose of the doctrine to
“maintain the physician-patient relationship in the belief that the most efficacious medical care will be obtained when the attending physician remains on a case from onset to cure.” It is essential to establish a course of treatment with respect to the condition that gives rise to the lawsuit for this doctrine to apply. Accordingly, “Where the physician and patient reasonably intend the patient’s uninterrupted reliance upon the physicians’ observations, diagnosis, and treatment of the patient’s condition will determine the patient’s progress,” the requirements of the continuous treatment doctrine are satisfied.

Hereditary cancer litigation may evolve into the new frontier of medical litigation. Allegations include failure to diagnose, failure to consult, the failure to inform other family members (one must be cognizant of Health Insurance Portability and Accountability Act [HIPAA] considerations), and failure to offer testing. This has already occurred in obstetrics with Tay-Sachs testing. Physicians should familiarize themselves with risk assessment models or refer patients when susceptibility testing is deemed appropriate. Counseling must stress these figures are estimates and not absolute risks, and thus balance the magnitude of risk for the individual patient. Clinicians must also become familiar with the eligibility criteria for breast cancer susceptibility gene testing, the principles of genetic counseling, options available to those at high risk, and follow-up of patients at high risk.

As proffered by one expert, “The price of skill in the diagnosis of breast carcinoma is a kind of eternal vigilance based upon an awareness that any indication of disease in the breast may be due to carcinoma.” The most common reason underlying delay in diagnosis was physical examination findings that did not impress the physician (35%). Other reasons included failure to follow up in a timely fashion (31%), negative/misread mammogram (11%/12%), communication failure (11%), and poor clinical examination (10%). Because mammography has a 15% to 20% false-negative rate, the practitioner should not rely on a “negative” mammogram in the face of a dominant lesion or suspicious examination. However, because mammography may not detect neoplastic changes in the breast until the cancer has been developing for 6 years, some lesions will not be seen on mammography in retrospect, some should be considered as subthreshold, and some are appropriately classified as missed.

The significance of medicolegal issues in the arena of breast cancer compels practitioners to develop risk-management techniques that incorporate policies for reducing malpractice liability risk. The old adage “Good medicine is good law” is apropos as the guiding principles for care of women with breast disorders, which must be grounded in medical science and sound clinical judgment. Patient education and effective communication are key components of good clinical care and effective risk management. Inadequate or lack of informed consent is a pervasive issue in allegations against obstetricians and gynecologists. Physicians have been sued despite “successful” breast cancer surgery for breaching the physician’s duty in failing to obtain informed consent. Additionally, one should not undereemphasize significant diagnostic or therapeutic uncertainty in critical clinical decisions while maintaining an optimistic tenor in the doctor-patient relationship. This prevents the patient from misconstruing the importance or timeliness of returning for follow-up examinations, repeat diagnostic tests, or other procedures. The clinician should allow the patient to participate in the decision-making process.

“the best defense is an adequate record. For women with breast symptoms, the medical record should include a description and diagram of findings from the history and physical examination that will allow effective comparison during follow-up examinations. The chart notation “breasts okay” or “breasts normal” is not adequate chart documentation for a woman who presents with breast symptoms. The use of a printed encounter form designed specifically for breast symptoms may facilitate suitable chart documentation. Documentation of a dominant mass, which may be measured or diagrammed, requires evaluation and resolution. Practitioners should make a record of each visit and any changes that occurred in the interval from the previous checkup. The results of any diagnostic tests should be documented, including patient notification and discussion. Clinicians should also record the rationale and factors of importance in their decision making in the medical record. If, ultimately, the patient’s clinical course is unfavorable, prior documentation of the clinical reasoning may prove that the action taken was appropriate in light of the information available at the time.

The desired follow-up visits in women with breast symptoms should be explicit and clear. Scheduled appointment dates are preferable to patient-initiated (“PRN”) follow-up. Continuity of care for breast symptoms must be carefully ensured, even when other medical problems or referred specialists become interposed. An extra effort to dispatch reminder telephone calls and letters are appropriate for patients with particularly suspicious clinical presentations who do not follow up for appointments. If a referral is made, follow-up is necessary to ensure the patient has seen the appropriate consultant, and a copy of their recommendations should be made a part of the chart.

**CONCLUSION**

The epidemic of breast cancer represents a significant public health problem affecting a large number of women. As obstetricians/gynecologists continue to care for women and expand their primary care function, we must remain knowledgeable of the changes in the field of breast disease. Advanced technology has improved the ability to define risk status and identify women with genetic predisposition to breast cancer development. Increased access to and use of screening mammography have been instrumental in decreasing the mortality rate associated with breast cancer by identifying earlier stage disease. Although changes in mammographic screening have occurred, a consensus on the evaluation of women younger than 50 years is controversial. Further radiologic technology in the arena of DM may provide an alternative or adjunct to current conventional screen film, especially in subpopulations of women such as those with dense breasts and/or perimenopausal status. Although the impact of OCPs and HRT on the risk of breast cancer continues to be debated, the information must be used to provide informed consent for patients while continuing to keep an eye on the horizon for supplementary information. Medicoegal concerns will continue to hover, but an accurate assessment and attention to testing and follow-up will decrease the delayed diagnosis in the future. Ultimately, reaching all segments of the population with comprehensive prevention, early detection, and treatment services could reduce cancer incidence and mortality even when the technology is still evolving.

Continued monitoring and preparation in ensuring uniformly high standards of care is an important aspect of future national policy goals.
BEST SURGICAL PRACTICES

- Lumpectomy plus irradiation has been shown in RCT to be equally efficacious as modified radical mastectomy for treatment of stage I and II disease.
- Iatrogenic pneumothorax is a potentially dangerous, although rare, complication of FNA, which may be reduced by stabilizing the lesion over a rib before needle insertion.
- Positioning of the patient at the margin of the exam table for an FNA is helpful to improve access to breast structures.
- Care must be taken in performing CNB to avoid advancing the cutting needle beyond the suspect mass, lest the contiguous normal breast or chest wall be injured or implanted with malignant cells.
- Vacuum-assisted CNB technique using a 11-gauge needle is becoming the method of choice for stereotactic and ultrasound biopsies with placement of a radiopaque clip.
- Risk-reducing breast procedures include total mastectomy (involving the nipple/areola complex and the biopsy site) and the nipple/areola complex, skin-sparing mastectomy (resection of the nipple/areola complex and the biopsy site, and removal of the breast parenchyma), and subcu-

naneous mastectomy (removal of most of the breast tissue with preservation of the nipple/areola complex). Breast can-
cers have been noted after subcutaneous mastectomy, but additional studies are needed.
- Masses within 2 cm of the areolar margin may be best dissected through a circumareolar incision at the areolar margin.
- The most cosmetically acceptable scars result from incisions that follow the contour of Langer’s lines.
- Closure of mastectomy incisions with decreased tension is improved by undermining the attached skin flaps 3 to 4 cm.
- It is best to keep biopsy incisions within the boundaries of “potential” incisions for future mastectomy or wide local excision should those therapies be required for definitive treatment.
- Use of tissue expanders has become the predominant means of breast reconstruction in patients who have not had extensive skin removal.
- Risk-reducing salpingo-oophorectomy should include complete removal of the ovaries and fallopian tubes with serial sectioning by the pathologist.

DEFINITIONS

Appendicitis—Inflammation of the appendix, usually initiated by obstruction of the appendiceal lumen and subsequent production of frank pus. Obstruction may be caused by hyperplasia of lymphoid follicles in response to systemic infectious disease, by bacterial enterocolitis, by a fecolith, by a tumor or other invasive process, or by a foreign body.

Incidental appendectomy—Prophylactic removal of the normal-appearing appendix during surgery for another condition.

McBurney’s point—Located at the junction of the middle and lateral thirds of a line drawn from the umbilicus to right anterolateral spine.

Oburator sign—Increased pain in the right lower abdomen when passively flexing the hip.

Psoas sign—Increased pain as the right leg is extended when passively flexing the hip.

Rovsing sign—Pain in the right lower quadrant when pressure is applied to the left lower quadrant.

Appendectomy is the most common surgical procedure performed on an emergency basis and the most common cause of abdominal pain requiring surgery. The differential diagnosis of lower abdominal pain not only includes acute appendicitis, but many gynecologic problems, such as pelvic inflammatory disease, ectopic pregnancy, ovarian torsion, and ruptured ovarian cyst. Therefore, the differential diagnosis of lower abdominal pain is one of the most common and difficult diagnoses that the gynecologist is called on to make. It is a serious undertaking and one in which a mistake could be fatal.

Individuals have a 7% lifetime risk of developing appendicitis. In the United States, reports show that approximately 300,000 operations are done per year, with the greatest incidence in the second and third decade of life. Although the overall mortality rate with appropriate and timely treatment is much less than 1%, it remains approximately 3% to 5% in the elderly. The higher mortality and morbidity rate in the elderly is caused by the increased difficulty in diagnosing appendicitis in older people, which leads to a higher rate of perforation. The incidence of perforation in patients ranges from 17% to 40%, with a median of 20%. The perforation rate in the elderly patient is significantly higher, with rates as high as 60% to 70% reported. Several factors contribute to this, including significant delay in seeking care, nonspecificity of the presenting symptoms and signs, diminished febrile response, and fewer abnormal laboratory parameters, such as the white blood cell count. Although the mortality rate for acute appendicitis is less than 0.1%, the mortality rate for gangrenous appendicitis is about 0.6%, and the mortality rate for perforated appendix is 5%. Death usually is the result of uncontrollable sepsis with generalized peritonitis, intraabdominal abscesses, intestinal obstruction, pyelonephritis, and Gram-negative septicemia. The overall morbidity rate is about 15% to 20% in most reports of appendicitis, with wound infection from a gangrenous or perforated appendix being the most common complication. Preoperative antibiotic therapy has greatly improved the morbidity rate, but perforation of the appendix is not prevented by antibiotics. Nor has the incidence of perforation decreased in recent years. Acute inflammation of the appendix commonly extends to the right adnexa (Fig. 42.1) and can involve the left as well when a large periappendical abscess develops in the pelvis. When the appendix ruptures, bilateral tubal abscesses commonly occur that may result in sterility or tubal pregnancy as a sequela. Incidental appendectomy at the time of other pelvic surgery remains controversial, but proponents argue that appendectomy simplifies the differential diagnosis of lower abdominal pain and prevents the possibility of a ruptured appendix in the future. This controversy is discussed later in the chapter.

HISTORY

The first known surgical removal of the appendix occurred in December 1735 when Claudius Amyand operated on an 11-year-old boy with a longstanding scrotal hernia and fecal fistula. He found a perforated appendix in the hernia sac and removed it. The fistula closed, and the boy recovered. The first known successful appendectomy for acute appendicitis was performed in 1880 by Lawson Tait, the renowned British abdominal and gynecologic surgeon who was also the first to operate successfully on a patient with a ruptured tubal pregnancy.

The recognition of appendicitis as a significant problem necessitating surgical removal was described by Fitz in 1886 and McBurney in 1889. Fitz described the sequence of appendiceal inflammation, perforation, abscess formation, and peritonitis.

In 1905, Kelly and Hurdon coauthored a beautifully illustrated book titled The Vermiform Appendix and Its Diseases. The book is unexcelled in its definition of the pathology, clinical manifestations, and natural history of appendicitis and its complications. There have been numerous reviews through the years since that time.

ANATOMY AND FUNCTION OF THE APPENDIX

The base of the appendix arises from the inferior wall of the cecum about 2.5 cm from the ileocecal valve. The taeniae coli of the cecum form the outer longitudinal muscle of the...
appendix and, therefore, can be followed inferorly to help locate an appendix that is hidden. The appendical tip is found most commonly in a retrocecal position (65% of cases). Signs and symptoms of appendicitis may vary depending on the location of the appendix. The main blood supply to the appendix, the appendicular artery, is a branch of the ileocolic artery and is located in the mesoappendix. The base of the appendix is supplied by a branch of the posterior cecal artery.

The appendiceal wall is composed of smooth muscle; the narrow lumen is lined by colonic mucosa. A large number of submucosal lymphoid follicles are found in the appendix in teenagers and young adults. This number declines rapidly after 30 years of age. These lymphoid follicles function in the gut-associated lymphoid tissue secretory globulin immune system, but their function is not indispensable in the secretory immune system of the gut.

Anatomists have questioned the purpose of the appendix since its initial description. Leonardo da Vinci considered the appendix to serve and protect the cecum from rupture by too great an accumulation of “superfluous wind” because it had the ability to dilate and contract. Current belief is that the appendix is a vestigial organ with no function in humans. The appendix is absent in carnivores such as the dog, wolf, tiger, and lion. In herbivores, a long and well-developed cecum is noted. In omnivores, which include apes and humans, a portion of the cecum is smaller in diameter with a prominent lymphoid aggregation susceptible to inflammation or atrophy. The preserve of lymphoid aggregation has led to the hypothesis that the appendix has a role in immune surveillance of the gut. Others postulate an exocrine function to assist in the digestion of plants. In a 24-hour period, the adult human appendix produces a maximum of 2 mL of fluid containing mucin, amylase, and proteolytic enzymes. It is unlikely that this volume aids substantially in digestion. A pressure gradient normally exists along the long axis and prohibits the entrance of food or other intestinal contents into the lumen of the appendix.

**ACUTE APPENDICITIS**

Acute appendicitis is initiated by an obstruction of the appendiceal lumen. The obstruction can be caused by hyperplasia of lymphoid follicles of the appendix as part of a generalized response of lymphoid tissue to a systemic infectious disease, by bacterial enterocolitis, or by a fecalith, a foreign body, or intestinal parasites in the appendiceal lumen. An increase in intraluminal pressure distal to the obstruction from increased mucus secretion is followed by an increase in bacteria and, finally, the production of frank pus. The appendix becomes swollen, and the appendiceal wall becomes edematous from obstruction of lymphatic and venous drainage. Ulceration of the mucosa allows invasion of the wall by bacteria. Further progression causes venous thrombosis and obstruction of blood flow through the appendiceal artery. Because this is an end artery, no collateral circulation is available to prevent ischemic necrosis and gangrene with eventual rupture of the wall. Escape of bacteria through the perforation causes peritonitis. Unless necrosis of the base of the appendix occurs, continued fecal contamination of the peritoneal cavity is prevented by the initial blockage of the appendiceal lumen. The infection in the right lower quadrant can be walled off efficiently in young, healthy patients. In women, this abscess usually involves the right adnexal organs to some extent. Generalized peritonitis may ensue in advanced age or in the presence of reduced host resistance from other illnesses or immunosuppression. A correlation between the clinical course and pathologic progress of appendicitis is illustrated in Figure 42.2.

**Diagnosis of Acute Appendicitis**

The diagnosis of acute appendicitis is based primarily on history and physical examination, although today computed

In infants and children, the diagnosis is also more difficult, and the incidence of appendicular perforation higher. Improvement in the results for these two age groups depends on a higher index of suspicion and a lower threshold for intervention, which inevitably results in the removal of a larger number of normal appendices. Improved diagnosis with ultrasound and CT scanning may decrease the incidence of appendicular rupture and also the frequency of exploratory laparotomy for what turns out to be a normal appendix. However, removal of a normal appendix in a symptomatic patient who is thought to have appendicitis, a potentially lethal disease, should not be considered an unnecessary operation. The number of elderly patients and children who die of appendicitis because of failure to operate early enough when the diagnosis is in doubt is much higher than the number of patients who die from a complication following removal of a normal appendix. The morbidity of negative laparoscopy or laparotomy is minimal and is much more acceptable than the significantly higher morbidity of a perforated appendix. Unfortunately, after 60 years of age, about 50% of patients are found to have a ruptured appendix when the operation is finally done. The mortality rate in these patients is 5%; however, this represents more than 50% of all deaths from appendicitis.

Twelve to forty-eight hours usually elapse from the onset of symptoms until the patient consults his physician. On physical examination, patients with appendicitis classically have tenderness to direct palpation, rebound tenderness, and muscle guarding in the right lower quadrant. Clinical and laboratory findings are not as helpful in making the diagnosis. In 1% to 2% of children and elderly patients, peritonitis with small bowel obstruction may be present. Tumors of the colon, not appendicitis, may be the cause of symptoms that resemble appendicitis.

However, removal of a normal appendix in a symptomatic patient who is thought to have appendicitis, a potentially lethal disease, should not be considered an unnecessary operation. The number of elderly patients and children who die of appendicitis because of failure to operate early enough when the diagnosis is in doubt is much higher than the number of patients who die from a complication following removal of a normal appendix. The morbidity of negative laparoscopy or laparotomy is minimal and is much more acceptable than the significantly higher morbidity of a perforated appendix. Unfortunately, after 60 years of age, about 50% of patients are found to have a ruptured appendix when the operation is finally done. The mortality rate in these patients is 5%; however, this represents more than 50% of all deaths from appendicitis.
Inflamed appendiceal serosa is in contact with the parietal peritoneum, often at McBurney’s point, which is located at the junction of the middle and lateral thirds of a line drawn from the umbilicus to the right anterosuperior spine. The Rovsing sign (pain in the right lower quadrant when pressure is applied in the left lower quadrant) as well as psoas and obturator muscle signs may be positive. A positive psoas sign is increased pain in the right lower abdomen when passively flexing the right hip and knee and internally rotating the leg at the hip, indicating irritation of the obturator muscle. Rectal and pelvic examinations always should be done and often reveal tenderness high on the right side of the pelvis. Pelvic inflammatory disease is almost always associated with bilateral adnexal tenderness. A pelvic mass from an inflamed appendix sometimes can be felt on pelvic examination. A tender, unilateral adnexal mass also may be found in a patient with ovarian torsion, but ultrasound should help make the diagnosis. As the disease progresses to gangrene and appendiceal perforation, the sensitivity of ultrasound in the diagnosis of appendicitis increases with diffuse tenderness, guarding, distention, ileus, dehydration, tachycardia, and spiking fever. All these signs may be less apparent in the elderly. Several studies over the past few decades have evaluated the clinical presentation of patients with acute appendicitis. A summary of the common history and physical findings is shown in Table 42.1.

### Laboratory and Radiology Diagnosis

Minimal investigation is required when the history and physical examination are definitive. About two thirds of patients with appendicitis have an elevated white blood cell (WBC) count of greater than 10,000 WBC/mL. However, an elevated WBC is not specific for appendicitis, as the cells may be leukopenic or neutropenic in appendicitis. A summary of the common history and physical findings is shown in Table 42.1.

psos shadow may be noted and represents late appendicitis with retroperitoneal inflammation. A perforated or gangrenous appendix may exhibit extrabdominal gas on radiographs, but this occurs in only 1% of cases. A sentinel loop ileus or a soft-tissue mass with or without gas bubbles also may be seen in advanced cases.

Barium contrast studies remain a simple, safe, and readily available test that may be helpful. However, ultrasound and CT examinations now are preferred. A barium study assures luminal patency of the appendix, colonic wall for mass effects or secondary effects of appendicitis, and right colonic or terminal ileal mucosal disease that may simulate appendicitis. When the barium contrast fills the appendix, a diagnosis of acute appendicitis is very unlikely but not impossible. Up to 10% to 20% of normal appendices do not fill during a barium study. Laparoscopy can be both diagnostic and therapeutic for acute appendicitis. Some have advocated diagnostic laparoscopy in all women presenting with symptoms associated with acute appendicitis to reduce unnecessary appendectomy while also examining for gynecologic pathologies. The diagnostic error of presumed appendicitis in young, adult women in the reproductive years is 35% to 50%. According to Leape and Romanofsky, and Deutech and associates, about one third of patients who underwent laparoscopy for suspected appendicitis did not have appendicitis.

Because there is no single diagnostic test for acute appendicitis that is accurate and applicable to the general population, most physicians agree with Levine and associates that a decrease in the number of negative explorations is most likely to be achieved by sound clinical judgment supplemented by basic laboratory and radiologic studies. Using this standard classical approach assiduously, these authors reported negative laparotomy in only 7.4% of 282 patients with a preoperative diagnosis of suspected appendicitis. Most patients with the classic pattern of migratory abdominal pain, direct and rebound tenderness in the right lower abdominal quadrant, and increased metamyelocytes in the peripheral blood smear require prompt operation. However, when there is an atypical presentation in a young adult women, close in-hospital observation may be indicated to allow progression of the clinical picture and complete the radiologic workup. Simultaneous evaluation by the general surgeon and gynecologist is also of benefit in improving diagnostic accuracy.

Laparoscopy may be indicated in problem patients. In almost all circumstances, a laparoscopy with negative findings is preferred to expectantly watching the appendix rupture or pelvic inflammatory disease progress untreated. An unnecessary delay increases the likelihood of perforation, increasing morbidity and mortality. In the younger patient, it also increases the risk of pelvic adhesions, infertility, and chronic pain. When surgery is performed within 24 hours of the onset of symptoms, less than 20% of appendices are perforated, compared with more than 70% when operation is delayed more than 48 hours after symptoms began. A delay in diagnosis in pregnant patients has especially devastating effects on the outcome. A proper evaluation of clinical presentation allows the index of suspicion to be set at the proper level so that a threshold for intervention can be reached before the appendix ruptures. According to Condon and Tellford,

The removal of a normal appendix in appropriate clinical circumstances never constitutes an unnecessary appendectomy. A policy of active surgical intervention on the basis of minimal clinical suspicion has been demonstrated to reduce both the morbidity and mortality of appendicitis. Watching and waiting, however careful it may be, runs the risk of increasing both morbidity and mortality.
There is general agreement that the treatment of acute appendicitis is appendectomy. Clinical experience and numerous reports on mortality clearly show the advantage of early operation. The current operative mortality without perforation is essentially nil, and only 3% of patients have postoperative complications. After perforation, the overall mortality rate is less than 5%, but more than 30% of patients have postoperative complications. These statistics have improved with the use of antibiotics and earlier intervention.

The patient with acute appendicitis should not be rushed to the operating room without adequate hydration and antibiotic treatment. Most surgeons use short-course (≤24 hours) antimicrobial prophylaxis. One common combination is cefazolin and metronidazole to cover Gram-negative, positive, and anaerobic bacteria. Recent studies have recommended monotherapy with a second-generation, broad-spectrum cephalosporin such as cefotetan for patients undergoing surgery. Antibiotics have been shown to be effective in reducing the incidence of postoperative wound infections if started preoperatively. Antibiotics can be discontinued immediately following surgery if the appendix is not gangrenous or perforated. However, if the appendix has ruptured, many surgeons switch to triple antibiotic therapy including ampicillin, metronidazole, and gentamicin to encompass a wide spectrum of enteric bacteria. Intravenous antibiotic therapy should be continued until the patient is well on the way to recovery, which is usually 3 to 5 days.

Postoperatively, if the appendix is not ruptured, the patient usually is discharged within 24 hours. However, if the appendix was ruptured or gangrenous, supportive treatment is continued in the ill patient. Food and fluid by mouth are restricted. Nasogastric suction is rarely used today. Wound infection is the most common complication after appendectomy. Other more serious complications include pelvic, subphrenic, and intraabdominal abscess; fecal fistula; peritonitis; pylonephritis; and sometimes intestinal obstruction. Septicemia, pneumonia, septic shock, renal failure, and pulmonary edema can lead to death in the most advanced or neglected cases. It is relatively safe to remove the appendix in virtually any patient. However, if there are significant medical contraindications to surgery in a non-toxic patient with a clear diagnosis of an appendiceal abscess, a nonoperative approach can be considered. If a distinct mass in the right iliac fossa is palpated and the patient has no systemic manifestations, the patient is kept nil per os (NPO) while intravenous fluids and broad-spectrum antibiotics are given to cover enteric organisms. The patient should be kept under close observation with the pulse closely followed because tachycardia is one of the first signs of sepsis. Other clinical parameters to follow include change in pain quality, white blood cell counts, differential counts, and serial radiologic evaluations, including ultrasound and/or CT. Failure to respond to therapy after 24 to 48 hours indicates that operative intervention should be reconsidered. Patients with well-formed perineal abscesses can undergo CT-guided placement of pigtail drainage catheters to help resolve the abscess more rapidly, rather than depending on the abscess to drain internally into the cecum. If the abscess is palpable, it is usually large and should be drained. Limitations of percutaneous drainage include the inaccessibility of multiloculated abscesses, inaccessible location, and possible need for anesthesia. Periapendical abscesses usually resolve in 10 to 14 days without appendectomy or drainage. Most surgeons wait 6 to 12 weeks after nonoperative therapy to perform an interval appendectomy. Technical difficulties during interval appendectomy may be minimal but can be extreme, depending on the nature of the initial abscess.

Laparoscopic Technique

Since it was first described by Semm in 1983, laparoscopic appendectomy has gained acceptance as both a diagnostic and treatment method for acute appendicitis. Many studies have demonstrated that a videolaparoscopic approach to acute appendicitis is safe and effective for the experienced endoscopist. The laparoscopic approach offers many potential advantages, including less surgical tissue trauma, a better postoperative course, the ability to explore the entire abdominal cavity, assessment for the presence of associated pathologies, better cosmetic results, and a rapid return to normal activity. The ability to completely evaluate the pelvis and the entire peritoneal cavity when a healthy appendix is found is extremely important for the gynecologist in light of the other conditions that mimic appendicitis in women, such as adnexitis, endometriosis, ovarian cysts, ectopic pregnancies, and even cholecystitis.

Removing a normal appendix during laparoscopic evaluation for suspected acute appendicitis can be performed with no added morbidity or increased length of hospitalization as compared with diagnostic laparoscopy. Initially, there were some concerns about an increased risk of intraabdominal abscess formation following laparoscopic surgery for acute appendicitis, possibly secondary to peritoneal insufflation spreading local infection throughout the abdominal cavity and the carbon dioxide pneumoperitoneum creating a favorable environment for the survival of virulent anaerobic bacteria. However, many studies comparing open versus laparoscopic appendectomies have shown a lower morbidity rate with laparoscopy. The laparoscopic approach offers the advantage of shorter hospitalization and less morbidity, with a lower rate of abdominal wall infection. There is no significant difference in the rate of abscess formation in patients with perforated appendicitis. The interval until the patient may return to work is shortened and postoperative pain is decreased with the laparoscopic approach, and the quality of life appears to improve faster than with the traditional open approach is used. Obese patients may benefit substantially from the laparoscopic approach as it obviates the problems of a large incision, strong retraction, prolonged surgery, and wound infection that are associated with open surgery in the obese.

The disadvantages of the laparoscopic approach have been longer duration of surgery and higher costs. However, the length of surgery has been significantly reduced with improved surgical skills and experience. Also, the immediate cost difference appears to be diminished with the use of reusable laparoscopic equipment, and when the more rapid return to work and other activities is included, the laparoscopic approach turns out to be extremely cost-effective. It is increasingly recommended as the procedure of choice for the diagnosis and treatment of suspected acute appendicitis.

The operation is conducted under general anesthesia with endotracheal intubation and muscle relaxation to allow controlled ventilation after the patient has been positioned in the modified dorsal lithotomy position with low stirrups. The position of the patient may be adjusted by Trendelenburg tilt or tipping the table to the left to optimize visualization of the pelvis and better exposure to the structures on the right side of the pelvis and the right iliac fossa. The stomach and bladder are decompressed to minimize risk of injury during trocar insertion.
FIGURE 42.5. Laparoscopic appendectomy technique. A: The appendix is elevated with atraumatic forceps, and a pretied suture loop is placed around the distal end to provide traction. B: The mesoappendix is divided using cautery. Clips or the harmonic scalpel also can be used. C: The skeletonized base of the appendix is then crushed with forceps to empty its contents, and three ligatures are placed around the base. D: The appendix is divided, leaving two absorbable ligatures on the stump.

and allow optimal visualization of the operative field. Initially, an open or closed laparoscopic trocar insertion technique is used to place a 5- or 10-mm laparoscope. After viewing the location of the appendix, the accessory trocars can be placed in several different ways, again depending on the preference of the surgeon and anatomy of the appendix. We prefer placing the accessory trocars in the right and left lower quadrants and then one in the midline two finger breadths above the symphysis pubis. This places the trocars in positions familiar to the gynecologist and results in cosmetically appealing incisions. Atraumatic forceps are used through the lower right trocar to secure the tip of the appendix. If the appendix is markedly swollen, a pretied surgical loop can be placed at the tip and used for traction (Fig. 42.5). The appendix is elevated and retracted toward the pelvis, keeping the mesoappendix stretched. Adhesions can be separated from the appendix with sharp or blunt dissection. Dense and vascular adhesions require bipolar cautery, the harmonic scalpel, or clips. The appendix is skeletonized and isolated from the mesoappendix with bipolar cautery. (Metal clips, unipolar cautery, and the harmonic shears also may be used.) Special attention should be given to the appendicular artery that is located near the base of the appendix. The base of the appendix is secured by various methods: (a) three metal clips or three Endoloops with transection between them so that two ligatures remain at the base of the appendix, (b) the use of bipolar coagulation and resection, (c) the use of mechanical cutting and stapling devices, and (d) the use of endoloops with which self-locking extracorporeal slip-knots or normal surgical knots are made. Mechanical suturing devices can be used offering a secure and technically easy method, but this is an expensive option. We prefer the Endoloop technique using no. 1 chromic sutures. After isolating the appendix, two chronic Endoloop ties are placed securely at the base of the appendix. The area distal to the ties is then milked, and the third Endoloop is placed 2 to 4 mm from the other ties. The appendix can be excised with scissors or harmonic scalpel and removed through the larger trocar under direct visualization. The appendix can be placed in an endobag or surgical glove when there is the possibility of rupture. Some advocate cauterizing the stump; however, this can cause necrosis of the cecum at the site of the ligature on the appendicular stump and result in a subsequent cecal fistula. Care should be taken to remove the entire appendix because appendicitis is cleared off the base of the appendix until the three taenia on the cecum can be identified clearly. Stump invagination is not necessary and not performed routinely by this author because of the reasons...
Common incisions for appendectomy. The classic McBurney’s point, at the junction of the middle and lateral thirds of a line drawn from the umbilicus to the right anterior superior iliac spine, does not universally mark the tip of the appendix. In general, an inferior incision below the area of maximal tenderness helps in rotating the cecum into the wound. The McBurney incision is the classical oblique appendectomy incision through McBurney’s point to the lateral edge of the rectus sheath; it can be extended into the lateral rectus sheath, if necessary. It is quite cosmetically acceptable when healed (Fig. 42.6). Alternatively, a skin line or transverse incision placed 1 to 2 cm medial to the anterosuperior iliac spine can be used. Both incisions generally are performed with a muscle-splitting technique through all layers lateral to the rectus abdominis muscle as an entrance into the abdomen is gained. A low, horizontal skin incision also can be used and is possibly more cosmetically. The incision is continued through the superficial fascia until the external oblique muscle is exposed. The fibers of the aponeurosis are opened sharply, and the muscle fibers are bluntly separated, as are the fibers of the internal oblique and transverse abdominis muscles. The peritoneum is incised, and cultures can be obtained. The cecum is mobilized into the wound, and the appendix is mobilized as adhesions are bluntly and/or sharply dissected. The base of the appendix always lies at the confluence of the taeniae. When the appendix is mobile, the mesoappendix can be grasped near the tip of the appendix with a Kelly clamp and the appendiceal stump is then doubly ligated with 2-0 absorbable suture. The appendiceal stump is then dropped into a small basin to avoid contamination. The peritoneal cavity is then closed. If the appendix is inflamed. An abscess can form in the cecum on barium enema leading to diagnostic confusion. Copious irrigation with saline or antibiotic solution should be performed in cases of perforated appendicitis, but delayed primary closure is routine in cases of ruptured appendicitis. Skin mattress sutures can be placed and left untied until the third to fifth postoperative day. If the wound is clean, the skin sutures are tied and adhesive strips placed. If the wound is not healthy, it should not be closed but packed with wet to dry dressings and allowed to granulate from the previously discussed. If the surgeon desires to bury the stump, it is performed in a fashion similar to the open technique using no. 0 chromic catgut suture and one extracorporeal knot. Careful irrigation and suction is performed after removal of the appendix.

Open Technique

The standard management of appendicitis has been open appendectomy by way of a limited right lower quadrant incision. The surgeon should note the point of maximal tenderness before anesthesia and attempt to palpate masses after anesthesia. McBurney’s point, at the junction of the middle and lateral thirds of a line drawn from the umbilicus to the right anterosuperior iliac spine, does not universally mark the tip of the appendix. In general, an inferior incision below the area of maximal tenderness helps in rotating the cecum into the wound. The McBurney incision is the classical oblique appendectomy incision through McBurney’s point to the lateral edge of the rectus sheath; it can be extended into the lateral rectus sheath, if necessary. It is quite cosmetically acceptable when healed (Fig. 42.6). Alternatively, a skin incision placed 1 to 2 cm medial to the anterosuperior iliac spine can be used. Both incisions generally are performed with a muscle-splitting technique through all layers lateral to the rectus abdominis muscle as an entrance into the abdomen is gained. A low, horizontal skin incision also can be used and is possibly more cosmetically. The incision is continued through the superficial fascia until the external oblique muscle is exposed. The fibers of the aponeurosis are opened sharply, and the muscle fibers are bluntly separated, as are the fibers of the internal oblique and transverse abdominis muscles. The peritoneum is incised, and cultures can be obtained. The cecum is mobilized into the wound, and the appendix is mobilized as adhesions are bluntly and/or sharply dissected. The base of the appendix always lies at the confluence of the taeniae. When the appendix is mobile, the mesoappendix can be grasped near the tip of the appendix with a Kelly clamp and the appendiceal stump is then doubly ligated with 2-0 absorbable suture. The appendiceal stump is then dropped into a small basin to avoid contamination. The peritoneal cavity is then closed.
FIGURE 42.7. Technique of open appendectomy. A: The appendix is elevated by a Babcock clamp, and the mesoappendix is ligated. Alternatively, small clamps may be used to clamp, cut, and tie the mesoappendix. B: The operative field is isolated with gauze packs, and the appendix is cross-clamped and divided between the two closely placed clamps. C: The stump of the appendix is ligated with a 2.0 absorbable ligature. D: The stump is usually cauterized and covered with the adjacent mesoappendix.

APPENDICITIS IN PREGNANCY

In 1898, Hancock reported the first case of appendicitis complicating pregnancy. Appendectomy is the most common nonobstetric operative intervention in the pregnant patient. The reported incidence of appendicitis in pregnancy varies from 1 in 355 to 1 in 11,479 deliveries. If ectopic pregnancy is excluded, appendicitis is responsible for about 75% of all cases of an acute abdomen during pregnancy. The incidence of acute appendicitis does not seem to be increased during pregnancy above that of the nonpregnant state, but the diagnosis often is delayed. Acute appendicitis occurs more often during the second trimester (50%) than during the first (10%) or third trimester (35%). Five percent of cases occur during labor or in puerperium. Although pregnancy does not appear to increase the incidence of appendicitis, it does increase the difficulty of diagnosis. This is because many abdominal symptoms are considered "normal" during pregnancy. Added to this are the anatomic changes in the location of the appendix. Bier and associates showed by repeat roentgenographic studies...
throughout pregnancy and the puerperium that the appendix rotated in a counterclockwise direction, with the tip displaced near the right kidney at term. The base of the appendix under-went upward and outward displacement after the third month, caused by the enlarging uterus, and reached the level of the iliac crest at the end of the sixth month. After the seventh month of pregnancy, in 88% of their cases, the appendix was found above the iliac crest. However, in interpreting these findings in relation to abdominal pain and tenderness, one must remember that in dealing with an abnormal appendix in which previous attacks of appendicitis may have occurred, adhesions can fix it in a low position and do not permit its upward displacement.

Ultrasound may be particularly useful in the diagnosis in pregnancy; but as noted, it may not be located in its normal, nonpregnant, right lower quadrant location. The most impor-tant step for the clinician is to consider the diagnosis of appen-dicitis in pregnancy.

The incidence of gangrenous and perforated appendix has been reported to be twice as high in pregnant patients as in women who are not pregnant and is highest in advanced preg-nancy. In a pregnant patient, the omentum may not be able to reach the site of infection and perform its walling off func-tion efficiently. If rupture is followed by abscess formation, the uterus is always a part of the abscess wall because of its prox-imity. Generalized peritonitis without abscess is more common in advanced pregnancy and is a serious threat to the expectant mother and her unborn child. The speed of onset and spread of peritonitis in pregnant patients can be insidious and strikingly rapid. The patient can become seriously ill and appear mor-tally ill within 24 hours. Peritonitis increases uterine irritability and the risk of preterm labor. Premature labor and delivery are the most serious fetal risks with up to 30% fetal mortality re-port against abortion if perforation occurs. Maternal complications include wound infections, pelvic abscess, peritonitis, and pulmonary complications.

**Treatment of Appendicitis in Pregnancy**

Immediate operation is the treatment for acute appendicitis in pregnancy, regardless of the duration of pregnancy. Precoopera-tive measures to improve the patient’s condition should be brief and intensive. Although antibiotics may not be needed in sim-ple acute appendicitis, antibiotic therapy should be initiated 30 minutes before surgery so that an adequate level can be present in the tissues when the incision is made. When a gangrenous or perforated appendix is found, antibiotics with broad-spectrum bacterial coverage should be continued or ini-tiated immediately in both the pregnant and nonpregnant pa-tient. One may choose to give cefoxitin and metronidazole. In the more serious cases, triple antibiotic therapy with ampicillin, gentamicin, and clindamycin should be used.

In this inflammatory environment, some suggest the use of nonsteroidal antiinflammatory drugs, such as indomethacin or ibuprofen, for tocolysis. Intravenous magnesium sulfate also can be used. Although the use of tocolytic agents to combat premature labor might seem reasonable, they should be used only in patients who are hemodynamically stable because they can increase pulmonary edema. As pointed out by deVeciana and associates, injurious fluid management and tocolytic use can greatly increase the risk of pulmonary complications with a significant morbidity and even mortality associated with appendicitis in those days led Fischer in 1909 and Goldspohn in 1911 to endorse incidental appendectomy during other abdominal operations. However, the risk of morbidity and mortality have been substantially reduced in the past 50 years, and presently the use of incidental appendectomy at the time of gynecologic surgery is controversial. The decision to select the

Delay in operating also can stem from concern about what harm the operation will do to the pregnancy, with the conse-quent desire to operate only when acute appendicitis is defi-nitely present. Such a delay only increases the risk of perfo-ration with its attendant problems for both mother and fetus. Proper removal of a normal appendix found at operation for suspected appendicitis rarely is associated with preterm labor, so the benefits clearly outweigh the minimal risks.

The anesthetic should be planned and administered to avoid hypotension and hypoxia. If the pregnancy is 3 months or less in duration, the appendix can be removed through the usual gridiron McBurney or Rockey-Davis incision. The more ad-vanced the pregnancy, the higher the risk will be the incision. If a midline incision is not used, it is important to center the in-cision over the point of maximum tenderness, which usually means using a high transverse muscle-cutting or a right para-median incision. Tilting the patient to her left side minimizes displacement and handling of the uterus and relieves the com-pression of the vena cava by the gravid uterus. The appendec-toomy should be done as quickly andatraumatically as possible, and the patient should be given intensive antibiotic therapy. In the case of appendiceal rupture with or without frank abscess formation, the patient should be treated immediately, in the same way as in the nonpregnant state, with the understanding that premature labor usually occurs as a result of the infec-tion. Cesarean section should not be performed at that time of appendectomy with or without rupture to avoid infection in the newborn and postoperative endometritis and parametritis. Cesarean section in the third-trimester patient with appendici-tis is indicated only for strict obstetric reasons. Some authors have advised that a cesarean section hysterectomy be performed to control the spread of infection into the uterus and broad ligaments.

Laparoscopic management of appendicitis now has been de-scribed with good results. The open laparoscopic technique is used, and all reports have shown success during all trimesters without complications. Some argue that the laparoscopic ap-proach exposes the fetus to excessive risks from trocar place-ment and CO₂ insufflation. Others, however, note that laparo-scopic expands the ability to explore the abdomen with less uterine manipulation and offers an increased ability for irri-gation. Further, it increases the speed of appendectomy, and results in relatively small incisions compared with the open technique.
appendix during routine gynecologic procedures depends on the risk:benefit ratio. It is estimated that at 60 years of age, about 125 incidental appendectomies need to be performed to prevent one case of appendicitis, 250 to prevent one ruptured appendix, and 5,000 to prevent one death. These benefits are greater in younger women in whom acute appendicitis is more common.

There are potential risks of the surgery. These include bleeding and hematoma formation, adhesion formation with subsequent intestinal obstruction, blowout of the appendiceal stump with abscess or fecal fistula or both, and others. However, in a careful review of the literature, Snyder and Selanders concluded that there was no statistically significant increase in morbidity or mortality when incidental appendectomy is performed at the time of routine abdominal hysterectomy, salpingectomy, tubal ligation, or cesarean section. Good judgment must be exercised and good technique used in performance of the procedure, and circumstances should be favorable, including satisfactory condition of the patient during the operation, satisfactory tolerance of the anesthesia, and easy exposure of the appendix. If the patient has lost a great deal of blood or the operation has been unusually prolonged, appendectomy should be performed only when significant pathology of the appendix is found. Incidental appendectomy should not be performed in the presence of bowel obstruction or when severe postoperative ileus is likely.

One of the main advantages of incidental appendectomy is to eliminate the appendix from consideration when a patient presents subsequently with perplexing pelvic or abdominal pain. In addition to preventing appendicitis in future years, incidental appendectomy offers the advantage of removing unsuspected pathology. In a retrospective study of 260 women with pelvic or right iliac fossa pain, Lynch and coworkers reported that 90% of the women who had appendectomy in addition to hysterectomy, oophorectomy, or other gynecologic surgery reported relief of symptoms, compared with only 49% in the group who did not have an appendectomy. Quite probably all these appendices did not look grossly normal, and this was not a prospective, randomized study; however, a significant incidence of "chronic obstructive appendicitis," endometriosis, and granuloma were found on microscopic examination of the removed appendices. Among the pathologic findings in clinically normal-appearing appendixes are acute, subacute, and chronic appendicitis, carcinoid tumors, and endometriosis. Others have reported that about 10% of incidental appendectomy specimens show significant pathology. The incidence obviously depends on the definition of "incidental" and how carefully the appendix is examined by the pathologist.

Ectopic pregnancy and endometriosis have been reported in association with appendicitis. Panganiban and Corning reported that 4 of 31 patients with endometriosis of the appendix had symptoms of appendicitis. The appendix is a common site of involvement in patients with pelvic endometriosis, although endometriosis is rarely confined only to the appendix. Pittaway found endometriosis in 13% of appendixes removed from patients with pelvic endometriosis at the Johns Hopkins Hospital. In 38% of these women, the appendix was grossly normal when histologic evidence of endometriosis was found. The author concluded from the study that (a) appendectomy is warranted in patients who are not interested in having children and are undergoing definitive surgery for endometriosis, and (b) appendectomy should be done when the appendix is abnormal, even in patients with endometriosis who are undergoing surgery to restore fertility.

Appendicitis is the most common site for carcinoid tumors, with an incidence of 0.031% of all appendixes removed. Almost all appendiceal carcinoids are benign. It is rare for the carcinoid syndrome to be present. In Waters’ series of 830 patients in whom elective appendectomy was performed, six appendiceal carcinoid tumors were suspected or diagnosed on gross surgical appearance.

In summary, there are three main reasons to perform incidental appendectomy:

1. To reduce the risk of future mortality and morbidity from appendicitis, including possible infertility after a perforated appendix.
2. To eliminate undiagnosed incidental pathology in the appendix.
3. To eliminate the appendix from diagnostic consideration when the patient has abdominal or pelvic symptoms in the immediate postoperative period and in future years.

The incidence of appendicitis decreases with increasing age. The risk is greatest in girls 15 to 19 years old, and 70% of acute appendicitis occurs in patients younger than age 30. However, the rate of perforation increases with advancing age; in women older than age 65, perforation occurs about 50% of the time. Using life table analysis, Snyder and Selanders estimated that for girls 15 to 19 years old, 1,000 incidental appendectomies would prevent 52 cases of appendicitis, 5 of which would be ruptured. For women 35 to 39 years old, 24 cases of appendicitis would be prevented by 1,000 incidental appendectomies; for patients 60 to 64 years old, only 8 cases of acute appendicitis would be prevented, but 4 of these would rupture before diagnosis.

Studies show that incidental appendectomy is far more commonly done in women, probably because they more often have abdominal or pelvic surgical procedures, such as hysterectomy, oophorectomy, or cholecystectomy. It is also more commonly done in women 35 to 55 years old, probably for the same reason.

In a careful analysis of the potential cost savings of incidental appendectomy, Wang and Sax evaluated the impact of laparoscopy and managed care on this question. They reasoned that many of the primary procedures performed at the time of incidental appendectomy were now done via the laparoscope (laparoscopically assisted vaginal hysterectomy and laparoscopic cholecystectomy). Taking into account long-term risk of appendicitis and complication, as well as various fee schedules and other surgical costs, they calculated that laparoscopic incidental appendectomy was not cost-effective at any age. Because there is very minimal cost associated with slightly increased operating time and a few sutures, with open appendectomy there are more cost savings for women younger than 30 years when incidental appendectomy is done as part of an open abdominal procedure. With the frequent changes in managed care plans and strong pressure to minimize costs, they felt there was no incentive to spend money today for incidental appendectomy with the hope of saving money in the future (decreased risk of appendicitis at a later time).

Analyzing the various factors, it is easy to see why incidental appendectomy remains controversial. Many experts have suggested that it is most appropriate for women younger than 30 or 35 years, especially if they have a history of pelvic pain, pelvic inflammatory disease, or endometriosis. Because of the low risk of appendicitis, many experts do not recommend incidental appendectomy for women older than 30 years. In women between ages 35 and 59 who are undergoing gynecologic surgery, the status of the abdomen and pelvis, diagnosis, overall condition of the patient, and appearance of the appendix and surrounding structures all should be taken into account when deciding on the advisability of incidental appendectomy. The possibility of appendectomy should be discussed with the patient during
Appendicitis is the most common cause of acute abdominal pain requiring surgery, with a 7% lifetime risk. The mortality rate of appendicitis is 0.1%, which increases to 5% with perforation. There is an elevated mortality rate of 5% to 15% in the elderly population, mainly because of the difficulty in diagnosing the condition in this group. The morbidity rate of appendicitis, which is mainly due to infection, is 15% to 20% but has been greatly improved with the use of perioperative antibiotics.

Acute appendicitis is diagnosed primarily on physical examination, and 50% of patients present with the classic sequence of anorexia, nausea, and vomiting. Other potential findings include tenderness at McBurney’s point, a positive Psoas sign, a positive psoas sign, and a positive obturator sign. A pelvic exam should always be performed to rule out gynecologic causes. Ultrasound and computed tomography have assisted in more accurate diagnosis and thus have contributed to decreased rates of rupture and exploratory laparotomy.

The standard treatment for acute appendicitis is appendectomy, and the operative mortality without perforation is close to zero. Preoperative use of broad-spectrum antibiotics is important in preventing associated morbidity, and continuation of the regimen postoperatively should be considered in cases of appendiceal rupture. Common complications of appendectomy include wound infection, abscess or fistula formation, ileus, phlegmon, peritonitis, pneumothorax, and intestinal obstruction.

Standard management of appendicitis has been with open laparotomy per variations of a right lower quadrant incision. Alternatively, laparoscopy is an option. When performed by an experienced surgeon, the latter offers many potential advantages, including decreased surgical morbidity. Laparoscopic assessment of the peritoneal cavity may prove especially useful for the gynecologist, as many other abdominopelvic conditions can mimic appendicitis.

Appendectomy is the most common nonobstetrical operative intervention in the pregnant patient and occurs most frequently in the second trimester. Diagnosis, which may be improved through ultrasonography, can be more challenging as a result of displacement of the appendix by the gravid uterus. The incidence of perforation and its repercussions, including an increased risk of preterm labor, is twice as high in pregnancy. Immediate operation is the treatment, regard less of duration of the pregnancy.

Incidental appendectomy refers to the prophylactic removal of the normal-appearing appendix during surgery for another condition. The appropriateness of this procedure is widely debated and should be judged on a case-by-case basis.

CHAPTER 43 ■ INTESTINAL TRACT IN GYNECOLOGIC SURGERY

KELLY L. MOLPUS

DEFINITIONS

Abdominal hernia—Defect in the fascia through which peritoneum-encased visceras may protrude.

Adhesion—Intrapertitoneal scar tissue that connects opposing peritoneal and/or serosal surfaces.

Anastomosis—Surgical communication created between two segments of the gastrointestinal tract.

Anastomotic bursting pressure—Experimental measure of the magnitude of intraluminal pressure required to disrupt the bowel wall at the site of anastomosis.

Antimesenteric edge—Anatomical edge along the intestine opposite to where the mesentery is attached.

Bacterial translocation—In the setting of intestinal obstruction, the process whereby enteric bacteria traverse the damaged bowel wall to seed the peritoneal cavity.

Bezoar—Concretion formed within the alimentary canal due to impaction of indigestible substances.

Blind loop syndrome—Progressive symptomatic dilation of a nonfunctioning bowel segment, such as may occur when a large segment of cecum persists distal to an ileoascending anastomosis.

Bowel prep—Preoperative cleansing of the intestinal tract with cathartics to reduce enteric volume and antibiotics to decrease colonic flora.

Bridge—Apparatus secured between the abdominal wall and exteriorized bowel loop to provide support until tissue healing secures the stoma in place.

Cheatle slit—A longitudinal full-thickness incision made in the antimesenteric bowel wall to increase the diameter of the anastomosis.

Closed loop obstruction—Isolated segment of bowel with diminished influx and efflux of enteric content at risk for distention and perforation.

Closed techniques—Generalized term to include methods of gastrointestinal anastomosis in which the lumens of the involved segments are not exposed.

Colocolostomy—Communication and/or surgical anastomosis between two segments of the large intestine.

Colostomy—Segment of large bowel exteriorized through the abdominal wall to divert fecal output.

Crohn's disease—An inflammatory process of uncertain etiology that adversely affects the colon and intermittent segments of small intestine (regional enteritis) and manifests clinically as recurrent diarrhea, intestinal cramping, and weight loss.

Dehiscence—Postoperative wound separation that most commonly involves the skin and subcutaneous tissue (superficial or incomplete) or, less commonly, the fascia (deep or complete).

EndoGIA—General term for endoscopic stapling instrument used during laparoscopic gastrointestinal procedures.

End-to-end (EEA) stapler—Surgical stapling instrument designed to join the ends of two bowel segments of similar diameter.

Enteral nutrition—Use of the gut to provide nutrition.

Enterenterostomy—Communication and/or surgical anastomosis between two segments of small intestine.

Enteroenteral therapist—Nurse with specialized training in ostomy-related issues, who is an invaluable resource in providing perioperative counseling, education, and clinical care.

Enterotomy—Full-thickness opening in the small bowel wall.

Evisceration—An acute full-thickness wound disruption through which abdominal contents extrude.

Fistula—Abnormal communication between two organ systems that have no inherent anatomical connection (i.e., enteroenteric, rectovaginal, vesicovaginal, or entero vesical fistula).

Gastrocolic ligament—Intraabdominal fibroadipose tissue that arises from the greater curvature of the stomach and fuses with the greater omentum along the transverse colon.

Gastrointestinal anastomosis (GIA) stapler—General term for surgical stapling instrument used during open gastrointestinal procedures.

Gastrostomy—Artificial opening in the stomach for the purpose of decompression, nutrition, or anastomosis.

Greater omentum—Intraabdominal fibroadipose tissue that arises from the inferior surface of the transverse colon.

Haustra—Widely spaced, transverse, partially encircling folds within the wall of the colon.

Ileocele valve—Functional communication between the terminal ileum and cecum that facilitates forward motility of digestive contents.

Ileoceleonic anastomosis—Surgical communication established between the ileum and colon.

Ileostomy—Segment of ileum exteriorized through the abdominal wall to divert enteric output.

Ileus—Mechanical dysfunction in which the normal antegrade gastrointestinal peristalsis is temporarily disrupted.

Ileococcal valve—Functional communication between the terminal ileum and cecum that facilitates forward motility of digestive contents.

Incarceration—Extrusion of a hernia sac that becomes edematous, entrapped, and at risk for vascular compromise (strangulation).

Inferior mesenteric artery—Major artery arising from the abdominal aorta that supplies the left colon via left colic and sigmoid arteries.
Related Surgery

Inflammatory bowel disease—A general descriptive term referring to any inflammatory condition of the intestines, including Crohn’s disease and ulcerative colitis.

Intestinal adaptation—Subsequent to small bowel resection, compensatory mechanisms whereby the absorptive capacity and surface area of the remaining small intestine increase over time.

Jejunostomy—Artificial opening in the jejunum for the purpose of decompression, nutrition, or anastomosis.

Loop ileostomy, loop colostomy—Intact segment of ileum, or nonresectoretroperitonealized large bowel, which is exteriorized and opened to divert the digestive output.

Mucosal barrier of the gut—Protective layer of the intestinal wall that establishes vascular communication from the cecum to the rectum and gives off numerous terminal vasa recta.

Maturation of the stoma—Process of opening the exteriorized intestine and suturing the everted bowel edge to the skin of the abdominal wall.

Mesenteric border—Anatomical edge along the intestine where blood supply is derived via the attached mesentery.

Mesentry—Dual layer of peritoneum and fibroadipose tissue, attached to the posterior abdominal wall, which carries the arteriovenous and lymphatic structures to and from the intestines.

Nasogastric decompression—Use of a tube passed through the nose into the stomach for the purpose of re- lieving gastric pressure or decompressing the intestines. Nasogastric decompression may be used for decompression, nutrition, or anastomosis.

Neovascularization—Process whereby blood and oxygen delivery to tissue is increased via the proliferation of new blood vessels.

Ogilvie’s syndrome—Acute colonic pseudo-obstruction resulting from dysfunction of colonic peristalsis that may be clinically indistinguishable from a large bowel obstruction.

Omental flap—Surgical rotation of the infracolic omentum to a specific area to increase blood supply to that area.

Open techniques—Generalized term to include methods of gastrointestinal anastomosis in which the lumens of the involved segments are exposed.

Ostomy—Any artificial opening in the gastrointestinal tract.

Parenteral nutrition—Use of an alternative route to the gut for provision of nutrition (i.e., intravenous infusion).

Perforation—Spontaneous full-thickness defect in the gastrointestinal tract with resultant intraabdominal efflux of bacteria and digestive content.

Peristalsis—Normal antegrade movement of digestive content via rhythmic circular contractions and relaxations of the intestinal wall musculature.

Plieae circulares (valvae conniventes)—Numerous closely spaced, transverse, encircling folds within the wall of the small intestine.

Short bowel syndrome—Insufficient nutrient absorption to meet the body’s metabolic requirements as a result of extensive intestinal resection and/or inadequate function of intact bowel.

Small bowel obstruction—Partial or complete imped- ance to the antegrade movement of enteric content through the small bowel that is due to extrinsic or intrinsic compromise of the lumen.

Stoma—Terminal segment of intestine that is exteriorized and secured to the abdominal wall, through which digestive output is diverted.

Stoma appliance—Fitted wafer adherent to the skin surrounding the stoma that serves as an attachment site for the collection bag.

Structure—Circumferential narrowing of the intestinal lumen.

and broad-spectrum antibiotic coverage for anaerobes, Gram-negative rods, and enterococci. Diagnostic computed tomography (CT) scan clarifies whether a periconic abscess is present, and CT-directed drainage of an abscess expedites recovery and avoids surgical exploration in most cases. Nasogastric decompresion is necessary in the setting of obstruction. If obstructive symptoms persist, percutaneous abscess drainage is warranted. If bowel perforation results in generalized peritonitis, consideration is given to diverting colostomy, with extensive irrigation and drainage of the peritoneal cavity.

Appendicitis
Perhaps one of the most frequently encountered diagnostic dilemmas is that of acute appendicitis versus PID. Appendicitis is most frequently seen during the second and third decades of life, which coincides with that of reproductive-aged women at risk for PID. Whereas cervical motion tenderness is helpful in the diagnosis of PID and right-sided pain on rectal examination is helpful in the diagnosis of appendicitis, neither is pathognomonic. Peritoneal irritation from any source can be elicited by manipulation of the pelvic organs, so that manual manipulation of the cervix elicits an intensely painful response (cervical motion tenderness) in women with either PID or appendicitis. Similarly, rectal examination may elicit pain in a woman who has PID. Acute appendicitis may be overlooked by clinicians who assume the ailment is PID after finding cervical motion tenderness.

Progressive anorexia and lateralization of pain (vague periumbilical discomfort that intensifies over time while gravitating toward McBurney's point) raise suspicion for appendicitis. A history of prior PID, multiple sex partners, recent acquisition of a new sex partner, recent menses, and physical findings of a purulent vaginal discharge suggest PID. Radiographic studies may be needed to clarify the diagnosis because acute appendicitis is a surgical emergency; PID, however, is usually treated with broad-spectrum antibiotics and supportive care. Spiral CT scan has gained acceptance as an accurate determinant of the appendiceal anatomy. Contrast-enhanced CT imaging is also invaluable in the diagnosis of pelvic abscess. Bilateral pelvic abscesses are more characteristics of PID than an appendiceal process.

Meckel's Diverticulum
Meckel's diverticulum represents a residual portion of the vitelline (yolk) duct and is present in 1% of women. Diverticula average 3 cm in length and are located along the antimesenteric border of the ileum within 2 feet of the ileocecal valve. They are lined by ileal-type mucosa, but at least one in five cases has ectopic gastric mucosa. Meckel's diverticulum is present in 1% of women. Diverticula may not localize in the right lower quadrant.

Most complications from Meckel's diverticula are during early childhood, and the likelihood of problems significantly decreases with advancing age. Accordingly, most surgeons believe routine resection of an asymptomatic Meckel's diverticulum in adulthood is unnecessary. Some recommend prophylactic resection if encountered during surgery, because morbidity associated with resection is low. It is generally agreed, however, that resection should be undertaken if the individual has previously been symptomatic, if the diverticulum is unusually long or has a narrow neck, or if thickening at the tip suggests ectopic gastric mucosa. Resection is accomplished by excising the base of the diverticulum with circular closure of the entero- tomy. Care is taken to avoid unnecessary resection of bowel wall to prevent luminal narrowing. Alternatively, transection may be completed via an automated stapler secured across the diverticular base.

Volvulus
Sigmoid volvulus is an acute malrotation that presents with sudden onset of intense pain, similar to that of ovarian torsion. Volvulus is generally accompanied by obstipation, abdominal pain, and distention. Nausea and vomiting may occur. Volvulus is most commonly seen after the age of 60 years; however, cases in young individuals have been reported. Flat-plate abdominal radiographic features are that of a markedly dilated, gas-filled sigmoid colon. Barium enema shows a tapered obstruction at the rectosigmoid junction with a typical bird's beak deformity. Sigmoid volvulus can usually be corrected nonoperatively with sigmoidoscopy or cautious barium enema. If volvulus is discovered at the time of surgery, initial management consists of untwisting the loop of bowel and observing for viability. Resection is infrequently necessary and should be reserved for devitalized bowel. Cecal volvulus is rare and tends to occur in the elderly population. This too is best managed by derotation, and resection is reserved for nonviability.

Pelvic Malignancies
Colorectal carcinomas may be difficult to distinguish from other pelvic malignancies. Advanced colorectal carcinoma may invade the vagina and/or bladder, producing symptoms suggestive of a gynecologic or urologic problem. Advanced ovarian, cervical, and endometrial cancers may also invade the bowel leading to rectal bleeding. Resultant inflammation, tissue necrosis, and abscess formation contribute to the diagnostic dilemma. Historical information, thorough physical examination, colonoscopy or barium enema, cystoscopy, CT scan, and tissue biopsy can clarify the origin of pelvic malignancies in most cases.

Inflammatory Bowel Disease
Inflammatory bowel disease includes Crohn's disease (regional enteritis) and ulcerative colitis. Crohn's disease is an inflammatory process of uncertain etiology that usually involves the small bowel. It most frequently occurs in young adults with symptoms of onset during the late teens, but may occur at any age. Those affected have intermittent diarrhea, intestinal cramping, and weight loss. The extent of intestinal symptoms generally enables the clinician to distinguish inflammatory bowel disease from PID. Clinical findings, such as a functional ovarian cyst, may lead to overdiagnosis of a gynecologic disorder and result in unnecessary surgery. Gynecologic surgery is best avoided if possible in Crohn's patients because of the high risk of intestinal complications, even if the bowel is uninvolved.

Medical management is the mainstay of treatment because there is a high recurrence rate that follows surgical resection. Therapy consists of bowel rest, total parenteral nutrition, and antiinflammatory medication such as sulfasalazine and...
corticosteroids. Surgery is reserved for patients whose disease is complicated by obstruction, perforation, fistula, or hemorrhage. Affected areas of the small intestine may be interspersed by normal segments of bowel. The appearance of Crohn's intestine is thickened walls with dull, purple-red discoloration, inflammatory exudate, and adherent mesenteric fat. If surgical resection is necessary, only the involved segments of bowel are removed. Management of women with inflammatory bowel disease should be left to specialists in the field.

Because of the high rate of anastomotic dehiscence follow- ing resections for Crohn's disease, some surgeons advocate stricturoplasty as an alternative to resection. Stricturoplasty is accomplished by opening the bowel longitudinally and closing transversely, creating a wider lumen. The appendix is eventually affected by Crohn's disease and ulcerative colitis in 25% and 50% of cases, respectively. Prophylactic appendectomy may be considered if the terminal ileum and cecum are not involved by active disease at the time of exploration. Fistulas (i.e., enterocutaneous, enterovaginal, enteroxovaginal) are frequently associated with inflammatory bowel disease and its surgical management. Surgical correction is reserved for problematic fistulas that fail to respond to extended medical management. The intestinal defect, as the source of fistulous drainage, must be corrected for any chance of successful resolution. Ulcerative colitis is a chronic illness of uncertain etiology characterized by ulcerative lesions of the colon and rectum. Clinical symptoms are pain, bleeding, and diarrhea. Additional manifestations are weight loss, anemia, mucosal crypt abscesses, inflammatory pseudopolyps, and low serum protein. Ulcerative colitis is infrequently complicated by toxic megacolon, peritonitis, and colon cancer.

Hemorrhoids

It has been said of hemorrhoids that few human afflictions cause greater distress without posing threat to life. Hemor rhoids are dilated perianal and rectal veins. Chronic pressure causes distention and loss of resistance in the venous wall, resulting in varicos. The collection of blood further draws fluids into the dilated perianal skin. Internal hemorrhoids protrude into the rectal lumen and cause painless bleeding, which may be severe. Larger internal hemorrhoids can protrude through the anus, resulting in pain, itching, and burning. Spasms of the external sphincter may constrict the hemorrhoid, resulting in stran gulation, necrosis, and extreme discomfort. This process is recognized clinically as thrombosed hemorrhoids, which are not actually thrombosed vessels but rather perianal hematomas. An understanding of the Bartholin's gland anatomy helps delineate a Bartholin's abscess from hemorrhoidal inflammation. Recognition of inflammatory exudate, and adherent mesenteric fat. If surgical resection is necessary, only the involved segments of bowel are removed. Management of women with inflammatory bowel disease should be left to specialists in the field.

Because of the high rate of anastomotic dehiscence follow- ing resections for Crohn's disease, some surgeons advocate stricturoplasty as an alternative to resection. Stricturoplasty is accomplished by opening the bowel longitudinally and closing transversely, creating a wider lumen. The appendix is eventually affected by Crohn's disease and ulcerative colitis in 25% and 50% of cases, respectively. Prophylactic appendectomy may be considered if the terminal ileum and cecum are not involved by active disease at the time of exploration. Fistulas (i.e., enterocutaneous, enterovaginal, enteroxovaginal) are frequently associated with inflammatory bowel disease and its surgical management. Surgical correction is reserved for problematic fistulas that fail to respond to extended medical management. The intestinal defect, as the source of fistulous drainage, must be corrected for any chance of successful resolution. Ulcerative colitis is a chronic illness of uncertain etiology characterized by ulcerative lesions of the colon and rectum. Clinical symptoms are pain, bleeding, and diarrhea. Additional manifestations are weight loss, anemia, mucosal crypt abscesses, inflammatory pseudopolyps, and low serum protein. Ulcerative colitis is infrequently complicated by toxic megacolon, peritonitis, and colon cancer.

Hemorrhoids

Preoperative Bowel Prep

The objectives of preoperative bowel prep are to reduce enteric volume and bacterial load. Potential benefits include better operative handling and exposure, reduced infectious complications, and enhanced anastomotic healing. Efficient mechanical bowel prep does eliminate stool and gas from the colon, thus improving exposure and making it easier to pack the bowel out of the operative field. Mechanical cleansing also allows for better visibility during intraoperative colonoscopy, if needed. Various bowel preps have been proposed and used, including oral antibiotics, with or without parenteral antibiotics. In the past, such agents as castor oil, senna, bisacodyl, and magnesium citrate were used, but frequently resulted in inadequate bowel cleansing. Large volumes of isotonic solution and osmotic agents such as mannitol were more effective in bowel preparation; however, the prohibitive side effects included electrolyte and fluid abnormalities, nausea, vomiting, and abdominal distention. Newer mechanical preparations usually consist of either polyethylene glycol or sodium phosphate. Polyethylene gly col is an effective, osmotically balanced solution that causes fewer electrolyte and fluid abnormalities. The major disadvan tage is that 4 L must be consumed. Many patients are unable to complete this prep because of the large volume and the resultant gastrointestinal symptoms. Sodium phosphate has the advantage of being an effective cathartic while only requiring
90 cc of oral liquid. In randomized clinical trials comparing polyethylene glycol with sodium phosphate, patients who took sodium phosphate had significantly less abdominal discomfort. Sodium phosphate provided a significantly better prep for colonoscopy. This trend was also observed in surgical patients, although not statistically significant. Polyethylene glycol and sodium phosphate should be used cautiously in debilitated patients and those with cirrhosis, renal impairment, electrolyte abnormalities, or ascites. They should not be used in patients with renal failure, congenital megacolon, bowel obstruction, or congestive heart failure.

Nonabsorbable or minimally absorbed oral antibiotics have traditionally been used in bowel preparation to reduce the intraluminal colonic flora. It is presumed that reduction in the bacterial load causes less peritoneal contamination and complications if the bowel is opened during surgery. Following colorectal surgery, cultures from wound infections and complications if the bowel is opened during surgery. Following infections. Metronidazole with either erythromycin or compared with no oral antibiotic has been noted to reduce postoperative infections. Metronidazole with either erythromycin or neomycin has also been effectively used. There are no data to support that one regimen is superior to another.

The literature is inconclusive as to whether bowel prep consistently reduces operative morbidity. There are few randomized trials comparing mechanical bowel preparation with no preparation. The utility of bowel prep is called into question with collective retrospective data from trauma surgeries involving colon injury and from emergent colorectal surgery for bowel obstruction. A review of 2,964 unprepared patients who underwent primary repair of colon injury reported an anastomotic leak rate of only 2.3%. Some studies have suggested that bowel prep may actually increase the risk of intraoperative spillage and anastomotic leak. A metaanalysis of seven randomized clinical trials, including 1,297 patients, showed a leak rate of 5.6% in patients given a bowel prep compared with 2.8% in those with no prep ($p = 0.03$).

Despite lack of consistent evidence supporting reduced morbidity, there is a general consensus regarding the potential benefit, such that the majority of gynecologic oncologists, surgical oncologists, and colorectal surgeons continue to recommend preoperative bowel prep. In selected patients, the bowel prep regimen that we prefer is summarized in Table 43.1.

### Positioning the Patient

Examination under anesthesia facilitates evaluation of anatomy and may clarify the likelihood of intestinal involvement by disease. Low dorsal lithotomy position is used if there is an expectation of possible resected anastomosis. Proper positioning reduces the risk of injury. The anesthetized patient is placed with her hips at the end of the table and buttocks extending several centimeters beyond the table end. Padding is secured below the coccyx to avoid pressure point injury. Careful positioning ensures the thighs are slightly flexed and the weight of the legs is distributed evenly, with

We understand this bowel prep may be difficult for you. However, we strongly encourage you to follow all of these steps as outlined. Proper bowel prep may help maximize your effective healing and minimize your chance of problems after surgery. If you have any questions about these instructions, please call our office.
Inadvertent tissue injury is less likely with adhesiolysis close to the bowel wall than with cutting through the center of dense adhesions. Controlled traction and countertraction facilitates isolation and dissection, but excessive force is avoided. With dense adhesive bands, excessive force may literally tear a hole in the bowel wall, which may go unrecognized during surgery.

### Intestinal Injury in Open Gynecologic Surgery

Enterotomy refers to a full-thickness opening in the bowel wall such that the lumen is entered. Enterotomy may be an incidental occurrence during dissection or an intentional surgical maneuver during gastrointestinal surgery. Inadvertent enterotomies are best avoided by cautious entry into the peritoneal cavity and meticulous dissection of adhesions.

Adequate visualization and access are necessary for safe adhesiolysis. Ongoing visual and manual bowel inspection is advisable to ensure there is no compromise to wall integrity. If an inadvertent enterotomy occurs, the affected bowel must be mobilized from surrounding tissues to allow adequate exposure and a tension-free repair. Although it is generally best to repair an enterotomy immediately, if the dissection is particularly difficult, it is advisable to finish the dissection so the extent of injuries can be assessed and the best plan for repair of any and all injuries can be accomplished. The initial impression of a single enterotomy can be incorrect. Mobilization of tissues from the surrounding area may demonstrate multiple enterotomies within a single bowel segment or involvement of more than one loop of bowel (Fig. 43.2).

If an enterotomy is not immediately repaired, it should be marked with a suture of 3-0 silk tied loosely with the tails left long for easy identification. Eventual suture repair should be accomplished in a transverse direction to avoid excessive narrowing of the lumen. This is most important in the small bowel. Staple repair is also acceptable if luminal diameter is not compromised. If multiple enterotomies occur within a localized segment of small bowel, the best plan may be to resect the damaged segment rather than individually repair three or four injuries. Resection of an affected bowel segment may also be necessary if greater than 50% of the circumference is injured, if irregular edges preclude repair, if the blood supply is compromised, or if repair would result in excessive luminal narrowing.

In general, small bowel injury with intraperitoneal contamination by enteric content is associated with less morbidity than a similar occurrence in the large bowel. Historically, large bowel injury (colotomy) with gross intraperitoneal contamination has been managed by diverting colostomy, with delayed surgical repair and colostomy closure after several months. Collective clinical experience from scheduled procedures and trauma surgeries has demonstrated that immediate repair without colostomy is associated with acceptably low morbidity. Suture and staple closure techniques, as well as segmental resection with anastomosis, have been successfully used. Furthermore, some studies suggest that immediate recognition and repair of intestinal injury is associated with less morbidity than the diversion techniques previously thought to be mandatory. Aggressive peritoneal irrigation and administration of intravenous broad-spectrum antibiotics reduce bacterial count. Peritoneal drains should not be placed in the immediate vicinity of an anastomosis, because this can actually impede healing. However, there may be therapeutic benefit from suction drains in dependent regions, such as the pelvis and paracolic gutters, which prevent accumulation of fluid. A diverting colostomy is indicated when a full-thickness colonic injury occurs in those who have undergone irradiation, who are profoundly

---

**Related Surgery**

no pressure points from the stirrups. Lithotomy position also allows access for intraoperative pelvic examination and provides easy exposure to assess bladder or rectal integrity after pelvic dissection. Additionally, a surgeon can be positioned between the stirrups to elevate the vaginal apex or assist with a rectal examination, or to enable dissection in the paraaortic and upper abdominal areas.

### INTRAOPERATIVE CONSIDERATIONS

#### Lysis of Adhesions

Intraperitoneal adhesions are fibrous bands of scar tissue that connect opposing peritoneal and/or serosal surfaces. Adhesions may be associated with prior surgical procedures, trauma, irradiation, infection, bleeding, or chemical irritants. Prior abdominal or pelvic surgery is the most frequently noted predisposing factor. After surgery, desiccated tissue surfaces in direct opposition are those at greatest risk for adhesion formation. History alone is not predictive in that certain individuals have adhesions without identifiable predisposing factors. Others have a predilection for an exaggerated healing response and excessive adhesion formation.

Adhesiolysis may be necessary to mobilize the bowel, expose the surgical field, and circumvent obstruction. Constricting adhesive bands require transaction. It is best to start with translucent adhesive bands that can be sharply lysed without difficulty. As adhesions become more dense, efforts are made to isolate a window such that an index finger and thumb can be placed behind and in front of the adhesions, respectively. Gentle blunt tissue dissection by rubbing the index finger and thumb back and forth helps to identify translucent adhesive bands that can be sharply lysed. There is often a recognizable white line between adhesions and their peritoneal attachment, which identifies a safe tissue plane for dissection (Fig. 43.1). Another plane ideal for sharp dissection is one followed in close parallel proximity to a recognizable structure, such as along a loop of small bowel.

**FIGURE 43.1.** Traction-countertraction gives good exposure of an abdominal adhesion, which is lysed with scissors.
malnourished, or whose condition is unstable from shock or sepsis.

**Intestinal Injury during Endoscopic Procedures**

Historically, most intestinal injuries in gynecologic surgery have occurred during open abdominal procedures. Exponential growth in the number of laparoscopic cases, however, has shifted the spectrum of risk. Gastrointestinal injury during laparoscopy most commonly occurs during initial peritoneal entry. Injury can occur from use of a scalpel, insufflating needle, trocar, or blunt dissection. Use of the open (Hasson) technique does not prevent bowel injuries. Good clinical judgment is necessary to determine which patients are appropriate candidates for laparoscopy. Previous surgeries, inflammatory conditions, and prior irradiation increase risk of injury from enteric adhesions, which fix intestine to the abdominal wall. Oxygenating the patient via bag-mask in preparation for intubation can displace the stomach below the level of the umbilicus, placing it at risk for injury. Nasogastric decompression before introduction of a Veress needle or trocar reduces this risk. In the presence of enteric adhesions, the laparoscopic trocar can be inadvertently placed into the stomach, transverse colon, or small intestine. Perforation is suspected by nonvisualization of intraperitoneal structures, identification of intraluminal tissue, and reflux of enteric content. If perforation occurs, it is prudent to leave the trocar in position, as it is much easier to recognize injuries using the trocar as a guide to the affected anatomy (Fig. 43.3). If the extent of injury cannot be determined, or the necessary repair cannot be accomplished via laparoscopy, then a laparotomy should be performed.

Cautery or sharp dissection can result in enterotomy, which commonly occurs during adhesiolysis. The skill and comfort level of the laparoscopic surgeon determines whether the defect can be successfully repaired via endoscopy or whether laparotomy is required. The most serious laparoscopic intestinal injuries are those that go unrecognized at the time of surgery. Thermal injury from electrocautery or laser can have a potentially disastrous outcome. With electrosurgical injury, a progressive zone of tissue destruction extends well beyond the area of thermal contact, resulting in tissue necrosis and perforation 72 to 96 hours after surgery. Perforation may be signaled by high fever, leukocytosis, nausea, vomiting, and a generalized ill appearance. Signs of peritonitis are present on examination. Flat-plate x-rays may be of limited benefit in the early postoperative period, because intraperitoneal air can persist for 7 days following surgery. CT scan using water-soluble contrast is better suited for this evaluation and should demonstrate extravasation of contrast material into the peritoneal cavity with possible abscess formation.

If perforation is suspected or confirmed, urgent exploration is warranted. Hypovolemia, electrolyte abnormalities, and anemia should be aggressively corrected. Broad-spectrum antibiotics are administered, and nasogastric decompression is performed as the patient is prepared for surgery. At surgery, aggressive irrigation is necessary to enhance visibility. Copious enteric exudate causes a profound inflammatory response and generalized matting together of intraperitoneal content. Inspection of the small bowel is initiated at the ileocecal junction and is continued proximally in a hand-over-hand fashion. Careful examination of the bowel and mesentery is continued to the ligament of Treitz, followed by thorough inspection of the large intestine. The stomach and proximal small bowel are also inspected. In contrast to sharp enterotomy, which can be repaired primarily, significant thermal injury is best corrected by resection of affected bowel. At the very least, a wide margin of bowel wall is removed beyond any visible thermal injury. Because of enteric contamination, other necrotic tissues, such as fulgurated endometriotic implants, are at high risk for abscess formation and should be excised.

**Intestinal Injury during Uterine Curettage and Other Gynecologic Procedures**

It is estimated that most uterine perforations go unrecognized; therefore, injury to pelvic viscera may also go unrecognized. If fundal perforation occurs during sharp or suction curettage, intestine and mesentery can be drawn into the uterine cavity by the curette. Evisceration as a consequence most commonly occurs during dilatation and curettage of the gravid uterus. Tactile feedback may suggest products of conception, when in fact prolapsed abdominal viscera are being curetted (Fig. 43.4). Recognition of this injury warrants immediate surgical exploration. With the abdomen open, the bowel is retracted by gentle traction from above. The surgical objectives are to control hemorrhage from the uterine injury thoroughly inspect the bowel, repair injuries, and complete the uterine...
Evacuation. In women of reproductive age, hysterectomy is avoided unless uterine preservation poses a significant threat to her health.

Intestinal injury has been associated with a vast array of other gynecologic procedures, including those generally considered to be minor outpatient surgeries. For example, rectal lacerations and thermal injuries have occurred during cervical conization and loop electrosurgical excision procedure, respectively. Intestinal perforations and obstructions have resulted from placement of tension-free vaginal tape. A variety of pelvic reconstructive grafts have reportedly eroded into the small or large bowel, and intestinal perforations have resulted from extraterine migration of an intrauterine contraceptive device. Accordingly, the gynecologic surgeon should be cognizant of possible intestinal ramifications of his/her operative endeavors.

**Radiation Injury**

Radiation therapy for gynecologic cancers can cause intestinal injuries that require surgical correction. Also, damage from prior irradiation contributes to complications during other surgical procedures. The intestinal tract is adversely affected by radiation during treatment and soon thereafter (acute injury) and/or remote from treatment (late injury). The acute phase is associated with small bowel irritability, cramping, and diarrhea, with onset generally 2 to 3 weeks after initiation of therapy. Injury to the large bowel manifests acutely as pseudomembranous colitis, with resultant pain, tenesmus, frequent bowel movements, and bleeding. Low-residue diet, antispasmodics, and antiinflammatories are helpful in uncomplicated cases. In more severe cases, debilitating symptoms can adversely affect lifestyle. Intestinal adhesions, fibrosis, obstruction, perforation, abscess, and fistulae are potential late complications.
Surgery in previously irradiated patients warrants special attention and is best performed by those experienced in this regard. Whenever possible, the surgical incision is made in a location beyond the radiation field. Extensive lysis of adhesions is best avoided, and dissection should be confined to the minimum area necessary to complete the surgical objectives. If obstruction occurs, consideration is given to intestinal bypass as opposed to extensive mobilization. Resection is avoided unless the anastomosis can be completed with non-irradiated bowel segments. This objective is often theoretical, because damaged bowel may appear normal and yet have significant microscopic endarteritis and vasculature obliteration. The characteristic pale, thickened bowel wall, telangiectatic vessels, and strictured lumen need not be present to indicate significant radiation injury. If resection is unavoidable, the surgery can be reinforced by wrapping the anastomosis with omentum, which elicits support of exogenous blood supply.

A vesicovaginal or rectovaginal fistula may develop if there is extensive damage to the intervening tissue. The time course of fistula occurrence is usually between 6 and 24 months after therapy, but it may present years after irradiation. The mechanism of late radiation injuries is believed to be oblitative vascular injury with compromised blood flow and tissue necrosis. Postradiation rectovaginal fistulae are complex problems that rarely heal with simple excision, mobilization, and closure, such that they are probably best corrected using a three-staged approach. First, a diverting ileostomy or colostomy is performed to redirect the colonic content, reduce bacterial infiltration, and allow resolution of inflammation. Several months later, the objectives of the second surgery are complete resection of the fistulous tract and surrounding damaged tissue plus neovascularization via an omental flap or myocutaneous graft. The goal of the eventual third surgery is to reverse the diverting ostomy to reestablish normal intestinal continuity.

POSTOPERATIVE CONSIDERATIONS

Nasogastric Decompression

Some surgeons use routine postoperative nasogastric decompression to reduce nausea, vomiting, and abdominal distention and to enable healing of bowel anastomoses. These prophylactic objectives differ from the therapeutic goals of nasogastric decompression used to alleviate symptoms and expedite recovery from an existing ileus or small bowel obstruction. The literature, however, does not support routine postoperative use. Nasogastric tubes increase patient discomfort and increase the occurrence of sinus infections and epistaxis. A meta-analysis of selective versus routine nasogastric decompression after elective laparotomy included 26 trials and 3,964 patients. Routine postoperative decompression was associated with an increased incidence of pneumonia, atelectasis, and fever. Abdominal distention and vomiting were increased in selectively treated patients who did not have nasogastric tubes, and eventual tube insertion was required in 5% to 7% of patients in this group. Nasogastric tube reinsertion was required in 2% of routinely decompressed patients. There was no significant difference in the occurrence of wound infections, wound dehiscence, or anastomotic leaks. The authors of this analysis concluded that through the selective use of nasogastric decompression, only 1 in 20 patients require a nasogastric tube.

Acute Gastric Distention

Acute gastric distention results from inhibition of gastric peristalsis. Postoperative gastric distention more commonly occurs after surgical manipulation in the vicinity of the stomach. Patients at increased risk are those who are diabetic, elderly, or medically debilitated. Short-term postoperative nasogastric decompression can prevent and manage this problem in those who are at high risk for aspiration. Stimulatory agents such as metoclopramide may expedite gastric emptying in the nonobstructed patient.

Ileus

Postoperative ileus is a mechanical dysfunction in which the normal anterograde gastrointestinal peristalsis is disrupted.

Early Postoperative Feeding

There is a wide spectrum of practice patterns among surgeons regarding postoperative diet. For many decades, the conventional approach has been to wait for auscultation of bowel sounds before providing clear liquids and to wait for the occurrence of flatus before giving solid food. Inpatient managed care pressures and successful outpatient recovery following laparoscopic procedures have challenged clinicians to reevaluate traditional postoperative feeding regimens. Current trends are toward much more aggressive early postoperative feeding, even in the setting of bowel resection and anastomosis. Some randomized clinical trials have shown early feeding to be associated with increased frequency of nausea and vomiting, whereas others have shown no difference. The overall rates of ileus, anastomotic complications, and times required for return of bowel function are generally comparable. Early postoperative feeding, however, has not consistently resulted in shorter average length of hospital stay.

Supplemental Nutrition

Perioperative nutritional support is indicated in patients who have been without nutrition for more than 7 days, in patients who are malnourished (weight loss exceeds 15% of usual weight), and when expected duration of recovery is longer than 10 days. Total parenteral nutrition (TPN) has extended the lives of numerous surgical patients and enabled the resumption of normal lifestyle in many. Long-term parenteral nutrition, however, has morbidity that is not insignificant. The need for indwelling central venous access puts patients at risk for catheter sepsis and other catheter-related complications. Metabolic derangements and pancreatic or hepatic dysfunction are common. Intestinal mucosal atrophy results from nonuse in patients who are reliant solely on parenteral nutrition.

Use of the gut for nutrition is advisable whenever possible. The advantages of enteral tube feeding over TPN include no requirement for venous access, enhanced intestinal lymphatic function, reversal of mucosal atrophy, decreased risk of bacterial translocation, and stimulation of intestinal adaptation. Adaptation is the process whereby the villous height and crypt depth increase, with gradual bowel dilation and lengthening, resulting in increased absorptive surface area. Enteral feeding is not indicated in patients with a nonfunctional intestinal tract or intestinal obstruction, or in those at high risk for aspiration.
Ileus may involve any segment of the digestive tract, including the stomach, small bowel, or colon. In fact, ileus is most frequently a large bowel dysfunction in that the colon is generally the last segment in the gastrointestinal tract to regain function after pelvic surgery. Postoperatively, the stomach and small intestine usually resume activity within 8 hours. At times, active small bowel peristalsis is noted at the conclusion of even complex abdominal procedures. In contrast, the colon may take 48 to 72 hours to regain function. Colonic dysfunction generally resolves from proximal to distal, such that rectosigmoid activity is the last to return.

Factors that predispose to ileus or worsen the severity of ileus include dehydration, electrolyte abnormalities, diabetes, chronic laxative use, bowel manipulation during surgery, extensive retroperitoneal dissection, general anesthetic agents, narcotic analgesics, immobility, urinary or gastrointestinal leak, peritonitis, abscess, and hematomata. Some degree of adynamic ileus results from all intrabdominal procedures. With return of bowel function, peristaltic pains are often severe, such that many patients describe them as being worse than surgical pain. Normal recovery of bowel function is evident by gradual increase in appetite, tolerance of oral nutrition, and flatus.

Delay in bowel function, worsening gas pains, nausea, and vomiting are suggestive of a clinically significant ileus. Physical examination confirms abdominal distention with diffuse discomfort, hypoactive bowel sounds, and tympanic percussion. Correction of contributing factors and supportive care are the cornerstones of management. Therapeutic interventions include bowel rest, intravenous hydration, correction of electrolytes (i.e., potassium, sodium, and magnesium), physical activity, and judicious use of narcotic analgesia. If good bowel sounds for 24 hours or more suggest that colonic dysfunction is a predominant underlying factor, colonic stimulation (e.g., docusate sodium suppository or enema) may be helpful. Patients with vomiting, those not responding to supportive measures, and those with evidence of gastric or small bowel dilatations on x-ray study benefit from nasogastric decompression. Decompression is generally continued until flatus ensues and abdominal distention resolves.

Adynamic ileus must be distinguished from a mechanical small bowel obstruction. If the patient has not passed flatus within 4 to 5 days or does not respond to conservative measures, then the possibility of a mechanical small bowel obstruction should be considered. Early in the disease process, radiographs may provide little assistance in clarifying the diagnosis because the changes of postoperative ileus and early obstruction are similar. However, after 3 to 5 days, plain abdominal radiographs with supine, upright, and/or lateral recumbent views will help distinguish ileus from mechanical small bowel obstruction. The typical radiographic pattern of an ileus is that of intermittent air found throughout the gastrointestinal tract, including the colon and rectum. Upright views may show air-fluid levels within the small bowel and stomach, and, on occasion, the transverse colon (Fig. 43.5). In contrast, radiographic characteristics of mechanical small bowel obstruction include proximal distended loops with a paucity or absence of gas in the colon. The dilated small bowel loops with air-fluid levels may follow a stair-step pattern from the right lower quadrant to the left upper quadrant in parallel with the anatomic base of the small bowel mesentery.

With intermittent or partial small bowel obstruction, some gas is seen in the colon. Conversely, if the obstruction is in the proximal small bowel, there may be no distended loops at all. Radiographic studies can at times clarify the type of obstruction (partial vs. complete), and the location of obstruction (stomach vs. small bowel vs. colon). If the diagnosis remains unclear, a water-soluble contrasted CT scan or gastrointestinal study with small bowel follow-through can clarify the situation and localize the point of obstruction if present. Contrast material may also stimulate peristalsis and has been reportedly therapeutic in some cases of paralytic ileus.

Small Bowel Obstruction

Intraperitoneal adhesions are the most common etiology of intestinal obstruction. Malignancies and hernias are also frequent extrinsic causes. An estimated 85% of all small bowel obstructions are secondary to one of these three conditions. Intramural causes include tumors, polyps, gallstones, and bezoars. Obstructive intramural strictures can complicate irradiation or inflammatory bowel disease.

Early postoperative obstruction deserves a trial of nonsurgical management. Nasogastric decompression, supportive care, and correction of underlying contributing factors are as described for adynamic ileus. Supine position with legs flexed helps relax rectus abdominis muscles to facilitate examination. Early in the course of obstruction, there may be minimal to absent distention. Proximal obstruction may also manifest with minimal abdominal distention. High-pitched bowel sounds with metallic tones and rushes are suggestive of an obstructive process. Hypoactive or absent bowel sounds are more suggestive of paralytic ileus. Hypoactive bowel sounds may also occur with intestinal fatigue from long-standing obstruction, closed loop obstruction, or pseudo-obstruction. Fewer than half of obstructed patients manifest the classic triad of rebound tenderness, guarding, and rigidity. Also, the physical findings of focal tenderness and guarding are neither sensitive nor specific in confirming underlying obstruction or ischemia.

The duration of asymptomatic intervals between peristaltic pains may suggest the level of obstruction. Peristaltic waves tend to be 3 to 5 minutes apart in high obstruction, whereas in distal obstruction, 10 to 15 minutes may lapse between episodes. On flat-plate abdominal x-ray, small bowel distended by gas outlines the valvulae conniventes (plicate circularis), which traverse the entire diameter of the dilated bowel lumen.
FIGURE 43.6. Computed tomography scan of small bowel obstruction; air-fluid levels in dilated small bowel.

Valvulae conniventes are closely spaced and may appear to interdigitate. In contrast, distended colon highlights the haustra, which partially traverse the bowel lumen and are spaced more widely apart. The central abdomen is occupied by distended small bowel loops, whereas the abdominal periphery houses the colon. In the decompressed patient, character of gastric aspirate suggests the potential anatomic site of obstruction. Gastric outlet obstruction produces clear gastric secretions. Bilious output is suggestive of obstruction in the proximal to mid small bowel, or a colonic obstruction with a competent ileocecal valve. Feculent drainage is characteristic of a distal small bowel obstruction or colonic obstruction with an incompetent ileocecal valve.

Intestinal obstruction leads to an accumulation of intraluminal fluid and gas with distention proximal to the occlusion (Fig. 43.6). It is estimated that more than 70% of air in the gastrointestinal tract is from swallowing. Accordingly, distention is significantly worsened by swallowed air. With progressing distention comes tension and venous compression. Arterial inflow continues, resulting in blood accumulation within the bowel wall and lumen. Protein-rich fluid exudes from the capillaries, adding to tissue edema. Malabsorption combined with intestinal secretion further exacerbates intraluminal fluid collection. In the setting of complete obstruction, up to 7 to 8 L of fluid can accumulate, including 50% of plasma volume and 30% of circulating blood volume. Mucosal integrity is disrupted, and enteric bacteria traverse the defective bowel wall, seeding the peritoneum. If the process goes uncorrected, intestinal viability is irreversibly damaged as tissue necrosis ensues.

If a decision is made for operative intervention, preparation concentrates on correction of hypovolemia, anemia, and electrolyte imbalances. Broad-spectrum antibiotics may suppress bacterial translocation and delay intestinal ischemia. Upon exploration, the point of obstruction is identified and corrected. All necrotic bowel must be resected. It is not always possible, however, to discern the viability of bowel in the setting of obstruction. Visible characteristics—such as tissue color, extent of edema, and peristalsis—are not consistently reliable. Active bleeding from the cut bowel edge is a more accurate indicator. Intraoperative Doppler testing of the antimesenteric border should provide characteristic arterial pulsations. Absent Doppler sounds do not necessarily indicate inadequate arterial blood flow. In this setting, viability can be confirmed by intravenous 10% fluorescein (15 mg/kg), followed in 30 minutes by Wood’s lamp illumination. Observation of bowel wall fluorescence suggests adequate blood flow to support anastomotic healing. Bowel segments that are less than 2 cm in length with no fluorescence can be preserved, but should not be included in the anastomoses. Larger areas of nonfluorescence suggest ischemia and likely require resection.

Large Bowel Obstruction

The vast majority of large bowel obstructions are due to malignancy or inflammatory conditions. This is in contrast to small bowel obstructions, for which adhesions are the principal etiology. The gynecologic surgeon may encounter large bowel obstruction from a primary colon or a gynecologic malignancy, ulcerative colitis, diverticular disease, pelvic abscess, or radiation injury. The onset of most colonic obstructions is insidious because of gradual luminal narrowing, which manifests clinically as decreased caliber stools, constipation, and bloating. Progressive obstruction leads to obstipation, abdominal distention, colicky pain, nausea, and vomiting. Radiographic studies reveal a dilated colon proximal to the point of obstruction (Fig. 43.7). If the ileocecal valve is incompetent, the distention extends proximally into the small bowel, as evidenced by dilated bowel loops with air-fluid levels. A more serious closed loop obstruction occurs when the ileocecal valve is competent. The cecum is commonly involved; as cecal dilation exceeds 10 to 12 cm, the risk of perforation increases significantly. Preoperative endoscopy or water-soluble contrast study can clarify the etiology and location of obstruction. Barium enema should not be performed in the setting of acute obstruction or suspected perforation to avoid barium peritonitis. If necessary, any viable segment of large bowel proximal to the point of obstruction can be exteriorized as a colostomy.

Ogilvie Syndrome

Ogilvie syndrome (acute colonic pseudoobstruction) is a dysfunction of colonic peristalsis. Clinical presentation may be...
indistinguishable from a large bowel obstruction. The mecha-
nism of colonic pseudoobstruction is theorized to be an im-
balance between the proximal and distal colonic innervation.
Parasympathetic innervation from the vagus nerve supplies
the colon proximal to the splenic flexure. In contrast, the left
colon receives parasympathetic innervation from the sacral
plexus (S2–S4). Most commonly, only the right colon is di-
lated. Ogilvie syndrome is seen more commonly in elderly
and debilitated patients and in those who are on narcotics and
phosphatase or tricyclic antidepressants. Supportive care in-
cludes hydration, correction of electrolyte abnormalities, and
gastrointestinal decompensation (nasogastric tube, rectal tube).
Sequential radiographs are used to monitor cecal dilation to
assess the risk of perforation. Endoscopic decompensation or
tube cecostomy are preferred alternatives to exploration, be-
cause surgical morbidity is significant. If necessary, intraop-
erative colonic decompensation can be accomplished using an
18-gauge needle passed obliquely through the taenia coli and
attached to suction. Decompression facilitates exteriorization
of the bowel for diverting colostomy, if necessary.

Fistulae

Postoperative intestinal fistulae are an especially challenging
problem for patients and clinicians. An enterocutaneous or
enterovaginal fistula may be difficult to confirm, even when
clinical findings are strongly suggestive of a fistulous commu-
nication. The high-pressure bowel defect may be small with
only intermittent drainage, thus obscuring localization. Oral
administration of charcoal or of bright blue or carmine red
dye confirms the diagnosis if characteristic color change is ob-
served in the effluent. Clarification of the fistulous tract can be
aided by an intraluminal contrast material introduced tran-
cutaneously, and the pattern of flow is evaluated radiographically.
Excessive force during injection is avoided to prevent dislodg-
ment of the bowel from its adherence to the abdominal or
vaginal wall.

Nonoperative management of fistulas in selected cases
has gained wide acceptance. The fundamentals of conservative
management include correction of underlying inflammatory
processes and electrolyte abnormalities, nutritional support,
and maintenance of adequate hydration. The more proximal
the fistula, the greater the potential for physiologic derange-
ments, and the less likely the fistula is to close spontaneously
without a fistulectomy. Gastric, duodenal, and proximal
jejunal fistulae can cause potentially fatal physiologic dis-
turbances and thus require prompt intervention. Distal ileal
or colonic fistulae are generally well tolerated and tend to close
spontaneously if predisposing factors are circumvented. There
must be no abscess, peritonitis, distal bowel obstruction, or for-
eginous body within the fistulous tract. Prior irradiation is likely
associated with suture tearing through the tissue and is sus-
pected in the setting of copious serous or serosanguineous drainage
from the abdominal wound. The incision is explored with a sterile
swab or gloved finger to assess for fascial defects. A small de-
fect (1 to 2 cm) in an otherwise intact fascia with no associated
bowel extrusion may be reaproximated with an interrupted
fascial suture. Larger fascial defects and all defects with bowel
perforation (evisceration) require immediate surgical attention.
Evisceration and abdominal wall injuries are discussed in
Chapter 43. Evisceration is an acute full-thickness wound disruption
through which abdominal contents extrude and most com-
monly includes loops of distal small bowel and omentum. Evi-
sceration is rare following laparoscopic procedures but should
be suspected with a palpable or visible hernia defect and
serosanguineous fluid drainage. Concomitant problems may
include abnormal bowel function, nausea, vomiting, or evi-
dence of bowel incarceration. CT and ultrasound imaging are
useful if the diagnosis is uncertain. In preparing the eviscerated
patient for surgery, she is kept in supine position, and the ex-
posed bowel is covered with towels moistened by sterile saline
or povidone-iodine solution. If accomplished without difficulty,
eviscerated organs should be cautiously replaced back into the
abdomen. The protective towels can be secured using a sterile
plastic drape and reinforced with an abdominal binder. Broad-
spectrum antibiotics are administered, and steps are taken to
establish a clear fluid and electrolyte abnormalities. Sedatives and anal-
gesics can reduce intraperitoneal pressure. Intraoperatively, all
layers of the wound are inspected for infection, and devital-
ized abdominal wall tissue is sharply debried. The bowel and
mesentery are inspected for injury, viability, hemostasis, and
obstruction. The peritoneal contents are copiously suctioned.
Bowel resection is generally not necessary, but it may be re-
quired if obstruction or ischemia is present.

Vaginal Evisceration

Protrusion of viscera through the vagina (Fig. 43.8) has been
reported in association with surgery, enterocoele, trauma, Val-
salva maneuver, cystus, radiation, and foreign bodies. Small
bowel and mesentery are most commonly involved, but evis-
ceration may also include large bowel and omentum. Approx-
imately two thirds of reported cases have occurred in patients
with a history of prior surgery for pelvic relaxation or in the
setting of symptomatic enterocoele. Prior hysterectomy is a fac-
tor in only half of reported cases. This distressing situation
tends to occur outside of the hospital setting, and bacterial
contamination is inevitable. Severe abdominal pain may indi-
cate mesenteric compromise. Surgical preparation is similar to
that for an abdominal evisceration, but in contrast, it is best to
resect preoperative attempts at replacing the bowel through the
vagina. Surgical management should be via exploratory la-
poratomy. During exploration, the eviscerated contents are
placed into the peritoneal cavity with a combination of gen-
tile traction from above and guidance from below. Copious
intrapерitoneal irrigation and broad-spectrum antibiotics are
used. Careful inspection of the bowel and mesentery are necessary to identify and repair injuries and to ensure viability. Severely damaged or obstructed bowel requires resection.

**Short Bowel Syndrome**

Short bowel syndrome (SBS) results from loss of significant bowel length or inadequate function of normal-length bowel. The net result is insufficient nutrient absorption necessary to meet the body’s metabolic requirements. Causes include extensive surgical resection, regional enteritis (Crohn’s disease), and radiation injury. An increasingly frequent etiology of SBS is reexploration subsequent to prior abdominal procedures. Extensive bowel resection is most often necessary as a result of postoperative adhesions or volvulus. In a 20-year review from the University of Nebraska Medical Center, 25% of adult SBS cases were attributed to secondary surgeries. Initial operations included colectomy, hysterectomy, appendectomy, gastric bypass, and others, with hysterectomy being the second-most-common predisposing procedure.

In women, the average length of small bowel is approximately 600 cm (range 350–700 cm). Some authors define SBS as having less than 200 cm of functional small intestine. In general, 50% of the small bowel can be resected without long-term impairment of nutritional status, as long as there is normal function in the remainder of the bowel. Severe nutritional deficiencies will likely result with loss of two thirds to three fourths of the small intestine. Malabsorption manifests as diarrhea, dehydration, weight loss, metabolic derangements, nutrient deficits, low serum protein, and anemia (iron, folate, and B12).

Therapy for SBS begins with preemptive planning. A concerted effort is made to preserve as much small bowel and colon as possible at the time of any surgical resection. Preemptive strategies include steps taken to prevent adhesions, to avoid technical errors, and to act expediously on potentially ischemic bowel. After undergoing an intestinal resection, the remaining small bowel has adaptation capacity that
than are the specific techniques or materials used (Table 43.2).

General Principles

Intestinal anastomosis should:

- Be tension free
- Avoid intraperitoneal spill of gastrointestinal content
- Incorporate healthy tissue in the proximal and distal segments
- Preserve adequate lumen
- Be hemostatic and watertight/airtight
- Be completed under optimal surgical exposure
- Preserve maximum amount of normal bowel
- Invert the tissue edges
- Incorporate the submucosa, which is the strongest layer
- Include bowel segments of the same diameter
- Be performed in an infection-free tissue bed
- Not be done with an interrupted obstruction or fistula

Broad categories for consideration include whether to use open or closed technique and whether to use hand-sewn or staple closure. Anastomotic communication can be established via an end-to-end, side-to-side, or end-to-end alignment. Hand-sewn closure may be effectively accomplished using one or two layers of absorbable or permanent suture via continuous or interrupted methods. Additionally, specific suturing techniques (i.e., Lembert, Connell) can be selected (Fig. 43.9).

Staple anastomoses have largely replaced hand-sewn techniques. Technical ease and equivalent to superior results are among the potential advantages of stapling methods (Table 43.3). Recent advances in stapling instruments and techniques have been vital to the exponential growth in laparoscopic surgery. Essentially any procedure described in this text as an open technique can be accomplished endoscopically by the advanced laparoscopic surgeon. An overview of selected surgical procedures in this chapter includes hand-sewn and staple techniques, with a focus on modern surgical stapling. A more expansive discussion of hand-sewn maneuvers is found in the seventh edition of Te Linde's Operative Gynecology.

Familiarity with open and closed anastomotic techniques provides the surgeon with a choice of repairs and facilitates intraoperative decision making. Open techniques (bowel lumens exposed) have gradually replaced closed techniques (lumens occluded) in most circumstances. Morbidity associated with open techniques is acceptably low. The extent of intraperitoneal spill can generally be controlled with aggressive preoperative bowel prep and atraumatic bowel clamps. Closed techniques are potentially advantageous in reducing complications from unprepped bowel and with anastomosis involving the colon.

Anastomosis at the anastomotic margins begins within the first 72 hours of surgery if not impeded by infection or inflammation. The most important strength layer of the bowel wall is the submucosa, which must be incorporated into any anastomosis. Collagen is believed to be the single most important contributor to submucosal strength. The maximum anastomotic bursting pressure reflects the pressure required to disrupt an anastomosis and has been used experimentally to assess the strength of healing. The bursting pressure of an anastomosis increases rapidly during the early postoperative period. Sixty percent of the surrounding bowel wall strength is reached by postoperative day 3 to 4, and pressure tolerated by the anastomotic site approximates 100% of that tolerated by intact bowel wall by postoperative day 7. The ideal suture material should provide maximum strength during the

Hernias

Ventral or incisional hernias occur subsequent to 1% of gynecologic surgeries. Abdominal viscera are encased by a peritoneal lining. Abdominal wall defects are frequently present in the setting of gynecologic surgeries. Abdominal viscera are encased by a peritoneal lining. Abdominal wall defects are frequently present in the setting of gynecologic surgeries. Hernias tend to describe an insidious onset of abdominal fullness or pressure and often notice a focal area of distention. Symptoms generally worsen with prolonged standing and physical activity, and lessen at rest. Hernias that reduce spontaneously and those easily reduced manually can be managed nonoperatively. Any suspicion of bowel obstruction, incarceration, or strangulation, or necrosis requires immediate surgical evaluation. The surgical objectives are to isolate and resect the hernia sac, reduce the sac contents, lyse pertinent adhesions, and inspect the viscera to ensure gastrointestinal integrity. Reoperation may be necessary to alleviate intestinal obstruction or remove severely damaged bowel. Before closure, steps are taken to acquire hemostasis, control infection, excise preexisting scar tissue, and mobilize the abdominal wall to enable a tension-free fascial approximation.

OPERATIVE TECHNIQUES

General Principles

Numerous variations exist on bowel resection and anastomotic techniques. Discussed in this text are some of the more commonly used methods, instruments, and materials. This review is by no means exhaustive, given the vast array of reported options on this theme. Strict adherence to the fundamental principles described above is more important to successful healing than are the specific techniques or materials used (Table 43.2).
lag phase of wound healing with minimal tissue reaction and inflammation. Although the perfect suture material is yet to be identified, modern monofilament and coated braided sutures represent progress toward this goal.

Double-layer intestinal closures have long been touted as more secure than single-layer closures. The traditional anastomosis includes a running inner layer of 3-0 chromic cat gut (absorbable) and an interrupted outer layer of 3-0 silk (nonabsorbable). Extensive clinical evidence, however, suggests single-layer closure to be equivalent and may offer some advantages over double-layer anastomosis. Comparative animal studies have demonstrated more rapid vascularization and mucosal healing, and greater early anastomotic strength associated with single-layer repair. Double-layer closures, along with traditional sutures such as cat gut and silk, are associated with greater inflammation, reduced microvascular growth, and less blood flow across the anastomosis. A single-layer reapproximation generally causes less narrowing of the intestinal lumen and can be accomplished in less time. When done properly, all hand-sewn techniques result in an inverted suture line.

Either continuous or interrupted closures can be used for intestinal anastomosis. Continuous technique is rapid and has the potential advantage of a more even tension distribution along the suture line. In comparing running versus interrupted closure, animal studies have also shown reduced tissue oxygen tension, impaired collagen synthesis, and increased anastomotic complications using running closure. To date, however, randomized clinical trials are lacking, and retrospective studies show no consistent benefit of one technique over the other. Clinical and subclinical anastomotic leak rates, associated morbidity, and length of hospitalization are generally equivalent, even for high-risk patients (e.g., patients with prior radiation therapy, malnutrition, or carcinomatosis).

### SURGERY ON THE SMALL INTESTINE

#### Blood Supply to the Small Intestine

The small bowel receives its arterial blood supply from the superior mesenteric artery (SMA), which arises from the ventral surface of the abdominal aorta (Fig. 43.10). In addition to the small bowel, the SMA also gives rise to the middle and right colic arteries, which supply those regions of the colon. The most proximal small bowel is supported by the common inferior pancreaticoduodenal artery from the SMA, arising from the left side of the SMA is a series of jejunal and ileal arteries that branch to form anastomotic arcades. Primary arcades terminate directly into the small bowel via vasa recta or extend to form secondary, tertiary, and quaternary arcades that eventually give rise to terminal vasa recta. Avascular spaces between the vasa recta are known as windows of Deaver. In general, up to 8 cm of small intestine can remain viable distal to the closest vasa recta because of intramural vascular communications.

The ileocolic artery arises from the right side of the SMA and traverses the base of the mesentery to form a loop anastomosis with the SMA in the region of the terminal ileum. This loop encircles an area devoid of vessels known as the avascular space of Treves. The arterial blood supply to the distal ileum is considered tenuous because of a decreased number of
FIGURE 43.10. Intestinal blood supply: superior mesenteric artery. The peritoneum is in part stripped off. Observe the following: (1) The superior mesenteric artery, which ends by anastomosing with the ileal branch of the ileocolic artery. (2) Its branches: from its left side, (a) 12 or more jejunal and ileal branches. These anastomose to form arcades from which vasa recta pass to the small gut. From its right side, (b) the middle colic, the descends, and commonly, but not here, an independent right colic artery. These anastomose to form a marginal artery (labeled in Fig. 43.14) from which vasa recta pass to the large gut. (c) The two inferior pancreaticoduodenal arteries (not in view) arise from the main artery either directly or in conjunction with the first jejunal branch. (3) Taeniae coli, sacculations, and appendices epiploicae distinguish the large gut from the smooth-walled small gut.

vasa recta from only primary vascular arcades. Because of the uncertain vascular status in this area, it is recommended that 10 cm of terminal ileum also be removed during cecal resection to improve the anastomotic blood supply.

Small Bowel Resection

It is important to resect only the length of bowel necessary to adequately address the disease process, thereby sparing as much normal intestine as possible. For benign disease, bowel transection sites are located just proximal and distal to the abnormal segment. Most laparotomy pads are positioned to isolate the surgical field from the remaining peritoneal contents. At the proposed transaction sites, blunt dissection is used to make a small opening through the avascular mesenteric window adjacent to the bowel wall. The staple cartridge half of the gastrointestinal anastomotic (GIA) stapler is passed through the proximal mesenteric defect, perpendicular to the axis of the bowel. The anvil half is placed across the bowel and aligned with the cartridge. This effectively occludes the bowel as the GIA stapler is closed. Proper positioning is confirmed, and the stapler is fired by steady forward motion on the pusher-bar knife assembly. Upon release of the assembly and opening of the GIA handles, two double-staggered staple lines are noted with the intervening bowel transected. The
FIGURE 43.11. Small bowel resection with side-to-side (functional end-to-end) staple anastomosis. A: The two halves of the gastrointestinal anastomotic (GIA) stapler are passed through the mesenteric window and secured across the bowel. B: The GIA stapler has been fired proximal and distal to the abnormal bowel. Staggered double staple lines are noted to occlude each segment. Extent of mesenteric resection is tailored to the case-specific disease process. (Continued)

same steps are carried out at the distal site for transection (Fig. 43.11).

For benign disease, the mesenteric resection can be carried out in close proximity to the bowel, with no need to remove an intervening wedge. The objective is to preserve as much intact mesenteric blood supply as possible. The peritoneum overlying the mesentery is opened with cautery. Visual inspection and transillumination help to identify mesenteric vessels, which are clamped, cut, and suture-ligated using 2-0 silk ligatures. Division of the mesentery completes the resection. In preparation for anastomosis, tissue attachments are cleared 5 mm from both stapled bowel edges to avoid incorporation of mesenteric fat.

**Staple Anastomosis**

Staple end-to-end anastomosis in the small bowel is rarely used because of excess narrowing of the lumen. More favorable are the staple side-to-side anastomotic techniques that are functionally likened to an end-to-end anastomosis. Staple end-to-end techniques are more aptly used to create an anastomosis between two segments of large bowel following transverse colectomy or rectosigmoid resection.

**Side-to-Side (Functional End-to-End) Staple Anastomosis**

The side-to-side functional end-to-end staple techniques have gained wide acceptance because of the technical ease, availability of reliable instruments, and capacity to join bowel lumens of different diameters. Following resection, the occluded bowel ends are juxtaposed with the antimesenteric edges aligned in parallel along a distance of approximately 8 cm. This alignment is secured by a seromuscular 3-0 silk suture placed at the proximal end. Mayo scissors are used to excise a full-thickness oblique segment from the antimesenteric corner of each staple-occluded bowel segment. The anvil half of the GIA stapler and the cartridge half are inserted into each enterotomy (Fig. 43.11). The stapler is secured into position by closing the lock lever such that the antimesenteric borders are aligned. Proper positioning is confirmed, and the instrument is fired by sliding the pusher-bar knife assembly forward, and then returning it to the neutral position. This maneuver delivers two double-staggered staple rows and cuts the intervening bowel walls. The GIA instrument is disengaged and removed. The resultant enteroteroenterostomy is inspected to ensure patency, viability, and hemostasis.

The open bowel edges are grasped with Allis clamps, and a linear thoracoabdominal (TA) stapler is placed across the common lumen, ensuring that full-thickness bowel wall is circumferentially elevated above the staple line. After releasing the safety, the TA stapler is fired via steady closing grip on the handles. Excess tissue above the edge of the stapler is excised, and the instrument is released. Luminal capacity is evaluated by transmural palpation between the thumb and index finger, moving in a circular motion to outline the two layers of bowel wall (in contrast to the four palpable layers proximal to the common lumen). Oversewing the staple line is unnecessary unless there is concern regarding the anastomotic integrity. An open variation of this technique is such that after resection, the ends of the in situ bowel are not occluded. Atraumatic bowel clamps, protective moist laparotomy pads, irrigation, and povidone-iodine-soaked gauze reduce enteric contamination. The antimesenteric borders are aligned and secured as described above. The anvil half of the GIA stapler is introduced through one open bowel lumen, and the cartridge half is introduced through the other. The GIA stapler is locked and fired along the antimesenteric borders, and the TA stapler is used to close the resultant common enterotomy. These staple techniques are also ideal for joining bowel segments of discordant diameters (i.e., ilocolonic anastomosis). The ileum and colon are aligned and secured in parallel along their antimesenteric borders. An enterotomy and colotomy are made
FIGURE 43.11. (Continued) C: Full-thickness corners are sharply excised from the antimesenteric end of each bowel segment. The anvil and cartridge halves of the GIA stapler are inserted into each enterotomy. D: An open variation of this technique is such that the bowel segments are not occluded, and the GIA anvil and cartridge are introduced through each open lumen. E: Using either closed or open techniques, the GIA stapler is locked into position along the antimesenteric borders and fired by forward motion on the pusher-bar knife assembly. F: Firing the GIA stapler establishes a common enterotomy. G: The thoracoabdominal (TA) stapler is used to secure the open ends. Full-thickness bowel wall is circumferentially elevated above the staple line before firing. H: Shown is the resultant side-to-side functional end-to-end anastomosis. The mesenteric defect is closed with interrupted 3-0 silk sutures.

through which the anvil and cartridge halves of the GIA stapler are placed to initiate the anastomosis as described earlier. Proper alignment minimizes the residual large bowel segment that extends beyond the anastomosis, which is at risk for nonfunction and progressive symptomatic dilation (blind loop syndrome).

Side-to-Side Staple Anastomosis
Side-to-side techniques are less commonly used than they once were and have largely been replaced by end-to-end or functional end-to-end anastomoses. Nevertheless, side-to-side techniques are an effective means of reanastomosis, and they can be used to bypass an obstructed intestinal segment. Either hand-sewn or staple closure may be used. The antimesenteric borders are aligned, and the bowel segments are overlapped along 8 cm and secured into position such that the stapled bowel edges are at opposite ends of this alignment. Subsequent steps taken for the staple method are as previously described.

End-to-End Hand-Sewn Double-Layer Anastomosis
In performing an end-to-end anastomosis, it is desirable to have adequate and equivalent lumens in both the proximal and distal segments. The diameter of any lumen can be increased
Intestinal Tract in Gynecologic Surgery

FIGURE 43.12. End-to-end hand-sewn double-layer small bowel anastomosis. A: The bowel segments are aligned end-to-end and secured by stay sutures placed midway between the mesenteric and antimesenteric borders. Each luminal diameter is increased via a linear incision along the antimesenteric border (Cheatle slit). B: The inner running layer is started on the mesenteric (posterior) bowel edges. A double-arm needle facilitates bidirectional sewing as the closure continues around the corners onto the antimesenteric (anterior) edges. C: The anterior inner layer is completed in a continuous over-and-over or Connell suture (shown). D: The bowel is rotated 180 degrees to expose the posterior wall. Interrupted seromuscular 3-0 silk sutures are placed to finish the posterior outer layer. E: The bowel is rotated back into its normal alignment, and the anterior outer layer is closed with interrupted silk Lembert sutures. The mesenteric defect is reaproximated, and the adequacy of the lumen is assessed. Inset: Conventional inner layer inverting technique.

by transecting the bowel obliquely or via linear incision along the antimesenteric border (Cheatle slit). Atraumatic linen-shod or rubber-shod intestinal clamps are placed across the proximal and distal bowel to decrease intestinal spill. The bowel segments and mesenteries are aligned and secured by 3-0 silk seromuscular sutures placed midway between the mesenteric and antimesenteric borders. The traditional two-layer anastomosis includes a running inner layer of 3-0 chromic catgut and an outer layer of interrupted 3-0 silk sutures (Fig. 43.12).

The inner layer is closed first, starting on the mesenteric (posterior) bowel edges and continuing the closure around to incorporate the antimesenteric (anterior) edges. This is best accomplished with a double-arm needle, sewing in both directions. Suturing begins on the mucosal side, passing from in to out, and then out to in, bringing the inverted bowel edges together. Full-thickness tissue bites are initiated approximately 3 mm from the edge and advanced approximately 3 mm between throws. After circumferential closure, the knot is tied toward the lumen, and the bowel is rotated 180 degrees to expose the posterior wall. Rotation is facilitated by passing one stay suture through the mesenteric defect, with sustained counterclockwise rotational traction on both stay sutures. Interrupted seromuscular 3-0 silk sutures are placed to complete the mesenteric (posterior) outer layer. The bowel is rotated back 180 degrees into its normal anatomic position, and the anterior outer layer is lastly closed with interrupted silk Lembert sutures. If the bowel cannot be rotated, the mesenteric (posterior) outer segment must be sewn first.
Side-to-Side Hand-Sewn Anastomosis

For hand-sewn technique, 5 cm-length parallel linear enterotomies are made along the antimesenteric borders of each bowel segment. Elevation of the anterior bowel wall with gastrointestinal forceps during incision will reduce the likelihood of posterior wall injury. A row of interrupted 3-0 silk sutures are placed in Lembert fashion to join the posterior outer edges of the enterotomies. A running absorbable 3-0 suture is then used on the posterior inner layer sewing toward the surgeon and continuing around to the anterior edges of the enterotomies. The two suture ends are tied together across the anastomosis. The final anterior outer layer is placed using interrupted seromuscular sutures of 3-0 silk in Lembert fashion. Stay sutures are secured or removed, and the anastomosis is checked for integrity.

As a modification to the aforementioned procedure, the initial posterior layer of interrupted 3-0 silk Lembert sutures are placed before performing the enterotomies (Fig. 43.13). Silk sutures are placed such that the knots are secured on the outside. Parallel enterotomies are made approximately 4 mm above and below the edges of the suture line. The remaining steps in the anastomosis are completed as described previously.

Blood Supply to the Large Intestine

The SMA arises from the abdominal aorta and gives rise to the ileocolic, right colic, and middle colic arteries, which supply the right and transverse portions of the colon. The inferior mesenteric artery (IMA) also arises from the abdominal aorta and gives off the left colic and sigmoid branches, which supply the descending and sigmoid colon. Each of these major vessels divides into numerous smaller branches, forming an anastomotic arcade that communicates from the cecum to the rectum via the marginal artery of Drummond. The marginal artery gives off numerous terminal vasa recta that directly supply the colon (Fig. 43.14). Arterial perfusion is thus preserved to any segment of the colon as long as the marginal artery is not disrupted. The marginal artery, however, is absent at the hepatic or splenic flexure in 1% to 2% of the population. This anatomic inconsistency most often affects the left side, such
that colon resection in this area should include removal of the splenic flexure. Again noted is the tenuous ileocolic blood supply, such that if the cecum is resected, 10 cm of terminal ileum should also be removed. The rectum derives its oxygenation from the IMA via the superior rectal artery and from the hypogastric artery via the middle and inferior rectal arteries. An elaborate anastomotic lattice with other pelvic vessels encircles the rectum and anus.

Large Bowel Resection

The principles important in large bowel resection and anastomosis are essentially the same as those described previously for the small bowel. Segmental colon resection in gynecologic surgery is most commonly necessary because of malignancy or radiation injury. The gynecologic surgeon may also encounter benign conditions that require resection, such as severe endometriosis, diverticular disease, extensive adhesions, or non-reparable colonic injury. Large bowel resection for benign gynecologic conditions does not require segmental wedge resection of the mesentery. The integrity of the marginal artery is protected when the mesentery is transected close to the bowel wall through the vasa recta.

Mobilization of the Colon

The majority of large bowel resections require some degree of mobilization to ensure a tension-free anastomosis. The general objectives of colon mobilization are to gain retroperitoneal access and transect avascular attachments from the splenic and/or hepatic flexures. If needed, additional mobility is acquired via transecting the gastrocolic ligament and infracolic omentum if necessary. Also, the inferior mesenteric artery can usually be sacrificed without significant compromise because of the rich vascular network surrounding the rectum. Mobilization can be carried out before or after the segmental colon resection, depending on the clinical situation. To free the right colon, retroperitoneal dissection is initiated at the base of the cecum and continued lateral and parallel to the ascending colon along the white line of Toldt. This
Related Surgery

is aided by medial traction on the ascending colon. The hepa-
tocystocolic ligament is transected as dissection is carried into
Morison’s pouch and along the proximal transverse colon. Mo-
bilization of the left colon is initiated at the most distal site of
retroperitonealized sigmoid colon, which is usually located at
the pelvic brim. With medial retraction on the bowel, a peri-
toneal incision is made lateral and parallel to the descending
colon. Dissection is continued around the splenic flexure as the
lienocolic and phrenicocolic ligaments are transected. Exces-
sive traction is avoided to prevent splenic capsule injury. The
left lateral portion of the gastroscolic ligament is divided to ac-
cess the lesser omental sac. This ligament can be completely
transected along the transverse colon by dividing the anteri-
oral vessels. If necessary, division of the gastroscolic ligament
is accomplished along the greater curvature of the stomach by
dividing the gastrotroplic and short gastric vessels.

End-to-End Staple Anastomosis

Transverse colon resection is used as an illustrative example
of this technique. After completing the resection and mobili-
zaion of the left and right colon, the proximal and distal bowel
edges are brought into close opposition. Their mesenteries are
aligned, and seromuscular 3-0 silk sutures are placed, dividing
the bowel circumference into equal one-third segments. The
mesenteric (posterior) segment of the anastomosis is completed
first. Bowel rotation of 180 degrees is facilitated by counter-
tickness bowel walls into the noncutting TA stapler. The sta-
pler is positioned such that the staple line extends just beyond
the lateral edge of both stay sutures. Steady closing grip se-
cures the device into position. After confirming proper placement,
the safety latch is released, and firm closure of the handles fires the
staple line. Excess tissue is sharply excised, and the stapler is
released (Fig. 43.13).

The bowel is rotated back 180 degrees to its normal
anatomic alignment. The two remaining equal segmental
staples are stapled from the serosal side in similar fashion. Alterna-
tively, if the bowel is not easily rotated, the mesenteric (poste-
rior) segment can be stapled first from the mucosal side. The re-
maning segments are closed from the serosal side as described
earlier. Slight overlap of adjoining staple lines ensures complete
_closure without hindering anastomotic healing. Aderacy of the
lumen, integrity of repair, and hemostasis are confirmed
before closing the mesenteric defect.

Sigmoid Resection

The appropriate site for sigmoid transection is identified prox-
imal to the area of diseased bowel. A small mesenteric opening
is made adjacent to the colon, through which the GIA cartridge
is introduced. The GIA anvil is placed across the bowel, and
the stapler is secured and fired, resulting in a transected sigmoid
with occluded proximal and distal segments. Most laparotomy
wetls are used to pack the proximal segment above the surgi-
cal field. The mesenteric peritoneum is opened adjacent to the
bowel, and the incision is continued parallel to the sigmoid as
the mesenteric transitions from a medial to a posterior insertion
(Fig. 43.16). Moist laparotomy towels are used to pack the prox-
imal segment above the surgical field. The mesentery is divided
with cautery and sharp dissec-
tion. Blunt retroperitoneal dissection between the medial ureter
and lateral hypogastric vessel exposes the perirectal space. En-
try into the retrorectal space is aided by lifting the transected
sigmoid. Retrorectal dissection is carried out to release the rec-
tum from its attachments along the sacrum. Care is taken to
avoid laceration of the presacral veins. The uterosacral liga-
ments are transected to gain exposure toward the distal rectum as
the ureters are retracted laterally with a handheld malleable
retractor. The rectal stalks are secured by dividing and ligating
the posterior portion of the cardinal ligaments.

The extent of required dissection depends on the location
and severity of disease. For nonmalignant pathology, dissection
beyond the pelvic peritoneal reflection and levator ani is rarely
necessary and may actually disrupt the blood supply. When
normal rectum has been isolated below the diseased segment,
the rectosigmoid resection can be completed. Pericolonic tis-
sue attachments are cleared to expose smooth bowel wall. The
Newly described stapled anastomosis incorporates only the rectum. The stapler is locked into posi-
tion, checked for proper alignment, and fired by firm closure of the handles. Occluding clamps are placed across the bowel just
above the staple line, and sharp dissection is used to transect
the rectum and complete the resection.

The number of total laparoscopic sigmoid resections and
hand-assisted laparoscopic sigmoid resections has increased
significantly in recent years. Reports of clinical experience to
date suggest comparable morbidity in comparison to open pro-
cedures, and endoscopic resection may offer the advantage of
more rapid postoperative recovery. Timing of surgery is also
an important factor to consider. For example, in patients with
a history of diverticular disease, the morbidity associated with
elective sigmoid resection is reportedly less than with resection
during an acute bout of diverticulitis.

Rectosigmoid End-to-End Staple Anastomosis

Before anastomosis, the descending colon is laid in the pelvis
to ensure the colon and rectum can be approximated without
tension. Redundant laxity of the colon should be observed.
Any resistance or tension indicates the need for additional
mobilization. The descending colonic lumen is occluded via
an atraumatic clamp, and the staple line is sharply excised.
The appropriate diameter end-to-end anastomosis (EEA) stap-
pler is selected based on the largest EEA obturator that can
be placed into the lumen without undue stretch on the bowel
wall. One milligram (one ampule) of intravenous glucagon
causes relaxation of the muscularis and allows more accurate
sizing.

Various designs of the EEA stapler exist, but generally
the proximal portion consists of an anvil with a spike. An auto-
purse string or hand-sewn purse string is placed circumferen-
tially around the open end of the descending colon. The anvil
is positioned within the lumen, and the purse string is secured
around the base of the spike, the tip of which is directed to-
ward the rectal stump. The anus is digitally dilated, and the
lubricated shaft of the EEA stapler is introduced into the anal
canal. The shaft is visually and manually guided to the apex
of the rectal stump. Clockwise rotation of the central wing nut
advances the sharp trocar to pierce the apex of the rectal stump.
The trocar is removed, leaving the hollow center shaft of the
EEA in place through the rectum. The anvil spike from the descen-
ding colon is guided into the hollow center shaft of the
EEA. The bowel remains within the hollow center shaft of the
rectal stump until it locks into place (Fig. 43.17). The central
wing nut is further rotated clockwise until the indicator line
End-to-end colon staple anastomosis. A: The colon segments are aligned end-to-end, and 3-0 silk sutures are placed to divide the bowel circumference into equal one-third segments. Inset: The mesenteric (posterior) bowel edges are joined first. The bowel is rotated 180 degrees counterclockwise. This is done by passing stay suture (y) through the mesenteric defect, with continued counterclockwise rotational traction on sutures (z) and (y). B: The thoracoabdominal (TA) stapler is used to close the posterior segments. Full-thickness bowel walls are lifted above the staple line with Allis clamps. C: After firing the stapler, excess tissue is sharply excised. The bowel is then rotated 180 degrees clockwise into its normal alignment. (Continued)

is readily visible in the indicator window. This rotation draws the rectum and sigmoid colon into direct opposition. Normal anatomic alignment of the mesentery is confirmed. The safety is released, and steady, firm closure of the handles fires the instrument. The handles are released, and the central wing nut is rotated counterclockwise two complete turns. A gentle rocking motion back and forth frees the instrument tip from the anastomosis, as the EEA shaft is slowly withdrawn from the rectum.

The anastomotic integrity is confirmed by a series of checks. First, the staple line is visually and manually inspected. Second, the EEA instrument is inspected for two complete 360-degree tissue rings. This confirms circumferential stapling and resection of both the colonic and rectal segments. Third, the pelvis is filled with sterile crystalloid, and a rigid sigmoidoscope is used to insufflate the bowel. Manual occlusion of the proximal sigmoid ensures adequate testing pressure across the anastomosis. The anastomosis is observed while underwater, looking for air bubbles that would indicate an anastomotic leak (Fig. 43.18). Rigid sigmoidoscopy also allows direct internal inspection of the staple line. If any of these methods suggest an incomplete anastomosis, the area in question is reinforced with interrupted 3-0 silk sutures, and the integrity is retested. Care is taken to avoid vascular compromise as the mesenteric defect is closed with interrupted sutures.

Postanastomotic morbidity and symptoms are largely related to the amount of residual rectum at the time of repair. Patients with a high colorectal anastomosis (11 cm or more
related surgery have relatively low morbidity and excellent functional results. Those who have undergone a low anastomosis (between 7 and 11 cm) have intermediate levels of morbidity, but generally have satisfactory functional results after several months of physiologic adaptation. In contrast, patients with a very low colorectal anastomosis [less than 7 cm from the anal verge] are at highest risk for complications, including anastomotic leak. These patients are also more likely to have chronic symptoms of gastrointestinal frequency, urgency, and incontinence. The sigmoid J-pouch for rectosigmoid anastomosis provides a reservoir that may decrease the frequency of stools and reduce the incidence of incontinence (Fig. 43.19). Accordingly, the J-pouch is considered if resection leaves less than 7 cm of rectum and if the colon is redundant enough to

FIGURE 43.15. (Continued) D: The two remaining one-third segments are closed with the TA stapler in similar fashion. E: The end-to-end repair is complete. Stay sutures are secured or removed, and the anastomosis is evaluated for integrity. Alternative method: F: If the bowel cannot be effectively rotated, the mesenteric (posterior) one-third segment is closed first, using the TA-stapler applied to the mucosal surfaces. G: Excessive tissue is sharply excised. The two remaining one-third segments are closed from the serosal surfaces as described.
FIGURE 43.16. Sigmoid resection. A: An appropriate site for sigmoid transection is identified proximal to the area of diseased bowel. The amount of mesentery removed depends on the disease process. For most gynecologic conditions, an extensive mesenteric resection is not necessary. B: The gastrointestinal anastomosis stapler is used to divide the sigmoid colon. Sigmoid mesentery is transected by clamping, cutting, and securing the vessels with suture ligatures. C: The rectovaginal, retrorectal, and perirectal spaces are opened. Dissection is carried out until normal rectum is isolated below the diseased segment. The thoracoabdominal stapler is fired to occlude the rectum, which is then sharply excised to complete the resection.
FIGURE 43.17. End-to-end rectosigmoid staple anastomosis. A: A purse-string suture holds the anvil and spike within the sigmoid lumen. The end-to-end anastomosis (EEA) stapler is inserted transanally. Clockwise rotation of the central wing nut advances the sharp trocar to pierce the apex of the rectal stump. In this illustration, the trocar has been removed, and the hollow center shaft of the EEA remains in place. B: The spike and hollow center shaft are locked into position. Further rotation of the EEA central wing nut brings the sigmoid and rectum into direct opposition. The stapler is fired to deliver dual circular staple rows, as the knife transects the central tissue core to complete the anastomosis.

allow tension-free pouch construction. Postoperatively, some patients have a sense of incomplete evacuation and require suppositories or enemas.

Anastomotic leak is more common in colorectal anastomoses than in colon-to-colon anastomoses, in part because the rectum has no serosa. In ovarian cancer surgery, the estimated incidence of clinically significant anastomotic leak is 3% to 5%. Traditionally, a temporary diverting colostomy or ileostomy has been used to protect the distal colonic anastomosis. Clinical studies do not support the notion that routine protective intestinal diversion reduces the risk of anastomotic breakdown. Diversion of fecal contents, however, may reduce the severity of infectious complications if a leak occurs.

Selective intestinal diversion may be of benefit in cases of very low rectal anastomosis, prior radiation, unprepared bowel, and abscess or hematoma in the perianastomotic region.

End-to-Side Staple Anastomosis

End-to-side anastomotic techniques are advantageous for intestinal closure when the anorectal region is not readily accessible (e.g., supine position) or when access is not necessary to complete the closure (e.g., ileocolonic or high rectosigmoid anastomosis). A high rectosigmoid repair is used for illustrative purposes. Following sigmoid resection, a small colotomy
FIGURE 43.18. Testing the anastomotic integrity. The pelvis is filled with sterile crystalloid. The descending colon is manually occluded as air is insufflated via a rigid sigmoidoscope to create pressure across the anastomosis. Holding the anastomosis under water, it is examined for air bubbles that would suggest an anastomotic leak.

is made 3 to 4 cm from the end of the descending colon. The EEA instrument is introduced through the open lumen, and the hollow center shaft is advanced through the colotomy. The instrument is positioned such that the tip of the EEA rests perpendicular to bowel wall. A purse-string suture is used to secure the anvil spike within the rectal lumen. The end of the rectum is brought into close proximity with the side of the descending colon as the anvil spike is secured into the EEA hollow center shaft. Clockwise rotation of the central wing nut brings the bowel edges into direct opposition. Rotation is continued until adequate closure is confirmed via the indicator window. The stapler is fired by closing the instrument grips. Counter-clockwise rotation of the wing nut, followed by a subtle back-and-forth rocking motion, frees the instrument from the staple line. The open end of the descending colon is repaired using the TA stapler as previously described, and the integrity of the anastomosis is assessed.

End-to-End Hand-Sewn Single-Layer Colon Anastomosis

Before the common availability of surgical staplers, intestinal anastomoses were accomplished using hand-sewn techniques. Suture is still preferred over staple repair by some surgeons. Anastomosis can be accomplished using a single layer of delayed absorbable monofilament suture (small or large intestine) or nonabsorbable suture for large bowel (i.e., 4-0 polypropylene). The continuous closure has been proven efficacious in colon-to-colon repair and is used for this illustration. The bowel segments and mesenteric edges are aligned and secured with stay sutures. Suturing begins on the mesenteric (posterior) mucosal edges and is facilitated by a double-arm needle. The running stitch is carried out such that the needle enters near the transected mucosal edge and passes obliquely through the bowel wall to exit the serosa approximately 5 mm from the edge. The needle is passed through the adjoining segment in the same oblique fashion. Sequential tissue bites are placed 2 to 3 mm apart. This effectively inverts the bowel wall as the running suture is secured (Fig. 43.20). Bidirectional suturing is continued around the corners onto the antimesenteric (anterior) surfaces, which are closed from the serosal side. The Gambee single-layer technique is an equally effective method

FIGURE 43.19. Rectal J-pouch coloproctostomy.
that results in end-to-end opposition of bowel edges without puckering the mucosa.

The interrupted single-layer anastomosis has generally been done as a closed technique designed to minimize intraoperative spill of enteric content. This closed technique is infrequently used today, but still plays a role in selected cases of unprepared bowel, especially those involving the colon. A pair of atraumatic clamps is placed across the lumen at both the proximal and distal sites for resection. The bowel is sharply transected between these paired clamps, and the mesenteric resection is completed as previously described. All bowel lumens remain occluded by a surgical clamp. The cut edges are held in close proximity with their respective mesenteries aligned. Interrupted 3-0 silk Lembert sutures are passed full thickness through the bowel wall, being placed approximately 3 mm apart until they encompass the entire circumference. Some surgeons prefer to exclude the mucosa, because this adds no strength and may contribute to local tissue ischemia. Gentle traction and countertraction are applied along the untied sutures to guide the opposing bowel edges together. As the clamps are slowly removed, the sutures are tied. Patency of the lumen is assessed, and any insecure anastomotic areas are reinforced with additional sutures.

Colostomy

A colostomy should include tension-free bowel with uncompromised blood supply. The colon remains viable only about 2 cm beyond the closest intact vasa recta. The abdominal wall aperture must be generous enough to allow easy passage of the bowel with its intact mesentery, because even mild constriction may result in venous congestion, tissue edema, and necrosis. In gynecologic surgery, temporary colonic diversion may be necessary because of severe radiation injury (proctosigmoiditis), distal obstruction, perforation, or fistula. Permanent colostomy may be required if the rectum has been completely resected or is unacceptable for anastomosis. A diverting colostomy can also provide emergent decompression in the setting of complete large bowel obstruction at risk for perforation.

Perioperative Considerations

Preoperative consultation with an enterostomal therapist is very important in the perioperative planning and care. Counseling sessions, reading materials, support groups, and contact with other ostomy patients provide educational and emotional benefit. In nonemergent cases, the stoma appliance can be worn preoperatively to determine appropriate positioning and clarify postoperative expectations. The stoma should be located in an area that is easily seen and reached by the patient (Fig. 43.21). The tentative stoma site is marked preoperatively with indelible ink. As a general guide, a line is drawn connecting the anterior-superior iliac spine to the umbilicus, and the colostomy is exteriorized through the rectus muscles at some point along this line. Placement is avoided within skin folds, surgical scars, and the umbilicus because the appliance will not seal securely with these skin irregularities.

Postoperatively, the enterostomal therapist can assist in teaching the patient independent ostomy care. Daily inspection is important to ensure tissue viability, adequate function,
and nonretraction of the stoma. If tissue viability is in question, closer investigation under bright light is warranted. Insertion of a glass test tube or syringe with penlight transillumination allows for an easy bedside inspection of the internal bowel wall. If tissue viability remains uncertain, an anoscope or sigmoidoscope can be used. Focal ischemia is suggested if the mucosa is gray or dusky in appearance. Tissue necrosis distal to the skin edge may be safely observed and reevaluated after tissue sloughing has occurred. Surgical correction is generally unnecessary in this setting. Deeper and more extensive necrosis indicates compromised blood flow and the need for colostomy revision. Excessive retraction, stricture, or peristomal herniation may also require surgical correction. Some patients with an end sigmoid or descending colostomy prefer irrigation management over a collection appliance. Motivation, capacity for self-care, and relatively normal preoperative bowel function are requisite. Irrigation is started early in the postoperative period and is continued on a daily basis thereafter. The eventual goal is fecal continence between irrigations. Irrigation can also help reduce stoma odor and flatus, which can be further suppressed with a charcoal-based stoma cap. Some patients will develop predictable evacuation patterns which can be further suppressed with a charcoal-based stoma cap. Some patients with an end sigmoid or descending colostomy prefer irrigation management over a collection appliance. Motivation, capacity for self-care, and relatively normal preoperative bowel function are requisite. Irrigation is started early in the postoperative period and is continued on a daily basis thereafter. The eventual goal is fecal continence between irrigations. Irrigation can also help reduce stoma odor and flatus, which can be further suppressed with a charcoal-based stoma cap. Some patients will develop predictable evacuation patterns such that irrigation is eventually not required. Others will be satisfied with the security of a continuous appliance.

**End Colostomy Technique**

Efforts are made to create the stoma at the site marked on the abdominal wall preoperatively. The bowel selected for use should be adequately mobilized so the distal end can be brought beyond the abdominal wall by several centimeters. To fashion the abdominal wall aperture, a 3-cm diameter circle is drawn on the skin at the marked site. Symmetry is aided by a circular guide such as the flat, round end of a 60-cc syringe plunger. Dissection is carried through the skin and subcutaneous tissue to the level of the rectus fascia. A core of subcutaneous adipose tissue is not necessarily removed. Cruciate incisions are made in the anterior rectus sheath, with each incision being approximately 4 cm in length. The rectus muscle fibers are bluntly separated until the posterior rectus sheath and peritoneum are reached, through which similar cruciate incisions are made. When separating the rectus abdominis muscle, care is taken to avoid injury of the inferior epigastric vessels. All layers of the abdominal aperture are manually dilated and should easily admit three fingers without stricture.

A Babcock clamp is inserted through the aperture to grasp the colon for exteriorization. The bowel is brought through the abdominal wall, such that the occluded end rests easily above the skin surface without tension. Large epiploic appendices can be removed with electrocautery if needed to ease exteriorization. Tissue viability is assessed to ensure uncompromised blood flow. Interrupted 3-0 silk seromuscular sutures are fixed to the posterior and anterior rectus sheaths to secure the alignment and reduce the chance of retraction or herniation. The lateral paracolic gutter is obliterated to prevent small bowel herniation. Maturation of the stoma is deferred until after the abdomen is closed. Any remaining surgical objectives are completed, and the peritoneal cavity is irrigated and checked for hemostasis. The intraperitoneal and extraperitoneal bowel is again inspected before closing the surgical wound. After closure, the incision is protected with collodion or sterile towels. The exteriorized colon is opened, and the cut edges are observed for bleeding to ensure viability. Excessive bowel is trimmed such that approximately 2 to 3 cm remain above the skin surface. If viability is questionable, the edges are trimmed further until adequate blood flow is confirmed.

The stoma is matured using interrupted delayed absorbable sutures (3-0 polyglycolic acid). Stitches are initiated at the skin surface and carried in and out through the seromuscular bowel wall approximately 2 cm from the distal end and then full thickness through the cut bowel edge (Fig. 43.22). Sutures are placed circumferentially at about 5-mm intervals. As the sutures are tied, the everted bowel wall is folded back on itself. The result is a slightly protruding stoma that enables a better appliance fit and is less prone to retraction. In patients with a thick abdominal wall, it may not be possible to evert the stoma. In this scenario, a stoma flush with the skin surface is matured by securing the skin to full-thickness bowel edge using interrupted sutures. The appliance is fashioned and secured intraoperatively.

**Diverting Loop Colostomy**

A loop colostomy is technically less difficult to create and/or reverse than an end colostomy. This is a good technique when a temporary diverting colostomy is needed, and it can often be accomplished through a single incision. Readily mobile transverse or sigmoid colostomy is preferred. As a general rule, the loop colostomy is fashioned from the most distal site along the bowel.
FIGURE 43.22. End colostomy. Technique for creating a bowel stoma that is elevated from the skin surface. This everted stoma is developed by excising a 3-cm circumferential segment of abdominal wall (A), anchoring the skin margin with the adjacent wall of the exteriorized bowel (B), and approximating the mucosal edge of the bowel to the skin (C). The cross-sectional view demonstrates how the bowel wall is anchored to the skin margin to prevent retraction (D).

that can be effectively used. Factors to consider are that the transverse colon is generally outside of the previous surgical or radiation field and the transverse colon has a lower bacterial count than the more distal colon. Alternatively, use of the sigmoid preserves a greater length of intact bowel. The traditional loop colostomy is described for illustrative purposes and uses the transverse colon with the stoma created in the left upper quadrant.

In comparison to an end colostomy, a larger aperture is required to bring two full segments of colon and intervening mesentery through the abdominal wall. A stoma site is selected overlying the rectus muscle, which avoids skin folds, surgical scars, and the umbilicus. A transverse incision is carried down through the anterior rectus fascia. Two evenly spaced, perpendicular fascial incisions can be used to increase the diameter of this aperture. The rectus muscle fibers are bluntly separated, and the posterior rectus sheath and peritoneum are incised in a manner similar to that of the anterior fascia. The opening is manually dilated and should easily admit four fingers without stricture.

The transverse colon is identified by the presence of teniae and the omental attachment. Once isolated, the bowel is lowered in a hand-over-hand fashion until the most distal yet readily mobile segment is brought through the abdominal wall. Lifting the loop is simplified by using a half-inch diameter Penrose drain passed under the intestine. A bridge device is also passed through the adjacent mesenteric window and positioned onto the skin, thereby supporting the bowel loop above the skin surface. Fascial supporting sutures are generally not necessary as the normal healing process scars the stoma into position. Any extra length of the abdominal incision is closed. The stoma is matured by a sharp longitudinal incision through the teniae that is extended to within 1.0 cm of the skin edge at both ends. The stoma edges are everted and secured with interrupted skin to full-thickness bowel sutures using 3-0 delayed absorbable material (Fig. 43.23).

The traditional Hollister bridge frequently precludes a secure appliance fit. A number of various supporting devices have been used effectively. We prefer a supporting bridge fashioned from a 20-French thoracostomy tube. A segment of about 20 cm length is cut and passed through the mesenteric window underneath the bowel. The ends are brought together over the bowel and sutured together to form a loop. This method requires no skin sutures, does not interfere with application of
the collecting bag, and permits secure adherence between the stomach wafer and skin. After adequate healing (10 to 14 days), the bridge is easily removed by cutting the suture to open the loop and withdraw the tube.

Variations of the loop colostomy include the double-barrel colostomy, in which the bowel is transected and both stomas are matured. An end colostomy with mucous fistula is used in the setting of distal obstruction, because the decompression provided by the mucous fistula avoids a closed loop obstruction. When the mucous fistula is placed immediately adjacent to the end colostomy, it is known as an end loop or terminal loop colostomy.

### GASTRIC PROCEDURE

#### Open Gastrostomy

A gastrostomy tube avoids prolonged nasogastric intubation when long-term gastric decompression is needed. This access route can also be used for enteral hydration, nutrition, and medication administration in patients who have an intact intestinal tract. Gastrostomy is avoided in obtunded patients and those with massive ascites, esophageal varices, coagulopathy, or extensive tumor that precludes tension-free placement. Other potential gastrostomy complications include bleeding balloon tension against the undersurface of the abdominal wall, which can lead to intraperitoneal leakage of gastric content with resultant abscess and/or peritonitis. Surgical exploration is necessary if the leak cannot be corrected by increasing balloon tension against the undersurface of the abdominal wall. Other potential gastrostomy complications include bleeding, tube malfunction, skin irritation, infection, and migration through the pylorus or gastroesophageal junction.

Endoscopic Gastric Procedures

Percutaneous procedures are currently available for patients in need of gastrostomy who are not undergoing laparotomy. Percutaneous endoscopic gastrostomy (PEG) and percutaneous endoscopic jejunostomy (PEJ) are performed under local anesthesia with intravenous sedation. The PEG tube is placed via endoscopic gastric insufflation and transillumination to guide percutaneous needle and guide wire placement through the abdominal wall. An introducer is passed transcutaneously into the stomach over the guide wire. The introducer is withdrawn, leaving a sheath through which the gastrostomy tube is inserted. As the sheath is peeled away, traction on the tube draws the flange and stomach wall into direct contact with the abdominal wall. Another external flange or fixation suture is used to secure the apparatus into position. Using similar endoscopic techniques, a jejunostomy tube can be guided through the pylorus and duodenum, into the jejunum.

BEST SURGICAL PRACTICES

- The gynecologic surgeon should have a basic understanding of the anatomy and physiology of the intestinal tract and should possess the fundamental skills necessary to recognize and correct common conditions affecting the digestive system.
- Peritoneal irritation from any source can be elicited by manipulation of the pelvic organs, such that manual manipulation of the cervix can create an intensely painful response (cervical motion tenderness) in women with either PID or appendicitis.
- Medical management is the cornerstone of treatment for inflammatory bowel disease (Crohn’s disease and ulcerative colitis), as intestinal surgery is reserved for obstruction, perforation, fistula, or hemorrhage. Elective gynecologic surgery is best avoided in patients with Crohn’s disease or ulcerative colitis because of the high risk of intestinal complications.
- In previously irradiated patients, elective surgical procedures within the radiation field should not be attempted.
- The objectives of prophylactic bowel prep are to reduce enteric volume and bacterial load. The literature, however, is inconclusive regarding the effectiveness of prophylactic bowel prep in reducing infectious complications and facilitating anastomotic healing.
- Prior gynecologic surgery is the most frequently noted pre-disposing factor to intra-peritoneal adhesions, with other risk factors being trauma, irradiation, infection, bleeding, and chemical irritants. An estimated 85% of all small bowel obstructions are secondary to intra-peritoneal adhesions, malignancies, or hernias, with the most common etiology being adhesions.
- The vast majority of large bowel obstructions are caused by malignancies or inflammatory conditions. In the setting of a large bowel obstruction, the risk of perforation increases significantly as the cecum is dilated beyond 10 to 12 cm. Barium enema should not be performed in the setting of acute colonic obstruction or suspected perforation to avoid barium peritonitis.
- If intestinal perforation occurs during introduction of a laparoscopic needle or trocar, it is prudent to leave the instrument in position to guide identification of the affected anatomy. Thermal injury from electrocautery or laser results in a progressive zone of tissue destruction that extends well beyond the area of thermal contact, resulting in tissue necrosis and perforation 72 to 96 hours after surgery. In contrast to sharp enterotomy, which can be repaired primarily, significant thermal injury is best corrected by resection of the affected bowel segment.
- Enterotomies are best avoided by cautious entry into the peritoneal cavity and meticulous dissection of adhesions. If an inadvertent enterotomy occurs, the affected bowel is mobilized from surrounding tissues to allow adequate exposure and a tension-free repair. Resection of an affected bowel segment may be necessary if the blood supply is compromised, if greater than 50% of the circumference is injured, or if irregular edges preclude reaproximation, or if repair would result in excessive luminal narrowing. Immediate repair of a large obstruction is necessary to prevent enterocolitis and sepsis.
bowel injury is associated with acceptably low morbidity and does not usually require a diverting colostomy. A diverting colostomy is indicated when a full-thickness colonic injury occurs in someone who has previously been irradiated, or who is profoundly malnourished, or who is unstable from shock or sepsis.

- Peritoneal drains should not be placed in the immediate vicinity of an anastomosis as this can impede healing.

- Current trends are toward much more aggressive early postoperative feeding, even in the setting of bowel resection and anastomosis. Use of the gut for nutrition is advisable whenever possible. Perioperative nutritional support is indicated in patients who have not been fed for more than 7 days before surgery, in those who are malnourished (weight loss exceeds 15% of usual weight), and in those whose expected duration of recovery is longer than 10 days.

- Therapeutic nasogastric decompression is indicated in symptomatic patients with an ileus who are perpetually nauseated, markedly distended, actively vomiting, and/or who are not responding to supportive measures. Decompression is generally continued until consistent flatus ensues and abdominal distention resolves. The typical radiographic pattern of an ileus is that of air-fluid levels in the stomach and small bowel with intermittent air throughout the entire gastrointestinal tract. In contrast to an ileus, radiographic characteristics of mechanical small bowel obstruction include proximal distended bowel loops with a paucity or absence of gas in the colon.

- Fewer than half of obstructed patients manifest the classic triad of rebound tenderness, guarding, and rigidity. If no complicating factors persist, approximately two thirds of distal intestinal fistulae are expected to heal within 6 weeks from nonoperative management. The more proximal the fistula, the greater the potential for physiologic rearrangement, and the less likely the chance of spontaneous closure. The fundamentals of conservative fistula management include correction of electrolyte abnormalities, resolution of underlying inflammatory processes, maintenance of adequate hydration, and nutritional support.

- Short bowel syndrome occurs when there is insufficient nutrient absorption to meet the body’s metabolic requirements because of extensive bowel resection or inadequate function of normal-length bowel. In general, 50% of the small bowel (300 cm on average) can be resected without long-term impairment of nutritional status, as long as there is normal function in the remainder of the intestine. For approximately 24 months after an intestinal resection, the remaining small bowel undergoes adaptation to increase the functional surface area via increasing villous height and crypt depth, and through gradual dilation and lengthening of the bowel.

- Strict adherence to the fundamental principles of anastomosis is more important to successful healing than are the specific techniques or materials used. Open anastomotic techniques (bowel lumens exposed) have gradually replaced closed techniques (lumens occluded) in most circumstances because of technical ease and acceptably low morbidity. The most important strength layer of the bowel wall is the submucosa, which must be incorporated into any anastomosis. Sixty percent of the bowel wall strength is reached by postoperative day 3 to 4, and pressure tolerated by the anastomotic site approximates 100% of that tolerated by intact bowel wall as of postoperative day 7. Clinical evidence suggests that single-layer anastomosis is equivalent to double-layer closure and may provide some advantages.

- In general, as much as 8 cm of small intestine can remain viable despite the loss of anastomotic vascular communications. It is recommended that ~10 cm of terminal ileum be removed during right colon resection because of the tenuous blood supply of the distal ileum. It is important to resect only the length of bowel necessary to adequately address the disease process. The diameter of any lumen can be increased by transecting the bowel obliquely or via linear incision along the antimesenteric border (Cheylet slit).

- Arterial perfusion can generally be preserved to any segment of the colon as long as the marginal artery of Drummond is not disrupted. The integrity of the marginal artery is protected when the mesentery is transected close to the bowel wall through the vasa recta. The marginal artery is absent at the hepatic flexure, or more commonly the splenic flexure, in 1% to 2% of the population. Colon resection near the splenic flexure should include removal of the flexure due to the arterial inconsistency in that region. The superior mesenteric artery (SMA) can be sacrificed during rectosigmoid resection, without significant compromise, because of collateral circulation from the middle and inferior rectal arteries. The colon remains viable when the close to the cecum, above the vasa recta. Subsequent to a rectosigmoid resection, morbidity is inversely related to the length of intact rectum at the time of repair.

- Preoperative consultation with an enterostomal therapist enhances surgical planning, patient education, and postoperative care. As a general guide, a line is drawn connecting the anterior-superior iliac spine to the umbilicus, and the colostomy is exteriorized through the rectus muscles at the anterior-superior iliac spine to the umbilicus, and the colostomy is exteriorized through the rectus muscles at this point along this line. The stoma is secured in an area that is easily seen and reached by the patient, and placement is avoided within skin folds, surgical scars, or the umbilicus.

- A loop colostomy is technically less difficult to create and/or to reverse than an end colostomy and can often be accomplished through a single incision. An end colostomy is more satisfactory from a long-term-care standpoint because it is generally smaller, easier to fit with an appliance, and usually more distal, resulting in formed stools. Maturation of the stoma is deferred until after the abdomen is closed.

CHAPTER 44  ■ NONGYNECOLOGIC CONDITIONS ENCOUNTERED BY THE GYNECOLOGIC SURGEON

JAMES R. DOLAN AND MICHAEL D. MOEN

DEFINITIONS

Air contrast barium enema—Sometimes called a “double-contrast” barium enema. The colon is filled with barium, and x-ray films are taken. The barium is then allowed to empty, leaving a thin film on the internal bowel wall. The colon is filled with air, making the colonic mucosa more easily seen. This is especially useful for diagnosis of polyps and inflammatory bowel disease.

Carcinomembryonic antigen (CEA)—A glycoprotein tumor marker that is elevated in the serum of many patients with colorectal cancer. It may also be elevated in patients with lung cancer. It is often elevated in patients who smoke cigarettes.

Hartmann procedure—The colon is divided or resected and an end colostomy is brought up. The distal colonic stump is stapled or sewn closed and left as is in the pelvis.

Methyl methacrylate—Cement used to anchor orthopedic screws or implants to bony structures. Excess cement may form a hard mass adjacent to the site of application, and this new mass may create a diagnostic dilemma.

Protrusio acetabuli—Inward protrusion of the femoral head through the inner wall of the acetabulum. This may be palpated as a hard pelvic wall mass. This condition can occur with rheumatoid arthritis, osteomalacia, Marfan syndrome, and other conditions.

Women of all ages look to their gynecologist to diagnose and treat problems that arise within the pelvis. Because the pelvis contains multiple organ systems, it is possible the gynecologic surgeon will unexpectedly encounter a nongynecologic condition. It is extremely important, therefore, that the gynecologic surgeon be aware of the various conditions that may be present in the pelvis and search for them preoperatively.

Preoperative evaluation should include lower gastrointestinal (GI) radiologic studies. The gynecologic surgeon should be aware that radiologic studies of the colon can be in error from 10% of the time in cooperative and well-prepared patients to as often as 50% in uncooperative or improperly prepared patients. A large number of colon lesions are missed on radiologic examination because they are not reliable in symptomatic patients. Approximately 50% of patients with documented colorectal cancer have a negative fecal hemoccult test. This is consistent with the intermittent bleeding patterns of these tumors and, if negative, may give the physician a false sense of security.

Preoperative evaluation should include lower gastrointestinal radiologic studies and possibly a colonoscopic examination, especially in patients with gastrointestinal symptoms. The gynecologic surgeon should be aware that radiologic studies of the colon are not reliable in symptomatic patients, but this may not be the true situation. Line drawings and representative computed tomography scanning (CT scans) depict various intestinal disorders that may seem to be an inflammatory or neoplastic disorder of the tube or ovary or both, but this may not be the true situation.

Even if the air-contrast barium enema is performed, a conscientious gynecologist should carefully and critically review the films with the radiologist before surgery is undertaken.

To ensure that the colon is properly prepared, the patient should be given instructions on how to clean the colon before the radiologic studies. On the day before the test, a regular breakfast is advised, but only clear liquids for lunch and dinner. Although cathartics and cleansing enemas are acceptable, the colon is best prepared by using an isotonic lavage solution (such as GoLYTELY or Colyte), which washes the colon clean.

In addition to being an invaluable aid in the detection of colon cancer and diverticulitis, the barium enema may detect appendicitis or an appendiceal abscess. Additionally, CT studies may be of tremendous benefit in delineating small bowel, colon, cecal, or appendiceal pathology. Figures 44.6 through 44.9 are examples of colonic pathology diagnosed by barium enema and CT studies.

Laparoscopy can be used to distinguish gynecologic disease and ileitis from appendicitis. If the diagnosis of appendicitis is made, laparoscopic appendectomy using ligatures or stapling devices can be performed.

Although the value of digital rectal examination and sigmoidoscopy in detecting lesions of the rectum and sigmoid cannot be overemphasized, the changing distribution of colon cancer makes colonoscopy more important in the diagnostic workup. Cohn and Nance have noted that the incidence of left-sided colon and rectal cancer in their 1950–1954 series was 78.6%, and right-sided colon and rectal cancer was 21.4%. In their 1975–1979 series, the incidence of left colon and rectal cancer had dropped to 68.4%, and the incidence of right-sided colon cancers had increased to 31.6%. McCallion and colleagues reported an increase in proximal colon cancers from 23.3% in 1970 to 36.7% between 1990 and 1997. If symptoms suggest colon pathology, even if the barium enema is reported normal, colonoscopy is indicated.

Unusual small bowel lesions may present as a pelvic mass; thus, small-bowel barium-contrast radiologic studies and CT scans often are helpful. CT scans are particularly useful in delineating mesenteric cysts (Fig. 44.10), volvulus of the small bowel, small bowel intussusception (Fig. 44.11), and Crohn’s disease of the ileum (Fig. 44.12), any one of which may prolapse into the pelvis and be mistaken for gynecologic pathology. Gastrointestinal stromal tumors (previously termed leiomyomas or
FIGURE 44.2. Cecal carcinoma. A: A cecal carcinoma en-croaching on the right adnexa can be mistaken for an ad-nexal condition. B: CT image shows a large neoplasm (ar-rows) extending from the cecum. leiomiosarcomas) may occur in the small bowel and present as a solid pelvic mass, which easily could be mistaken for a pedunculated uterine leiomyoma. These tumors appear as solid masses adjacent to normal bowel on CT scan.

Urologic Tumors

Urinary conditions that occur concomitant with or mimicking gynecologic disease include pelvic kidney, carcinoma of the distal ureter, tumors of the bladder wall, hemangopericytoma posterior to the bladder, and bladder cancers (Fig. 44.13). Figure 44.14 is a CT scan of a large urachal cyst. A routine urinalysis that reveals hematuria should alert the gynecologist to the possibility of urinary tract disease. A urine culture should be obtained; if an infection is present, the hematuria should clear after a course of antibiotic therapy. For those patients without infection or with persistent hematuria following antibiotic therapy, a cystoscopy and radiologic imaging of the upper urinary tract (intravenous pyelogram, CT scan, or renal ultrasound) are warranted.

A CT scan of the urinary tract before laparotomy in a patient with a pelvic mass may be helpful in diagnosing nongynecologic conditions. It establishes the function of the kidneys and determines the presence of a pelvic kidney or a partially obstructed distal ureter. When performing a bimanual examination, bear in mind that a large tumor of the distal ureter may be confused with an intraligamentous leiomyoma. Bladder tumors or bladder stones should be palpable anterior to the cervix and uterine fundus, and will not move with the uterus, as does an anterior uterine fibroid. Cystoscopy and retrograde pyelography are indicated in patients in whom suspicion of urinary tract disease is high and in patients who are allergic to the intravenous contrast media used for excretory urography and CT studies.

Retroperitoneal Tumors

Although gastrointestinal tract disease is the most frequent pathology mistaken for gynecologic disease, retroperitoneal

tumors occur often enough within the pelvis that the gynecologic surgeon must keep such tumors in mind, especially when dealing with vague or unusual pelvic symptoms and physical findings. Beck reported on seven collected series of retroperitoneal tumors and noted that the major symptoms include abdominal pain, abdominal mass or swelling, and weight loss or anorexia, or both. The symptoms depend on the location of the tumor in the retroperitoneal space. Retroperitoneal tumors in the pelvis may become manifest earlier than those in the abdomen because the bony confines of the pelvis cause pressure on adjacent organs earlier than in the upper abdomen. Sarcomas of the pelvic or buttocks muscles or bone will usually present with hip pain and leg edema.

Abnormal findings noted on an excretory urogram and on upper and lower gastrointestinal x-ray studies may be secondary to extrinsic involvement rather than intrinsic pathology. The most reliable tools for diagnosing retroperitoneal tumors are CT scanning and magnetic resonance imaging (MRI).

Figures 44.15 through 44.17 demonstrate CT and MRI images of retroperitoneal pathology.

If the tumor is a lymphoma, a careful history may elicit reports of fever, night sweats, pruritus, and weight loss. On physical examination, patients with a lymphoma may have skin nodules, enlarged lymph nodes, liver and spleen enlargement, and areas of joint or bone tenderness. On pelvic examination, large external iliac lymph nodes may be mistaken for an adnexal mass, but careful examination will often reveal that these firm, smooth masses bulge outward from the pelvic sidewall, where they are firmly fixed and the uterus remains viable. There is no nodular tumor or inflammatory induration in the cul-de-sac. Figure 44.18 illustrates a CT image of a patient with an ileocecal lymphoma and mesenteric adenopathy. A biopsy of a peripheral lymph node or skin nodule may establish the diagnosis of lymphoma and allow enough tissue for proper characterization of the correct subtype. Additionally, a core needle biopsy of the bone marrow can be helpful as a staging procedure for the lymphoma. Staging and response to therapy of lymphomas is currently performed with positron emission tomography scans and CT.

There are rare neurogenic tumors that can arise in the pelvis in addition to very rare anterior meningoceles and arachnoid cysts (Figs. 44.19 and 44.20). The most common are those that arise from the nerve sheath of the obturator or sacral nerve complex, which are the neurofibromas (often associated with von Recklinghausen disease) and the neurilemmomas. Tumors may develop from the sympathetic nervous system of the pelvis and include ganglioneuroma, sympathicoblastoma, and neuroblastoma. As with the lymphomas noted above, a firmly fixed mass bulging outward from the pelvic sidewall is often palpable on pelvic examination.
Soft-tissue sarcomas may occur anywhere in the retroperitoneal space. According to Adam and associates, these tumors are diagnosed most easily by CT scan, but ultrasonography, arteriography, and venography may be useful. Figure 44.21 demonstrates an intravenous urogram of a large pelvic neurofibroma with sarcomatous degeneration. Figure 44.22 demonstrates a CT scan of a large neurofibrosarcoma in the right sciatic notch in a 25-year-old patient with von Recklinghausen disease.

Lewis and colleagues reported on 500 patients with retroperitoneal sarcomas and found the most common were liposarcomas and leiomyosarcomas. Survival was inversely related to tumor size, and complete surgical resection with a tumor-free margin offered the best survival.

Orthopedic Disorders

Disorders that may arise from the bony pelvis include those that are congenital, iatrogenic, metabolic, or septic, as well as fractures and tumors. The congenital or developmental abnormalities include anterior sacral meningocele (discussed above), spondylolisthesis, and sacrococcygeal teratomas. Spondylolisthesis is a slow, forward displacement of the lumbar spine over
the sacrum. The degree of slip usually is not severe enough to cause significant impairment. If the entire fifth lumbar vertebra is displaced forward of the sacrum (spondylolisthesis), severe narrowing of the anteroposterior diameter of the pelvis and displacement of the pelvic viscera are noted. Pelvic examination is significantly abnormal. A pelvic radiograph or CT defines the problem.

Sacrococcygeal teratomas usually are diagnosed by age 2 or 3, but occasionally the dermoid forms are not discovered until early adulthood. These anomalies are four times more common in women, and malignant forms are more common in adults. Such lesions usually can be defined by ultrasonography and CT (Fig. 44.23).

Total hip arthroplasty has become commonplace since it was introduced in the 1960s. In some earlier cases, the inner wall of the acetabulum was penetrated, allowing the cement (methyl methacrylate) to flow into the pelvis to improve fixation. The cement produces a bony, hard mass fixed to the pelvic wall that varies in size, shape, and convolution. If such a mass is encountered on pelvic examination, it may well represent a challenging diagnostic problem. Patients with prior total hip arthroplasty may develop an intrapelvic protrusion of the acetabular cup caused by trauma or weakness of the inner wall. This protrusion may be seen as a mass fixed to the pelvic sidewall, causing confusion and difficulty with diagnosis. Only a high degree of suspicion can alert the examining gynecologist that the hard, nodular fixed pelvic mass is, indeed, a cementing substance that should not be disturbed.

Certain metabolic disorders of the skeletal system can cause gradual development of pelvic deformities that may be confusing on pelvic examination. With bone deficiency, sometimes there is inward protrusion of the femoral head through the inner acetabular wall (protrusio acetabuli). Other causes of protrusio acetabuli include Marfan syndrome, Paget disease of the bone, rheumatoid arthritis, and osteomalacia.

Fungal, parasitic, and pyogenic affections of the bony pelvis can cause the development of soft tissue masses that may be difficult to diagnose. Most of these cases present as acute, painful infectious processes, but some develop as subacute or chronic pyogenic infections. Pelvic examination may cause severe
discomfort and produce findings suggestive of a deep fullness or masses on either pelvic sidewall. Sometimes such infections present as a presacral abscess. There usually is an associated tenderness over the sacroiliac joints and both buttocks.

A rather common cause of intrapelvic distortion is a residual bony deformity resulting from a pelvic fracture. These are often the result of an automobile accident or other major trauma. Radiologic examination of the pelvis reveals the cause of the unusual findings.

Primary bone tumors that involve the pelvis are quite rare except for those on the anterior sacrum. The sacrum is the primary site of more than 50% of chordomas (malignant) and 6% of giant cell tumors (benign). These tumors usually may be discovered on pelvic or rectal examination. Urinary frequency and constipation are common presenting symptoms. Radiographic studies of the pelvis usually are sufficient for diagnosis, and a technetium 99 bone scan may demonstrate bone destruction not apparent on the radiographic films. MRI gives far better detail to delineate bone and nerve involvement.

Vascular Considerations

Two significant vascular lesions of the pelvis are iliac aneurysms and arteriovenous fistulas. Isolated iliac aneurysms are rare, but many patients with abdominal aortic aneurysms have associated iliac aneurysms. They are more common on the common iliac and hypogastric arteries and very rare on the external iliac artery. Most iliac aneurysms remain asymptomatic until rupture unless they impinge on adjacent structures. Diagnosis of iliac artery aneurysms is difficult, but ultrasonography and CT scanning occasionally detect these vascular conditions. Figure 44.24A shows a barium enema with extrinsic pressure on the colon by the iliac aneurysm. Figure 44.24B demonstrates an iliac arterial aneurysm on CT scan. Contrast angiography is necessary to formulate the therapeutic plan.

Pelvic arteriography is a valuable part of preoperative evaluation of unusual pelvic tumors or findings. Although pelvic arteriography is not often necessary, it helps to delineate a highly vascular tumor. Hasty exploration without knowledge of the source of the blood supply of the tumor could lead to uncontrollable hemorrhage.

Aneurysms that are symptomatic because of local factors or because of distal emboli should be carefully evaluated. Growing aneurysms should almost always be resected. Internal iliac aneurysms are usually not resected but are treated by simple ligation.

Metastatic Lesions to the Pelvis

The ovary is a frequent recipient of metastases from numerous primary sites. In comparison with the ovary, solitary extragenital metastases to the fallopian tubes or uterus are rare. Although statistics vary, probably 5% to 10% of all ovarian tumors are metastatic in origin. The most common metastases to the ovary are from the colon, stomach, breast, and the uterus.
FIGURE 44.23. Presacral teratoma. CT image shows a soft tissue mass (M), which deforms the sacrum and displaces the rectum (R) anteriorly. (Courtesy of K. Baliga, Rockford, IL.)

FIGURE 44.24. Iliac artery aneurysm. A: Barium enema shows extrinsic filling defect (arrows) of the rectosigmoid. B: CT image shows an iliac artery aneurysm (A), which contains a clot. Adjacent bowel is displaced. (Courtesy of T. Demos, Maywood, IL.)
The functional ovary seems particularly prone to extragenital metastatic disease. The possibility of an extragenital primary cancer with metastases to one or both ovaries should always be considered and can usually be ruled out by a careful preoperative history, physical examination, and appropriate imaging. When the ovarian metastases are from the gastrointestinal tract, they are almost always bilateral. When the ovarian metastases are from gastrointestinal cancer, both ovaries usually become symmetrically enlarged while retaining their shape and capsular integrity.

**Nonsurgical Acute Abdomen**

There are a number of nonsurgical causes of acute abdominal pain that may be mistaken for a gynecologic problem. Sickle cell anemia is one of these conditions. Such patients may have attacks of bone and joint pain, but also may suffer abdominal pain. The major disabilities suffered by patients with sickle cell anemia are related to painful vasoocclusive crises and occlusion of the microvasculature by the sickling phenomenon. Precipitating factors are infection, hypoxia, dehydration, and acidosis. A careful history and laboratory testing for sickle cells and hemoglobin S usually establish the diagnosis. Recurrent attacks of abdominal pain occur with acute porphyria. This disease is an autosomal dominant condition and is most common in women in the third and fourth decades of life. Abdominal tenderness is much less than would be expected, considering the severity of pain. Activation of the disease is related to factors such as medications, infections, low-calorie diets, and steroid hormones. Fever and leukocytosis may be present, and abdominal radiologic studies show distended loops of bowel. Diagnosis is made by a history of similar attacks and by the quantitative detection of excessive porphobilinogen and aminolevulinate in a 24-hour urine collection.

Other nonsurgical causes of abdominal pain include familial Mediterranean fever, lower-lobe pneumonia, rectus sheath hematomata (frequently preceded by a paroxysm of coughing), pseudonephritis, and acute viral gastroenteritis.

**PREOPERATIVE PREPARATION**

Preparation of the patient for pelvic surgery begins with the establishment of an accurate diagnosis as possible. Because an absolute diagnosis is not always possible, the extent of the surgery is difficult and sometimes impossible to determine. Thus, when major pelvic surgery is anticipated, it is imperative that the patient (and often the family) be as well informed as possible. If the patient understands that bowel or bladder resection may be needed, requiring a colostomy, ileostomy, or urinary conduit, she will be much better prepared to cope with the surgical complications. Preoperative consultation with other surgical subspecialists may be necessary. If consultation is likely, it is very appropriate for the patient to meet these specialists before the contemplated surgery.

**Preoperative Bowel Preparation**

If there is a possibility that a portion of the colon will be opened or resected, bowel preparation should be carried out. We prefer a combined mechanical and antibiotic bowel preparation. The most commonly used bowel prep is an isotonic lavage solution such as GoLYTELY or Colyte. The patient may have a light lunch of a high-protein, low-residue diet and clear liquid dinner the day before surgery. To achieve sufficient cleansing of the colon, approximately 4 L of solution must be ingested over a 4-hour period. We usually have the patient begin the Colyte at around noon the day before surgery and ask that they drink 8 to 16 ounces every 10 to 15 minutes. Most surgeons also use a combination of oral antibiotics, erythromycin base (1 g) and neomycin (1 g) at 1 a.m., 2 a.m., and 11 a.m. the day before the operation. Additionally, broad-spectrum intravenous antibiotics are given preoperatively and may be continued after surgery if there is gross contamination or if an infectious process is encountered.

**Additional Preoperative Preparation**

If the patient is nutritionally depleted because of extrinsic or intrinsic bowel obstruction or dysfuction, preoperative nutritional support is indicated, usually by instituting total parenteral nutrition. Dehydrated patients undergoing bowel preparation should be given intravenous fluids and appropriate electrolytes for 16 to 24 hours before major pelvic surgery. This is particularly important in the older patient. Prior bleeding problems must be investigated. Patients on broad-spectrum antibiotics and those with multiple or prolonged bowel prep for imaging studies, colonoscopy, or surgery may have a prolonged prothrombin time secondary to depressed vitamin K absorption. Such patients usually respond well to vitamin K in doses of 10 mg/day for 2 days preoperatively. Some medications, such as aspirin and coumarin, may be forgotten by the patient, and the physician should ask specifically about recent use of these medications.

Patients receiving chronic corticosteroids will need additional corticosteroids during surgery. Postoperatively, the corticosteroids are tapered down over 4 to 5 days to their usual maintenance dose.

Patients with cardiopulmonary problems should have maximum pulmonary preparation. Smoking should be stopped several days before surgery. If possible, pulmonary toilet with chest physiotherapy and incentive spirometry can begin when preoperative workup takes place. Preoperative consultation with anesthesiologists, pulmonologists, and cardiologists may be appropriate for the elderly patient and patients with multiple concomitant severe medical problems.

**INTRAOPERATIVE MANAGEMENT OF NONGYNECOLOGIC PELVIC DISORDERS**

After a thorough history and physical examination and a meticulous diagnostic laboratory workup, most nongynecologic conditions should have been diagnosed, or at least highly suspected, before laparotomy. However, situations may still arise that are outside the purview of the gynecologic surgeon, and intraoperative consultation is indicated.

Once the abdomen has been opened, a thorough evaluation of the upper abdomen and the pelvis is necessary. If the upper abdomen is normal, the upper abdominal contents should be packed away with laparotomy pads and the patient placed in...
Related Surgery

Trendelenburg position. Next, the pelvic findings are assessed and the problem analyzed, with the tissues being put in as near an anatomically normal position as possible. If dense adhesions are present, these should be lysed by sharp dissection. If the disease involves the uterus or fallopian tubes and ovaries with extension into the surrounding organs, the appropriate surgery to remove the diseased organs should be undertaken. Depending on the pathology, this may be within the gynecologist’s expertise; if not, another surgical specialist should be consulted.

If the findings are not gynecologic in nature, then a determination of the problem is essential. The most common nongynecologic condition encountered is disease of the gastrointestinal tract, including colon cancer and a diverticular abscess. If the colon and small bowel are normal, the gynecologic surgeon must consider retroperitoneal tumors or pathology of the distal ureter or urinary bladder. If the patient has had an adequate bowel preparation and has been apprised of the various possibilities (i.e., colostomy, bowel resection, urinary diversion, excessive blood loss, and possibly prolonged hospital stay), then definitive surgery should be carried out. If these precautions have not been taken preoperatively, the abdomen should be closed; the surgeon must explain to the patient and family the diagnosis and plans for further management, including consultation and referral.

Gastrointestinal Disease

Appendicitis

Appendicitis frequently involves gynecologic conditions in the differential diagnosis. It is discussed in Chapter 42.

Diverticulitis

The usual therapy for diverticulitis is medical. Most patients with acute diverticulitis should be hospitalized for bowel rest, intravenous fluids, and broad-spectrum antibiotics. Repeated attacks of diverticulitis in the same area generally require surgical resection. Severe attacks with acute peritoneal signs, fistula formation, suspected abscess, or perforation require intravenous antibiotics directed against Gram-negative anaerobic bacteria, followed by surgical drainage or resection.

In operating on a patient for what was presumed to be recurring attacks of pelvic inflammatory disease or an ovarian mass, the gynecologist may find a portion of the rectosigmoid colon involved with diverticulitis. If the colon has been preoperatively prepared and cleansed, the patient may undergo elective resection of the involved segment of colon and a primary anastomosis with a very low operative risk. On the other hand, if there is acute inflammation with evidence of perforation, fistula, obstruction, or bleeding, the diseased colon must be mobilized and resected. The proximal colon is brought out as an end colostomy, and the distal rectal segment is closed (Hartmann procedure). The colon may be reanastomosed 2 to 3 months after recovery.

Cancer of the Colon and Rectum

Cancer of the colon is predominantly a disease of older people, but it can occur at any age. It is important to remember that the incidence of right-sided colon cancer is steadily increasing. Radical surgical removal of the primary lesion is the only acceptable curative therapy. If a colon cancer is found unexpectedly in the bowel, has had both mechanical and antibiotic preparation, an appropriate resection should be carried out by a surgeon experienced in colorectal surgery. A carcinoembryonic (CEA) blood sample should be obtained. This is helpful when follow-up CEA levels are obtained. If the patient has not had suitable bowel preparation, or if a surgeon experienced in colorectal surgery is not available, the first (‘‘furrowing’’) closed and definitive surgery performed at a later date. The resection includes the entire segment of the involved portion of the colon and its associated lymphovascular pedicle up to the level of its takeoff from the aorta for left colon lesions or to the mesenteric vessels for right colon lesions. Primary resection and anastomosis of right colon lesions may be carried out even in the absence of prior bowel preparation with a very low incidence of postoperative infection.

Crohn’s Disease

Crohn’s disease (regional enteritis) is a chronic inflammatory disorder of the gastrointestinal tract of unknown cause. Because it usually involves the terminal ileum and proximal colon, it may easily be mistaken by history and pelvic examination as an inflammatory process of the appendix, fallopian tube, or ovary. The most common symptom is right lower quadrant pain that usually is associated with fever, diarrhea without blood, weight loss, fatigability, and a tender, palpable abdominal mass. The disease most commonly has its onset in the young, but there appears to be an increased incidence in people after age 60. The complications of the disease are often local, resulting from intestinal inflammation and involvement of adjacent viscera. Intestinal obstruction, fistula formation, right ureteral obstruction and hydro nephrosis, malabsorption, anorexia, and intestinal perforation with abscess formation are all possible manifestations and complications of this disease. Endoscopic examination of the colon and radiologic studies of the bowel are most important in establishing the diagnosis of inflammatory bowel disease. At laparotomy, the finding of thickened mesentery with growth of mesenteric fat (“fat wrapping”) around the circumference of leathery fibrotic bowel is almost always pathognomonic of Crohn’s disease. Intraoperative management of incidentally discovered Crohn’s disease depends on the indication for operation and the experience of the surgeon. Patients explored for pelvic inflammatory disease who are found to have perforated Crohn’s disease need resection, possibly including an ileostomy. Like complicated diverticular disease, these resections can be quite challenging and hazardous for the occasional surgeon. Patients explored for a mass and found to have diseased terminal ileum without perforation may be resected in some cases (if there is evidence of proximal obstruction), or the patient may be closed and further examinations carried out. Most patients with small-bowel disease can have endoscopic biopsies to confirm the diagnosis and then be managed medically. Surgery is held in reserve until complications (stricture, obstruction, abscess) develop. Current surgical management of Crohn’s disease involves very conservative resections, preserving bowel length to avoid short-bowel syndrome, caused by repeated resections of progressively involved bowel. Crohn’s disease is not cured surgically and recurs in more than 75% of patients with ileosacral Crohn’s disease, the most common site of the disease. Bypass procedures for obstructing Crohn’s disease are of historical interest only; current surgical treatment involves resection or structuroplasty.

Metastatic Carcinoma of the Ovaries

Metastatic carcinoma to the endometrium or fallopian tube from distant sites may occur, but this is relatively rare and does not present a surgical dilemma to the gynecologist. The
uterus, tubes, and ovaries are removed, and the presence of metastatic lesions most often is discovered in the pathology laboratory.

The ovaries, on the other hand, are a frequent site of metastases from cancer originating in many different organs, including the breast, stomach, pancreas, and colon. It has been reported by Israel and colleagues and by Webb and coworkers that young women are more prone to metastatic carcinoma than to primary ovarian cancer and that one half of all women with ovarian metastases are premenopausal.

In most situational ovarian metastases can be regarded as a local manifestation of generalized carcinomatosis, and extensive resection is not indicated. Ovarian metastases from the colon may have a better prognosis if aggressive resection is undertaken, providing all gross tumor can be exenpted. Morrow and associates have reported that the most important determinants of survival in patients with metastatic ovarian disease from colorectal cancer was whether the patient could be surgically rendered free of gross disease. In their series, the mean survival rate for patients rendered free of gross disease was 48 months, compared with 8 months for all other patients. Thus, significant palliation is achieved by removing large tumor masses in and around the ovaries. Aggressive resection seems justified if such a lesion is encountered by the gynecologic surgeon, particularly if the metastases represents a late recurrence of colon cancer.

Urologic Disease

The most common retroperitoneal urologic mass to be encountered is a pelvic or horseshoe kidney. It is important to realize that pelvic and horseshoe kidneys have an arterial supply that courses much more anteriorly than the normal kidney, and their collecting system lies anteriorly as well, exposing both to risk of injury. An attempt should be made to identify a renal pelvis or ureter if the retroperitoneal mass appears to be a kidney. Aspiration with a 22-gauge needle may reveal the presence of urine within the mass. Excretory urography can be performed during surgery by intravenously injecting 50 to 100 mL of contrast material and taking a 10- to 20-minute supine film. An alternative is to inject 3 to 10 mL of indigo carmine intravenously and obtain an aspirate from the suspected renal pelvis 5 to 10 minutes later. The presence of blue or green urine confirms that the mass is a functioning kidney. One cannot rely on palpation of the ipsilateral or contralateral side to ascertain that a kidney is present. According to Schuster, “palpating the kidney” was done in about half of the reported cases of removal of a solitary pelvic kidney, and the surgeon thought a normal kidney was present in its usual proper position. If the surgeon unwittingly attempts to remove a pelvic kidney, bleeding will become profuse as the “tumor mass” is entered. If the tumor mass is recognized as a kidney, the injured kidney usually can be repaired. Packing the wound will stop some of the small bleeders and around the ovaries. Aggressive resection seems justified if such a lesion is encountered by the gynecologic surgeon, particularly if the metastases represents a late recurrence of colon cancer.

Retroperitoneal Tumors

Although retroperitoneal tumors are relatively rare, the pelvic surgeon should be prepared to deal with them. Primary retroperitoneal tumors arise from retroperitoneal tissue that does not represent growth from another body organ in the retroperitoneum. Ackerman has compiled and classified a lengthy list of all the possible retroperitoneal tumors. There is virtually no retroperitoneal tumor that should be resected if found unexpectedly at the time of operation for other pelvic disease. Retroperitoneal sarcomas, teratomas, sacral chordomas, and anterior meningoceles all need careful resection imaging and very specialized surgical techniques. Anterior meningoceles are best treated by neurosurgeons via a posterior transsacral laminectomy. Anterior meningoceles all need careful preresection planning of the involved portion of the bladder wall and small bowel. Hemangiopericytomas posterior to the bladder require total resection of the tumor mass.

Summary

A thorough history, a physical examination, and appropriate laboratory and imaging procedures usually detect unsuspected pathology before laparotomy. Even if a thorough workup suggests gynecologic pathology, bowel preparation and a thorough discussion with the patient of problems that may be encountered will prevent many otherwise difficult, if not impossible situations. Because gastrointestinal disease most often is the unexpected pathology, the gynecologist should be aware of the coret management of these disorders. Urinary tract pathology and retroperitoneal tumors should also be familiar to the gynecologic surgeon. Surgical management of retroperitoneal tumors requires a thorough knowledge of the retroperitoneal space and typically requires consultation with appropriate specialists if successful surgery is to be achieved.

Best Surgical Practices

The pelvic surgeon must give careful consideration to the broad differential diagnosis of possible gynecologic causes of a pelvic mass. Particular attention to the
gastrointestinal tract is extremely important since the gas-
trointestinal tract is the most common nongynecologic
source of a pelvic mass.
■ When the diagnosis of a pelvic mass is uncertain, thorough
evaluation of the gastrointestinal-tract and urologic systems
before surgery using modern imaging techniques and en-
doscopy to further delineate normal from abnormal struc-
ture is often necessary.
■ Thorough bowel preparation and consideration of cyst-
toscopy with ureteral stent placement is helpful if there is
a high degree of suspicion of potential secondary or possi-
bly primary involvement of these organ systems.
■ Intraoperative evaluation should entail complete and thor-
ough assessment of the entire abdominal cavity, including
the upper abdomen as well as the pelvis. The choice of
the operative incision should also be predicated on the likeli-
hood for need of exposure or access to the upper abdomen.
■ Judicious use of nongynecologic surgical consultations is ad-
vised whenever the preoperative assessment or the intraop-
erative evaluation determines that the pelvic mass is nongyn-
ocologic in origin.

SECTION IX • GYNECOLOGIC ONCOLOGY
CHAPTER 45 MALIGNANCIES OF THE VULVA
MITCHEL S. HOFFMAN

DEFINITIONS
Lymphoscintigraphy—A nuclear medicine study examining the distribution of uptake of radiocolloid (injected percutaneously) into the lymphatic system.
Modified radical vulvectomy—Radical removal of the portion of the vulva containing the tumor with approximately a 2-cm margin.
Radical vulvectomy—Removal of the vulvar soft tissue. The lateral borders are the labiocutaneous folds. The anterior border is located in the mons pubis. The posterior border is across the perineal body. The medial borders are within the vestibule.
Sentinel lymph node—The concept of a sentinel lymph node in the context of malignancy relies on the presumption that this lymph node(s) is the initial site of metastatic disease and that the histology of the sentinel lymph node reflects the histology of the rest of the lymph nodes in the basin.
Superficial inguinal lymphadenectomy—Removal of the inguinal lymph nodes superficial to the cribriform fascia, mainly associated with the great saphenous and superficial epigastric veins.

Carcinoma of the vulva is an uncommon malignancy accounting for 0.5% of all female cancers in the United States and 2% of all female genital malignancies. It is predominantly a disease of older women. In this country as a whole, the steady increase in life expectancy has brought carcinoma of the vulva into a place of more importance among gynecologic malignancies. The predominant histologic type is squamous cell carcinoma, which accounts for about 90% of the tumors in most series. This malignancy metastasizes primarily through the lymphatic system in an orderly manner through the superficial inguinal, deep inguinal, and pelvic lymph nodes. During the first half of the 20th century, the absolute 5-year survival rate for carcinoma of the vulva was 15%. During the first 19th and early 20th centuries, principles of surgical oncology were developed and put into clinical practice. The application of these surgical principles to the treatment of vulvar cancer resulted in a significant improvement in survival. The survival of patients with invasive squamous cell carcinoma of the vulva is dependent on a number of histopathologic factors, but it most closely relates to the pathologic status of the inguinal lymph nodes. Until the early 1980s, patients with invasive carcinoma of the vulva were routinely treated with radical vulvectomy and bilateral inguinoscrotal and pelvic lymphadenectomy. Accumulation of data on vulvar cancer during the mid- to late-20th century led to earlier diagnosis and a better understanding of the nature and modes of spread of this disease. Especially over the past 2 decades, treatment of this malignancy has undergone a number of significant modifications that are applicable to most patients.

This chapter first reviews the epidemiology, clinical characteristics, staging, and prognostic factors for invasive carcinoma of the vulva. The broad spectrum of treatment of this disease is then reviewed with an emphasis on the surgical treatment. Finally, histologic variants of vulvar malignancy and their treatment are discussed individually.

EPIDEMIOLOGY
Invasive squamous cell carcinoma of the vulva is typically a disease of postmenopausal women, with a median age at diagnosis of about 65 years. However, the age range is wide, and some data suggest an increasing incidence in younger women. This has been attributed to some extent to the human papillomavirus. Human papillomavirus does not appear to play a significant role in the epidemiology of invasive squamous cell carcinoma of the vulva in older women, who frequently have concomitant lichen sclerosis (Fig. 45.3).

The other sexually transmitted factors that have been epidemiologically associated with vulvar cancer are the granulomatous venereal diseases, especially in countries where these are prevalent.

Vulvar carcinoma in situ (Fig. 45.2A–B), like cervical carcinoma in situ, is considered a precursor to invasive disease, although the risk of progression appears to be lower. There are no substantial long-term natural history studies of untreated patients. Although Jones and Rowan found in seven of eight women with untreated vulvar intraepithelial neoplasia (VIN) that invasive cancer developed within 8 years, three other studies found progression rates of 5% to 16%. In a recent systematic review of 3,322 published patients, 8 of 88 untreated women with VIN 3 progressed to invasive cancer in 12 to 96 months. Occult invasion has been discovered in 16% to 22% of patients undergoing excision of VIN 3 (although it was only 3.2% in the systematic review). The risk for invasive cancer may be greater with perianal location, increased age, immunosuppression, and previous radiotherapy. Vulvar carcinoma in situ tends to be multifocal with a lower risk of invasive cancer in younger women, but it tends to be unifocal with a higher risk of invasive disease in older women. Most patients with VIN 3 should be treated, and long-term follow-up is mandatory. Although progression of VIN from grade 1 to grade 2 and grade 3 has been demonstrated, in the absence of atypical changes, other vulvar epithelial abnormalities do not appear to have significant precancerous potential. Patients who have cervical neoplasia are at increased risk for developing vulvar neoplasia, and vice versa. This so-called field phenomenon should heighten the physician’s surveillance for the development of other lesions once a lower genital tract neoplasm occurs.

1151
Hypertension and diabetes mellitus are common in patients with invasive vulvar cancer, but this may simply be related to the elderly population affected. The associations of vulvar cancer with obesity and cigarette smoking are also unclear.

There does not appear to be any significant association with parity or race. One group that does appear to be at increased risk for the development of invasive vulvar cancer is chronically immunosuppressed women.

**CLINICAL PRESENTATION**

The most common initial symptom of vulvar cancer is pruritus vulvae, which may be of long duration. Vulvar pain, discharge, and bleeding are less commonly reported. The patient often becomes aware of a lesion on her vulva; but despite the superficial nature of the lesion, delay in seeking medical help is common. Physician delay has also been commonly reported, often related to prolonged medical treatment before a biopsy is done. These findings underscore the need for patient and physician education with regard to the early diagnosis of carcinoma of the vulva and the importance of having a biopsy diagnosis before treating vulvar lesions. Biopsy of the vulva is a simple procedure that can be performed in the physician’s office (see Chapter 23).

Invasive squamous cell carcinoma of the vulva involves the labia majora in about two thirds of patients. The remaining tumors involve the clitoris, labia minora or posterior fourchette, and perineum. These cancers can be exophytic, ulcerating, or flat (Figs. 45.3–45.5).

HISTOLOGY

Squamous cell carcinoma accounts for about 90% of the invasive vulvar malignancies in most large series. Melanoma is the second most common histologic type, accounting for 5% to 10% of vulvar cancers. Some of the less common vulvar malignancies include Bartholin carcinoma (with most of these being adenocarcinoma or squamous carcinoma), basal cell carcinoma, verrucous carcinoma, adenocarcinoma, invasive Paget disease, and sarcomas. This chapter mainly deals with invasive squamous cell carcinoma, followed by a discussion of the less common vulvar malignancies.

ROUTES OF SPREAD

Squamous cell carcinoma of the vulva can spread by local extension to involve the vagina, urethra, anus, or pubic bone. Metastasis from the primary site can occur by the lymphatic or the vascular system, but, by far, the most common is the lymphatic route. The lymphatics of the labia communicate to the inguinal lymph nodes. The lymphatics of the perianal area drain in a similar manner, but lesions that extensively involve the anus or rectovaginal septum can drain directly into the pelvic lymph nodes. Although there are channels that interconnect the clitoris to the deep pelvic nodes, it appears that they are of minimal clinical significance. The lymphatics of
the vulva are numerous and tend to cross the midline. The regional lymph nodes include the superficial inguinal lymph nodes, the deep inguinal femoral lymph nodes, and the pelvic lymph nodes (external iliac, obturator, internal iliac, and common iliac lymph nodes). The superficial inguinal lymph nodes are the primary nodal group of the vulva and are located around the saphenous, superficial epigastric, and superficial circumflex iliac veins. These lymph nodes drain through the cribriform fascia to the femoral lymph nodes, which are mainly located medial to the femoral vein. Draining from here is under the inguinal ligament into the pelvic lymph nodes. The pelvic lymph nodes are virtually never positive in the absence of inguinoscrotal lymph node metastases. Overall, 20% to 40% of all patients with invasive squamous cell carcinoma of the vulva have lymph node metastases.

STAGING

In 1979, the International Federation of Gynecology and Obstetrics (FIGO) approved a clinical classification for invasive squamous cell carcinoma of the vulva (Table 45.1). This was based on an analysis of tumor (T) by size and location; node (N) status by palpation; distant metastases (M) as assessed by general and pelvic examination; evaluation of the bladder or rectum, or both; and radiologic investigation. Most patients with invasive carcinoma of the vulva are treated surgically, and it was recognized through a number of studies that there are substantial discrepancies between the clinical assessment and it was recognized through a number of studies that there are substantial discrepancies between the clinical assessment of the inguinal lymph node status and the surgical pathologic findings. In 1988, FIGO approved a surgical staging system (Table 45.2). This system is based on well-established surgical-pathologic prognostic criteria. In 1995, stage I was divided into A and B based on a depth of invasion less or greater than 1 mm.

PROGNOSTIC FACTORS

Invasive squamous cell carcinoma of the vulva has a relatively low propensity for distant metastases. Recurrences tend to be local or regional, and even unremitting disease tends to remain locoregional for long periods of time. The dominant prognostic factor in this disease is the status of the inguinoscrotal lymph nodes. Further definition of prognosis includes evaluation of a number of factors relating to the regional lymph nodes. In addition, several prognostic factors related to the primary tumor have been delineated. These primary tumor characteristics have been correlated with the likelihood of regional nodal involvement and/or risk of local recurrence.

Primary tumor factors that appear to have prognostic importance include depth of invasion or tumor thickness, tumor diameter, tumor differentiation, lymph-vascular space involvement, and margin status. Tumor involvement of the distal urethra, vagina, or perineum is also an adverse prognostic factor. Of less clear importance are cytologic grading, the local immunologic response to the tumor, tumor volume, tumor growth pattern, location, ulceration, amount of keratin, the presence of associated vulvar intraepithelial neoplasia or vulvar dystrophy, p53 overexpression, DNA ploidy, and proliferation index. Sedlis and colleagues reported on a Gynecologic Oncology Group (GOG) study of 272 patients with lesions less than or equal to 5 mm in tumor thickness. They found that histologic grade, capillarylike space involvement, tumor thickness, and clitoral or perineal location were all significant predictors of groin node metastases. A subsequent GOG study reported by Homesley and associates on 188 evaluable patients with invasive carcinoma found lymph-vascular space involvement, GOG tumor differentiation, age, and tumor thickness to be significant independent risk factors for groin node metastases. A few of the primary tumor characteristics, such as tumor diameter and lymph-vascular space involvement, may be significant independent predictors of survival. Other factors may be predictive of an increased risk of local recurrence, including margin status, larger tumor size, and deep invasion.

A few histologic variants have been described that have been associated with a favorable prognosis, including verrucous
carcinoma (discussed later), warty carcinoma, carcinoma in situ with early stromal invasion, and keratoacanthoma.

The status of the groin nodes is clearly the most important prognostic factor for patients with invasive squamous cell carcinoma of the vulva. The overall 5-year survival rate for all treated patients is about 60%, with a corrected 5-year survival rate of about 70%. In the GOG study previously mentioned, 65.5% of the patients had negative groin nodes and 34.5% had positive nodes; this is consistent with my own experience and with other reports in the literature. In the GOG report, the survival rate was 90.9% for patients with negative lymph nodes and 57.7% for patients with positive lymph nodes, again consistent with the other reports in the literature. When the pelvic lymph nodes are known to be positive, the survival rate decreases to about 20%.

Further definition of prognosis is achieved by examining a number of variables related to the lymph node metastases; the most significant of these is the number of nodes involved. Other factors that have been reported to be prognostically significant include bilateral involvement, extracapsular extension, clinical nodal status, size of the metastatic deposit inside the lymph node, percentage of nodal replacement, nodal immune response, and location of the metastasis within the lymph node. Several studies have shown that when only one lymph node is involved, survival is still quite good; it decreases drastically with metastases to three or more nodes or with bilateral nodal involvement. In the 1991 GOG report, the relative survival rate was 75.2% when one or two nodes were involved and decreased to 36.1% when three or more nodes were involved. The survival rate was 70.7% with unilateral involvement versus 25.4% with bilateral involvement. On the basis of limited data from a few studies, it appears that large nodal diameter, extensive nodal replacement, and especially extracapsular extension of a lymph node metastasis are adverse prognostic factors. In a report by Origoni and colleagues in 1992 that was based on 53 vulvar cancer patients with groin node metastases, the survival rate varied from 90.9% when the diameter of the metastasis was less than 5 mm to 20% when it was larger than 15 mm, and from 85.7% to 25% when the metastases were intracapsular and extracapsular, respectively. Especially important are the data from the 19 patients in that study with a single positive node. For these patients, the 5-year cancer-related survival rate was 90% when the metastasis diameter was less than 5 mm versus 37.5% when it was 15 mm, and 85.7% when the metastasis was intracapsular versus 20% when it was extracapsular. Results from a study by Paladini and associates were similar; they reported that patients with intracapsular metastases tended to have recurrence at distant sites, whereas patients with extracapsular nodal disease were more likely to have local or groin recurrence. Both of the previously mentioned studies also revealed that a lack of active immune response within the lymph node metastasis was an adverse prognostic factor. A 1995 study from the Netherlands (van der Velden and colleagues) found a predominantly distant failure pattern in a subgroup of patients with extranodal spread, multiple positive lymph nodes, and lymph node replaced greater than 50% by tumor. Hoffman and coworkers studied 48 patients with groin node metastases and reported prognostic significance for the size and number of the nodal metastases, but they found that the immune response and the location of the metastasis within the lymph node were much less important. Groin nodes that are both clinically and surgically positive may also portend a worse prognosis, which is probably a reflection of the factors mentioned earlier.

**TREATMENT OF INVASIVE SQUAMOUS CELL CARCINOMA OF THE VULVA**

Invasive squamous cell carcinoma of the vulva is a heterogeneous group of tumors requiring considerable flexibility in the approaches to treatment. Dating back to the favorable reports of Tussing in 1940 and Way in 1948, radical vulvectomy with bilateral inguinal lymphadenectomy performed by en bloc excision became the standard therapy applied to most patients with carcinoma of the vulva. This operation involves radical removal of the entire vulva, the mons pubis, the inguinofemoral lymph nodes, and often the pelvic lymph nodes. A large surgical defect is created that is generally closed under tension with a high subsequent breakdown rate and marked disfigurement.
FIGURE 45.7. Closure of en bloc radical vulvectomy with bilateral inguinofemoral lymphadenectomy. Foley catheter and vaginal stent are in place.

of the genital area (Fig. 45.7). Important concerns with this approach for the treatment of vulvar cancer have led to a number of modifications, especially over the past 25 years (Fig. 45.8). Some of these concerns include the high rate and the severity of wound complications and the psychosexual effects of radical removal of the vulvar tissues. Other potential problems related to the en-bloc radical resection include urinary or fecal incontinence and vaginal relaxation, the overtreatment of early cancer, the inadequate treatment of more advanced disease, and the lack of attention directed specifically at the local vulvar lesion to ensure an adequate margin of resection. What I wish to emphasize in this section are some treatment recommendations based on my own experience as well as current literature on the subject.

Regional Nodal Management

It should be kept in mind that certain vulvar cancers, by virtue of their anatomic extent, may have access to lymphatics that bypass the groins. These include tumors that extensively involve the anus (particularly the anal canal or its surrounding tissue), the rectovaginal septum, the vagina above the lower third, and the proximal urethra.

Separate Incisions

Although reported earlier by Kehler, Taussig, Byron and associates, and Ballon and Lamb, it was only after later reports by Hacker and colleagues, DiSaia and associates, and others that separate incisions for the vulvar and inguinal phases of the operation came into increasing use (Fig. 45.8B). This was the most important modification of the classic en bloc excision. The separation of incisions results in a significant reduction in wound morbidity. Importantly, the separation allows for increased flexibility in the modification of the two aspects of the operation (regional and local). The report by Hacker and colleagues in 1981 consisted of 100 patients in whom three separate incisions were used to perform the bilateral inguinofemoral lymphadenectomy and radical vulvectomy, leaving a bridge of tissue between the incisions and sparing the mons pubis. Major groin wound breakdown occurred in 14 patients, which was a considerable reduction from the 50% or higher groin wound breakdown rate generally seen with the en bloc excision. In this report, there were no isolated recurrences in the groin or the inguinal skin bridge. There were two recurrences in the inguinal skin bridge associated with other recurrence sites, both patients originally had positive inguinal lymph nodes. In addition to these two patients, there have been other isolated reports of inguinal skin bridge recurrence. However, this still appears to be a rare event. Some authors believe that in the presence of advanced disease or grossly positive inguinal lymph nodes, an en bloc excision of the tumor and the lymph nodes is still the best approach. En bloc excision is certainly warranted at times to obtain an adequate resection of the malignancy.

Unilateral Groin Lymphadenectomy

Removing the inguinal lymph nodes only on the side of a unilateral vulvar tumor has been another modification of surgical treatment that has been used for selected patients (Fig. 45.8C). In 1981, Iversen reported on 53 women with unilateral tumors and lymph node metastases. Eighty-three percent of these patients had only one positive ipsilateral node, 15% had bilateral positive nodes, and one patient had contralateral positive lymph nodes only. Other retrospective studies have confirmed these results. It has been the opinion of a number of authors that capillary or lymphatic space involvement by tumor may increase the risk of contralateral nodal metastases. Patients with tumors approaching the midline or involving more medial structures (perineum, clitoral hood or clitoris, vagina, and labia minora) are at increased risk for contralateral lymph node metastases. The issue of unilateral groin lymphadenectomy was studied to some extent in 1992 by Stehman and associates in a GOG study. Briefly, patients with early disease and negative ipsilateral superficial inguinal lymph nodes were treated with ipsilateral superficial inguinal lymphadenectomy and a modified radical vulvectomy. A few patients in this study did have a bilateral inguinal lymphadenectomy because of midline involvement. A total of 121 patients were in the study, and 3 experienced contralateral inguinal lymph node recurrences. The vulvar lesions of these 3 patients ranged from 0.6 to 2.5 mm in depth of invasion, and all were poorly differentiated. Although lesion location was not given for these three cases,
a large percentage of patients included in this study had lesions approaching the midline, as defined by involvement of the labia minora. Tumors with capillary or lymphatic space involvement were excluded from this study. The role of unilateral inguinal lymphadenectomy in the management of invasive squamous cell carcinoma of the vulva requires further evaluation; at present, it appears to be a reasonable approach in a patient with a well-lateralized early tumor that is well differentiated, with no capillary or lymphatic space involvement, and with negative ipsilateral inguinal lymph nodes.

**Superficial Inguinal Lymphadenectomy**

A more limited resection of the inguinal lymph nodes in the management of superficially invasive vulvar cancer was reported by DiSaia and coworkers in 1979. The dissection they described is aimed at removal of the superficial lymph nodes above the crural/fascia, mainly associated with the great saphenous and superficial epigastric veins. These lymph nodes are sent for frozen section analysis. If results are positive, a complete bilateral inguinalfemoral lymphadenectomy is performed. In the 1979 study, DiSaia and colleagues also reported 79 cases of invasive squamous cell carcinoma of the vulva treated with radical vulvectomy and bilateral inguinal lymphadenectomy. In these cases, it was noted that the deep femoral lymph nodes were never positive in the absence of positive superficial inguinal lymph nodes. The purpose of this modification is to reduce the morbidity of the inguinal lymphadenectomy. The dissection is less radical and resulted in only one groin breakdown in the 18 patients in the series of DiSaia and associates. The series was updated in 1989 and reported no groin recurrences in 50 patients, 42 of whom had been followed for a median of 36 months. The previously mentioned GOG study specifically studied the issue of superficial inguinal lymphadenectomy in patients with early carcinoma of the vulva. The study group included clinical stage I patients with tumor invasion of 5 mm or less and no capillary or lymphatic space involvement. A modified radical vulvectomy and ipsilateral
superficial inguinal lymphadenectomy were performed, and 121 patients were evaluable. These were compared with a historical control group in the GOG registry who had undergone radical vulvectomy with bilateral inguinofemoral lymphadenectomy. Nine patients in this study, or 7.3%, experienced groin recurrences versus no recurrence in the control group. Six of the groin recurrences were in the ipsilateral groin, and five of the nine patients died of the recurrent vulvar cancer. The interpretation from this study was that superficial inguinal lymphadenectomy may not be adequate treatment even for early vulvar carcinoma. However, in a number of patients in this study, the tumors approached the midline; there is evidence that more medial tumors may have direct drainage to the deep inguinal lymph nodes. Another area of concern in this study is the high percentage of poorly differentiated tumors—almost twice as many as in the control group. Six of the nine groin recurrences in this study were from the poorly differentiated tumors. Whether poorly differentiated tumors are more likely to metastasize to deep inguinal or contralateral inguinal lymph nodes deserves further study. Subsequent additional retrospective data from large cancer centers also report a 5% to 10% incidence of groin relapse in patients with negative nodes from superficial inguinal lymphadenectomy.

Factors requiring further study with respect to the efficacy of superficial inguinal lymphadenectomy appear to be tumor grade, depth of invasion, the presence of capillary or lymphatic space involvement, and tumor location. The patients should be those generally at low risk for lymph node metastases with a tumor confined to the labia majora. Until further information is available on this approach, extending dissection to include removal of lymph nodes medial to the femoral vein should be considered in most patients.

Sentinel Lymph Node Identification

A large number of reports have been published over the past 15 years on sentinel lymph node detection. The concept relies on the presumption that the sentinel lymph node is the initial site of metastatic disease and that the histology of the sentinel lymph node reflects the histology of the rest of the lymph nodes in the basin. Lymphatic mapping is considered by many authorities to be the standard of care in the United States for the surgical treatment of patients with clinically early-stage melanoma and breast cancer.

With lymphatic mapping, the pathologist has only a few lymph nodes to examine, allowing a more detailed examination. Techniques such as serial sectioning, immunohistochemical staining, and reverse transcriptase-polymerase chain reaction analysis can be applied, increasing the sensitivity of the examination and allowing the detection of micrometastases. Sentinel lymph node detection is currently accomplished using two methods of lymphatic mapping: blue dye and radiocolloid. One to 2 milliliters of isosulfan blue dye (Lymphazurin) is injected superficially around the periphery of the primary tumor, and the blue-dyed lymphatic channels are followed. An incision is made over the anticipated location, and the dyed lymph node or nodes are removed. Alternatively, the periphery of the tumor is injected with 400 mCi of technetium-labeled sulfur colloid 2 to 4 hours before surgery. A preoperative technetium scan is done, which may be helpful in confirming lymph node uptake, localization of target lymph nodes, unilateral versus bilateral lymphatic drainage, and identification of the unusual case of predominant drainage to pelvic lymph nodes (Fig. 45.9A–B). An intraoperative gamma counter is used to identify one or more sentinel lymph nodes (Fig. 45.10). The removed lymph nodes are checked with the gamma counter, and complete removal is assured when the radioactivity in the inguinal area returns to background levels. In practice, the two techniques are complementary.

When using the combined technique for vulvar cancer patients, lymphatic mapping is nearly always successful in identifying sentinel lymph nodes (Fig. 45.11). Further, the false negative rate (based on standard pathology) is very low. A formal lymph node dissection is reserved for those cases in which the sentinel node is positive or has not been successfully identified.

Experience with lymphatic mapping of vulvar cancer patients has increased substantially over the past 10 years. The technique is promising as a method to substantially reduce the morbidity of inguinal lymphadenectomy. Another
Intraoperative use of the gamma probe to identify sentinel inguinal lymph nodes. An important benefit may be more reliable clearance of at-risk lymph nodes. Injection of radiocolloid is best done 2 to 4 hours before surgery, but this is painful. Many unanswered questions remain, including who the best candidates are for the technique, the role of frozen section, the role of immunohistochemistry, the role of lymphoscintigraphy, the reliability of an isolated lymphoscintigraphy-directed unilateral negative sentinel node with a midline lesion, the role of ultrasound, management of a patient with a microscopically positive sentinel lymph node, the incidence of "skip" metastases, the reliability of lymphatic mapping after prior excisional biopsy, and the optimal lymphatic mapping methodology for vulvar cancer patients.

"Blue" lymph node found with the help of the gamma probe. Pelvic Lymph Nodes During the late 1970s and early 1980s, several studies were published showing that carcinoma of the vulva metastasizes to the inguinofemoral lymph nodes before spreading to the pelvic lymph nodes. Extension of the groin lymphadenectomy to include removal of the pelvic lymph nodes continued to be performed in selected patients with positive inguinofemoral lymph nodes. A number of studies also showed that the 5-year survival rate of vulvar cancer patients with positive pelvic lymph nodes is less than 20%. A 1986 study by the GOG directed by Homesley compared pelvic lymph node dissection with groin and pelvic radiotherapy in patients with positive inguinofemoral lymph nodes. The study included 114 patients and showed no difference in morbidity between the two treatment arms and a better 2-year survival rate in the radiotherapy group (68% versus 54%). The improved survival was seen in those patients with suspicious or grossly positive lymph nodes or those with more than one positive groin lymph node. There was no evidence that groin radiation therapy was beneficial to those patients with occult metastases and only one positive groin node. Review of the pattern of recurrence in that study suggested that adjuvant radiation was more effective largely because groin recurrences were reduced. A recent report described laparoscopic pelvic lymphadenectomy as a method to potentially avoid pelvic radiotherapy in patients with positive groin lymph nodes. The value of removing positive pelvic lymph nodes before radiotherapy is unknown. In a patient with obvious inguinal lymph node metastases who is otherwise suitable for surgical resection, consideration may be given to extending the dissection and removing enlarged pelvic lymph nodes. Preoperative CT may help with such a decision (Fig. 45.6).

Primary Inguinal Radiotherapy The use of elective radiotherapy to the groins in the place of bilateral inguinofemoral lymphadenectomy offers the potential for avoiding operative morbidity. The method is believed to be appropriate only in the absence of clinically suspicious lymph nodes. Frischbier and Thomsen reported on this method for the
treatment of 118 patients and reported a 70% survival rate for the N0, N1 group. Henderson and colleagues used the method for 91 N0, N1 patients with minimum morbidity. In that series, there were no groin recurrences in the radiotherapy field and two outside the field. In addition, there are extensive supportive data on elective nodal radiation for other sites, including the cervix, endometrium, vulva (pelvic), and head and neck. This issue was later addressed in another GOG study by Stehman and coworkers in 1992 in which there was a randomization of patients with nonsuspicious groin lymph nodes to radical vulvectomy plus bilateral inguinal lymphadenectomy, or radical vulvectomy plus radiation therapy to the groins bilaterally. This study was closed early because of a high incidence of recurrence in the irradiated groins and reduced survival (in the first 49 evaluable patients, there were five groin recurrences in the irradiated patients and no groin failures in the operated group). Upon review, however, it was believed that the radiation program used in the study may not have provided an adequate dose to the depth where the lymph nodes were located. The role of elective primary groin radiotherapy in the management of invasive squamous cell carcinoma of the vulva, therefore, remains unclear.

Omitting Groin Dissection for Superficial Disease

Extensive data support the contention that a subset of early vulvar carcinomas (carefully studied pathologically) can be identified that have an extremely low risk of nodal involvement. In another GOG study reported by Sedlis and associates, a subgroup (63 of 272) of patients with early disease was identified as having a zero incidence of lymph node metastases. This subset included nonmidline tumors with no capillary or lymphatic space involvement that were well differentiated or were grade 2 and limited to 2 mm in thickness. Other factors that have been considered for the purpose of identifying a low-risk group include tumor volume (which does not appear to have received further attention since Wilkinson's report in 1985), tumors that are largely carcinoma in situ with very early stromal invasion and with a pushing rather than an infiltrative pattern, tumor diameter, squamous cell type, the presence of an inflammatory response, and tumor ploidy.

There seems to be general agreement that the patients for whom it would be most reasonable to omit the lymphadenectomy are those with tumor invasion less than or equal to 1 mm. The risk of lymph node metastases in this group of patients is about 1% (Table 45.3). Based on this, FIGO stage I was divided into stages IA and IB. As reported in the literature, three of five patients with nodal disease or nodal recurrence in association with tumor invasion less than or equal to 1 mm had poorly differentiated cancers (Table 45.4). Thus, certain high-risk patients with superficially invasive tumors should still undergo a groin node dissection. These include women with suspicious lymph nodes, poorly differentiated tumors, tumors with capillary or lymphatic space involvement, and perhaps those with multiple foci or broad areas of invasion, or anaplasia. Meanwhile, it is important to remember that in the report by Sedlis and colleagues on 272 patients with invasion of 3 mm or less, the groin nodes were positive in approximately 20%.

**Modifications in Management of the Vulvar Phase of Treatment**

The main type of morbidity relating to a radical vulvectomy is subsequent sexual dysfunction and a sense of disfigurement. In some cases, there may also be compromised function of the anus or urethra. Additional types of morbidity are encountered in the treatment of locally advanced tumors because of the extensive therapy required. In a 1979 study, DiSaia and colleagues reported complete preservation of sexual function in 17 of 18 patients who underwent local excision for

<sup>a</sup>Month to diagnosis of nodal disease.

<sup>b</sup>Gynecologic Oncology Group grading system.
early invasive tumors. They also reported that preservation of
the mons pubis as well as the major portion of the superior
aspect of the vulva resulted in an appreciably more satisfac-
tory cosmetic result. There is little additional information in
the literature on sexual function as it relates to modifications
of radical vulvectomy. It seems reasonable to assume, how-
ever, that the sparing of as much normal vulvar tissue as pos-
sible is less likely to produce sexual dysfunction and a sense
of disfigurement than is radical vulvectomy. Modified radical
vulvectomy is an ambiguously defined operation that generally
refers to radical removal of the portion of the vulva containing
the tumor (Fig. 45.12). Recommendations have included 1- to
3-cm skin margins for the treatment of well-localized, unifocal
lesions.

The chief concerns with a modified radical vulvectomy are
the possibility of an increased risk of local recurrence and later
an increased risk of a second primary vulvar cancer. Multicen-
tricity has been reported to occur in 20% to 28% of invasive
squamous cell carcinomas of the vulva (Fig. 45.13). Ross and
Ehrmann reported 15 of 64 stage I patients as having micro-
scopic multifocal disease and 3 of 64 patients with grossly mul-
tifocal disease. There may be an ongoing occult process within
the vulva of patients with vulvar carcinoma, and biochemi-
cal abnormalities have been demonstrated in normal-appearing
epithelium adjacent to malignancy. In the report by Ross and
Ehrmann, occult microscopic multifocal disease appeared in
the immediate vicinity of the grossly evident tumor as surface
noncontiguity of the primary lesion. Occult microscopic dis-

vectomy.
modified radical vulvectomy, the local recurrence rates were 2.2% and 4.4%, respectively. Several additional studies have reported excellent local control with a modified radical vulvec-
tomy (Tables 45.5 and 45.6). In another GOG study, Stehman and colleagues analyzed recurrences following modified radi-
cal hemivulvectomy. The mean time to “relapse” on the vulva was 43.4 months, and 11 of 18 patients had recurrence on the contralateral side from the primary lesion. A study by de Hullu and associates also reported a significant number of late recurrences following modified radical vulvectomy. From these results, it is apparent that women undergoing a modified vulvar operation for cancer are at high risk for later development of a new primary vulvar tumor and should have long-term close follow-up.

It appears reasonable to conclude that a modified radical vulvectomy is efficacious treatment for well-localized invasive squamous cell carcinoma of the vulva. Attention should be fo-
cused on obtaining a 2-cm skin margin around the tumor while sparing as much vulvar tissue beyond this as possible. Most pa-
tients with squamous cell carcinoma of the vulva are candidates for a modified radical vulvectomy performed separately from the groin lymphadenectomy. A few patients, however, by virtue of disease extent, require a radical vulvectomy. Whatever the vulvar phase of the operation is called, the aim should be to excise the tumor with a 2-cm margin.

**Partial Urethral Resection**

Because of tumor proximity, it is occasionally necessary to re-
move a portion of the urethra to obtain an adequate resection of a vulvar carcinoma (Fig. 45.14A–C). Although several authors have stated that removal of the outer urethra does not result in significant problems with incontinence, there are no substan-
tial confirming data. In one small study, Reid and colleagues did find urinary incontinence to be a problem after resection of the distal urethra or even an excision close to the urethra. If a portion of the urethra is resected, a Foley catheter should be left in place (carefully taped to the leg) for about 1 week postop-
eratively to facilitate healing and splint the urethra. A surgical antiincontinence procedure should also be strongly considered at the time of resection, especially if there is any preoperative stress urinary incontinence or if more than 1 cm of the urethra has to be removed. Alternatively, consideration can be given to treating these patients preoperatively with radiotherapy.

**Vulvar Cancer with Perianal Involvement**

There is scant literature concerning the local management of vulvar cancer with perianal involvement (Figs. 45.5 and 45.15). However, we have noted that about one third of our patients who are referred for vulvar cancer have lesions with perianal or anal involvement. The chief problems in the management of vulvar cancer with perianal involvement are the need for radical resection and the relatively high risk of local recurrence. The role of adjuvant therapy is not clear, although some authors have suggested that adjuvant therapy may be beneficial in selected cases.

patients with these tumors are the difficulty in obtaining ade-
quate surgical margins on the resection while attempting to pre-
save anal sphincter function, and deciding on which patients
would be better treated either with a more radical excision and
colostomy or with preoperative radiotherapy (Fig. 45.16). In
our experience with vulvar carcinoma, partial resection of the
external anal sphincter in combination with radical local resec-
tion of perineal tissue is associated with a significant rate of sub-
sequent fecal incontinence. Careful sphincter reapproximation
and levator muscle plication are done in an effort to minimize
incontinence. Other important measures include good bowel
preparation preoperatively, prophylactic antibiotics, and care-
ful postoperative bowel management. In addition, we have had
good results with the use of cutaneous rhomboid flaps in the
reconstruction of the perineum and perianal area. These flaps
allow for reconstruction of a perineal body, they bring tissue
with a good blood supply into the area that promotes healing,
and they allow closure of the wound without tension on the
anus. As with urethral involvement, an option for these patients
is preoperative radiotherapy.

**LOCALLY ADVANCED DISEASE**

About 30% to 40% of vulvar cancers have FIGO (clinical)
stage III or IV disease. Although surgical staging was intro-
duced by FIGO in 1988 and hard data on this system are still
in relatively short supply, a review of our own patients sug-
gests that this percentage probably still holds. We have consid-
ered carcinoma of the vulva to be locally advanced when the
primary or recurring tumor cannot be locally managed by a radical vulvar resection (Fig. 45.17A–C). Current approaches to the treatment of locally advanced vulvar cancer include ultraradical surgery, radiotherapy, or a combination of treatment modalities. This section reviews the current approaches to the treatment of locally advanced vulvar cancer.

**Ultraradical Surgery**

Ultraradical surgery has been used for patients with clinically resectable vulvar lesions and has generally consisted of a radical vulvar operation extended to include the anorectum and/or the lower urinary tract. This has included resection of bone in a few reports (Fig. 45.18). Inguinofemoral and pelvic lymphadenectomies are usually performed as well (Fig. 45.19).

In some cases, resection can be limited to partial removal of the urethra, anus, or anterior rectal wall. Subsequent incontinence may occur, but this can be prevented to some degree by reconstructive efforts. Reid and associates reported problems with urinary incontinence in 4 of 4 patients who underwent resection of 1 to 1.5 cm of the distal urethra and in 2 of 14 patients who underwent resection within 1 cm of the urethra for carcinoma of the vulva. The value of urethral reconstruction in this setting is uncertain, but it would seem worthwhile. Three recent studies have reported preservation of anal continence after partial sphincter resection and reconstruction for posteriorly located carcinoma of the vulva.

The cumulative literature from 1970 to 2006 includes 163 vulvar cancer “exenteration” patients (Table 45.7). The postoperative mortality rate ranges from 0% to 20%, with a mean of about 4%. The cumulative disease-free survival rate for these patients is 46%. In those series that have included an analysis, the survival has correlated well with the status of the regional lymph nodes. Most studies have not differentiated inguinal and pelvic lymph nodes. There have been very few survivors with positive nodes, either in our series or elsewhere. Although not well addressed in the literature, there is also significant physical and psychological morbidity resulting from these operations as a result of the extensive nature of the surgery and the need for a permanent colostomy and/or urostomy. It appears that the use of a combination of treatment modalities avoids the need for such extensive surgery in many of these patients (see later text). Likely in large part related to this, utilization of the “ultraradical” surgical approach for primary management of locally advanced vulvar cancer appears to have markedly decreased over the past decade. It may be reasonable to confine the use of ultraradical surgery to highly selected patients with...
FIGURE 45.17. A: Locally advanced vulvar carcinoma. The lesion extensively involved the anus and lower rectovaginal septum but was mobile. There was no suspicious adenopathy. B: Large and locally extensive vulvar cancer. C: Vulvar cancer extensively involving perineum and anus.

clearly respectable lesions who have negative—or perhaps one or two microscopically positive—regional lymph nodes. It may be the only option for a patient who has previously received radiotherapy to the region (Fig. 45.20).

Radiotherapy

The role of primary radiotherapy as the sole method of treatment for carcinoma of the vulva remains unclear, but may be the only option available when the patient presents with unresectable disease. The literature concerning the use of radiotherapy for this disease consists of retrospective studies with small numbers of patients (many of whom were medically infirm or had locally advanced disease) who were treated with a variety of radiotherapy techniques (Table 45.8). Overall, this information is difficult to interpret. The older literature is discouraging in terms of both low cure rates and vulvar skin intolerance.
Contemporary literature with use of high-energy radiotherapy with its relative skin-sparing effects as well as the use of modern radiotherapy techniques has been more encouraging. Whether normal bladder and bowel function is preserved with this type of treatment is difficult to determine.

The optimal techniques for radiotherapeutic treatment of carcinoma of the vulva have not been well defined. In the more recent literature, teletherapy has been administered to the whole pelvis, including the vulva and the groins, at a dose of 45 to 55 Gy. It is not uncommon for patients to require treatment interruption because of vulvitis. The treatment regimen has been modified in some studies, with only brachytherapy or palliative treatment used. A few studies have described the use of a direct perineal portal. We reported a series of 10 patients with locally advanced vulvovaginal malignancy treated mainly with teletherapy followed by interstitial needles (Fig. 45.21) to the local tumor bed for a tumor dose of 70 to 90 Gy. The therapy was highly morbid, with six patients developing severe radionecrosis (Fig. 45.22). Treatment fields, the role of interstitial radiotherapy, the overall dose, and the integration of combination treatment with chemotherapy or surgery, or both, are among the issues to be studied. Preliminary results suggest that radiotherapy (possibly combined with chemotherapy) followed

by a more limited resection is more efficacious than radiotherapy alone. These treatment methods are discussed in the next two sections.

### Preoperative Radiotherapy

From the work of Boronow and others, data confirm that megavoltage radiotherapy can cause marked regression of even locally advanced vulvar carcinoma to the point to which a more limited resection can be undertaken (often with an improved resection margin) with sparing of organ function and improved quality of life. In an update of his study in 1987, Boronow reported that, of 48 bladders and 48 rectums at risk, one bladder and two rectums were lost because of local failure, and one bladder and one rectum were lost because of radiation injury. The report did not mention other types of bladder or bowel morbidity. Of 40 patients who underwent vulvectomy, 17 contained no identifiable residual cancer. There were no reported problems with wound healing. Similar results have been reported in other studies. In these studies, survival with locally advanced disease so far has been comparable to that with ultraradical surgery. Again, the optimal radiotherapeutic techniques for such treatment are not well defined. Boronow’s group generally used a combination of external beam radiation and intracavitary brachytherapy, delivering a mean vaginal surface maximum dose of 86.26 Gy. His group and others have also used preoperative external beam therapy only, generally delivering a dose of about 50 Gy to the whole pelvis, including the vulva and groins. Surgery has generally been performed 2 to 6 weeks after completion of radiotherapy. Boronow and associates reported 42.5% of

vulvectomy specimens and Hacker and colleagues reported 4 of 7 (57%) vulvectomy specimens to be negative for residual tumor.

Chemoradiotherapy

As with preoperative radiotherapy, combined chemoradiotherapy with or without resection has been used increasingly over the past 25 years with promising results in squamous cell carcinomas of several different primary sites. This approach has been particularly successful in the treatment of squamous cell carcinoma of the anus. This type of carcinoma may be somewhat analogous to carcinoma of the vulva in terms of location and, in some instances, preservation of the anus. Although the cumulative data on this type of treatment for carcinoma of the vulva is quite limited, the results are promising.

The most commonly used chemotherapeutic agents are 5-fluorouracil, mitomycin-C, and cisplatin. Chemotherapy has been combined with external radiotherapy administered in a manner similar to that described in the previous sections. Most data have been accumulated over the past 20 years with the use of regimens similar to those used at other sites. Results suggest a high rate of local control for locally advanced or recurrent disease (Table 45.10). However, an increase in the degree of local morbidity is seen with this type of therapy. Most of these patients develop a moderate amount of mucositis in the vulvovaginal area (Fig. 45.23). This leads to dysuria and generalized pelvic and perineal discomfort. An indwelling catheter (suprapubic in some cases) and the use of various perianal and rectal preparations help ease the discomfort, although treatment interruption is necessary at times. The GOG investigated the use of chemoradiotherapy for the treatment of advanced squamous cell carcinoma of the vulva. Results from this study are included in Table 45.10 and confirm those reported by the other investigators.

Neoadjuvant Chemotherapy

A large number of pilot studies in the recent literature have reported on the use of neoadjuvant chemotherapy (NACT)

1988 staging.
1992 staging.

In cervical cancer, the planned course of chemotherapy has been followed by surgery, radiotherapy, or both. Reported response rates have been high, and preliminary results with NACT followed by radical surgery are somewhat encouraging.

In 1993, Benedetti-Panici and colleagues reported the results of a pilot study using NACT followed by surgery in patients with locally advanced carcinoma of the vulva. Twenty-one patients with FIGO stage IVA (clinical) were treated. Chemotherapy consisted of cisplatin, 100 mg/m² intravenously on day 1; bleomycin, 15 mg intravenously on days 1 and 8; and methotrexate, 300 mg/m² intravenously plus citrovorum factor rescue dose on day 8, repeated every 21 days for two to three cycles. A partial response was observed in the primary tumor in two patients, and progression of disease was seen in two other patients. Eleven complete and three partial responses...
FIGURE 45.23. Desquamative vulvitis and mucositis during chemoradiotherapy.

were noted in the patients with nodal disease. On pathologic examination of the 19 patients undergoing resection, 15 had inguinal lymph node metastases and 9 of these had pelvis lymph node metastases. Local control was achieved in 12 of 21 (57%) of the patients (3 to 37 months), and the 3-year corrected survival rate was 24%.

The study just discussed does not suggest any benefit of NACT over the previously described treatment approaches, and the authors of that report subsequently have used the chemoradiotherapeutic approach. Two European cooperative studies used bleomycin, methotrexate, and CCNU and reported similar results.

Treatment of Locally Advanced Disease: Summary

Ultraradical surgery appears to be a reasonable treatment option for selected patients with locally advanced but resectable carcinoma of the vulva, especially in the absence of nodal metastases. The role of radiotherapy in the treatment of this malignancy is still being defined. In our experience, teletherapy combined with interstitial needles for locally advanced carcinoma of the vulva appears to be effective but associated with extensive morbidity. With the use of more modern treatment techniques and better definition of the optimal delivery of radiotherapy to the vulva, the role of this modality has been expanded. A modified course of radiotherapy used in combination with other treatment modalities appears to be more efficacious than radiotherapy alone in the treatment of this disease. Combined treatment modalities for this disease present an important form of management. Especially in patients with locally unresectable disease, initial treatment with external radiation therapy possibly combined with chemotherapy appears to be the most reasonable approach. With the use of radiosurgical techniques and perhaps random biopsies, an additional treatment course could be planned. Careful planning of how much surgery may be necessary or how much volume needs additional radiation therapy may contribute to an overall decrease in morbidity in these patients.

Management of the regional lymph nodes in the context of combined treatment modalities has been variable and, by necessity, highly individualized.

The management of locally advanced vulvar cancer continues to evolve as reports of small series of these patients accumulate. Considering the relative paucity of data and the rarity and heterogeneity of these tumors, no clear-cut management guidelines can be constructed. It seems reasonable to individualize the management of these patients, carefully considering all of the various treatment modalities available.

RECURRENT SQUAMOUS CELL CARCINOMA OF THE VULVA

About 15% to 40% of patients with squamous cell carcinoma of the vulva develop recurrence after treatment. As discussed previously, the incidence of recurrence is influenced by a number of factors, including the original stage of the disease, the depth of invasion, and the regional lymph node status. About 70% of recurrences have a local component, and 55% to 90% of these are isolated local recurrences (Fig. 45.24A-B). This is more likely to occur in the patient with negative lymph nodes at initial treatment. For patients with recurrent squamous cell carcinoma of the vulva, recurrence site is the strongest predictor of outcome. Only with an isolated local recurrence is there a reasonable expectation of successful salvage therapy (Table 45.11).

The presence of inguinal nodal metastases, especially when multiple, bilateral, or extranodal, predisposes the patient to recurrence within the groin or pelvis and systemically. The prognosis for a patient with regional or systemic recurrence is poor. Regional recurrences do not lend themselves well to salvage resection, radiotherapy is not very effective against grossly recurrent disease, and there is no effective systemic therapy. A small percentage of patients with groin recurrence can be salvaged with resection followed by radiotherapy.

Certain factors predispose the patient to develop local recurrence, including a close resection margin (less than 1 cm), deep invasion, and a large tumor size. When a patient develops

an isolated local recurrence, the reported salvage rate ranges from 40% to 80%. Treatment depends on the individual situation. When feasible, radical resection is performed. Otherwise, the best approach is probably preoperative radiotherapy with or without chemotherapy followed by resection.

Operative Techniques

Radical Vulvectomy with Bilateral Inguinofemoral Lymphadenectomy

The patient is placed in the “ski position” in adjustable stirrups so that the legs can be elevated to high lithotomy during the perineal phase of the operation.

The radical vulvectomy with bilateral inguinofemoral lymphadenectomy is ideally performed with the use of two teams, and dissection of each groin is performed simultaneously. A crescent-shaped incision is made starting about 2 to 4 cm medial and about 2 cm caudal to the anterior superior iliac spine (Fig. 45.25). The incision gradually curves downward.
just above the superior border of the inguinal ligament medi-
ally to the inguinal ring or about 2 cm below and 2 cm medial

to the pubic tubercle. Unless there is a large cutaneous lesion or
palpably suspicious nodes, the mons pubis is spared, and sep-

arate incisions with a skin bridge are made as illustrated. For
anterior lesions, such as those involving the clitoris, a portion
of the mons pubis is included in the resection and the lymph-

adenectomy on one or both sides may be done en bloc with
the radical vulvectomy as illustrated in Figure 45.8A. From the
lateral points, caudal incisions are carried medially so as to ex-
cise a strip of skin (optional) 2 to 4 cm in width. Excising an
ellipse of skin may reduce the likelihood of skin necrosis and
facilitate more complete dissection of the groin. This incision
is designed to extend from just below the fossa ovalis (this can
generally be identified clinically as the area just medial to the
femoral pulsation in the groin) to the top of the labioscrotal
fold above a point just medial to the external inguinal ring. In
the presence of grossly positive inguinal lymph nodes, a wider
resection of both the groin skin and fat is necessary to help
ensure adequate tumor clearance. The separate groin skin inci-
sion may also be done vertically (with the leg), centered across
the fossa ovalis and about halfway between the femoral artery
and pubic tubercle.

Leaving a layer of subcutaneous tissue with the skin, the su-

perior incision is undermined so that the lymph node-bearing
adipose tissue above the inguinal ligament and around the su-

uperficial circumflex iliac, as well as the superficial epigastric
vessels, are included with the resection. These vessels are lig-
ated as they are encountered. The superior dissection over the
groin area is carried down to the superior border of the in-

guinal ligament. The midline aspect of the superior flap can be
mobilized off the pubic bone and rectus fascia at this point to
facilitate later closure of the wound without tension. Dissection
of the block of inguinal tissue is carried inferiorly off of the in-

guinal ligament. The lateral corner is dissected medially off of
the sartorius fascia (Fig. 45.26). The inferior flap of the lower
incision is also mobilized, especially medially, and the saph-

enos vein is identified as it enters the region of the femoral
triangle (Figs. 45.27-45.29). Accessory saphenous veins can
also be seen entering this area. The long saphenous vein is
isolated and ligated with a free-tie and a transfixion ligature of
2-0 polyglactin (Vicryl). The vein with its surrounding block of
lymph node-bearing tissue is dissected superficially off of the sar-
torius and adductor fascia. Dissection of the block of inguinal
tissue is continued from the three sides toward the fossa ovalis.
As this area is approached, the overlying cribriform fascia is
recognized, and the femoral artery pulsation can be palpated
in the lateral aspect. En bloc dissection continues and includes
the contents of the fossa ovalis (Fig. 45.30). The area under the
fascia lateral to the femoral artery should be left undisturbed.
There are no lymph nodes of consequence here, and
avoidance of this area prevents injury to the femoral nerve and
possibly reduces subsequent lymphedema. Rather, resection of
the cribriform fascia begins over the area of femoral pulsation,
exposing the underlying femoral vessels. A few small branches
of the femoral nerve are sacrificed during this dissection. The
sheath of the femoral artery is incised along its anteromedial
aspect from somewhere between the base of the fossa ovalis
and the apex of the femoral triangle to its emergence from
under the inguinal ligament. Branches, such as the external pu-
dendral artery, are ligated as they are encountered. There is no
purpose in dissecting under the artery or between the femoral
artery and vein. Rather, the dissection that has been performed
over the top of the artery is continued over the top of the vein,
mobilizing the specimen to the medial aspect of the femoral
vein. During this process, the saphenofemoral venous junction
is identified, ligated with a 2-0 silk free-tie followed by a suture
ligature for security, and transected, thus removing several cen-
timeters of the saphenous vein with the specimen (Figs. 45.31
and 45.32).

An alternative method, as long as there are no adher-
ent suspicious lymph nodes, is to dissect the saphenous vein
free of the specimen so that it can be preserved, poten-
tially reducing the risk of subsequent leg edema. Complete

FIGURE 45.26. Corner of groin specimen dissected
up medially off sartorius muscle. Lateral portion of
fossa ovalis and cribriform fascia are exposed.
dissection of the space medial to the vein is important because this is where most of the femoral groin nodes are located. The specimen is freed from the femoral vein medially, from the inguinal ligament superiorly, and from the underlying pectineal fascia. Dissection is continued toward and off of the adductor longus fascia until the labiocutaneous fold is reached.

To protect the femoral vessels in the event of subsequent wound breakdown, the sartorius muscle can be transposed over them at this point. Alternatively, the vessels can be covered by a variety of other materials or simple approximation of musculofascial tissues. To accomplish sartorius transposition, the muscle is divided with cautery at its tendinous attachment to the anterior superior iliac spine. The proximal end of the muscle is then mobilized and transposed so that it covers the femoral vessels. It is sutured at this location to the inguinal ligament and pectineal fascia with 0 polyglactin (Fig. 45.33). We have largely discontinued the practice of transposing the sartorius flesh.
muscles because of the improved healing of these wounds and less radical dissection.

If a superficial inguinal lymphadenectomy has been chosen (also generally done through separate incisions), the same general dissection is done except that the cribriform fascia and underlying femoral lymph node-bearing tissue are left intact (Figs. 45.34 and 45.35). All lymph nodes around the saphenofemoral junction should be included, and any prominent deeper lymph nodes medial to the femoral vein should be removed. In the absence of clinical suspicion, the only lymph nodes of concern deep to the cribriform fascia are those medial to the femoral vein. There is unlikely to be a significant increase in morbidity by extending the dissection to include removal of these femoral lymph nodes. There is not an apparent major distinction between this dissection and a contemporary formal inguinofemoral lymphadenectomy.

If a prominent femoral lymph node can be identified at the most superior aspect of the dissection in the space just medial to the femoral vein (Cloquet node or node of Rosenmüller), this can be used as a sentinel lymph node when deciding on the risk of pelvic lymph node metastases. When such a lymph node is positive, a search should be made for further nodes above this by carrying the dissection up the femoral ring under the inguinal ligament.

A pelvic lymphadenectomy, when chosen, is done immediately after completion of the groin dissection. The pelvic lymphadenectomy is performed in a retroperitoneal manner through the same groin incision, which can be extended...
FIGURE 45.33. Transposed sartorius muscle.

laterally and superiorly (in a “J” or vertical manner), if necessary. About 2 cm above and parallel to the inguinal ligament, an incision is made through the external oblique, internal oblique, and transversalis musculofascial layers (Fig. 45.36). The retroperitoneal space is then opened bluntly, mobilizing the peritoneum and ureter medially. It is necessary to ligate and transect the inferior epigastric vessels and round ligament to fully develop this space. A self-retaining retractor or handheld retractors can be used for adequate exposure of the retroperitoneal space. The pararectal and paravesical spaces are opened bluntly, fully exposing the iliac vessels and obturator fossa. All (or suspicious) lymph node–bearing tissue from the external iliac and internal iliac vessels and the superficial obturator fossa is removed. Separate pelvic Jackson-Pratt drains can be placed at the discretion of the surgeon. The incised musculofascial tissues are closed in a single layer with no. 1 synthetic, absorbable, monofilament sutures. Special attention is paid to closure of the internal inguinal ring with 2-0 silk sutures. The wounds are irrigated, and hemostasis is secured. When performed through separate incisions, the groin wounds are closed at this point.

Soft, active suction drains are placed in each groin and are brought out through separate stab wounds superolaterally. The groin wound may be approximated with a large mass closure using no. 2 polypropylene vertical mattress retention sutures (Fig. 45.37A). Three to five sutures are placed on each side. Each suture starts several centimeters from the edge of the superior flap, with a bite then taken of the underlying inguinal ligament. This is designed to close the dead space under the superior flap. Under the inferior flap, a bite of sartorius, adductor, or pectinealis fascia is taken (with care taken to avoid injury to the femoral vessels and nerve), followed by placement of the suture from inside to out through the inferior flap several centimeters from the edge. Again, this is designed to close the dead space of the inferior flap and, once pulled together, to close the dead space of the midline wound. Going back from inferior to superior, a small bite of each skin edge is then taken, which is designed to approximate these edges. The sutures are not tied until all have been placed. The sutures are tied somewhat loosely, with only enough tension to bring the wound together (Fig. 45.37A). The skin is further closed with stainless steel staples (Fig. 45.37C). When there has been less extensive dissection, the groin wound may be closed with 2-0 polyglycolic acid suture, approximating first the dead space with interrupted sutures and then the skin with vertical mattress or subcuticular sutures. En bloc groin incisions are closed in an identical manner, but this is delayed until completion of the entire resection. With separate incisions, the medial aspects of the groin wounds are under much less tension and are easily closed because of preservation of the inguinal skin bridge.

Separation of the groin and vulvar wounds and especially closure without tension are the factors thought to be largely responsible for the reduced wound complications seen with the three-incision technique.

After completion of the inguinofemoral lymphadenectomy, attention is turned to the radical vulvectomy. The surgeon may elect to change the position of the legs to high lithotomy;
FIGURE 45.35. Completed superficial inguinal lymphadenectomy.

“high-low” Allen-Brown stirrups are useful for this purpose (for a difficult perineal dissection, high lithotomy with sling stirrups is preferred). With en bloc resection, the inguinal specimens are mobilized toward the vulva as just described (Fig. 45.38). From the point of completion of the inferior inguinal dissections, incisions are continued down along the labioscral folds on each side and across the perineum, where they meet. A medial mucosal incision is made along the introitus extending through the anterior vestibule and around the urethral meatus.

When radical vulvectomy is performed through a separate vulvar incision, the same labioscral, posterior, and mucosal incisions are used and the same vulvar tissue is excised (Fig. 45.39). The superior incision extends from the top of the labioscral folds as an inverted V, with the point above the base of the clitoris. As previously discussed, a variable amount of superior tissue (i.e., mons pubis) is removed, depending on the location and size of the lesion.

The radical vulvectomy incisions may be modified somewhat depending on the location and extent of the tumor and the condition of the remaining vulvar skin. The surgeon should attempt to attain at least a 2-cm margin of normal-appearing skin or mucosa around the tumor. To accomplish this, it may be necessary to excise a portion of vagina, anus, or distal urethra. For an anterior lesion, it is reasonable to spare the perineal body; but for a posterior lesion, it is important to incorporate radical resection of this area. For a lesion (especially superficial) in proximity to the urethral meatus or anus, it is reasonable to limit the margin of resection to 1 cm (but not less) to preserve these structures and their function.

The labioscral incisions are extended to the lateral margins of the deep fascia of the urogenital diaphragm (Fig. 45.40). The internal pudendal vessels are ligated as they are encountered entering the vulva at about the 4 o’clock and 8 o’clock positions. Superiorly, the specimen is dissected off the pubic peristomeum and adductor fascia. The vascular base of the clitoris is clamped and transected, and a transfixion suture ligature is placed (Fig. 45.41). If deemed necessary, the attachment of the ischiocavernous muscles can also be transected at this level. Dissection of the superior portion of the vulva off of the pubic bone and adductor fascia is completed and joined, in the midline, to the transvestibular mucosal incision above the urethra. Inferiorly, a variable portion of the perineum (and in some cases the anus) is dissected upward and cephalad toward the vaginal incision (Fig. 45.42). Care is taken as the vaginal incision is approached above the perineum to avoid injury to the anal canal. Using the index finger or a large Kelly clamp, the surgeon separates the vaginal tube bluntly from the underlying soft tissue cephalad to the vestibular structures. The mucosal incision is then completed, separating the vagina (with the urethra) from the specimen. This dissection can be facilitated by splitting the specimen in the midline anteriorly or posteriorly. The remainder of the dissection off the underlying deep fascia of the urogenital diaphragm is completed. Clamps and transfixion suture ligatures of no. 0 or 2-0 polyglactin are used during transection of the tissue along the side of the vaginal tube in the region of the vestibular bulbs (Fig. 45.43). After removal of the specimen, the wounds are copiously irrigated with antibiotic solution, and hemostasis is secured (Fig. 45.44). After en bloc resection, the superior abdominal wall flap and the groin and vulvar thigh flaps are further mobilized.
FIGURE 45.37. A: Large block closure of groin wounds (separate in this case) with vertical mattress retention sutures. Note drains in place. B: The groin closure sutures are tied somewhat loosely. C: Groin closure completed with stainless steel skin staples.

as necessary to achieve closure of the wounds without tension. Any ischemic-appearing skin is excised. It is very useful, especially if there is an element of vaginal relaxation, to mobilize the lower vagina to facilitate wound closure. Any pelvic relaxation defects (i.e., cystocele, rectocele, loss of the posterior urethrovesical angle) are repaired at this time. To the extent that it is necessary or possible, the perineal body is also reinforced or reconstructed at this time.

The vulvar wound and the perineal area are closed with vertical mattress 2-0 delayed-absorbable sutures (Fig. 45.45). Depending on the amount of tissue that has been removed, the superior portion of an en bloc wound may be difficult to close. When done through a separate incision, closure of the vulvar wound is under much less tension, again because of preservation of the inguinial skin bridges. Careful attention must be paid to closure of the periurethral area. The urethra should be secured on a straight course without tension. A hood of skin above the urethra is also avoided because this can obstruct the path of the urinary stream and cause spraying.

As previously discussed, it is reasonable in most patients to manage the vulvar lesion locally with a modified radical vulvectomy. This operation consists of radical removal of the portion of the vulva containing the tumor. It is performed with the techniques described earlier except that the excision is basically limited to removal of that particular part of the vulva. The lateral and deep tumor margins are not compromised by this operation. After the surgeon carefully demarcates a 2-cm radius of normal skin or mucosa around the tumor, an encompassing incision is designed that will readily close and be as cosmetically acceptable as possible (Figs. 45.12, 45.46, and 45.47).

Postoperative Care. After closure, silver sulfadiazine (Silvadene, Hoechst Marion Roussel) cream is applied to the
FIGURE 45.38. Bilateral inguinofemoral lymphadenectomy is complete. Planned incisions for the en bloc radical vulvectomy are shown.

FIGURE 45.39. Bilateral inguinofemoral lymphadenectomy through separate incisions is completed, and wounds are closed. Separate incisions for radical vulvectomy are marked.

FIGURE 45.46. Radical hemivulvectomy.

perineal wound, and a light dressing is placed. In the recovery room, ice is applied to the vulvar wound, and this is continued off and on for 48 to 72 hours. On postoperative day 3 or 4, the patient is started on a regimen of cleansing the vulvar wound with a showerhead, followed immediately by complete drying of the area with a blow dryer using cool air. This is done three times a day and as needed (i.e., after a liquid bowel movement) and is continued until the wounds are healed. If moisture in the wound is a problem despite this regimen, other useful measures include placing a roll of gauze between the legs and against the wound between washings, increasing the frequency of washings, not wearing an undergarment, and applying a heat lamp to the area three times a day between washings. All of these efforts are aimed at keeping this normally warm and moist area clean and dry, which reduces the risk of infection and promotes healing. Intermittently leaving the legs slightly apart to air (the immodest position) is also beneficial. The patient should also avoid sitting on the healing wound.

If the vulvar wound is left open, postoperative management is the same except that silver sulfadiazine cream is applied after each showerhead, blow drying until there is good granulation tissue formation. In addition, these women are seen more frequently in the office to ensure good wound care and healing.

FIGURE 45.47. Closure of hemivulvectomy wound.
Reconstructive Techniques for the Vulva and Groin

After radical resection for carcinoma of the vulva, the wounds can generally be closed primarily. This is greatly facilitated when the incisions are modified somewhat (as with sparing of the mons pubis), and especially when separate incisions are used. When an extensive resection is necessary, it may not be possible to close the wound primarily, or at least not without considerable tension. This is often the case after resection of a recurrent tumor, where previous radical surgery has already left a paucity of tissue. If the area was treated previously with radiotherapy, then closure may be difficult because of the lack of elasticity of the fibrotic tissue and because of radiation-induced healing impairment. Under these various circumstances, closure of the incisions and healing can be facilitated by a variety of reconstructive procedures. Other potential benefits of such reconstruction include maintenance of anal, urethral, and sexual function and a more cosmetically acceptable result. However, leaving the wound open is sometimes the best option, and healing by secondary intention is usually quite satisfactory.

Closure of groin and vulvar wounds using reconstructive techniques involves moving a block of expendable tissue (with its blood supply intact) from some nearby site into the deficient area. The mobilized block of tissue is commonly referred to as a flap. Flaps are classified according to what layers of tissue they include and according to their blood supply. The types of flaps that have been useful in reconstruction of the vulva and groin are full-thickness skin (random and arterial based), fasciocutaneous, and myocutaneous flaps. Some flaps remain completely attached at their base and are rotated into the defect, whereas others are partially separated from the base and are transposed as an island of tissue.

A full-thickness skin flap involves rotating an adjacent block of skin with its underlying subcutaneous tissue into the defect. The flap is mobilized from the donor site but remains attached at its base; through this base travels the arterial and venous circulation. The blood supply of the flap may be random, or it may depend on a specifically planned arterial source. A random flap relies on the many small musculocutaneous perforating vessels that are retained through the base. For this reason, the subcutaneous layer must be kept thick, and the length of the flap should be greater than the width of the base (1.0 to 1.5 times greater). This is the type of flap most commonly used for reconstruction of a radical vaultectomy wound. The main disadvantage of such flaps is that they are less reliable in patients with impaired wound healing ability, such as those with diabetes, heavy tobacco users, those with vascular disease, and patients who have previously received radiation therapy to the region.

A few specific arterial-based full-thickness skin flaps, sometimes called axial flaps, have been used for reconstruction in vulvar cancer patients. Arterial sources of these flaps have included the internal pudendal, circumflex iliac, superficial circumflex iliac, superficial inferior epigastric, superficial branch of the deep femoral, and superficial external iliac arteries. With some of these arterial flaps, the deep fascia must be carefully mobilized with the subcutaneous tissue to maintain an adequate blood supply. The main advantage of an arterial flap, because of the good arterial blood supply, is that it can be considerably longer than a random flap. However, arterial flaps are technically more difficult to construct and have a low margin for error in terms of compromising blood supply. As previously mentioned, some full-thickness skin flaps are designed to include the deep fascia taken off the underlying muscle. These are known as fasciocutaneous flaps, and they are more reliable than random cutaneous flaps because the preserved fascial layer provides additional musclecutaneous perforators along its length. A fasciocutaneous flap can also be relatively long and is transposable as an island of tissue. Some fasciocutaneous flaps have a designated arterial blood supply. Locally useful fasciocutaneous flaps include the pudendal thigh, superior medial thigh, inferior gluteal, and groin flaps.

A myocutaneous flap makes use of an expendable muscle with its intact overlying fascia and cutaneous tissue. The use of these flaps for vulvovaginal reconstruction began after the 1976 report by McCraw and colleagues. A substantial blood supply is preserved through a narrow pedicle connected to the muscle, which allows the flap to be transposed as an island with a wide arc of rotation. Another advantage of a myocutaneous flap is the capacity to bring cutaneous perforators as a blood supply separate and independent from that of the operative site. This makes these flaps particularly valuable in the reconstruction of heavily radiated tissues. These flaps are also somewhat bulky and have the ability to fill a large tissue defect. The main disadvantage of myocutaneous flaps is that they are technically demanding, and the survival ability of some of these flaps is somewhat tenuous.

The difficulties resulting from a large wound created by extensive radical vulvectomy with bilateral inguinalfemoral lymphadenectomy were previously discussed. Reconstruction of these wounds with bilateral tensor fascia latae (TFL) myocutaneous flaps has been reported. The TFL originates from the anterior superior iliac spine. It inserts into the fascia lata and is supplied by the lateral femoral circumflex artery. The base is just lateral to the groin wound, into which the flap is directly rotated. The flaps are easily made long enough to reach and close the often large area created by resection of the mons pubis and anterior vulva. A TFL myocutaneous flap is also useful for reconstruction of the groin after extensive resection for recurrent disease (Fig. 45.48).

The rectus abdominis myocutaneous flap, based on the inferior epigastric artery, is also useful for reconstruction of a large groin defect. The block of tissue based on this muscle is taken from the abdominal wall, and the muscle is divided at the superior border of the flap. The island of cutaneous tissue is completely mobilized with its blood supply attached to the muscle, and this is further mobilized inferiorly. Thus allows the island flap to rotate down easily into the groin (or vulva) through a generous subcutaneous tunnel. The rectus abdominis myocutaneous flap is also suitable for the reconstruction of large vulvar wounds (Fig. 45.49).
tissues. Such a resection removes the entire perineal body as well as portions of the superficial muscles and leaves a large defect that is difficult to close (Fig. 45.50). Poor healing of this area may significantly compromise both anal and coital function. The use of flaps for such a defect allows closure without tension and brings tissue with a good blood supply into the area, which promotes healing and helps recreate a perineal body. Preventing tension on the anal apparatus helps promote healing of its associated reconstructed musculature and helps preserve its function. Reconstruction of a perineal body separates the vagina from fecal contamination and helps create a smooth and less scarred platform for intercourse. For reconstruction of such defects, we prefer to use local, full-thickness rhomboid skin flaps (Figs. 45.51–45.54). Closure of a larger defect involving the perineal or perianal and vulvar areas may be better accomplished with gluteal thigh fasciocutaneous, gluteus maximus myocutaneous, or gracilis myocutaneous flaps.

Closure of a heavily radiated wound should be accomplished with a block of relatively unradiated tissue, the blood supply to which is unlikely to have been significantly compromised by the prior treatment. In general, myocutaneous flaps are better for this purpose.
FIGURE 45.51. Planning rhomboid flap. Defect is divided into two rhomboids. Configuration and measurement of the flap are based on this rhomboid defect, as shown. Numbers and letters indicate proposed location of flap in reconstructed site.

POSTOPERATIVE ADJUVANT THERAPY

This section deals with adjuvant therapy following radical or modified radical vulvectomy with inguinofemoral lymphadenectomy. The role of adjuvant therapy in the management of locally advanced vulvar cancer is discussed elsewhere in this chapter. Other than with locally advanced disease, preoperative adjuvant therapy has generally not been used or recommended.

Postoperatively, the only adjuvant therapy that appears to be of value is radiotherapy (+/- chemotherapy). This can consist of radiotherapy to the local area of primary tumor resection, to the groins, to the pelvic nodal areas, or to all three.
Postoperative radiotherapy administered to the remaining vulvar tissues is rarely indicated, but should be considered when an extensive tumor has been resected with positive or close margins that cannot be readily excised further. As discussed later, this type of therapy may be particularly indicated in some Bartholin cancers because they are sometimes difficult to resect widely as a result of their deep-seated location.

Postoperative adjuvant radiotherapy has been used primarily in patients with metastases to the groin lymph nodes. Substantial data now exist regarding the prognosis and recurrence pattern in these patients. Because vulvar cancer has a recurrence pattern that tends to remain largely locoregional, its use for patients at high risk of recurrence is rational. There are further data to substantiate the benefit of radiotherapy in this setting. When a patient has metastases limited to microscopic involvement of one or perhaps two unilateral groin lymph nodes, the incidence of groin recurrence and pelvic lymph node metastases is very low, the overall prognosis is still reasonably good, and the benefit of postoperative radiotherapy is not great. If, however, there is gross replacement or extracapsular involvement of a lymph node, or involvement of three or more lymph nodes, the risk of groin recurrence and pelvic nodal metastases is substantial and the benefit of adjuvant postoperative radiotherapy is much more evident. In the GOG study previously discussed, the value of adjunctive radiation therapy was in the reduction of groin recurrences. When such treatment is anticipated, placement of metal clips to localize metastatic sites may aid the radiation oncologist in treatment planning. Postoperative adjuvant chemotherapy, either alone or in combination with radiotherapy, has not been extensively studied, but it is unlikely to be of substantial benefit with use of the currently available agents.

**Mortality and Morbidity of Radical Vulvar Surgery**

Even though most patients affected by invasive carcinoma of the vulva are elderly, radical vulvar surgery is generally well tolerated. This is attributed to the external nature of the operation, as well as to the intensive perioperative care that the patients receive. However, 2% to 4% of patients die in the first 4 weeks postoperatively, usually from cardiovascular or pulmonary complications. In addition, early groin wound complications are common, and long-term sexual dysfunction has generally been the rule. Treatment modifications over the past 3 decades undoubtedly have reduced the incidence and severity of these problems.

**Short-Term Complications**

In published series of large numbers of patients undergoing en bloc radical vulvectomy with bilateral inguinal/ femoral lymphadenectomy, a high percentage (overall about 50%) of significant wound breakdown in the inguinal sites has been reported (Fig. 45.55). Extensive undermining of skin, fluid collections in the wound, and infection are all contributing factors, but the main problem is the considerable tension placed on these wounds during closure. Suggested but unproven methods of prevention include prophylactic antibiotics, attempts to ligate lymphatic vessels, and prophylactic suction drainage. Modifying the resection by preserving the mons pubis, minimizing undermining of skin, leaving a layer of fat with the skin, and excising any dark or dusky skin at the end of the operation reduce groin wound complications. With more extensive resection, plastic reconstruction (such as with TFL flaps) is also likely to be helpful. However, the single most effective method of reducing groin wound complications. With more extensive resection, plastic reconstruction (such as with TFL flaps) is also likely to be helpful. However, the single most effective method of reducing groin wound breakdown (to around 20%) has been the use of separate incisions, as previously discussed. Management of groin wound breakdown is similar to that of other wounds, with debridement and wet-to-dry dressings. During debridement, the surgeon must be cognizant of the femoral vessels. If infection has completely cleared, the wound is clean, and the tissues are pliable, secondary closure may be attempted.

About 10% to 20% of patients develop a clinically evident fluid collection (seroma or lymphocyst) in the groin. When such fluid collections are small and asymptomatic, they should be left alone. The most commonly recommended treatment has been repeated aspirations until resolution. When there is
Late Complications

After groin node dissection, it is not uncommon for a patient to develop some degree of lower extremity edema. It is most often transient or mild, but persists chronically as a significant problem in about 10% of patients. Factors that have been implicated as contributing to this complication include the performance of a pelvic lymphadenectomy, groin radiotherapy, major groin wound breakdown, postoperative lower extremity lymphangitis, sartorius muscle transposition, and preoperative pelvic lymphangiography. Suggested methods for reducing this problem include limiting the groin dissection to the sentinel lymph nodes when feasible, confining femoral lymphadenectomy to the medial side of the femoral vein, preserving the fascia lata, and avoiding vessel skeletonization, postoperative femoral vessel rupture is now exceedingly rare.

Patients who have undergone radical vulvectomy with bilateral inguinalfemoral lymphadenectomy are at high risk for thromboembolic complications because most are elderly and have coexisting medical problems, malignancy, and femoral vein trauma, and have undergone prolonged surgery and prolonged bed rest. If prophylaxis fails, then treatment is promptly begun with heparin.

Rarely, a rectovaginal fistula develops days to weeks after radical vulvectomy. Prevention of this complication is based on preoperative evacuation of the colon, careful surgical dissection of this area, and prompt recognition of rectal entry. Surgical repair of the fistula is carried out once the area has healed and regained its elasticity.

Osteitis pubis and osteomyelitis are rare complications that may not become symptomatic until several weeks after radical vulvectomy. The patient reports pain over the pubic bone and difficulty with ambulation, which may become chronic and debilitating. This complication is more likely to develop if the periosteum is traumatized, although this is not always avoidable. Extensive use of the cautery on the periosteum should be avoided. The mainstay of treatment is bed rest and nonsteroidal antiinflammatory drugs. Even more rarely, frank osteomyelitis of the pubic bone develops. This is a serious condition that requires debridement and drainage of the bone, along with prolonged antibiotic therapy.

In the past, large series of patients undergoing en bloc radical vulvectomy with bilateral inguinalfemoral lymphadenectomy reported a 1% to 2% incidence of severe postoperative hemorrhage from femoral vessel rupture. This was related to the extensive wound breakdown that occurred in a high percentage of these patients, with associated infection and necrosis involving the exposed and denuded femoral vessel walls. Coverage of the vessels by transposition of the sartorius muscle largely prevented this complication. With the use of separate incisions as well as other techniques that have reduced groin wound breakdown, and with avoidance of vessel skeletonization, postoperative femoral vessel rupture is now exceedingly rare.

Patients who have undergone radical vulvectomy with bilateral inguinalfemoral lymphadenectomy are at high risk for thromboembolic complications because most are elderly and have coexisting medical problems, malignancy, and femoral vein trauma, and have undergone prolonged surgery and prolonged bed rest. If prophylaxis fails, then treatment is promptly begun with heparin.

Rarely, a rectovaginal fistula develops days to weeks after radical vulvectomy. Prevention of this complication is based on preoperative evacuation of the colon, careful surgical dissection of this area, and prompt recognition of rectal entry. Surgical repair of the fistula is carried out once the area has healed and regained its elasticity.
develop lymphangitis, which presents with fever, pain, and redness of the involved extremity. This condition is treated promptly with an intravenous antibiotic that covers streptococci.

A few good studies on sexual dysfunction after radical vulvectomy have been published. Generally, the capacity for intercourse remains. However, patients experience a marked sense of disfigurement and a reduction in genital sensitivity. Dyspareunia can occur as a result of stenosis or scar tissue (Fig. 45.57A–B), and these problems may be surgically treatable. Some patients remain orgasmic. There is evidence to suggest that a modified radical vulvectomy, especially with preservation of the anterior vulvar structures, helps maintain sexual function. It does seem reasonable to assume that sparing as much normal vulvar tissue as possible is less likely to produce sexual dysfunction and a sense of disfigurement than is radical resection.

During follow-up of radical vulvectomy patients, it is not uncommon to discover pelvic relaxation (cystocele or rectocele) (Fig. 45.58). This may be related to resection of the perineal body with the attendant loss of its support functions, or it may simply be a result of aging. If the patient’s medical condition and extent of cancer surgery permit, any stress urinary incontinence or defects in vaginal support should be repaired at the time of radical vulvectomy because they are likely to worsen subsequently.

Spraying or misdirection of the urinary stream is related to poor alignment of the urethra, a hood of periclitoral tissue obstructing the path of the urinary stream (Fig. 45.57), or asymmetry created by a hemivulvectomy. Digital manipulation or the use of an applied collection or directing device is useful, but in some cases minor surgical revision is necessary.

Rarely, after inguino-femoral lymphadenectomy, a femoral or inguinal hernia develops. When a hernia or any apparent weakness of the femoral or inguinal canal is noted at the time of surgery, it should be repaired at that time. Avoiding incision of the inguinal ligament is also important in the prevention of this complication.

Follow-Up

Following completion of treatment for vulvar cancer, long-term follow-up is warranted. It is reasonable to examine these women at least every 6 months for the first 5 years and annually thereafter. Some women are at higher risk for recurrence or have ongoing problems, and more frequent office visits may be warranted.

Follow-up is directed at early detection of recurrence (or later, a new primary vulvar tumor), identification and management of treatment-related complications, and surveillance for associated malignancies.

As previously discussed, it is only with local recurrence of vulvar cancer that there is a reasonable expectation for effective salvage treatment. Approximately 10% to 15% of women treated for vulvar cancer will develop an isolated local recurrence or a subsequent new primary vulvar tumor, well more than half of whom receive effective salvage therapy. During follow-up visits, attention is directed at careful inspection and palpation of the vulvovaginal area and groins. Annual cervical or vaginal cuff cytology is also recommended. Patients are encouraged to do self-examinations and promptly report new symptoms or lesions.
VULVAR MELANOMA

Melanoma is the second most common histologic type of malignancy of the vulva, but still accounts for only 5% to 10% of vulvar cancers (Fig. 45.59). This lesion occurs predominantly in white women in the seventh decade, and although the vulva covers only 1% to 2% of the body surface, vulvar melanoma accounts for 3% to 5% of malignant melanomas in women. The most common presenting symptoms are bleeding, a lump or changing mole, and pruritus or irritation. In a small percentage of patients, there is a family history of melanoma.

Melanoma of the vulva is uncommon, so most of the literature on the subject consists of retrospective studies of small numbers of patients. For this reason, the behavior of this tumor is difficult to define, and a rationale for treatment continues to evolve. However, it seems clear that the pattern of regional metastases is the same as that for squamous cell carcinoma; the behavior of the tumor is predicted best by a microstaging system. Importantly, the behavior of vulvar melanoma appears to be very similar to that of cutaneous melanomas in general.

Based on information that has accumulated over the past 3 decades, the treatment of vulvar melanoma is individualized based on clinical-pathologic factors, including microstaging, and modeled using experience derived from cutaneous melanomas in general.

What Do We Know about Cutaneous Melanoma?

Important areas of information that can be extrapolated from the general melanoma literature include individualization of management based primarily on microstaging, determination of what constitutes an adequate margin of resection, and definition of which groups of patients might benefit from an elective regional lymph node dissection.

Clark's classification had been used extensively for the microstaging of melanomas, with division into five levels of invasion (Fig. 45.60). Subsequently, Breslow's classification—based on millimeters of invasion from the upper granular layer of the epidermis to the deepest point of invasion—has become widely used. According to this method, tumor confined to a depth of 0.76 mm or less is generally within the epidermis and behaves as carcinoma in situ. Invasion of 0.76 to 1.49 mm is considered superficial; 1.5 to 4 mm, intermediate; and greater than 4 mm, deep. Some tumors can be quite superficial in measurement and yet be deep melanomas according to Clark's classification.

Over the past 3 decades, the independent prognostic factors in cutaneous melanoma have been well defined. For the

Histologic examination of a regional lymphadenectomy specimen ordinarily includes six or more lymph nodes. If the lymph nodes are negative, but the number ordinarily examined is not met, classify as pN0. Classification based solely on sentinel node biopsy without subsequent axillary lymph node dissection is designated (sn) for sentinel node, e.g., pN1 (sn).

</table>

Primary tumor, these include tumor thickness and ulceration. Clinical or microscopic satellites around the primary tumor are considered to be in-transit lymphatic metastases. The dominant regional prognostic factors include the number or percentage of metastatic lymph nodes, macroscopic versus microscopic metastases, and the presence of clinical or macroscopic satellites around a primary tumor. In patients with distant metastases, the site of metastases, the number of metastatic sites, and an elevated serum lactate dehydrogenase level are most predictive of poor survival. Based on the results of several large studies resulting in this more precise delineation of prognostic factors, the American Joint Committee on Cancer (AJCC) revised the melanoma staging system in 2002 (Table 45.12). The available literature suggests that adequate local treatment for a superficial cutaneous melanoma (less than 1.5 mm in thickness) consists of obtaining a 1-cm margin of skin and subcutaneous tissue. Current data support 2- to 3-cm margins for melanomas of intermediate thickness (1.5–4 mm). A study by the Intergroup Melanoma Trial supports a 2-cm margin for intermediate-thickness melanomas. Exclusion of underlying
fascia continues to be controversial. The local management of deep (greater than 4 mm) melanomas is less clear. The risk of metastatic disease in these patients is high, which lessens the impact of local therapy.

It is generally agreed that melanomas less than 0.76 mm in thickness are associated with a very low risk of lymph node metastases, and elective regional lymph node dissection is not indicated in this group. However, recent evidence suggests that subsets of these patients with adverse prognostic factors should be offered sentinel lymph node biopsy. Patients with melanomas greater than 4 mm in thickness have a high risk of both regional and systemic metastases, and they are less likely to benefit from elective lymph node dissection. There is significant controversy, however, about the benefit of prophylactic lymphadenectomy in patients with intermediate-thickness melanomas. The results of some retrospective studies have shown a beneficial effect of elective lymph node dissection on the survival of these patients. Two prospective studies, one from the Mayo Clinic and one multiinstitutional study directed by the World Health Organization, did not show any significant effect of elective lymph node dissection on survival. However, problems cited with these two studies have included the small numbers of intermediate-thickness melanomas and an imbalance of prognostic factors. In an Intergroup Melanoma Trial, patients with melanomas 1 to 4 mm thick on the trunk or proximal extremities were randomized to wide local excision or elective lymph node dissection versus wide local excision only. Overall survival was not significantly different. However, two subsets of patients had a significantly better overall 5-year survival rate with elective lymph node dissection. These subsets included patients age 60 years or younger and patients with a tumor thickness of 1.1 to 2.0 mm.

Intraoperative lymphatic mapping and sentinel lymph node biopsy were discussed earlier. Detection of occult melanoma cells by a more detailed examination of the sentinel nodes does correlate with recurrence and overall survival, and the information is potentially useful in the decision regarding adjuvant therapy. Since these techniques have come into more widespread use, recommendations regarding elective lymph node dissection are being reconsidered.

What Do We Know about Vulvar Melanoma?

As pointed out by Chung and colleagues, Clark’s microstaging system for melanoma may be less suitable for vulvar tumors because of the lack of a well-defined papillary dermis in much of the vulvar skin and its virtual absence in the mucosal areas. Chung and associates proposed an alternative microstaging system [Fig. 45.60], which combines aspects of the Clark and Breslow systems. Because of the large percentage of vulvar melanomas that arise from or include mucosal membranes, caution is warranted in extrapolating data from squamous cell carcinoma of the vulva and from cutaneous melanoma in general. However, many of the tumors only superficially extend onto mucosal surfaces; until further data are available, it does appear reasonable to consider the available data on cutaneous melanoma and the data on squamous cell carcinoma of the vulva when managing a vulvar melanoma. Factors besides depth of invasion that seem to have an impact on the incidence of nodal metastases and survival include the AJCC stage, the presence of satellite lesions, tumor ulceration, central tumor location, tumor size, and capillary or lymphatic space involvement. The presence of any metastases indicates systemic disease is usually present in women with a depth of invasion greater than 4 mm. In melanomas with depth of invasion between 0.75 and 4 mm, the data are unclear, and many experts continue to recommend regional lymphadenectomy in these patients. As with issues surrounding local tumor management, there is a small amount of literature supporting some of these concepts with site-specific vulvar melanoma data, including the possible benefit from elective lymph node dissection and removal of clinically positive lymph nodes. The overall incidence of lymph node metastases in vulvar melanoma patients is reported to be around 30%. As with squamous cell
Bartholin gland carcinoma. See color version of figure.

**Results**

Overall, about one third of vulvar melanoma patients survive 5 years. This rate is lower than that reported for patients with squamous cell carcinoma of the vulva and with cutaneous melanoma in general. The worse prognosis has been attributed to an older age and a large percentage of deeply invasive and generally more advanced tumors at the time of diagnosis. According to several reports, survival of vulvar melanoma patients does correlate closely with depth of invasion. Other factors include the worse prognosis associated with mucosal melanomas in general and the difficulty in obtaining an adequate resection for the more centrally located tumors. Local recurrence is a common problem after removal of vulvar melanoma and tends to occur on the medial margin of resection. Local recurrence is reported to occur in about one third of patients, and the prognosis for these women is poor. Local tumor control and survival are reduced with more central and deeply invasive tumors. The presence of lymph node metastases also carries a poor prognosis, which has been correlated with the extent and number of lymph nodes involved. When the inguinal lymph nodes are positive, the reported survival rate is in the range of 10% to 31%. Vulvar melanoma has a propensity for late recurrence, and 3-year survival may not be an accurate predictor of cure in these patients.

**BARTHOLIN GLAND CARCINOMA**

A malignancy can arise from the Bartholin gland or duct, with most of the cancers being adenocarcinoma or squamous cell carcinoma. Other much rarer histologic types include transitional cell carcinoma, mixed carcinoma, and sarcoma. Bartholin carcinoma accounts for only 1% to 2% of vulvar malignancies, and, in some cases, a Bartholin origin is not clearcut. Several criteria have been described to define a primary Bartholin malignancy, including anatomic position consistent with a Bartholin tumor, intact overlying skin, areas of apparent transition from normal to neoplastic elements, involvement of areas of the Bartholin gland with an origin histologically compatible with the gland, and no evidence of any other primary cancer. Although some of these criteria may not be met in an individual case, the tumor should at least be in a location consistent with a Bartholin tumor. As with the other rare types of vulvar malignancy, the available information on Bartholin malignancy is derived from retrospective studies of small series of patients.

**Diagnosis**

Bartholin carcinoma should be suspected when a tumor is noted in the region of the Bartholin gland, particularly in a woman older than 40 years of age (Fig. 45.61). The average age at diagnosis is about 50 years, but there is a wide age range. Many studies report a significant delay in diagnosis, attributed both to the deep-seated location of the tumor and to frequent misdiagnosis and treatment as a Bartholin abscess. When a woman presents with a Bartholin mass, biopsy or excision should be considered if she is older than 40 years of age (Fig. 45.61). The average age at diagnosis is about 50 years, but there is a wide age range. Many studies report a significant delay in diagnosis, attributed both to the deep-seated location of the tumor and to frequent misdiagnosis and treatment as a Bartholin abscess. When a woman presents with a Bartholin mass, biopsy or excision should be considered if she is older than 40 years of age (Fig. 45.61).
At the time of diagnosis, inguinal lymph node metastases are present in about half of patients with a Bartholin carcinoma. This propensity for lymphatic spread has been attributed to the frequent delay in diagnosis and the more advanced local extent of these tumors. The pattern of lymphatic spread is the same as that for other vulvar malignancies, primarily to the ipsilateral inguinalfemoral lymph nodes. There are not enough data on wholesale tumor size to provide an accurate estimate of the risk of metastases to the contralateral groin nodes. As with other vulvar cancers, if positive nodes are found, dissection of the opposite groin or radiotherapy to the inguinal and pelvic nodal basins, or both, may be warranted. Inguinal lymphadenectomy in these patients appears to be both prognostically and therapeutically valuable. Local, regional, and distant recurrences are common with Bartholin malignancies, and overall survival rate is lower than that for carcinoma of the vulva in general. Copeland and associates reported on a series of 36 patients with this cancer. The local recurrence rate was 2 of 12 (17%) for patients treated with hemivulvectomy (with or without radiotherapy) and 5 of 24 (21%) for patients treated with radical vulvectomy. The behavior of this rare malignancy appears to be different from that of other Bartholin and vulvar cancers and to be similar to that of adenoid cystic carcinomas arising from other sites, such as the salivary gland. These vulvar tumors have a high local recurrence rate and a propensity for hematogenous metastases. Approximately 20% develop isolated liver metastases. Both local recurrences and metastases can be slowly progressive over a period of years but are not very responsive to radiotherapy or chemotherapy. In view of the difficulty in obtaining adequate surgical margins with Bartholin malignancies in general, and the high local recurrence rate and uncertain sensitivity to radiotherapy with adenoid cystic carcinoma in particular, a concerted effort to obtain at least 2-cm margins should be made when resecting this tumor. Postoperative adjuvant radiotherapy for close or positive margins did appear to be of possible benefit in another 1986 report by Copeland and colleagues and in the report by Rosenberg and associates. From the scant information available, inguinal lymph node metastases occur less frequently with this tumor and have all been ipsilateral. The prognostic and therapeutic value of lymphadenectomy in these patients remains to be defined. The role of adjuvant postoperative chemotherapy for this malignancy also deserves further study.

**Basal Cell Carcinoma**

Although basal cell carcinoma is the most common malignancy of the skin, basal cell carcinoma of the vulva is a rarely reported tumor. Approximately 250 cases have been reported in the literature, and basal cell carcinoma constitutes 2% to 3% of vulvar cancers. The cause is unknown, but there is frequently a history of chronic vulvar irritation. This lesion shares many features with vulvar squamous cell carcinoma. The average age of patients at diagnosis is 65 years, and there is a predilection for white women. Common symptoms include chronic pruritus vulvae and the presence of a mass. Authors have repeatedly reported a delay in diagnosis. Most basal cell carcinomas occur on the labia majora and, less commonly, on the labia minora, urethral meatus, and prepuce of the clitoris. The gross appearance is variable. Tumor size has ranged from 0.2 to 13 cm in greatest diameter, averaging 1.5 to 2 cm. There are also reports of multifocal lesions. As many as 29% of patients with vulvar basal cell carcinoma have a history of other primary cancers. These other cancers have infrequently included coexistent melanoma or squamous cell carcinoma. Keratinization and mature squamous differentiation are commonly found in basal cell carcinomas and do not alter the prognosis. These lesions must be carefully distinguished from the rarer basosquamous carcinoma, which contains a malignant squamous component. This has been estimated to occur in 3% to 5% of basal cell carcinomas. Careful histologic evaluation of the biopsy material is necessary to rule out a malignant squamous component. With the exception of very large lesions, this is best accomplished by excisional biopsy.

One of the subtypes of basal cell carcinoma, adenoid basal cell carcinoma, must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or in the skin of the vulva. Merino and colleagues have suggested clinical and histologic criteria for this distinction. In 1977, Safai and Good reviewed the literature and found 109 cases of basal cell carcinoma of the skin with metastases. These are rare cases, with an incidence of less than 0.1%. Basosquamous carcinoma of the skin, including the vulva, is a more aggressive neoplasm, with the squamous component metastasizing. Basal cell carcinoma of the vulva is also an indolent, locally invasive lesion that rarely metastasizes. There are only ten well-documented cases of metastatic basal cell carcinoma of the vulva in the literature. Nine of these 10 have been lymphatic metastases. When a patient with basal cell carcinoma has suspicious inguinal lymph nodes, these lymph nodes probably should be removed, especially if the vulvar tumor is large or locally advanced. If the inguinal lymph nodes are not suspicious, they can be removed if they become suspicious during follow-up.

**Malignancies of the Vulva**

**Treatment**

Most authorities agree that the treatment of choice for vulvar basal cell carcinoma is wide local excision including a generous amount of underlying subcutaneous tissue. For a multifocal lesion, complete vulvectomy may be appropriate. If a malignant squamous component is present, however, then treatment is the same as that for invasive squamous cell carcinoma of the vulva as outlined above. There is little information available on the use of radiotherapy or chemotherapy in the treatment of primary or metastatic basal cell carcinoma of the vulva, but there is one report of a locally advanced lesion that had a complete response to radiotherapy. Close follow-up is essential, because the local recurrence rate has been reported to be 10% to 21.5%.

**Prognosis**

The overall prognosis for patients with vulvar basal cell carcinoma is difficult to ascertain. In a review by Brenn and colleagues, there was a 5-year survival rate of about 64%. However, they were unable to find documentation for a single death directly related to recurrent or residual basal cell carcinoma. Rather, they attributed the deaths to old age, attrition, and overseas therapy.
The prognosis for the rare metastatic basal cell carcinoma of the vulva is even more difficult to predict. Sworn and coworkers concluded that the prognosis is similar to that for basal cell carcinoma at other skin sites. With basal cell carcinoma elsewhere on the skin, the mean survival after discovery of metastatic disease has been reported to be 10 to 14 months. However, Conway and Hugo reported prolonged survival if only regional lymph nodes are involved.

**SARCOMA OF THE VULVA**

Primary sarcoma constitutes 1% to 3% of all vulvar malignancies. The literature consists of case reports and small series of patients, often with very limited follow-up. In addition, this is a heterogeneous group because of the variety of histologic types and their associated differences in behavior. Hence, the natural history and appropriate treatment of these tumors have not been well defined.

**Leiomyosarcoma**

The most common histologic type of primary vulvar sarcoma is leiomyosarcoma. Most of these patients are in the age range of 40 to 50 years, but a few are younger (one patient was 17). At least three cases of pregnant women with leiomyosarcoma have been reported. According to the descriptions, most patients present with an enlarging mass in the labia majora or Bartholin region (Fig. 45.62A–B). Like tumors at other sites, smooth-muscle tumors of the vulva appear to have a range of appearances and behavior, from benign to malignant. Tavassoli and Norris reported 32 smooth-muscle tumors of the vulva and attempted to delineate the histologic features that might relate to prognosis. They believed that their analysis was impeded by small numbers of patients in subgroups and by varied adequacy of excision. According to their results, prognosis was best predicted by three main determinants (size, tumor contour, and mitotic activity). Neoplasms greater than 5 cm that have infiltrating margins and five or more mitotic figures per 10 high-power fields are likely to recur unless controlled by total excision. It was also determined that lesions larger than 5 cm with infiltrative margins and prominent mitotic activity have a more aggressive behavior as the number of mitotic figures increases. The significance of mitotic activity could not be fully evaluated because of the small number of cases with intermediate grades of mitotic activity and because of other factors. The degree of cellular atypism did not correlate well with the mitotic activity or with recurrence. In 1996, Nielsen and colleagues proposed similar prognostic criteria but included cytologic atypia. In keeping with a range of behaviors, according to the available reports, vulvar leiomyosarcomas may do...
well with adequate excision, may follow a slowly progressive course, or may rapidly progress to fatal. Local recurrences are common, and several authors have recommended early radical excision of these tumors to improve treatment results. As with the other genital tract sarcomas, there is a propensity for hematogenous metastases that may develop early. From the few studies reporting long-term follow-up, it appears that only about half of these patients have inguinal lymph nodes that are visible on clinical examination. In a fit patient with a high-risk but apparently localized tumor, inguinal lymphadenectomy seems reasonable. Radiotherapy has been used in only a few cases with mixed results. Postoperative adjuvant radiotherapy to the pelvis (including the peritoneum) may be worthwhile in selected cases to improve local control. As with other genital tract leiomyosarcomas, chemotherapy has been of limited palliative benefit.

Six cases of myxoid leiomyosarcoma of the vulva have been reported. All were managed by local resection. Three experienced local recurrence that responded well to repeat excision. From available follow-up, five of the six remained alive without evidence of active cancer at 25 to 83 months.

Other Sarcomas

According to our review, 14 cases of dermatofibrosarcoma protuberans (DFSP) of the vulva have been reported. These patients ranged in age from 47 to 87 years and presented with a tumor characteristic of DFSP at other sites. The tumors range in maximum diameter from 1 to 8 cm and are multinodular, firm, seemingly well-circumscribed masses. The mass is reportedly mobile but fixed to the overlying skin from which it originated. The clinical impression of a mobile, well-circumscribed mass is apparent, and MRI and surgical margins. Intraoperative frozen section analysis of margins has also been recommended. Despite this tendency for local recurrence, DFSP behaves like a low-grade sarcoma that rarely metastasizes. In the absence of suspicious lymph nodes, a lymphadenectomy is not warranted. Hematogenous metastases may be seen after multiple local recurrences. Local radiotherapy has not been useful for these tumors, but may be of benefit as adjuvant postoperative treatment for a close resection margin. With adequate resection, the overall prognosis for DFSP of the vulva should be good. Two cases of a fibrosarcoma arising in a vulvar DFSP have been reported, but the clinical behavior and prognosis for such tumors appear to be the same as those for DFSP of other sites.

Six cases of malignant fibrous histiocytoma of the vulva have been reported. The age range of these patients is 38 to 79 years. Five of the six tumors were on the labia majora, and the sixth was vulvovaginal. Based on these few reports and the more extensive literature on malignant fibrous histiocytoma at other sites, recommended treatment includes radical excision of the tumor with an inguinal lymphadenectomy. Adjuvant radiotherapy and chemotherapy may have a role, and the one vulvovaginal tumor reported was without evidence of recurrence 6 years after sequential chemotherapy and radiotherapy. We found five reports of pure fibrosarcoma of the vulva. Two of these patients died with disseminated disease at 3 weeks and 16 months after diagnosis, and one patient had inguinal lymph node metastases but was without evidence of recurrence at 48 months. According to the general literature on fibrosarcomas, the malignant potential varies depending on the origin and the histologic pattern (cellularity, mitotic activity). Three of the four reported patients who were treated developed local recurrences (two of them repetitive). This is in agreement with the general behavior reported for these tumors. Again, the importance of wide excision at the time of primary treatment is emphasized. Fibrosarcoma is reported to only rarely metastasize to lymph nodes; however, as previously pointed out, one of the five described cases did have an isolated lymphatic metastasis.

Nineteen primary epithelioid sarcomas of the vulva have been reported. Nine of the women were 31 years of age or younger, and five of the lesions arose on the labium majus. Seven of the patients developed repetitive local recurrences (generally in the form of multiple subcutaneous nodules) and coincident or subsequent hematogenous or lymphatic metastases, or both, and died over the course of months to years. This tumor apparently penetrates along soft tissue planes, and there is reported difficulty in delineating tumor extent. Radical excision with wide, clear margins seems to be the most reasonable initial treatment. Regional lymphadenectomy should be considered on an individual basis.

A few malignant rhabdoid tumors of the vulva have also been reported. There is apparent difficulty distinguishing this malignancy histologically from epithelioid sarcoma. Both tumors present similarly as a benign-appearing labial mass in young women. Malignant rhabdoid tumors may follow an even more aggressive course.

Although sarcomas constitute only a small percentage of vulvar malignancies in general, they account for most vulvar cancers in children and young women. Overall, pediatric vulvovaginal rhabdomyosarcoma has a good prognosis and greatly reduced treatment morbidity because of the efficacy of combined treatment modalities (especially chemotherapy and brachytherapy). Rhabdomyosarcoma arising in older women and other histologic variants of rhabdomyosarcoma may not be so amenable to therapy.

At least 100 cases of aggressive angiosarcoma involving the female pelvis or perineum, or both, have been described, and at least 14 of these primarily involved the vulva. It is an unusual tumor derived from fibroblasts or myofibroblasts with nuclei that have no atypical features or mitotic activity. The tumor appears to be locally invasive and spreads by direct extension only. Local recurrences are common, although there have been no reported deaths attributable to this tumor. The mainstay of treatment is wide excision both primarily and for recurrences. Response to gonadotropin-releasing hormone has been reported.

Isolated reports of a variety of other types of sarcomas arising in the vulva have been published. Treatment of these various sarcomas must be individualized according to the specific tumor available, the potential aggressiveness of the malignancy as suggested by the pathologist, and the individual situation.

**PAGET DISEASE OF THE VULVA**

Paget disease is classified, according to location, as mammary or extramammary disease. The original lesion described by...
Paget is a skin (nipple and areola) lesion related to an underlying invasive ductal adenocarcinoma. Extramammary Paget disease most commonly involves the anogenital region, appearing as a patchy, redish, and whitish, velvety, and exzematous lesion (Fig. 45.63). Patients with Paget disease of the vulva are usually white, postmenopausal women who report localized itching and burning.

Paget disease of the vulva is of apocrine origin and is confined to the epithelium in most cases. However, invasive disease is present in about 15% to 25% of cases, either as a result of direct invasion through the basement membrane or, less commonly, because of the presence of an underlying apocrine gland adenocarcinoma. Histologically, intraepithelial Paget disease appears as large, pale cells, often in nests at the tips of the rete ridges (Figs. 45.64 and 45.65). The cells are often seen infiltrating upward in the epithelium, which is hyperkeratotic. The Paget cells can be located within any of the skin adnexa.

Vulvar Paget disease occurs with other malignancies in about 25% of patients; the most common of these is breast carcinoma. Other commonly associated malignancies are basal cell, rectal, and genitourinary carcinomas. When Paget disease involves the anus, there is a very high incidence of coexisting rectal cancer. Part of the preoperative workup should be directed at screening for these malignancies. Wilkinson and Brown proposed a classification of vulvar Paget disease as primary or secondary (involvement of the vulvar skin by a noncutaneous internal neoplasm). They subclassified primary disease according to the presence of invasive cancer and subclassified secondary disease according to tumor origin. They report that secondary vulvar Paget disease is always intraepithelial.

When a patient is diagnosed with Paget disease of the vulva, the lesion is usually nodular and palpated to detect areas suspicious for invasive cancer. If the disease clinically appears to be intraepithelial, a wide local excision is performed, including a small amount of subcutaneous tissue. A well-known characteristic of intraepithelial Paget disease is histologic extension far beyond that which is clinically apparent. Intraoperative assessment of margins with frozen sections may be helpful (Fig. 45.63B–D). Other methods that have been reported to be useful in ensuring clear margins include preoperative biopsies, Mohs micrographic surgery, and fluorescence dye with ultraviolet light. Colposcopy and toluidine blue staining are not helpful, according to Friedrich and colleagues. An experimental technique reported to be potentially useful in evaluating histologically negative margins is the application of a panel of monoclonal antibodies that may detect occult Paget disease, and many of the reports of such spread have shown histologic evidence of nests of squamous cell carcinoma invading the stroma beneath the tumor. Some authors have suggested that if areas of distinct invasion are found beneath a verrucous lesion, the behavior may be more aggressive, and treatment should be more radical. Inflammatory enlargement of the inguinal lymph nodes has been a frequently reported finding with verrucous carcinoma of the vulva.

Verrucous carcinoma of the vulva is excision with free margins. How the disease clinically appears to be intraepithelial, a wide local excision is performed, including a small amount of subcutaneous tissue. A well-known characteristic of intraepithelial Paget disease is histologic extension far beyond that which is clinically apparent. Intraoperative assessment of margins with frozen sections may be helpful (Fig. 45.63B–D). Other methods that have been reported to be useful in ensuring clear margins include preoperative biopsies, Mohs micrographic surgery, and fluorescence dye with ultraviolet light. Colposcopy and toluidine blue staining are not helpful, according to Friedrich and colleagues. An experimental technique reported to be potentially useful in evaluating histologically negative margins is the application of a panel of monoclonal antibodies that may detect occult Paget cells.

When intraepithelial Paget disease extends far beyond that which is clinically apparent, very extensive excision is necessary to obtain clear margins. Primary closure of vulvar wounds is desirable, but may not be possible. Reported means of dealing with such cases include skin grafting and laser vaporization of the occult disease (guided by peripheral biopsies). There are a few reports of Paget disease recurring within a skin graft.

Topical 5-fluorouracil or bichloracetic acid, administered either preoperatively or postoperatively, has also been used to treat the clinically negative disease. If it appears that excision of persistently positive margins may prevent primary closure, it is not unreasonable to close the wound and follow the patient closely.

After excision of intraepithelial Paget disease of the vulva, local recurrence develops in about one third of patients (Fig. 45.66). This tends to take the form of multiple recurrences over a prolonged period of time. In some studies, recurrence risk has been correlated with excisional margin status, but it also has been pointed out that the initial disease in some cases is multifocal. Of particular concern are a few reports of patients whose recurrent lesions eventually became invasive. Whether such instances are preventable by diligently eradicating the full histologic extent of the disease is not known.

When vulvar Paget disease is found to contain an invasive component, the treatment is radical surgery, as for squamous cell carcinoma. Overall, these patients have a high incidence of inguinal lymph node metastases with an associated poor prognosis. The role of adjuvant therapy in these patients is unclear.

Management of recurrent intraepithelial Paget disease of the vulva is similar to that of the primary lesion, with excision of at least the clinically evident disease.

Verrucous carcinoma of the vulva is a rare variant of squamous cell carcinoma, with about 30 cases reported in the literature. This tumor was first described in the oral cavity by Ackerman in 1948 and most commonly occurs in the oral cavity, larynx, and anogenital region. The mean age of the women diagnosed with this malignancy of the vulva is about 30 years. The reported tumors have ranged from 1 to 10 cm in maximum diameter and appear as a slow-growing, cauliflower-like tumor (Fig. 45.67). Characteristically, verrucous cancers have well-demarcated borders that are pushing rather than infiltrating. Verrucous carcinoma can be confused with condyloma; when an apparent condyloma (especially when large and in an older woman) does not respond to the usual conservative measures, it should be excised. About one third of patients with vulvar verrucous carcinoma have a history of genital warts, and human papillomavirus (HPV) has been detected in some lesions, the most common type being HPV-6.

The diagnosis of verrucous carcinoma requires a large (preferably excisional) biopsy that must include the base of the lesion. Verrucous carcinoma is rarely associated with metastatic disease, and many of the reports of such spread have shown histologic evidence of nests of squamous cell carcinoma invading the stroma beneath the tumor. Some authors have suggested that if areas of distinct invasion are found beneath a verrucous lesion, the behavior may be more aggressive, and treatment should be more radical. Inflammatory enlargement of the inguinal lymph nodes has been a frequently reported finding with verrucous carcinoma of the vulva.

It is generally agreed that the main treatment of verrucous carcinoma of the vulva is excision with free margins. How radical this resection should be is unclear, but local recurrences have not been uncommon (Fig. 45.68). Local lesions have had a good initial response to radiation therapy but a high rate of subsequent recurrence and about a 30% incidence of anaplastic transformation with associated aggressive behavior. The few reported cases of metastatic verrucous carcinoma of the genital tract have followed radiotherapy. However, many
FIGURE 45.63. A: Paget disease of the vulva. Reddish, eczematous, excoriated (from scratching) skin over the right anterior vulva. B: Outline for preliminary excision of margin in quadrants (skin within the two parallel lines will be removed as four separate strips, marked according to the clock). C: Strip of skin being excised from lower lateral quadrant. D: Margin strip is excised circumferentially. Lesion is excised while the surgeon waits for the frozen-section results.
tumors have been successfully treated with a combination of surgery and radiotherapy; when a tumor is locally advanced, this seems to be a reasonable treatment. Inguinal lymphadenectomy may be indicated in patients with large tumors, in patients with persistence or recurrence of disease, especially after radiotherapy, and in patients with infiltrating cancer beyond very early invasion below the verrucous tumor. Biopsy specimens may be obtained of enlarged lymph nodes thought to be inflammatory.

Verrucous carcinoma of the vulva has been associated with second malignant tumors, most commonly of the cervix, breast, and anogenital skin. Although verrucous carcinoma of the genital tract is a slow-growing tumor that rarely metastasizes, a 1988 review by Andersen and Sorensen reported that 26.1% of the patients with this type of carcinoma had died of disease.

**MERKEL CELL CARCINOMA OF THE VULVA**

Merkel cell cancers are small-cell (neuroendocrine) tumors of the skin that occur most commonly in sun-exposed areas (head, neck, and extremities) and behave in an aggressive manner. This malignancy was first described in 1972 by Toker, and about 500 cases have been reported since. At least 11 cases of vulvar origin have been reported. The ages of these
10 patients ranged from 28 to 74 years, and the tumors occurred in all regions of the vulva (three in the Bartholin gland). When originating from the vulva, Merkel cell carcinoma has behaved in a highly aggressive manner (even more so than Merkel cell tumors in general), with nine patients having regional lymph node metastases. At least seven had distant metastases and died within 2.5 years of diagnosis. Surgery and radiotherapy appear to be of value for local control only, and as yet no effective systemic treatment exists. As in the treatment of small-cell carcinoma of the lung, etoposide and cisplatin have been used for a few cases of Merkel cell carcinoma, with good responses. Three of the vulvar cases were treated with this regimen. Two progressed, and one had a partial response of very short duration.

**SUPERNUMERARY MAMMARY ADENOCARCINOMA**

Ectopic breast tissue in the vulva is very rare, but at least nine cases of mammary-type adenocarcinoma arising in the vulva have been reported. These patients ranged in age from 49 to 71 years, and five of the nine presented with an asymptomatic vulvar nodule. Only one of the patients had evidence of primary breast cancer, but rather than representing metastatic disease, the vulvar lesion appeared to be primary from ectopic tissue. The diagnosis of vulvar mammary adenocarcinoma is based primarily on the histologic pattern of the vulvar tumor. Other criteria can include the finding of adjacent normal mammary glandular elements (one case of adjacent in situ malignancy), the presence of estrogen or progesterone receptor positivity, positivity for common breast markers, and ruling out an origin from skin appendages.

One of the nine patients died of disease without treatment 1 month after diagnosis. The patient with coexistent primary
Gynecologic Oncology

breast carcinoma died of widespread metastatic (including cerebral) disease 22 months after the diagnosis. One patient had 2 of 10 positive ipsilateral inguinal lymph nodes and was placed on tamoxifen postoperatively; this patient remained without evidence of recurrence at 1 year. A fourth patient had extensive nodal metastases at the time of diagnosis, subsequently developed distant metastases, and died of disease 27 months after diagnosis despite chemotherapy. A fifth patient had 4 of 11 positive ipsilateral inguinal lymph nodes and was placed on tamoxifen postoperatively. After 2 years of disease-free survival, the patient stopped taking the tamoxifen and presented 4 months later with bony metastases. After radiotherapy and resection of tamoxifen, she was disease-free at 1 year of follow-up. A sixth patient had microscopic involvement in 1 of 14 ipsilateral lymph nodes. She received adjuvant chemother-apy with a plan for subsequent radiotherapy and tamoxifen. Follow-up was not available for the other three patients, but two of the three had undergone an inguinal lymphadenectomy, and in both cases there were positive lymph nodes.

Beyond surgical treatment, such a rare patient might be considered for adjuvant therapy (especially with metastatic disease) such as radiotherapy, tamoxifen (if estrogen receptor-positive), or chemotherapy.

OTHER REPORTED VULVAR MALIGNANCIES

There are scattered reports of a variety of adenocarcinomas arising in the vulva other than those previously discussed. Most of these have arisen from recognizable adenomatous sources, such as adnexal structures and endometriomas. There are five reports of malignancy arising in the vulva from isolated foci of extravascular endometriosis; four were clear-cell adenocarcinomas, and the fifth was an endometrial stromal sarcoma. There are also rare reports of vulvar sebaceous carcinoma, apocrine gland carcinoma, mucinous carcinoma, lymphoma, and a peripheral primitive neuroectodermal tumor.

At least four endodermal sinus tumors of the vulva have been reported. The ages of these patients were 22 months, 2 years, 15 years, and 26 years, and all four presented with a painless vulvar mass. Three of the four patients died of metastatic disease 6, 11, and 23 months after diagnosis. The 2-year-old patient remains without evidence of recurrence 5.5 years after local excision.

A variety of metastatic lesions to the vulva have been documented, most commonly from the gynecologic tract. Non-gynecologic metastatic disease to the vulva is rare, with isolated reports of primary sites such as the urinary tract, colorectum, skin (melanoma), non-Hodgkin’s lymphoma, lung and breast.

BEST SURGICAL PRACTICES

Prognostic Factors
— The dominant prognostic factor for invasive squamous cell carcinoma of the vulva is the status of the inguinofemoral lymph nodes.
— Primary tumor factors that appear to have prognostic importance include ulceration or tumor thickness, tumor diameter, tumor differentiation, lymph-vascular space involvement, and margin status.

Pretreatment Investigation
— A biopsy confirming the presence of invasive cancer is necessary before any therapy. Because of the frequent advanced age and coexisting medical problems typical of women with vulvar cancer, a thorough preoperative evaluation by internal medicine and anesthesiology consultants should be considered. Sophisticated radiologic evaluation is only of potential benefit in the presence of locoregionally advanced disease.

Treatment of Invasive Squamous Cell Carcinoma of the Vulva
— Unilateral groin lymphadenectomy. Limiting inguinofemoral lymphadenectomy to the ipsilateral side appears to be a reasonable approach in a patient with a well-lateralized early tumor that is well differentiated, with no lymph-vascular space involvement, and without positive ipsilateral inguinal lymph nodes.
— Superficial inguinal lymphadenectomy. In patients with early invasive squamous cell carcinoma of the vulva, removal of the lymph nodes superficial to the cribiform fascia may result in a lower incidence of wound complications and subsequent lymphedema. The approach has been widely used in recent years, but there is some concern that the risk of groin recurrences is higher than standard inguinofemoral lymphadenectomy.
— Sentinel lymph node identification. Preliminary results suggest that lymphatic mapping with a combination of isosulfan blue dye and technetium-labeled sulfur colloid followed by sentinel lymph node dissection is applicable to a large percentage of women with early invasive squamous cell carcinoma of the vulva. However, many questions require further investigation to better define the usefulness of the sentinel lymph node approach in women with vulvar cancer.
— Pelvic lymph nodes. Pelvic lymphadenectomy is not indicated in most patients with vulvar cancer. Pelvic radiation therapy is usually administered in patients with positive groin nodes, but surgical resection of enlarged pelvic nodes may be considered.

Locally Advanced Vulvar Cancer
— About 30% to 40% of vulvar cancers are locally advanced. Current approaches to the treatment of locally advanced vulvar cancer include ultraradical surgery, radiotherapy, or a combination of treatment modalities.

Recurrent Squamous Cell Carcinoma of the Vulva
— About 15% to 45% of patients with squamous cell carcinoma of the vulva develop recurrence after treatment. Only with an isolated local recurrence is there reasonable expectation of successful salvage therapy (preferably resection).

Reconstructive Techniques for the Vulva and Groin
— When an extensive resection of a vulvar malignancy or a groin node metastasis is necessary, it may not be possible to close the wound primarily. Under these circumstances, closure of the incision and healing can be facilitated by a variety of reconstructive procedures. Leaving the wound open is another reasonable option.

Uncommon Histologic Types
— Melanoma, basal-cell carcinoma, cancers of the Bartholin gland, invasive Paget disease, and other uncommon or rare vulvar tumors are often managed differently from squamous cell carcinoma. A biopsy of the lesion should identify these lesions to allow special treatment planning.

CHAPTER 46 ■ CERVICAL CANCER
PRECURSORS AND THEIR MANAGEMENT
HOWARD W. JONES III

DEFINITIONS

The Bethesda System (TBS)—Another classification system that was introduced in 1991 for grading cytologic abnormalities. It has also been used for histologic diagnoses. Low-grade squamous intraepithelial lesion (LSIL) = mild dysplasia/human papillomavirus changes. High-grade squamous intraepithelial lesion (HSIL) = moderate/severe dysplasia or carcinoma in situ.

Carcinoma in situ—A histopathologic diagnosis involving severe epithelial atypia. In the cervix, the full thickness of the cervical epithelium is atypical, but the basement membrane remains intact. Despite the confusing name, the lesion is not a cancer. It does not metastasize.

Cervical cytology—a diagnostic technique that involves microscopic examination of individual cells or cell clusters scraped, brushed, or washed from the surface of the cervix and stained with Papanicolaou’s stain. The nuclear/cytoplasmic ratio is used to diagnose the degree of cervical abnormality presently. It is a common screening test for cervical cancer.

Cervical dysplasia—Dysplasia is a pathologic term to indicate noninvasive epithelial atypia that involves various degrees of the cervical epithelium. By convention, in mild dysplasia, the nuclear atypia, mitoses, and cellular irregularity involved the lower one-third of the squamous epithelium. When the atypia involves the middle third, the diagnosis is moderate dysplasia; in severe dysplasia, the upper one-third of the epithelial layer is involved. A full-thickness change is called carcinoma in situ.

Cervical intraepithelial neoplasia (CIN)—A cytologic and histologic classification of preinvasive cervical atypias or neoplastic changes. In general, CIN 1 = mild dysplasia, CIN 2 = moderate dysplasia, and CIN 3 = severe dysplasia/carcinoma in situ.

Colposcopy—A diagnostic technique in which the examiner visualizes the cervix and other areas of the lower genital tract with a low-power (3–15×) binocular scope. The surface contour, vascular pattern, and staining pattern with dilute acetic acid and Lugol’s iodine allow the experienced colposcopist to diagnose the severity and extent of cervical abnormality and to select a location for biopsy confirmation.

LEEP—Leuk electrosurgical excision procedure; also called a LLETZ (large loop excision of the transformation zone). A thin wire electrosurgical loop electrode of 1 to 2.5 cm in diameter is used to excise the transformation zone under local anesthesia.

Squamosocolumnar junction—The junction between the squamous and columnar epithelium on the cervix. Although it is found in the area of the external cervical os in most women during the reproductive years, it is a dynamic, ever-changing location.

Terminology—A colposcopic term for the area of cellular change that is observed adjacent to the squamo-columnar junction.

Although cellular atypia adjacent to invasive squamous cell cancers of the cervix has long been recognized, it was not until the 1950s that carcinoma in situ of the cervix was characterized and its preinvasive potential became accepted. In their 1952 publication, Galvin, Jones, and Te Linde described their observations of the natural history of carcinoma in situ. Their report confirmed and advanced previous studies by Thomas Cullen and Pemberton and Smith. The concept of a clearly identifiable preinvasive neoplastic change in the cervical epithelium represented a major breakthrough in an understanding of the development and natural history of cervical cancer. However, it was the parallel development of cervical cytology that provided a technique that made this concept clinically useful. Because these preinvasive epithelial changes are asymptomatic and essentially unrecognizable on gross inspection or palpation, the concept of a preinvasive lesion was not particularly useful to the clinician until it was shown such lesions could be diagnosed by cervical cytology. The introduction of practical cytology by Papanicolaou and Traut in 1943 and its later widespread adaptation into clinical practice represented the second major development in cervical cancer prevention. These developments have been further assisted by the use of colposcopy, which allows the clinician to visually identify these preinvasive lesions on the cervix, determine their extent, and select a site for biopsy confirmation. Once the extent and severity of the lesion have been evaluated and invasive cancer has been ruled out, these preinvasive epithelial changes can usually be treated with simple, inexpensive conservative techniques with preservation of fertility. These developments have led to a dramatic 70% reduction in cervical cancer deaths in the United States over the past 50 years. In addition, the intense study of these preinvasive cervical epithelial changes has enabled us to understand the mechanisms of the development of cervical cancer and the role of human papillomavirus.

This chapter discusses the cytologic, histologic, and molecular changes that occur in the cervix as cervical cancer develops and how these preinvasive lesions can be diagnosed and treated.

TERMINOLOGY

Although carcinoma in situ became well recognized as a full-thickness epithelial change without stromal invasion, the terminology and clinical significance of adjacent,
less-than-full-thickness atypia was uncertain. In 1956, Reagan and Hamon introduced the term dysplasia to designate these cervical epithelial abnormalities that were characterized by cyto-
logic atypia, increased mitotic activity, and loss of polarity. If these biased changes involved only the basal one third of the epithelium, they were referred to as mild dysplasia. Changes extending into the middle third of the cervical epithelium were called moderate dysplasia, and when more than two thirds of the epithelium was involved, the lesion was designated severe dysplasia. At its first international meeting in 1961, the International Congress on Exfoliative Cytology accepted the following definition: “Only those cases should be classified as carcinoma in situ, or which, in the absence of invasion, show as surface lining epithelium in which, throughout its whole thick-
ness, no differentiation takes place. The process may involve the lining of the cervical glands without thereby creating a new group. It is recognized that the cells of the uppermost layers may show some slight flattening.” At this same meeting, dys-
plasia was defined as “all other disturbances of differentia-
tion of the squamous epithelium of surface and glands. They may be characterized as of high or low degrees, terms that are preferable to ‘suspicious’ and ‘non-suspicious’ as the proposed terms describe the histological appearance and do not express an opinion.” It generally was assumed that these lesions repre-
sented a spectrum of disease and that the more severe abnor-
malities were more likely to progress to invasive cancer and to do so in a shorter period of time. However, it was not un-
til the studies of Barron and Richart and later of Naeuil and colleagues that the natural history of these premalignant lesions became well understood.

The original cytologic classification introduced by Papani-
colaou was a four- or five-step “class” designation, in which “class 1” was normal or benign and “class 5” was suspicious of malignancy. This terminology was replaced gradually by the histologic terms of mild, moderate, or severe dysplasia and carcinoma in situ, although various modifications were formally or informally introduced and adopted in the United States and throughout the world. One of the most important values of an accurately defined and widely accepted terminol-
ogy is that it allows investigators and clinicians to accurately observe and classify the natural history of a disease or lesion and the effect of various treatments on the outcome and to communicate these findings to others. Over time, it became clear that histopathologists and cytopathologists could not accu-
curately and reproducibly differentiate between severe dyspla-
sia and carcinoma in situ. In addition, clinicians managed these two lesions in a similar fashion. Therefore, in 1976, Richart proposed the terminology of cervical intraepithelial neoplasia (CIN), which combined the categories of severe dysplasia and carcinoma in situ into the term CIN 3; Cervical intraepithe-
lial neoplasia, grade 1 (CIN 1) was essentially the same as mild dysplasia, and CIN 2 was similar to moderate dysplasia. But CIN 3 combined severe dysplasia and carcinoma in situ, thus simplifying the classification from four categories to three (Table 46.1). This practical terminology was favored by clin-
icians and widely adopted throughout the world. It has been used for both cytologic and histologic diagnoses.

However, as the role of human papillomavirus (HPV) in cervical neoplasia became more evident and the difficulties of intraobserver variation with a lack of reproducibility of cy-
tologic diagnoses became better accepted, another change in terminology was undertaken. At a series of conferences held at the National Institutes of Health, Bethesda, Maryland, The Bethesda System was introduced and first published in 1991 and subsequently updated and revised in 2001 (Table 46.2). These conferences clarified a number of ill defined or previ-
ously undefined problems with cytologic diagnoses, such as what constituted an adequate specimen for accurate interpreta-
tion. It tried to eliminate the term atypia, which had become in-
creasingly used to designate a wide range of nonspecific changes that were clinically confusing. The Bethesda System combined HPV cytopathologic effects, often referred to as koilocytoto-
sis, with mild dysplasia or CIN 1 into a category called low-
grade squamous intraepithelial lesion (LSIL). More significant lesions—including moderate and severe dysplasia and carci-
oma in situ, or CIN 2 and 3—were combined into high-grade squamous intraepithelial lesion (HSIL). Pap tests with “cellul-
ar abnormalities that are more marked than those attributable to reactive changes but that quantitatively or qualitatively fall short of a definitive diagnosis of squamous intraepithelial le-
ison” are placed in a category called atypical squamous cells (ASC). These specimens may be further categorized as of unde-
termined significance (ASC-US) or cannot exclude high grade (ASC-H). This latter category, together with more specific diag-
nostic terminology for glandular abnormalities, were new ad-
ditions in the 2001 revision of the Bethesda System. Although the Bethesda System terminology for reporting the results of cervical cytology has been almost universally accepted in the United States and is used in many other countries, other ter-
minality and definitions are used in Great Britain, Germany, Australia, and other countries, which creates some difficulty in publishing and understanding scientific studies from different countries.

In the United States, a typical laboratory that processes cer-
vical cytology from an average, generally low-risk population reports epithelial cell abnormalities in about 3% to 6% of pa-
tients. Usually one half to two thirds of these abnormalities are ASC (1%/4%), whereas 1%/2% are LSIL and 0.3% to 1.0% are HSIL diagnoses, with occasional glandular cell abnormali-
ties. The ratio of ASC to SIL diagnoses should be between 2:1 and 3:1 for most cytology laboratories.

The Bethesda System was designed and published to be used for cytologic diagnoses; however, it has been applied increas-
ingly to histologic or tissue diagnoses. This is advantageous in that it provides uniform terminology for both cytology and cervical biopsies. However, by combining moderate dysplasia, severe dysplasia, and carcinoma in situ, it lacks the imagined specificity that is occasionally helpful in clinical management decisions. The word imagined is used intentionally because many studies have shown that there is a significant lack of reproducibility in the diagnoses of various grades of dyspla-
sia and even carcinoma in situ. There is no clear dividing line between the different cytologic or histologic grades of cervi-
cal epithelial atypias, lesions, or neoplasias, and the diagnosis

*The Bethesda System classification of low-grade SIL includes both CIN 1 and HPV change; SIL, squamous intraepithelial lesion; CIN, cervical intraepithelial neoplasia; HPV, human papillomavirus.
TABLE 46.2

THE BETHESDA SYSTEM OF CYTOLOGIC CLASSIFICATION

The 2001 Bethesda System (Abridged)

SPECIMEN ADEQUACY

Satisfactory for evaluation (note presence/absence of endocervical/transformation zone component)

Unsatisfactory for evaluation: . . . (specify reason)

Specimen rejected/not processed (specify reason)

Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)

GENERAL CATEGORIZATION (OPTIONAL)

Negative for intrap epithelial lesion or malignancy

Epithelial cell abnormality

Other

INTERPRETATION/RESULT

Negative for Intrap epithelial Lesion or Malignancy

Organisms

Trichomonas vaginalis

Fungal organisms morphologically consistent with Candida species

Shift in flora suggestive of bacterial vaginosis

Bacteria morphologically consistent with Actinomycetes species

Cellular changes consistent with herpes simplex virus

Other nonneoplastic findings (Optional to report; list not comprehensive)

Reactive cellular changes associated with inflammation (includes typical repair), radiation, intrauterine contraceptive device

Glandular cells status posthysterectomy

Atrophy

Epithelial Cell Abnormalities

Squamous cell

Atypical squamous cells (ASC)

Of undetermined significance (ASC-US)

Cannot exclude high-grade squamous intraepithelial lesion (HSIL) (ASC-H)

Low-grade squamous intraepithelial lesion (LSIL)

Encompassing human papillomavirus/mild dysplasia/ cervical intraepithelial neoplasia (CIN) 1

High-grade squamous intraepithelial lesion (HSIL)

Encompassing moderate and severe dysplasia, carcinoma in situ, CIN 2 and CIN 3

Squamous cell carcinoma

Glandular cell

Atypical glandular cells (AGC) (specify endocervical, endometrial, or not otherwise specified)

Endocervical adenocarcinoma in situ (AIS)

Adenocarcinoma

Other (List not comprehensive)

Endometrial cells in a woman ≥40 years of age

AUTOMATED REVIEW AND ANCILLARY TESTING (INCLUDE AS APPROPRIATE)

EDUCATIONAL NOTES AND SUGGESTIONS (OPTIONAL)

on the Papanicolaou or biopsy report is a general impression, not a precise predictor of the benign or malignant behavior of the cervical epithelium sampled. Nevertheless, many clinicians would favor conservative follow-up only in an 18-year-old with CIN 2 or moderate dysplasia, but a diagnosis of CIN 3 or severe dysplasia would make the same clinicians favor treatment. Both diagnoses fit into the HSIL category, and this creates a problem of possible overtreatment or overevaluation for some patients with a cytologic or histologic diagnosis of HSIL. The clinician’s desire for a precise cytologic or histologic diagnosis that accurately predicts the likelihood of a given lesion to progress to invasive cancer cannot be satisfied by even the most experienced and expert pathologist. However, molecular markers, including HPV and P-16 testing, provide hope for more specific clinical predictors in the future.

EPIDEMIOLOGY

In 1842, Ragoni-Stern noted that cervical cancer was found in married women, but was virtually absent in celibate groups such as Catholic nuns. This observation was one of the earliest epidemiologic studies of any cancer. Others noted that cervical cancer was almost never found in virgin women and that a woman’s risk of developing cervical cancer was directly related to the number of male sex partners she had had. Subsequent epidemiologic studies reported that early age at first sexual intercourse, low socioeconomic status, cigarette smoking, and early age at first pregnancy increased a woman’s risk of cervical neoplasia. More recently, it became obvious that immunosuppression from any cause, including infection with human immunodeficiency virus (HIV), substantially increased a woman’s risk of cervical neoplasia. Oral contraceptive use has been reported to increase a woman’s risk of cervical cancer as well, but the odds ratios are relatively low, and it is difficult to control for confounding factors.

Many of these epidemiologic studies have shown a pattern of cervical cancer that is typical for a sexually transmitted infection. For this reason, investigators focused on etiologic agents that might be passed by intimate sexual contact. Virtually every sexually transmitted agent has been studied for its relation to cervical neoplasia, including Chlamydia, gonorrhea, Chel- nera, Mycoplasma, Trichomonas, and herpes simplex virus (HSV).

As the epidemiologists studied the lifestyle characteristics of women with cervical cancer and cytopathologists described the microscopic morphologic transition of the cervical epithelium, clinicians were observing certain abnormalities on the cervix in patients with the preinvasive changes of cervical dysplasia. First popularized by Hinselmann in Germany, the colposcope is a magnifying instrument used to examine the cervix. With the colposcope, vascular changes and other epithelial patterns were recognized and correlated with the cytologic and histologic changes that were being described. These early neoplastic changes were most prominent adjacent to the squamocolumnar junction (SC), and this area was called the transformation zone. With time, colposcopic patterns associated with the developing stages of dysplasia and early invasive cancer were identified and described by Mestwerdt, Wespi, Kolstad, Stoff, Bargarth, Cuzenx, Coppesson, and others. In 1974, Stoll and Mattingly brilliantly synthesized these observations and the work of the epidemiologists and proposed a theory of the development of cervical cancer (Fig. 46.1). They did not know the identity of the environmental carcinogen that they presumed was sexually transmitted, but they proposed a framework that has been enormously useful for the clinician.
In 1976, Meisels and Fortin—and in 1977, Purola and Savia—reported finding HPV in the nuclei of dysplastic squamous epithelial cells, particularly those that had koilocytotic features. These observations were confirmed by a number of other investigators, and it was suggested by zur Hausen that this virus might be important etiologically in cervical carcinogenesis. Using electron microscopy and antibodies to the HPV capsid protein, several investigators identified viral particles or HPV-related antigens in CIN. They were particularly prevalent in low-grade lesions and became less frequently observed in cells associated with higher-grade lesions. These observations strongly implicated HPV as a possible etiologic agent in cervical neoplasia and led to an explosion of molecular and clinical studies of HPV and its related lesions.

**HUMAN PAPILLOMAVIRUSES**

Human papillomaviruses are members of a large family of viruses known as the *Papovaviridae*. This includes another oncogenic DNA virus, the simian virus 40 (SV40), as well as the polyomavirus. All the viruses in this group are DNA tumor viruses. Although they have dissimilar DNA base-pair sequences and dissimilar capsular antigens, they appear to produce neoplasms through similar mechanisms. The papillomaviruses have a tightly coiled, circular, double-stranded DNA molecule about 8,000 base pairs in length. The complete virion consists of a DNA core and a surrounding protein capsid that measures about 45 to 55 nm in diameter. The capsid has an icosahedral shape. Papillomaviruses are found throughout the animal kingdom and infect not only humans but cattle, rabbits, dogs, deer, monkeys, and birds. The viruses are highly species specific. Cross-infections between species have not been reported. Unlike many viruses that infect humans and that are classified by their surface antigens, the papillomaviruses are classified according to their DNA base-pair sequence. The degree of relatedness is determined by the degree of hybridization homology.

Although in animals papillomaviruses can infect both epithelial cells and fibroblasts, the human papillomavirus is an exclusively epitheliotropic virus that produces alterations in the supporting structures solely as a secondary effect related to infection of the epithelium. HPV infects virtually all surface epithelia, including the skin and mucous membranes. The infected epithelium is characterized by epithelial proliferation at the infected site, by various degrees of epithelial thickening, and by papillomatosis.

At least 100 HPV types have been identified; about 25 of these affect the male and female anogenital tract. The most prevalent anogenital HPVs can be divided into three groups that are predictive of their ability to produce neoplasia (Table 46.3). Low-risk HPV types are commonly associated with...
cellular changes described as CIN 1, but they rarely, if ever, are associated with high-grade dysplasia or invasive cancer. They may also be associated with condyloma. HPV types 6 and 11 are responsible for approximately 90% of all benign genital warts (condyloma) seen in the United States. On the other hand, the anogenital HPV types with a high oncogenic risk are types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 38, 59, and 68. HPV types with a low oncogenic risk are represented in high-grade lesions. The group with a low oncogenic risk or no oncogenic risk includes HPV types 6, 11, 42, 43, and 44. HPV types 16 and 18 are very-high-risk cervical cancer viruses.

Recent epidemiologic studies from all parts of the world have shown that almost all women with CIN lesions and invasive cancers contain HPV DNA. In addition, the covariables that have traditionally been associated with a high risk of developing cervical neoplasia are also highly correlated with the presence of HPV DNA. In a relatively large study of women attending a university health clinic, it was found that HPV DNA positivity was strongly correlated with an increasing number of sexual partners; the prevalence of HPV infection in women with 10 or more lifetime sexual partners was 69%, compared with 21% in women with only a single sexual partner. In studies by Schiffman and colleagues, it was reported that women who are HPV DNA positive have a relative risk of 40% of having an abnormal Papanicalous smear. He also reported that the attributable risk of HPV in such populations is greater than 90%. The only other covariable that was a significant contributor to risk was cigarette smoking. He also noted that “relative risks and attributable risks of this strength and consistency are so rare that the statistical association of HPV and cervical neoplasia is beyond question” and that “the epidemiological data support a central, causal role for genital HPV infection in the etiology of cervical neoplasia.”

The papillomavirus infects only epithelium. In the cervix, the viral genome of HPV can be divided into three regions: the upstream regulatory region (URR), the early region, and the late region (Fig. 46-2). The URR is a noncoding region that has as its major functions the regulation of viral replication and the transcription of downstream sequences in the early region. The early and the late region both contain a series of open reading frames (ORFs), linear sequences that lack stop codons and hence are potentially transcribable into proteins. The early region encodes proteins that are important in the early life cycle of the virus and interact with the cellular genome to program the host cell to produce new viral RNA. The late region, as the name implies, encodes for capsid proteins that surround the DNA core to produce the infectious unit: the complete virion.

In patients whose lesions progress from a low-grade CIN to a high-grade CIN, the progression is accompanied by alterations in the virus-host interaction. These interactions appear to be critical to the transformation of normal epithelial cells to neoplastic cells. The key alteration seems to be the integration of the viral DNA into host chromosomes. Because the episomal (nonchromosomal) virus is found in latently infected individuals, the productive infection is in a circular form and because the DNA in the host chromosomes is linear, a change in the physical state of the virus must take place before viral DNA can be integrated into the host chromosome. What initiates this change and the mechanism by which it occurs is not yet understood, but the circular strand of viral DNA is opened and the linear DNA can be spliced into the host DNA. It can then use the protein production apparatus of the transformed host cell.

The viral genome of HPV can be divided into three regions: the upstream regulatory region (URR), the early region, and the late region. In the early region, the viral genome begins to replicate independent of the host cell cycle, and large numbers of complete virions are produced. This is referred to as a productive viral infection. In a productively infected epithelium, viral replication takes place principally in intermediate and superficial cells, with the greatest number of viral particles found in the terminally differentiated epithelium. The control of viral replication is determined by the early genes, but as the epithelial cells mature and become differentiated, cell-derived, differentiation-specific transcriptional factors are produced by the host epithelial cells, and capsid proteins are synthesized to surround the viral DNA. These latent or productive viral infections may be clinically unrecognized or may be associated with genital warts, but they do not result in neoplastic transformation of the infected epithelial cells.

Human Papillomavirus Genome and the Mechanism of Carcinogenesis

The HPV genome has been very well studied and is relevant to this chapter because the molecular mechanisms involved have allowed scientists and clinicians to understand the process of malignant transformation and thus develop diagnostic tests and prophylactic vaccines to screen for and, if necessary, prevent cervical cancer.

The papillomavirus infects only epithelium. In the cervix, viral access also occurs via microtrauma to the thin, immature basal- and parabasal-type cells. When a mitotically active epithelial cell is infected, the virus may remain in the cell in a latent form in which a low number of about 100 copies of the viral genome are produced. This is termed a latent infection. Latent infections can be detected only by molecular techniques such as HPV DNA hybridization. Patients who are latently infected cannot be identified clinically as having an HPV infection. Because latently infected individuals shed virus intermittently and in a nonpredictable fashion, there is substantial variation in HPV DNA detection in women screened sequentially over time. In most women with an initial HPV infection, the infection clears spontaneously as a result of normal immunologic host defense mechanisms. In some individuals, however, for reasons that are not well understood, the latent papillomavirus begins to replicate independently of the host cell cycle, and large numbers of complete virions are produced. This is referred to as a productive viral infection. In a productively infected epithelium, viral replication takes place principally in intermediate and superficial cells, with the greatest number of viral particles found in the terminally differentiated epithelium. The control of viral replication is determined by the early genes, but as the epithelial cells mature and become differentiated, cell-derived, differentiation-specific transcriptional factors are produced by the host epithelial cells, and capsid proteins are synthesized to surround the viral DNA. These latent or productive viral infections may be clinically unrecognized or may be associated with genital warts, but they do not result in neoplastic transformation of the infected epithelial cells.

protein binds to the RBP protein, which in turn triggers E2F transcription factor, which leads to the production of proteins required for cellular DNA synthesis. By this mechanism, the virus takes over control of the infected epithelial cell and uses its synthetic mechanism to produce new viral DNA and viral proteins. This out-of-sequence initiation of new (viral) DNA synthesis by the HPV E2 protein would ordinarily lead to activation of epithelial cell p53 protein, an important protector of the normal cell cycle. In such circumstances, p53 would initiate the process of apoptosis leading to death of the epithelial cell, thus halting the hijacked DNA synthetic mechanism. However, the HPV E6 protein targets p53 for proteolytic degradation, allowing oncogenic HPV types to bypass this key cellular control mechanism.

The late-region ORFs, designated L1 and L2, are transcribed late in the replication cycle and encode for major and minor capsid proteins. The L1-encoded protein predominates in the capsid, is highly conserved among papillomaviruses, and is similar in all HPV types. On the other hand, the L2-encoded protein is highly variable between different HPV types and largely accounts for the differences in antigenicity from one HPV type to another. The current prophylactic HPV vaccines are targeted against these HPV capsid proteins and thus are HPV-type specific. All the proteins that are transcribed in the late region appear to be regulated by cell-derived transcriptional proteins that are produced only by squamous epithelial cells undergoing terminal maturation. The quantity of L1 and L2-encoded capsid proteins is highly correlated with terminal maturation of the epithelium. Well-differentiated HPV-induced lesions, such as condylomata, are generally rich in L1- and L2-encoded proteins, whereas high-grade CIN lesions, which tend to be highly undifferentiated, contain only small quantities of capsid proteins.

Since the importance of HPV in the etiology of cervical neoplasia has become more certain, various investigators have suggested that a vaccine against papillomavirus might prevent infection and perhaps even eliminate the virus in already infected individuals. This idea of immunization against HPV type 16 was tested in a clinical trial by Koutsky and colleagues, who prospectively randomized almost 2,400 young women who tested negative for HPV type 16 infection, immunized half with three doses of viruslike particle vaccine, and treated the other half with placebo. The patients were then followed up for a median of 17 months, and the risk of developing a persistent HPV type 16 infection was 3.8 per 100 women-years in the placebo group compared with 0 in the vaccinated patients (p > 0.001). CIN developed in nine women in the placebo group, whereas there was no instance of CIN among the vaccinated women.

### Natural History of Human Papillomavirus Infections

For centuries, clinicians have speculated that cervical cancer was caused by some infectious agent transmitted by intimate sexual contact. We have seen how many investigators have shown that this agent is HPV. But although it is true that all women with cervical cancer have been infected with HPV, most women with an HPV infection do not develop cervical cancer. Infections with HPV are very common in young sexually active women throughout the world. In a study of 60 college women, Brown and associates found that 28% were infected with HPV at the time they entered college. These women were closely followed and tested at frequent intervals. Four years later, when they left college, 40% tested positive for HPV. However, the interval examinations showed that most women cleared their infection and later became positive again following exposure to a new boyfriend. Overall, 82% of these women tested positive for HPV, and 77% tested positive for high-risk oncogenic HPV during the 5 years of the study. In other studies of young women, similar results have been found, and it appears that most women clear their infections within 12 months or so. On average, about 50% of women who test positive for HPV will test negative at 6 months, about 70% will be negative at 12 months, and by 24 months, only 8% to 20% remain positive. It seems as if the highly oncogenic types 16 and 18 are more slowly cleared than the less oncogenic HPV types.

It has been observed that women with transient HPV infection have a much lower risk of developing high-grade CIN. Although women with transient infections may develop cervical abnormalities that result in abnormal Pap tests and even colposcopic abnormalities, these are usually low-grade lesions and often clear spontaneously. Approximately 50% of women with a diagnosis of CIN 1 will resolve their lesions over 2 years without any active therapy. Women with highly oncogenic HPV types are more likely to have persistent infections, and they are at increased risk to develop high-grade CIN. In an analysis of HPV screening data of more than 20,000 women in the Portland, Oregon, area, Khan and colleagues found that women who had a negative Pap test and tested negative for any HPV had a less than 1% risk of developing CIN 3 within 10 years of follow-up. This contrasted sharply with women who had a negative Pap but who tested positive for HPV 16 on study entry; they had a 17.3% risk of developing CIN 3 or greater during the next 10 years. The risk of CIN 3 was 11.8%; for those who tested positive for other HPV types, the risk was even lower. At least half of these women develop high-grade CIN within 24 months, so the rate of progression may be relatively rapid in some patients.

The patient's immune system clearly plays an important and yet poorly understood role in the clearance or progression of
HPV. Women with impaired immunocompetence, such as those infected with HIV, and women who are immunosuppressed by various medications or chronic disease have a higher rate and, perhaps, more rapid progression of CIN that may make it more difficult to achieve a long-term cure.

Human Papillomavirus Vaccine

The immunogenicity of the virus and the development of antibodies with clearance of detectable virus in many women suggested the possibility of developing a vaccine against HPV. Prophylactic vaccines against HPV-16 and -18 and -6 and -11 have been clinically tested and are highly effective in HPV-naïve women. These have been introduced and are available in many countries, including the United States. Very few serious adverse side effects have been noted. However, it must be remembered that the current vaccines are effective only for preventing cancer and high-grade CIN related to HPV-16 or -18. Although these two viral types cause approximately 70% of all cervical cancer, several other viral types (31, 33, 45, and others) are responsible for almost a third of cervical cancer. In addition, women who have already been exposed to HPV-16 or -18 will not be protected by the vaccine. Continued cervical cancer screening will certainly be required for the foreseeable future.

SCREENING FOR CERVICAL NEOPLASIA

Cervical Cytology

After the introduction of cervical cytology for cervical cancer screening more than 50 years ago, multiple screening programs from all parts of the world have reported decreased rates of invasive cervical cancer and decreased death rates from a malignancy that had previously been the number-one worldwide cause of cancer deaths in women. Yet, even today, cervical cancer remains one of the leading causes of death for women in developing nations where Papanicolaou smear screening programs are nonexistent. The cervical screening program in the Province of British Columbia, Canada, is one of many examples of how effective cervical cytology screening can be. Since the implementation of a population-based Papanicolaou smear screening program in 1949, the incidence rate of invasive cervical cancer has decreased from more than 30 per 100,000 women to less than 5, and the mortality rate has decreased from 12 to about 3 per 100,000 (Fig. 46.3). These excellent results have been obtained through a combination of a population-based program with a central registry that notifies women every 3 years that their screening visit is due and follows up to be sure they do not default (a “call and recall” system); an excellent central cytology laboratory with well-trained clinicians to obtain the smears; and a network of colposcopy follow-up clinics where women with abnormal results are evaluated and treated. The program is well organized, with quality control built in at every level, and funding for this preventive health service and any follow-up or treatment required is universally provided to all residents of the province. All of these elements are required to achieve excellent results from a screening program.

Despite the effectiveness of cervical screening programs, there are several limitations of Papanicolaou smear screening. A single Pap smear has a sensitivity of only about 30% to 60%. This means that a single test will not detect a cervical lesion in many women. However, the slow progression of CIN before the development of an invasive cancer provides the opportunity for multiple screening cytologies over a period of years. So even with limited sensitivity, if three consecutive tests are negative, there is less than a 1% chance that the patient will have a high-grade cervical abnormality.

A false-negative Papanicolaou smear may result from either screening or interpretation problems. Screening problems include lesions that do not shed cells or that are not sampled by the clinician. Often, the diagnostic cells are not transferred from the spatula or collection device to the glass slide. Rarely, the slide preparation or staining is unsatisfactory. In other patients, problems with interpretation include failure to identify abnormal cells or misinterpretation of cells that are diagnosed as reactive or metaplastic when a dysplastic lesion exists. Various studies have shown that women who are diagnosed with invasive cervical cancer after a reportedly “negative” Papanicolaou smear must often have abnormal cells on review of their slides. The diagnostic cells may be few in number or obscured by blood or inflammatory changes. It is unfortunate that litigation over the “missed diagnosis” of cervical neoplasia is such a common problem for cytology laboratories in the United States. The threat of a lawsuit may cause cytologists and cytopathologists to “overcall” a diagnosis and the gynecologist to recommend colposcopy and possibly cervical biopsy in a patient with any hint of abnormality. This not only increases the anxiety and morbidity associated with cervical cancer screening, but it also increases the costs.

Liquid-Based, Thin-Layer Cytology

To decrease the false-negative rates of cervical cytology, attempts have been made to improve both specimen collection and quality and to reduce errors of interpretation. Over the past several years, several liquid-based techniques have been approved by the Food and Drug Administration in the United States. These techniques differ from the conventional method of Papanicolaou smear collection in several ways. Once the clinician
obtains a scraping of the SCJ and transformation zone area of the exocervix, the spatula and brush are dipped and agitated in a small bottle of fixative solution to elute the cells rather than being smeared on a glass slide. This bottle is then labeled and sent to the cytology laboratory rather than sending a slide. Once in the lab, a machine prepares a slide containing about 40,000 representative epithelial cells in a thin layer. The slide is then stained with the Papanicolaou stain and reviewed by the cytologists and cytopathologist. Several studies have shown that more diagnostic cervical cells are collected by this liquid-based technique and that the slides prepared from this sample provide a “cleaner” appearance with less clumping, blood, and inflammatory cells. This results in a decrease of artifacts. The use of thin-layer, liquid-based cytology reduces the rate of false-negative results from both screening and interpretation errors.

Computer-Assisted Diagnosis

It has long been believed that optical scanning by computer could be used for Papanicolaou smear interpretation, but differences in staining and the overlap of cells has made practical evaluation of high-risk slides identified by the computer on primary screening difficult for cytotechnologists, who could concentrate on the diagnostic evaluation of high-risk slides identified by the computer. Several studies have been approved by the Food and Drug Administration. Although the initial cost of these technology costs more money than the conventional Papanicolaou smear, but theoretical analysis suggests that these costs are balanced by the possibility of less frequent screening intervals made possible by a more sensitive test. Liquid-based cytology reduces the rate of false-negative results from both screening and interpretation errors.

Visual Inspection

Although colposcopy has been used for cervical cancer screening in some areas of Europe and South America, it is time-consuming, it requires well-trained clinicians, and it is expensive in most countries. However, simple visual inspection of the cervix after application of acetic acid has been effectively used in resource-poor settings for cervical cancer screening. Areas of cervical dysplasia turn white after application of acetic acid, and inspection of the cervix using handheld 3× magnifying lenses can identify many CIN lesions. This technique, commonly referred to as VIA (visual inspection with acetic acid), has been effectively used in areas of Africa, India, and China. Nurses or even health care technicians can be trained to use the technique and do biopsies or refer women with suspicious lesions for more extensive evaluation. Although VIA is not as specific as cytology, it is almost as sensitive and does not require several visits or the considerable infrastructure needed by cytologic screening.

Human Papillomavirus Testing

With the knowledge that significant cervical neoplasia is always associated with HPV, it has been suggested that HPV testing could be used to screen women for cervical neoplasia. HPV testing in the past has been inaccurate, and the complex laboratory techniques were not conducive to large-volume clinical work. However, with the advent of new generation hybrid capture techniques, these problems seem to have been solved. Current technology uses DNA hybridization and quantification by a chemiluminescence reaction to identify the presence of any of 13 different, high-risk HPV subtypes. Indeed, HPV testing was demonstrated to be more sensitive than traditional Pap smear or liquid-based cytology in a study by Schiffman and colleagues. In a trial of 1,119 high-risk women in Costa Rica, HPV testing demonstrated an 88% sensitivity to detect high-grade lesions compared with a Papanicolaou test sensitivity of 77.7%. Twelve percent of the women screened were HPV positive and were referred for colposcopy as compared with a 6.9% referral rate with Papanicolaou smear screening. In a similar trial from South Africa, Wright and colleagues instructed patients on self-collection of vaginal samples and were able to detect high-risk HPV DNA in 66% of the patients with high-grade lesions. This was almost identical to the 68% pickup rate of abnormal cytology collected at the time of a pelvic examination by a clinician. High-risk HPV was detected in 84% of the specimens obtained by the clinician during a pelvic examination. However, in high-risk, sexually active populations, many women with a subclinical HPV infection clear the virus without ever developing cervical neoplasia. In the South African trial, 13% of the women who tested positive for HPV had no identifiable cervical lesion. Nevertheless, HPV testing is easy to perform and is a relatively inexpensive test that can be automated in the laboratory and requires no interpretation (a problem with the Papanicolaou test). These advantages must be weighed against its lack of specificity for high-grade lesions; however, it may be of particular benefit in resource-poor settings where cytology laboratories are not available. Many studies from various parts of the world have confirmed the excellent sensitivity of HPV screening for cervical cancer, but its lack of specificity compared with cytology remains a problem.

Several approaches have been suggested to improve the specificity of HPV testing. Because the prevalence of HPV infection in most populations decreases dramatically after age 30 or 35, it has been suggested that HPV screening would be more specific for cervical neoplasia in women. Indeed, when Cuzick and associates screened a series of 10,358 women older than age 30, they found a sensitivity of 97.1% and a specificity of 93.3% for detecting CIN 2 or worse. Only 7.5% required referral for colposcopy. Even better specificity and improved sensitivity can be achieved by combining HPV testing with cervical cytology. Several large studies from Europe, America, Africa, and China were reviewed by Wright and associates in 2004. They found that the combination of HPV testing plus cytology produced a sensitivity of more than 95% for detecting CIN 2 or greater in most studies. Even more important, when colposcopy was added to HPV testing, the specificity was better than 90% in most studies. Both sensitivity and specificity were better with the combination of the two tests than with either one alone. The
problem with this, of course, is the cost. Theoretical analysis indicates that in the United States, if HPV testing and cervical cytology were done in women older than age 30, and if both tests were done only every 3 years if they were both negative or both positive, would be more sensitive and less expensive than conventional Pap smears every year or liquid-based cytology every other year. The American College of Obstetricians and Gynecologists recognized this in their 2003 Cervical Cytology Screening Practice Bulletin. Management of women with a normal Pap but who test positive for high-risk HPV is still somewhat controversial, but it is probably reasonable to rescreen them again in 6 to 12 months.

**EVALUATION OF ABNORMAL CYTOLOGY**

Following the announcement of the 2001 Bethesda System terminology for reporting the results of cervical cytology, the American Society of Colposcopy and Cervical Pathology sponsored a 3-day consensus conference to develop management guidelines. These guidelines were revised at another Consensus Conference held in 2006. The guidelines, which are evidence based and carefully crafted to include almost all situations, were published by Wright and colleagues in 2007. It is important for the clinician to distinguish between cytologic or Papanicolaou smear diagnosis and biopsy or histologic diagnosis. In this subsection, the evaluation of cytologic abnormalities are discussed; in the following subsection, the management of patients with biopsy-proven abnormalities is presented. In both sections, high-grade abnormalities are discussed first because they are the least controversial and most important. Treatment rarely is initiated based on the results of cervical cytology alone. The Papanicolaou smear result, colposcopic impression, and biopsy diagnosis should all be in general agreement, although it is common that they vary slightly on the grade of abnormality.

**High-Grade Squamous Intraepithelial Lesions**

Approximately 0.5% of all Papanicolaou smears are diagnosed as HSIL (Fig. 46.4). When these patients are evaluated, more than 70% will have biopsy-proven moderate dysplasia (CIN 2) or worse, and 1% to 2% will have an invasive cancer. Because high-grade abnormalities may progress to invasive cancer or, indeed, be associated with an already existing invasive cancer, women with an HSIL cytologic diagnosis should be referred for colposcopic evaluation.

In many cases, biopsy confirmation of the lesion will be done by loop electrode excision procedure (LEEP) of the whole transformation zone, which serves as both a diagnostic and a treatment procedure. This is particularly important in large, high-grade lesions because the colposcopic diagnosis of microinvasive cancer is difficult. Unless excision and histologic study of the whole transformation zone is done, microinvasive cancer may be missed.

If a woman with an HSIL Papanicolaou smear does not have a high-grade lesion identified on colposcopy of the cervix and upper vagina, an endocervical curettage (ECC) should be done. If the origin of the HSIL Papanicolaou finding is still not identified, the clinician should request a review of the cytology, ECC, and any cervical biopsies. If the cytopathologist still believes that a high-grade lesion exists that has not been identified by biopsy, then the cervix and vagina should be reexamined and a LEEP or cone biopsy done, especially if the SCJ cannot be visualized. Consultation with an expert colposcopist should be considered.

**Low-Grade Squamous Intraepithelial Lesion**

Of all Pap smears diagnoses, about 1.5% to 2.0% are LSIL. Between 15% and 30% of these women have moderate dysplasia or worse, and 1 to 2 per 1,000 have invasive cancer (Fig. 46.5). Although the risk of a significant lesion is lower in these women, referral for colposcopic evaluation is still recommended.

There are many treatment options for women with mild dysplasia (CIN 1) on colposcopically directed biopsy. But...
because of the wide possibility of diagnosis in women with an LSIL Pap. Papainicolau finding, colposcopic evaluation and biopsy confirmation of the diagnosis is indicated. In a patient with no visible lesion on the exocervix and vagina to explain the abnormal Pap test, an ECC may be useful.

When no lesion to explain the LSIL Papainicolau finding can be found, the evaluation can be repeated in 4 to 6 months, a LEEP can be done, or consultation with a more experienced colposcopist can be requested. In postmenopausal women, atrophy can cause minor cellular atypia, which can produce an LSIL Papainicolau finding, so treatment with topical estrogen for 2 months may be helpful before repeating the cytologic study. HPV testing in these patients may be helpful.

**Atypical Squamous Cells**

A diagnosis of ASC is the most common abnormal Papainicolau diagnosis, occurring in 2.5% to 5.0% of all Papainicolau smears. Careful evaluation of women with an ASC-US diagnosis will identify 5% to 10% with a biopsy diagnosis of high-grade CIN. Although the incidence of CIN 3 may be low in women who are initially diagnosed with an ASC-US Pap, because of the large number of women who have ASC-US diagnoses, the total number with a final diagnosis of CIN 3 is large. In a review of 46,000 Pap, Kinney and associates reported 39% of the women with a final diagnosis of CIN 3 initially presented with an ASC-US Pap, more than the 31% who presented with an HSIL Pap. Although the risk of a high-grade cervical lesion is low in patients with an ASC-US Pap, because the number of patients in this category is so large, there are a significant number who will need further evaluation and treatment. Even so, immediate referral to colposcopy for all these patients is not cost-effective because there are so many women with no significant cervical abnormalities. A second option is to bring these patients back for repeat Pap testing in 4 to 6 months. This can lead to a delay in diagnosis, and it is not unusual for 20% or more of these individuals to be lost to follow-up, producing an even greater delay.

The third management option for women with an ASC-US Pap finding is triage by HPV testing. Several large prospective studies have demonstrated the effectiveness of this approach. In a National Cancer Institute–sponsored randomized trial, Schiffman and colleagues randomized a group of 4,500 women with ASC-US Papainicolau findings to immediate colposcopy, follow-up every 6 months until two consecutive ASC-US Pap, or HPV triage. All women were eventually colposcoped and treated by LEEP at 24 months if they had not already been diagnosed and treated for CIN earlier. In this study, HPV testing identified 95% of the patients with CIN 3 or greater and required colposcopy in only 53% of the patients. The follow-up arm was able to identify only 85% of the patients with a high-grade lesion and referred 60% for colposcopy. Even though the immediate colposcopy group should diagnose almost 100% of the CIN 3 lesions, it is very expensive in the United States, where colposcopy charges are three to four times greater than an HPV test. In locations where the cost of colposcopy is relatively less than HPV testing, immediate referral for colposcopy may be a more cost-effective management option.

Patients with a Papainicolau diagnosis of ASC-H should be referred for colposcopy because they have a 15% to 35% risk of having moderate dysplasia or worse. Even if colposcopic evaluation, including an ECC, is negative, these patients need to be followed up carefully. HPV testing for triage in these patients is not cost-effective and not recommended; 65% to 85% of such patients test positive for high-risk HPV.

**Glandular Abnormalities**

In the 2001 Bethesda System, there are four categories under the classification of glandular cell abnormalities. These include atypical glandular cells (AGC), atypical glandular cells–favor neoplastic, endocervical adenocarcinoma or its precursor, adenocarcinoma. The cytologist should state if possible whether the glandular cells are endocervical, endometrial, or not otherwise specified. Although it may be helpful for the clinician in the future, the experience with the different categories is still limited, and it remains to be proven whether cytology can reliably differentiate between glandular dysplasia and AIS—and, indeed, between AIS and invasive adenocarcinoma.

Therefore, all patients with abnormal glandular cells on Pap test should be referred for further evaluation. Follow-up studies show that 35% to 50% of these patients have a lesion and that most actually have squamous not glandular CIN (Fig. 46.6). A few have endocervical glandular dysplasia or AIS, and a few have endometrial hyperplasia or adenocarcinoma. Endocervical glandular neoplasia is also HPV related so that it is often accompanied by a squamous dysplasia. For this reason, the diagnosis of moderate squamous dysplasia on the exocervix in a woman with an AGC Papainicolau smear does not rule out an accompanying glandular lesion. The workup should be continued to rule out the possibility of a glandular abnormality. The association of HPV, especially type 18, suggests that HPV testing might also serve as a useful triage step in the evaluation of women with AGC findings, but this concept has not yet been proven clinically.

Evaluation of the patient with an AGC Papainicolau finding usually involves a colposcopic examination and an ECC, whether or not the SCJ can be visualized. An endometrial biopsy is indicated in women older than age 35 or in women with abnormal bleeding. If the ECC is positive for a glandular abnormality, a cone biopsy is indicated. Even though some experts are able to adequately excise endocervical glandular lesions with a LEEP specimen, we find that a LEEP often
Abnormal Papanicolaou Diagnosis in Pregnancy

The pregnant woman with an abnormal Papanicolaou finding generally is evaluated by colposcopic examination and directed biopsy if a high-grade lesion is suspected. The goal of evaluation of the pregnant patient with CIN is to rule out invasive cancer. CIN is not treated in pregnancy but is followed up until the postpartum period, when the patient is reevaluated and managed as indicated by the biopsy results and her social situation. During pregnancy, most clinicians do a cervical biopsy to confirm the diagnosis only if a high-grade lesion is suspected, although some recommend a confirming biopsy in all patients with a colposcopically visible lesion. The pregnant cervix is very vascular, especially in the last trimester, so a biopsy may bleed profusely, and cervical trauma can initiate uterine contractions. An ECC is contraindicated in pregnancy. Rarely, a cone biopsy is required in pregnancy to rule out invasive cancer when colposcopy with directed biopsy does not eliminate that possibility. This can be a difficult and potentially bloody procedure and should be undertaken by an experienced gynecologist only after all other avenues to rule out invasion have been exhausted.

Colposcopy

Clinicians have observed that the earliest and most severe epithelial changes on the cervix occur adjacent to the SCJ on the cervix. Anatomic studies have shown that the location of the SCJ is not fixed and changes during a woman's life. Under the influence of the vaginal pH, columnar cells on the exocervix are transformed into squamous cells by a process called metaplasia. There are three times in a woman's life that metaplasia is particularly active: during embryologic development of the vagina and cervix, at puberty, and after the first pregnancy. During puberty and after pregnancy, the columnar epithelium of the endocervix is everted out onto the exocervix or portion of the cervix, and metaplasia is stimulated. The columnar cells, starting with the epithelium on the tips of the glandular papillae, are changed into squamous epithelium. This process can be observed with the colposcope. The area of active metaplasia just lateral to the SCJ where this metaplastic change occurs is called the transformation zone—columnar epithelium is transformed into metaplastic squamous epithelium (Fig. 46.2). This epithelium can be recognized as a circumferential, pale white, translucent ring around the SCJ. These metaplastic cells are very active and are especially susceptible to HPV infection. As described earlier, certain oncogenic HPV types may infect and transform these epithelial cells, and the resulting increased mitotic activity and DNA density can be identified as white epithelium following application of 3% to 5% acetic acid to the cervix. As CIN develops, vascular changes occur, and these may be recognized as punctuation or mosaic. If the lesion progresses, bizarre vascular changes can be seen. These atypical vessels have grossly abnormal architecture and are colposcopic hallmarks of invasive cancer.

A standard colposcopic examination involves careful inspection of the cervix with both low- and high-power magnification after application of normal saline and then 3% to 5% acetic acid. After examination with the standard white light, a green filter may be used on the light source to increase the contrast of the red blood vessels and help clarify any vascular changes present. Lugol’s iodine solution may also be used to stain the cervix to clarify areas of dysplasia, metaplasia, or columnar epithelium.

To evaluate the cervix for abnormal squamous epithelium, all of the squamous epithelium needs to be examined. Therefore, for the examination to be adequate or satisfactory, the entire SCJ must be visualized. Once the adequacy of the examination has been evaluated, a careful systematic evaluation of the cervix and upper vagina is performed, concentrating on the transformation zone adjacent to the SCJ. Areas of white epithelium, punctuation, and mosaics are noted. The severity of any lesions seen are graded based on the whiteness of the epithelium, the intercapillary distance in vascular lesions, the sharpness of the lesion border, and the surface contour (flat, ulcerated, or raised). The staining characteristics of the lesion with Lugol’s iodine has also been used to grade CIN.

Once a lesion has been identified, the most severely abnormal area or areas are selected, and a colposcopically directed biopsy is done. Although experienced colposcopists can often accurately grade the cervical dysplasia based on examination alone, a histologic diagnosis based on one or more cervical biopsies is the gold standard for determining the final diagnosis of the cervical lesion.

These general guidelines should be helpful in most cases, but there are many special situations—including the evaluation of adolescents and postmenopausal patients—in which alternative management plans may be more suitable. More extensive management guidelines are available on the American Society for Colposcopy and Cervical Pathology Web site, www.ascp.org, where the most recent guidelines are available.
updated set of management guidelines arrived at by a Consensus Conference sponsored by the American Society for Colposcopy and Cervical Pathology is available online at www.asccp.org. The preceding sections on the natural history of the transformation zone and CIN need to be applied to the specific patient and the various management options reviewed to select the best plan for that patient. In many cases, the patient’s personal preference may tip the balance in the decision to treat or follow a lesion. Insurance coverage, school vacations, and equipment availability may also influence the choice or timing of treatment.

CIN 1—Mild Dysplasia

Reviews by Oster and, more recently, Nsouvo and colleagues have shown that during 12 to 24 months of follow-up, regression occurs with no treatment in about 30% of women with a cervical biopsy showing CIN 1 (Table 46.4). Current management guidelines for the management of biopsy-confirmed CIN 1 strongly recommend conservative follow-up with no therapeutic intervention. Although good data do not exist, larger lesions and lesions that have persisted for a longer time are probably less likely to regress spontaneously. Because the treatment options are the same and chance of complete cure approaches 100% for CIN 1, 2, or 3, the consequences of progression within the grades of CIN are minimal. It is therefore reasonable to manage a patient with CIN 1 by observation alone. Prolonged follow-up of CIN 1 (Fig. 46.7) without biopsy confirmation is not recommended because cytology and colposcopy are not sufficiently accurate to confidently rule out a more severe lesion. The only two risks to this approach are that invasive cancer already exists and has been missed on the diagnostic evaluation of this patient or that the patient becomes lost to follow-up and does not reappear until her condition has progressed to invasive cancer. These risks are minimal, but should be considered for each patient at each visit. In almost all series in which women with low-grade cervical abnormalities have been followed up with no treatment, invasive cancer has eventually been diagnosed in a few patients even under the careful follow-up protocol of a clinical study.

For this reason and because treatment is relatively easy with limited patient inconvenience, side effects, complications, and costs, CIN 1 lesions in women who have completed their families, who have three- or four-quadrant lesions, or who have had a lesion for 12 months or longer may be considered for treatment. These low-grade abnormalities have cure rates of 90% or better with LEEP, cryotherapy, or CO2 laser vaporization. Cryotherapy may result in less cervical destruction and be associated with a slightly lower risk of pregnancy complications than excisional techniques. Traditional cold-knife cone biopsy is probably associated with more morbidity and cost than is warranted by a diagnosis of CIN 1.

NATURAL HISTORY OF CIN: LITERATURE REVIEW

Although patients with “atypical metaplasia” or chronic cervicitis have been treated with cautery or cryotherapy in the past, these are not generally indications for treatment under modern guidelines.

CIN 2 or 3—Moderate or Severe Dysplasia, Carcinoma In Situ

Patients with a biopsy diagnosis of CIN 2 or 3 (Fig. 46.8) have a less than 50% chance of regression and a significant chance of progression to carcinoma in situ, so treatment is usually recommended. Adolescents, pregnant women, and women who previously have been treated for CIN should probably be followed up conservatively without treatment. There is an increasing tendency for conservative follow-up alone in young women with CIN 2 lesions.

Although treatment of these lesions can be successful using either ablative or excisional techniques, high-grade lesions bordering on invasive cancer are best managed by excision, which provides a tissue specimen for examination by the pathologist. In several large series of LEEP specimens, a few invasive cancers that had been unsuspected were diagnosed on histopathologic examination of the excised transformation zone. Cryotherapy or laser vaporization of undiagnosed invasive cancer could result in progression, resulting in a deeply invasive cancer that remains untreated for several months or even several years. In the past and in some limited resource settings, ablative therapy has been or still continues to be used successfully in women with high-grade lesions, but the risk of undiagnosed invasive lesions makes this approach less than ideal.

A cold-knife cone biopsy in the operating room under anesthesia is indicated when cytology, colposcopy, or directed punch biopsy suggests superficially invasive cancer. Negative margins and a large specimen in one piece that can be well oriented are essential for an accurate and complete diagnosis of
FIGURE 46.8. Histologic section of high-grade cervical intraepithelial neoplasia. This lesion has some features of low-grade cervical intraepithelial neoplasia but also contains abnormal mitotic figures—a diagnostic feature of an aneuploid, high-grade, human papillomavirus–related lesion.

microinvasive cervical cancer (Fig. 46.9). A final diagnosis of microinvasive cervical cancer cannot be made on punch biopsy or ECC. It is necessary to examine tissue on all sides of the microinvasive focus to be sure more deeply invasive disease does not exist adjacent to the focal area sampled by punch biopsy or ECC. If a grossly visible lesion on the cervix is seen, a simple punch biopsy may confirm the diagnosis of invasive cancer. A cone biopsy is not needed in these patients.

Adenocarcinoma In Situ or Glandular Dysplasia

These diagnoses also require a cone or large biopsy of the endocervical epithelium and stroma with negative margins for diagnosis. An ECC or punch biopsy is inadequate to rule out a more extensive, possibly invasive, lesion. These lesions may be multifocal. As previously noted, most experts favor cold-knife cone biopsy for the evaluation of glandular lesions.

The standard of care for AIS of the cervix in the United States is still simple hysterectomy, although there is growing acceptance of cone biopsy alone for these patients. If cone biopsy is used as definitive management of AIS, the margins should be negative, and enough sections of the specimen need to have been studied to be confident that an early invasive adenocarcinoma does not coexist. Glandular dysplasia can also be managed by cone biopsy if the margins are clear, but there are few data on this subject.

Treatment Techniques

In general, treatment techniques can be divided into ablative and excisional. Destructive methods such as cryotherapy, CO\textsubscript{2} laser ablation, and electrocautery rely on an accurate colposcopically directed biopsy diagnosis because no tissue specimen is provided by the treatment procedure. On the other hand, punch biopsy, LEEP, and cone biopsy all provide a specimen, so these techniques are both diagnostic and therapeutic.

Punch Biopsy as Therapy

In most developed countries, women are highly screened and invasive cancers are uncommon, particularly in younger age groups. High-grade CIN is relatively uncommon, and most lesions that are detected are low-grade CINs found as incident cases. Because most of the cases of CIN are low-grade lesions that have developed between screening visits, the lesions tend to be small, to be located at the SCJ, and to occur in younger, often nulliparous women. For patients with a single, focal lesion, simple removal of the lesion with one or two punch biopsies may result in a cure. In the patient with a focal lesion, this approach may be worth a try. Theoretically, the entire transformation zone should be destroyed or removed, but in some patients, these small biopsies clear the abnormalities. The inflammatory healing response to the cervical biopsy may stimulate a response in the tissue surrounding the biopsy, resulting in improvement of adjacent areas. Whether these women would have cleared the lesion even without a biopsy can be debated.

Cryotherapy

Cryosurgery is a destructive technique that was introduced to gynecologists in the late 1960s to treat CIN. The cryosurgical instruments use nitrous oxide or carbon dioxide as a refrigerant to lower the temperature of the tissue below -22°C and to produce cell death by intracellular and extracellular water crystallization. The refrigerant is applied to the cervix with a cryoprobe, which is placed in contact with the cervical epithelium. As the gas is circulated through the cryoprobe, it withdraws heat from the cervix until freezing temperatures occur. The cervix and cryoprobe generally reach a steady state after about 3 minutes of freezing, at which time the amount of heat brought to the cervix by the vascular supply balances the amount of heat withdrawn from the cervix by the evaporating cryogenic gas.

Tens of thousands of patients have been treated with cryotherapy, which has proved to be a predictable, reliable treatment technique with limited side effects and morbidity. Cryotherapy is used principally in patients whose lesions are confined to the exocervix because the depth of cryodestruction seldom exceeds 5 mm. The cure rates are dependent on the size of the lesion. They generally average about 90% for lesions...

LEEP introduces the United Kingdom by Prendeville as large loop excision of the transformation zone (LLETZ). The technique uses a modification of a small electrosurgical wire loop biopsy instrument originally developed by Carter in France. LEEP was introduced in North America in the early 1990s and, as in Europe, rapidly became the procedure of choice for the management of CIN. It is usually done under local anesthesia as an outpatient or clinic procedure.

Although low-grade lesions can readily be treated with cryotherapy, many gynecologists choose LEEP excision instead because of its ease of use, its limited morbidity, and the fact that it provides a specimen. Caution is advised in choosing LEEP for small lesions in women who have only small areas of CIN in a small, nuliparous cervix because it is possible to produce irre-

areas of CIN (Fig. 46.10). It is also possible to electrocoagulate
tissue with a 3-mm ball electrode. LEEP is used under colpo-

scope control and has the advantage of being a diagnostic and

therapeutic procedure at the same time. The fact that a tissue

specimen is provided makes the procedure particularly useful in ruling out early invasive cancer and in identifying unsuspected AIS. Many authors have reported that 0.4% to 0.6% of cases diagnosed as CIN by colposcopy, punch biopsies, and ICC in fact have invasive cancer or AIS in the LEEP specimen.

Because LEEP is easy to learn, easy to teach, and easy to ap-

LEEP can be used to treat patients with high-grade CIN without

the disadvantages and great cost of cold-knife conization. The

major advantage of LEEP over conventional cold-knife coniza-
tion is that the procedure can be performed under colposcopic

control and the margins can be examined colposcopically af-

fter the initial excisions are completed. This gives the operator

the opportunity to reexcise additional tissue if it is found col-

poscopically that residual CIN remains. For LEEP to be used

effectively, the extent of excision and the choice of electrodes

must be tailored to the size and distribution of the lesion (Fig.

46.11). If the lesion is present on both the portio and the canal,
a “cowboy hat” or “top hat” combined endocervical-portio

excision is appropriate. The first pass removes the excervical

lesion with a wide, shallower, second pass of the smaller
code excises the endocervical canal. The use of ex-

tremely large electrodes may lead to inadvertent cervical am-

putations and significant reproductive and obstetric morbidity.
FIGURE 46.10. Loop electrosurgical excision procedure. Endoscopic loop is passed through a Lugol-stained cervix from right to left. Note cut surface of cervical stroma from the 12-o’clock to the 6-o’clock position. Also note lack of charring so commonly seen with laser ablation.

The complications of LEEP are similar to those of cone biopsy or laser ablation of cervical dysplasia. Significant bleeding at the time of cervical LEEP is uncommon but can occur, and the surgical team and the clinic need to be prepared and equipped for such a situation. Hemorrhage requiring special techniques to control is more common if a larger loop is used, if epinephrine or some vasoconstrictive agent is not injected in the cervix locally, or if the vagina is accidentally lacerated with the electrode. The first step in controlling hemorrhage is the same as for any surgical bleeding: Apply direct pressure to stop the bleeding. This can be done with a large cotton-tipped swab or a gauze or cotton balls grasped in the tip of a ring forceps. After the blood is cleared away and the cervix visualized, the swab is carefully rolled off the bleeding site and the ball electrocautery used to vigorously coagulate the bleeder. More pressure is applied for 2 minutes or so, and the cautery reapplied, if necessary. Sometimes an additional injection of epinephrine will be helpful. Bleeding from the cervix can also be temporally controlled by clamping the cervical lip with a ring forceps. If these simple techniques do not work, the situation should be completely reevaluated. Is the patient stable and comfortable? Does she need a paracervical block? Should we start an intravenous line? Do we need suction to evacuate the blood? Do I have adequate assistance, adequate exposure, adequate lighting? Can this be controlled in an outpatient setting, or should the cervix be packed and the patient transported to a hospital?

With a paracervical block, more local anesthesia in the cervix, and/or systemic sedation, a large figure-of-eight hemostatic suture in the cervix will usually control the bleeding. For those situations, the clinic should be equipped with a long 12-inch needle holder and long 12-inch tissue forceps with teeth. We use a 0-gauge delayed absorbable suture on a 1-inch curved, taper-point needle. An emergency tray with this equipment should always be available in an outpatient area where cervical biopsies and LEEP are done. Suction equipment and equipment to start an intravenous line should also be available.

Infection in the cervix or an ascending endometritis, parametritis, or salpingitis can occasionally be seen following LEEP, but they are rare and usually represent a flare-up of an already existing subclinical infection. Long-term complications include cervical incompetence and cervical stenosis, which are relatively uncommon but can have serious implications.

Although cervical incompetence leading to premature cervical dilation and delivery in subsequent pregnancies has been a well-known complication of traditional cold-knife cone biopsy for many years, it was not until the large metaanalysis of

FIGURE 46.11. Diagram of approach to loop excision of small portio lesion, which can be removed by a single pass (A) of the 2-cm × 7-mm exoloop. B: Note the shallow dish configuration of the removed tissue. After the excervical excision is completed, the canal is recolposcoped after additional acetic acid is applied. If residual disease is found in the canal, it can be removed by a second pass with a smaller loop (C). (From Wright TC, Richart RM, Ferenczy A. Electrosurgery for HPV-related diseases of the anogenital tract. New York: ArthurVision; 1992.)
Kyrgian and colleagues that the risk of LEEP was well accepted. In this analysis of 27 studies that examined pregnancy outcomes after excisional cone biopsy by cold knife, LEEP, or laser, the authors concluded that all excisional techniques resulted in a roughly doubled rate of prematurity delivery. Patients treated with a LEEP greater than 1 cm deep had a higher incidence of prematurity. There was no increase in neonatal morbidity or mortality in women who underwent a large excisional cone following study from Denmark, Nohr and colleagues found a 3.5% incidence of preterm birth (>37 weeks) among untreated women compared with 6.6% for women after a LEEP. The problem is somewhat confounded by another large epidemiologic study of 5,548 births in Australia by Brumsted and colleagues. These authors noted that women with cervical dysplasia had a higher incidence of prematurity than the general population. But even within the cohort of women with dysplasia, those who had an excisional treatment had a 1.23-fold increased risk of a premature birth. However, when adjustments were made for other associated risks—such as prior spontaneous abortions, illicit drug use during pregnancy, and another major medical condition—excisional procedures were no longer associated with an increased risk of prematurity. These studies suggest that for a variety of reasons, women who undergo LEEP or cone are at an increased risk to deliver prematurely with subsequent pregnancies, but that serious neonatal complications are not increased.

The overall “cure” rate of LEEP is about 95%, but the incidence of persistent disease is related to the anatomy of the lesion. Lesions that involve the exocervix, no matter how severe, are easily visualized and can usually be excised successfully under direct vision. However, lesions that extend into the endocervical canal are more difficult because the upper extent of the lesion may not be easily seen, and it is more difficult to control the depth of excision. However, even with a histologically involved margin, immediate excision is not necessary (unless possible invasive cancer might be present). Healing of the cone bed and the electrosurgical injury of the margin often results in destruction of a minimal rim of residual epithelium. Thus, the lesion is removed in its entirety with use of the loop electrode. The patient does not have to undergo cervical biopsies and an ECC.

The advantages to this approach are that the procedure is done in one office visit, thus reducing patient anxiety by eliminating the need to wait for a diagnosis to be rendered and to then return for additional treatment. If used appropriately, it may save time and money. The disadvantage to this approach is that the colposcopic appearance of squamous metaplasia, repair, or other minor changes may mimic CIN, leading to inappropriate treatment. For see-and-treat to be used effectively and appropriately, the colposcopist must be certain that the colposcopic changes that are seen are sufficiently characteristic that a diagnosis of an HPV-related high-grade CIN lesion can be assured. Under these circumstances, see and treat may be the procedure of choice. If used appropriately, it may save time and money. The disadvantages to this approach are that the cone should be placed high on the anterior lip away from the anticipated line of excision. Sometimes two tenaculum are better, or the lateral stay sutures described above may be used if the cervix is large or the vagina is small. We prefer a pointed no. 11 scalpel blade, but a large no. 10 blade or a smaller no. 13 is the sharpened knife. The disadvantage to this approach is that the cervix is large and, thus, the term cold knife was introduced to differentiate these two procedures. A more or less cone-shaped biopsy can be excised from the cervix using a sharply focused laser beam or an electrosurgical wire as a scalpel. The laser is very expensive and requires considerable operator experience to be used effectively. The electrosurgical wire is quite effective and hemostatic. Both techniques often result in some thermal artifact, which may make interpretation of the surgical margins difficult.

Cervical Cone biopsy is generally planned to be both diagnostic and therapeutic, and the technique is widely understood and practiced. We recommend cone biopsy for endocervical glandular lesions and for suspected microinvasion because accurate diagnosis of these lesions requires a large, deep tissue specimen with negative margins. A large cold-knife cone biopsy is also recommended for treatment of persistent or recurrent CIN after failure of LEEP or ablation. The cone usually is performed in an operating room under anesthetic; thus, it is expensive.

The size and shape of the cone specimen to be excised will vary depending on the location of the cervical lesion and the size of the patient’s cervix. Although most glandular lesions are located within a few millimeters of the SCJ, a cone biopsy for a glandular abnormality needs to go deep into the cervix to include most of the length of the cervical canal. On the other hand, a clearly visible lesion on the exocervix in a 28-year-old woman with a Pap test, biopsy, or colposcopic exam showing possible microinvasion needs a wide—but not so deep—cone. Colposcopic examination and Lugol’s stain will help the surgeon determine the size and location of the lesion to be excised. After a careful examination under anesthesia, a gentle vaginal prep is done. The cervix should not be scrubbed too vigorously or the surface epithelium containing the intraepithelial lesion will be wiped away.

To decrease blood loss, the cervix is injected with a vasoconstrictive agent. We usually use a commercially available mixture of local anesthetic (lidoceaine) with 1:100,000 epinephrine. Acute hypertension can be caused by this drug, and its use should be considered and discussed with the anesthesiologist. Approximately 1.5 cc is injected directly into the cervix, where the incision will be made at 12, 2, 6, 8, 10, and 12 o’clock. This is a total of 9 to 10 cc, and it should cause some “ballooning” and blanching of the cervix. Although deep lateral sutures in the side of the cervix at 3 and 9 o'clock have been said to decrease blood loss by ligating the descending branch of the uterine artery, there is no evidence that this reduces bleeding with a cone biopsy.

The cervix is then retracted with Lugol’s solution to outline the lesion, and a scalpel is used to cut the cone. The cervix can be stabilized with a tenaculum placed high on the anterior lip or a posterior lip away from the anticipated line of excision. Sometimes two tenaculum are better, or the lateral stay sutures described above may be used if the cervix is large or the vagina is small. We prefer a pointed no. 11 scalpel blade, but a large no. 10 blade or smaller no. 13 is the preferred choice. Some experts will use a bare electrosurgical wire or thin pointed electrosurgical blade. Still others have used a sharply fo-cused laser beam to cut the cone biopsy. Each technique can be used with good success. As the cone is cut, it is...
retracted to the opposite side to provide visibility at the base of the incision. If possible, the cone should be symmetrical around the endocervical canal with the apex in the canal. It is desirable to remove the specimen intact as one piece and mark it with a suture at 10 or 6 o'clock so that the pathologist can orient any positive margins or foci of invasive cancer.

There are several ways to manage the cone bed once the specimen has been removed. If bleeding is minimal, bleeders may be cauterized and the cone bed left open to granulate. This may result in a visible SCJ more frequently than if the bed is sutured. If there is more bleeding, the bleeders may be cauterized as before; but the cone bed can be closed with a running locked suture placed from just lateral to the cone edge to deep in the cervical stroma by the canal. This is run circumferentially around the cervix—often called a “baseball stick,” because it is similar to the strong stitches used to sew the leather cover on a baseball. This is the most hemostatic way to close the cone bed. Finally, there is the classic Sturmdoff suture illustrated in Figure 46.12. The anterior and posterior cervical mucosa are pulled in to cover the cone defect. This is the most aesthetically pleasing closure, but in many cases, the SCJ cannot be seen after the cervix is healed.

The complications of cold-knife cone biopsy are similar but perhaps somewhat more common than those with LEEP because the specimen is larger. Significant bleeding may occur in the first 24 hours or 10 to 21 days after surgery when the sutures dissolve. Five to 10% of patients will require reevaluation, packing, or suturing after cold-knife cone biopsy, and occasional patients will require a transfusion. Cervical stenosis occurs in about 3% of patients. This is more common if the patient is not having monthly menstrual periods. This risk of premature labor and delivery caused by an excisional cone biopsy has already been discussed in the section on LEEP. The size of the cone is related to the risk of premature labor. The larger the cone, the greater the risk.

As with LEEP, the success of cone biopsy in the treatment of CIN is directly related to the incidence of positive margins. Persistence or recurrence of CIN after cold-knife cone biopsy is usually quoted at 5% to 10%; but as smaller lesions that do not extend into the canal are done by the simpler, less expensive LEEP, lesions with a higher risk of failure are left to be treated by cold-knife cone biopsy.

D: Anterior and posterior flaps have been drawn into the canal. Lateral mucosa wounds are being sutured.](image)
The identification of a preinvasive lesion that precedes the development of cervical cancer has greatly reduced the incidence of cervical cancer worldwide. It is now well established that cells adjacent to the squamo-columnar junction of the cervix become infected by HPV, which may produce a malignant transformation. These transformed cells may eventually progress through various degrees of dysplasia or cervical intraepithelial neoplasia to invasive cervical cancer. The viral subtype, the immunologic competence of the patient, and various associated events or activities such as cigarette smoking all influence the risk of progression to invasive cancer.

Effective screening for cervical cancer and its precursor lesions has been done in many areas of the world using cervical cytology. With an organized system of testing every 3 to 5 years and with good diagnostic follow-up and treatment, cervical cancer death rates have been reduced by more than 70%. Visual inspection using acetic acid (VIA) and HPV testing have been introduced in recent years and are also effective screening techniques in certain circumstances.

Following identification of a significant abnormality (LSIL or ASC-US/HPV positive in the U.S.) by screening techniques, the patient is evaluated by colposcopy and directed biopsy to determine the actual diagnosis and extent of disease. At least 50% of women with a diagnosis of mild dysplasia will resolve spontaneously within 2 years. Therefore, conservative follow-up is recommended for most patients with biopsy-confirmed low-grade lesions. In young women and women in whom future fertility is important, conservative management may be considered in high-grade lesions. As a general rule, a biopsy diagnosis of CIN 3 or severe dysplasia indicates a cervical lesion that should be treated. Excisional techniques such as loop electrosurgical excision procedure (LEEP) is recommended in high-grade lesions because excision provides histologic confirmation that invasive cancer is not present.

Traditional cold-knife cone biopsy of the cervix should be used for patients who might have microinvasive cancer or those with a glandular lesion. Cone biopsy under general anesthesia provides a large, deep specimen that can be well oriented and has a better chance of a clear margin. Many different treatment techniques are available for cervical dysplasia. In general, ablative or destructive techniques such as cryotherapy or laser ablation are less injurious to the cervix and have a lower risk of cervical incompetence in future pregnancies. Excisional techniques such as LEEP provide a specimen for histologic confirmation of the diagnosis. The severity and size of the lesion—together with the desire for future pregnancy and the training of the surgeon and availability of the equipment—all help to guide the choice of treatment technique.

CANCER OF THE CERVIX

DEFINITIONS

FIGO staging—The International Federation of Gynecology and Obstetrics (FIGO) has defined staging of gynecologic cancers for more than 50 years. The cancer stage defines the extent of disease at diagnosis before treatment. FIGO staging is used worldwide to compare clinical experience and results of treatment.

Lymph-vascular space invasion (LVSI)—Small endothelial-lined vessels within the cervical stroma may be either lymphatic vessels or small capillaries. On histologic examination of a surgical specimen, tumor cells or clusters of tumor cells are sometimes seen in these vessels. Tumor invasion or involvement of these lymph-vascular spaces is generally believed to increase the risk of nodal metastases and worsen prognosis.

Parametrium—Connective tissue lateral to the cervix and uterus within the broad ligament.

Pararectal space—The avascular space in the posterior-lateral pelvis. It is bounded medially by the rectum, laterally by the pelvic wall, posteriorly by the presacral fascia, and anteriorly by the broad ligament and cardinal ligament.

Paravaginal space—The avascular space in the anterior-lateral pelvis bounded by bladder mediad, the pelvic sidewall laterally and anteriorly, and the broad ligament and cardinal ligament posteriorly.

SEER Database—The Surveillance, Epidemiology and End Results Database is managed by the United States National Cancer Institute. It collects data from population-based tumor registries around the country that represent a cross section of 23% of the population.

Sentinel lymph node—The sentinel node is the first node involved in lymphatic metastases from the primary cancer. The sentinel node concept holds that lymph node metastasis occurs in an orderly, stepwise progression so that if the first or sentinel node is negative, then no other nodes are involved with metastatic cancer. Because cervical cancer is a midline tumor that may spread to either side and perhaps by more than one lymphatic pathway, it has not yet been proven whether the concept of the sentinel lymph node is applicable in this cancer.

In the first half of the 20th century, more women died from cervical cancer in the United States than from any other cancer. With the introduction of the Papnicolaou (Pap) smear in the 1940s, the early detection and treatment of preinvasive disease became possible. Consequently, both the incidence and mortality rates that are due to invasive cervical cancer in the United States declined approximately 75% by the end of the 20th century. The American Cancer Society estimates that in 2007, approximately 11,000 women will be diagnosed with cervical cancer. This represents a 13% decrease compared with the 13,000 estimated cases diagnosed in 2002. It is also estimated that 3,700 women will succumb to the disease in 2006 as compared with 4,100 in 2002. Based on these figures, cervical cancer currently ranks as the third most common female genital tract malignancy in the United States (behind uterine corpus and ovarian cancer) and the third most common cause of gynecologic cancer death.

Worldwide, however, more than 370,000 cases are diagnosed annually, leading to approximately 190,000 deaths. This makes cervical cancer not only the most common gynecologic malignancy, but also the third most frequently diagnosed cancer in women (behind breast and colorectal cancer). In general terms, the disease is much more common in developing countries. Overall, 78% of cases occur in these areas. In developing countries, cervical cancer accounts for 15% of female malignancies, carrying a lifetime risk of about 3%. In contrast, in developed countries, cervical cancer accounts for only 0.4% of female malignancies, with a lifetime risk of 1.1%. The highest incidence rates are observed in Latin America, the Caribbean, sub-Saharan Africa, and Southern and Southeast Asia. In developed countries, the incidence rates generally are low, with age-standardized rates less than 14 per 100,000.

This geographical disparity is felt to be related to the presence or absence of effective screening programs, because epidemiologic and biologic studies have not shown significant differences in tumor biology in countries with high rates of cervical cancer.

STAGING OF CERVICAL CANCER

In 1937, the Health Organization of the League of Nations adopted a clinical classification system for cervical cancer. Cervical cancer was the first cancer to be so classified. In 1950, this classification was modified to include preinvasive (in situ) cervical cancer, which was designated stage 0. New recommendations for the clinical classification of carcinoma of the cervix were adopted by the General Assembly of the International Federation of Gynecology and Obstetrics (FIGO) in 1961, and several other modifications have been made since then. The general use of this classification abroad and in the United States has been extremely helpful in reporting and comparing results of various modalities of therapy. Descriptions of the clinical stages in carcinoma of the cervix uteri as updated by FIGO in 1995 appear in Table 47.1. Although the TNM (tumor, regional nodes, and metastasis) staging system is included for completeness, most clinicians use the FIGO staging.

Stages II, III, and IV have remained essentially unchanged through the various modifications (Fig. 47.1). The major redefinition and refinements have occurred in stage I disease. Microinvasive (stage IA) carcinoma has been subdivided into stage IA1 and IA2 based on the depth of cervical stromal invasion by carcinoma. Stage IB has been subdivided into stage IB1 and IB2 based on the size of the clinical lesion.

HISTOPATHOLOGY

The principal histologic type of invasive cervical cancer, occurring in about 80% to 90% of cases, is the squamous (epidermoid) lesion. In 1923, Martzloff classified these squamous tumors into three main histologic subtypes and grades. Grade 1 tumors contain well-differentiated spinal cells, keratin, and squamous pearls (Fig. 47.2A). Grade 2 tumors, the most common, are predominantly composed of transitional cells of the large-cell nonkeratinizing type (Fig. 47.2B). Grade 3 tumors, the least common, are poorly differentiated small-basal-cell-type tumors (Fig. 47.2C). The classification of Martzloff did not prove to be clinically useful, mainly because biopsies taken from different areas of the same tumor often show different degrees of differentiation and different predominant cell types. Martzloff’s work did stimulate Broders, Wentz and Reagan, and others to continue to categorize the histologic types and degree of differentiation of squamous cell cervical tumors, and to study their clinical behavior and response to treatment. The histologic classification of squamous cell tumor types introduced in 1939 by Wentz and Reagan sometimes is used in pathology reports. However, Willen and coworkers were unable to confirm a predictive value for survival from the Wentz-Reagan classification. Similarly, most recent studies, including those by the Gynecologic Oncology Group (GOG), have shown the use of grading of squamous carcinomas to be of little predictive value.

A rare form of squamous cell cancer of the cervix is a verrucous carcinoma. It is a very well-differentiated squamous cell carcinoma with extensive keratinization that usually presents as a large bulky tumor of the cervix and often is confused with giant condylomas, such as those seen on the vulva. There is a sharp line between the tumor and underlying cervical stroma. Verrucous carcinoma has been shown to be associated with human papillomavirus (HPV) infection. Although metastatic disease is rare, this tumor has been said to become more virulent if treated with irradiation. Goldberger and coworkers reported an unusually aggressive verrucous carcinoma of the cervix. According to deJesus and coworkers, at least 49 cases of this tumor have been reported in the female genital tract, sometimes as verrucous carcinoma and sometimes as squamous papillary tumor.

Adenocarcinomas of the cervix are becoming more common, especially in younger women. In a review of the Surveillance, Epidemiology, and End Results (SEER) Cancer Incidence Public-Use database from 1973 to 1996, Smith and colleagues reported that although the age-adjusted incidence rates per 100,000 for all invasive cervical cancers and squamous cell cancers decreased by 37% and 42%, respectively, the rates for

C: Bulky stage IIA lesion with involvement of the vaginal fornix. D: Stage IIA: Carcinoma extends into the upper vagina or fornix. (Continued)
FIGURE 47.1. (Continued) E: Stage IIB: Carcinoma extends into the parametrium but does not extend to pelvic wall. F: Stage IIIA: Carcinoma involves the anterior vaginal wall, extending to the lower third. G: Stage IIIB: the parametrium is infiltrated, and the carcinoma extends to the pelvic wall. H: Stage IVA: the bladder base or rectum is involved.

Adenocarcinoma of the cervix actually increased 29% during the study period. These results suggest that current screening practices may be insufficient in detecting a significant proportion of adenocarcinoma precursor lesions. About one half of cervical adenocarcinomas are exophytic, usually polypoid, or papillary; others diffusely enlarge or ulcerate the cervix. Approximately 13% of patients have no visible lesion because the carcinoma is within the endocervical canal. Even without visible signs or symptoms, the lesion may infiltrate deeply into the cervix. Drescher and colleagues reported a higher frequency of uterine corpus invasion, nodal metastasis, and ascites in 26 patients with cervical adenocarcinoma compared with 139 cases of squamous cell carcinoma. More recent studies have reached contradictory conclusions regarding the prognostic significance of this histology.

In addition to pure (endocervical) adenocarcinoma (Fig. 47.3), cervical adenocarcinomas can exhibit a variety of patterns and can be composed of diverse cell types. Other histologic patterns include adenoma malignum, endometrioid, clear-cell, serous, and mesonephric. Different histologic patterns and cell types often appear in the same cervical tumor. Because mixtures are common, the designation of tumor type is based on the predominant component. If a second type composes 20% or more of the tumor, the lesion is designated as a mixed-cell type. Not infrequently, an adenocarcinoma and squamous cell carcinoma coexist in the same tumor, and these lesions are referred to as adenosquamous carcinomas. The so-called glassy cell adenocarcinoma of the cervix is rare and considered a variant of poorly differentiated adenosquamous carcinoma. It is known to be especially aggressive, with frequent early distant metastasis. Clear-cell adenocarcinoma of the cervix can occur in the presence or absence of intrauterine exposure to diethylstilbestrol. Saigo and coworkers found that the endometrioid pattern was associated with a more favorable prognosis than
FIGURE 47.2. A: Grade 1: Well-differentiated squamous cell carcinoma of the cervix. High-power view of spinal cell type. The tumor cells contain abundant keratin that forms epithelial pearls. B: Grade 2: Moderately differentiated squamous cell carcinoma of the cervix, transitional cell type. The tumor cells are characterized by a moderate amount of cytoplasm but are without pearl formation. Extensive pleomorphism and mitosis are evident. The tumor is frequently classified as being of large-cell, nonkeratinizing type. C: Grade 3: Poorly differentiated squamous cell carcinoma of the cervix, fat spindle or basal cell type. The tumor cells have little cytoplasm, numerous mitoses, and no keratin or epithelial pearls.

any other histologic type of cervical adenocarcinoma; however, other authors believe that the subpatterns have no prognostic significance.

The early classifications of squamous cell carcinoma of the cervix proposed by Martzloff and others divided these tumors into three categories: keratinizing squamous cell carcinoma, large-cell nonkeratinizing squamous cell carcinoma, and small-cell carcinoma. Over the years, however, it became apparent that the group designated as small-cell carcinoma was composed of a heterogeneous group of tumors, many of which displayed neuroendocrine differentiation. Recent changes in the nomenclature have led to the subdivision of these neuroendocrine tumors into typical carcinoid, atypical carcinoid, large-cell neuroendocrine carcinoma, and small-cell carcinoma. Typical carcinoid and atypical carcinoid tumors are rare in the cervix; therefore, their clinical and
Adenocarcinoma of the cervix.

Pathologic features have not been well characterized. Large-cell neuroendocrine and small-cell carcinomas are highly aggressive neoplasms, with a propensity to metastasize early and widely. Usual methods of therapy are not effective for these histologic types.

Various cervical sarcomas have been described by Rotmensch and coworkers. These tumors constitute less than 0.5% of all cervical cancers and include adenosarcomas, leiomyosarcomas, carcinosarcomas, and rhabdomyosarcomas. It is extremely rare for a lymphoma to develop primarily in the cervix, but lymphoma in the cervix is more likely to represent evidence of generalized lymphomatous disease.

**CLINICAL PRESENTATION**

Invasive cervical cancer is more likely than its intraepithelial precursors to cause symptoms such as abnormal vaginal bleeding (menorrhagia, metrorrhagia, postcoital bleeding, or postmenopausal bleeding). Many patients have a profuse and often malodorous discharge, especially when the disease is advanced. Thus, any patient with abnormal vaginal bleeding or discharge should have a complete pelvic examination, including a speculum examination with visualization of the cervix. Failure to examine the cervix in a patient with abnormal vaginal bleeding or discharge could result in failure to diagnose cervical cancer.

**Pain** is not a common symptom in patients with cervical cancer unless the disease is advanced. In more advanced stages, patients may report bladder and rectal symptoms. When the disease involves lumbosacral and sciatic nerve roots and the lateral pelvic sidewall, chronic boring pelvic bone pain radiating down the leg can be excruciating and indicative of advanced disease. Edema of the lower extremities likewise indicates tumor obstruction of lymphatic and/or venous drainage. Ascites is uncommon in cervical cancer.

Unfortunately, the physician cannot rely on the presence of symptoms to lead to a diagnosis of early carcinoma of the cervix. Many women remain without symptoms for many months. It is known that one third of patients with advanced stage III and IV disease have had symptoms for less than 3 months. The only way to diagnose cervical cancer in the earliest possible stages is to routinely apply special diagnostic procedures to large groups of women with and without gynecologic symptoms. This means screening the adult female population with Pap smears.

Invasive cervical lesions can be exophytic, infiltrative, ulcerative, or occult. The size of the visible lesion on the cervix may not correlate well with the extent or depth of invasion (Fig. 47.4).

An everted exophytic carcinomatous growth may be friable. Bits of tissue may break off on the examining fingers. On inspection, the friable exophytic cancer shows a rough, granular bleeding surface that can be sloughing and infected, with a foul-smelling discharge.

**FIGURE 47.3.** Adenocarcinoma of the cervix.

**FIGURE 47.4.** Squamous cell carcinoma, cervix uteri, FIGO stage IA.
A tumor that develops beneath the mucosa of the exocervix and infiltrates the cervical stroma usually causes cervical enlargement. The surface of the cervix may feel smooth, but the cervical consistency to palpation is firm or nodular. It is characteristic of cervical cancers that develop in the endocervical canal to cause cervical enlargement and a firm cervical consistency before breaking through the mucosa of the exocervix to cause a lesion. This also is characteristic of many cervical cancers that develop in postmenopausal women. In fact, it is possible, although uncommon, for a cervical cancer that is developing high in the endocervical canal to invade the parametrial tissue and even obstruct the ureters before causing a visible cervical lesion. An ulcerative lesion can look like a fairly clean punched-out ulcer, but more commonly it is an irregular crater with a necrotic bleeding base and a foul-smelling discharge.

Any grossly visible lesion of the cervix should be considered suspicious for cancer, and biopsy should be performed. Good visualization with a speculum and adequate illumination are essential. A Pap smear should be taken even though it can be less accurate in the presence of a grossly visible cervical lesion. Colposcopic examination is neither needed nor particularly effective for a gross cervical lesion, but can be helpful when there is a small surface lesion to identify the most abnormal area for directed biopsies. The primary benefit of colposcopy is in visualizing noninvasive, precursor, or minimally invasive lesions that cannot be visualized without magnification.

Cervical biopsy techniques are discussed in Chapter 46. Biopsies can be undertaken with any of a number of special instruments: the Kevorkian, Young, or Gaylor biopsy forceps are particularly functional for taking an adequate biopsy specimen. It is important to obtain a specimen where frank stromal invasion can be demonstrated, not from the exophytic portion where no benign stroma is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present. Surgical conization under anesthesia is unnecessary when a gross cervical lesion is present.
lesions by 10% to 20%. Lesions that involve the corpus also were found to have a twofold greater incidence of distant metastases when compared with lesions without corpus extension. Similar observations have been reported by Prempree and coworkers from 82 cases of stage I and II disease with endometrial extension. The absolute 5-year cure rates of 68% for stage I and 62% for stage II disease with endometrial extension reflects the higher risk of metastases: 20% for stage I cases and 24% for stage II cases. Such reports must be studied with consideration of the difficulty of establishing a diagnosis of endometrial extension by using microscopic study of endometrial curettage specimens. Frequently, the curettage specimen is contaminated by the cervical tumor, making it difficult to be certain about endometrial extension. Treatment planning is not altered by such observations, nor is a fractional curettage recommended as part of pretreatment evaluation.

Lymph node metastases, either regional (pelvic) or to higher-level (common iliac and paraaortic) lymph nodes, have proved to be one of the most reliable prognostic factors for patients with cervical cancer (Fig. 47.6). The frequency of metastases to pelvic lymph nodes is about 0% to 0.5% for patients with stage IA1; 7% to 9% for stage IA2; 12% to 20% for stage IB; 20% to 38% for stage IIA; 16% to 36% for stage IIB; 35% for stage III; and 50% for stage IV. Preoperative detection of positive pelvic lymph nodes is unreliable, even with newer radiologic imaging techniques. Detection of positive lymph nodes is more accurately determined when lymphadenectomy is used in preoperative staging or treatment. Although Kolstad showed that when intraoperative lymphography is used, 13% to 25% more patients with stage IB disease are found to have positive regional lymph nodes, this technique is rarely used outside the research setting.

When patients with stage IB cervical cancer are primarily treated with radical hysterectomy and pelvic lymphadenectomy, the 5-year cure rate is about 90% if there are no lymph node metastases. However, if metastatic disease to lymph nodes is detected, the 5-year cure rate falls to about 65% to 80%. The number of positive nodes also influences prognosis. In a review of the literature before the current standard of postoperative concurrent chemoradiation therapy, Hoskins reported an 83% survival rate for patients with stage IB and IIA disease who had negative lymph nodes at the time of radical hysterectomy and pelvic lymphadenectomy. The survival rate decreased to 57% in patients with one to two positive nodes and 31% in those with greater than three positive nodes.

Metastatic disease to paraaortic lymph nodes occurs in 4% to 7% of patients with stage I disease, 15% to 20% with stage II disease, 25% to 30% with stage III disease, and 30% to 50% with stage IV disease. Most studies confirm that metastasis to paraaortic nodes occurs more frequently when positive pelvic nodes also are present. The rarity of patients found to have positive paraaortic nodes when pelvic nodes are negative raises the question: How well sampled and/or sectioned were the pelvic nodes? Even with extended-field radiation therapy, the 5-year survival rate for patients with metastases to the paraaortic nodes is only about 25% to 35%.

Histologic tumor grade has been reported to affect prognosis. Early studies by Chung and coworkers and van Nagell and colleagues demonstrated a poorer prognosis among patients with poorly differentiated tumors. However, more recent studies by Zaino and GOG have shown the grading of squamous tumors to be of little predictive value in cervical carcinoma. Shingleton and Orr reviewed nine publications that reported on 3,764 patients with predominantly squamous cell carcinoma. Twenty-eight different factors were evaluated for prognostic significance. On multivariate analysis, tumor volume, lymph node metastasis, parametrial invasion, and LVSI were found to be significant independent prognostic factors, but patient age and tumor grade were not.

On the other hand, tumor differentiation may have a significant prognostic role in adenocarcinoma of the cervix. Shingleton and Orr also reviewed eight studies containing 577 patients with adenocarcinoma of the cervix. As with squamous cell carcinoma, the strongest independent prognostic variables were tumor size and nodal metastasis. However, unlike with squamous cell carcinoma, tumor grade appeared to have prognostic significance.

Several investigators, including Swan and Roddick, Wheless and Graham, and Julian and coworkers, have drawn attention to the fact that when there is a mixture of
adenocarcinomatous and squamous elements—so-called adenocarcinoma-in-situ tumors—tends to be poor and the incidence of pelvic lymph node metastases is high. Histologic combinations should be considered when comparing the prognoses of adenocarcinoma and squamous cancers of the cervix. The literature is mixed on the overall issue of whether adenocarcinoma in general and adenocarcinoma-in-situ tumors in particular are more virulent and less curable than their squamous counterparts. Stehman and colleagues performed a multivariate analysis of prognostic variables for 626 patients with locally advanced cervical carcinoma treated with radiation therapy on three GOG protocols. Histologic cell type was not found to be a significant prognostic factor. A national pattern of care and evaluation study of the American College of Surgeons also failed to report statistically significant 5-year survival rates for squamous and adenocarcinoma, regardless of type of therapy chosen.

In a GOG prospective study of 645 patients with stage IB squamous cell carcinoma of the cervix treated with radical hysterectomy and pelvic lymphadenectomy, Delgado and colleagues identified three independent risk factors in relation to disease-free survival: the depth of invasion, the size of the tumor, and LVSI. The disease-free interval was 89% for those patients without LVSI compared with 77% for those found to have LVSI. Although not all studies have found LVSI to be an independent prognostic factor, as stated, in a review of nine studies (including the study by Delgado et al.) containing 3,761 patients, Shingleton and Orr found LVSI to be a significant independent prognostic factor on multivariate analysis. The incidence of LVSI in early-stage lesions varies widely, depending on multiple factors, including the number of sections of the cervix prepared, the depth of stromal invasion, and the interest of the examining pathologist.

Observations from Austria and Germany indicate that there is considerable variation in the frequency with which LVSI is recognized by the pathologist. In a combined study of more than 1,000 patients at three different reference centers (Graz, Munich, and Erlangen), Burghardt and associates reported the frequency with which LVSI was identified ranged from 9% in Munich, where only blood vessel involvement was so classified, to 43% in Graz, where it was classified as capillarylike space involvement. At the third center, Erlangen, the corresponding value was intermediate at 23%. Such variations in histopathologic criteria may well contribute to some of the controversy that exists regarding the prognostic significance of LVSI.

To this point, this discussion of prognostic factors has included only anatomic and morphologic factors. Peipert and associates emphasize that cancer, including cervical cancer, has both form and function. Accordingly, other clinical variables, such as patient’s symptoms, symptom severity, and comorbidity, affect the survival rate of patients with invasive cervical cancer. Unless these variables are suitably included, prognostic estimates based on morphology alone are imprecise, and therapeutic evaluations can be misleading. According to Rutledge and associates, there is no consistent effect of age on survival rate in patients treated for cervical cancer. Younger patients with early-stage disease seemed to survive longer than older patients, but the tendency reversed when disease was advanced.

PRETREATMENT EVALUATION

When a diagnosis of invasive cervical cancer has been established histologically, the clinician should perform an evaluation of all pelvic organs to determine whether the tumor is confined to the cervix or has extended to the adjacent vagina, parametrium, endometrial cavity, bladder, ureters, or rectum. According to the FIGO guidelines for clinical staging, diagnostic studies may include intravenous urography (IVU), cystoscopic examination of the bladder and urethra, a proctosigmoidoscopic study, a barium enema (BE), and in the case of early-stage disease, a colposcopic study of the vagina and the vaginal fornices. Colposcopic findings may be used for assigning a stage to the tumor (for instance, FIGO stage IIA), but the results must be confirmed by biopsy. Chest radiographs and electrocardiographic studies are used to determine hypercalcemic disease, particularly in the older patient. Pulmonary function studies can be important, especially for evaluating patients who are candidates for extensive surgery.

When studies detect ureteral obstruction, a tumor is classified as a stage IB lesion, regardless of the size of the primary lesion. Ureteral obstruction, either hydronephrosis or nonfunction of the kidney, is well established as an indicator of poor prognosis, as recognized in the FIGO classification. Retrograde pyelography can be performed after the ureteral obstruction is located for further evaluation; however, it is not routinely recommended. Kidney function studies such as serum creatinine and creatinine clearance provide important baseline information before treatment; complete urinalysis is useful for detecting the presence of albumin or white and red blood cells and renal tubular casts.

In women with bulky or advanced-stage tumors, the bladder mucosa also should be inspected cystoscopically for possible bullous edema, which indicates lymphatic obstruction within the bladder wall. Evidence of tumor in the bladder must be confirmed by biopsy before the lesion can be classified as stage IV A. Rectal mucosal lesions also require a biopsy via proctosigmoidoscopy, because they can be related to an inflammatory process rather than to the cervical tumor.

A pelvic examination must be performed as part of the staging process, and it may be necessary to have the patient completely relaxed by general anesthesia. In as many as 20% of patients, the initial clinical classification of the disease based on office evaluation has been proven to be incorrect based on findings at the time of pelvic examination under anesthesia. Such an examination can reveal a more advanced stage of the disease than was originally found; additional biopsies (if indicated) or fractional curettage can be done as well as colposcopy, cystoscopy, and proctosigmoidoscopy. In today’s health care climate however, the cost of a separate examination under anesthesia may need to be reserved for only the most problematic cases.

Pretreatment pedal lymphangiography has been used in the past to detect pelvic and paraaortic lymph node metastases, but the procedure is tedious and associated with many false-negative and -positive findings. When compared with lymphadenectomy, positive lymphangiograms have an accuracy rate of less than 75% and a false-negative rate as high as 50%. Furthermore, a lymphangiogram only detects metastatic lesions when the parenchyma of the lymph node has become distorted, by which time the lesions are macroscopic. The procedure thus is not recommended for routine use in the pretreatment evaluation of cervical cancer patients.

Surgical experience from pelvic lymphadenectomy has confirmed an error rate of 15% to 25% in the clinical staging of patients with stage IB or II lesions. In 10% to 30% of cases with stage II or III tumors, in addition to positive findings of occult pelvic lymph nodes, other metastases may be found in the paraaortic nodes. Unfortunately, pelvic examinations and clinical staging as defined by FIGO cannot detect such metastases. Consequently, there is a growing body of literature showing...
the superiority of cross-sectional imaging (computed tomography [CT] and magnetic resonance imaging [MRI]) over clinical staging in delineating the extent of disease in patients with cervical cancer. As stated earlier, official FIGO guidelines do not incorporate the use of either CT or MRI findings into the staging of cervical cancer. This is due to FIGO guidelines that staging methods should be universally available so that staging can be a standardized means of communication between different institutions worldwide. However, as knowledge of prognostic factors and the value of cross-sectional imaging have accumulated, its use in treatment planning has increased despite the lack of change in the official FIGO clinical staging guidelines.

FIGO Patterns of Care Study conducted between 1978 and 1988, Montana et al. reported a decrease in the use of IVU (86% to 42%) and BE (38% to 32%) in the staging of cervical cancer patients. During the same time period, the use of CT scan increased from 6% to 70%. In another Patterns of Care Study in the United States recently reported by Amendola and colleagues, the use of lymphangiography, IVU, and BE had fallen to 1% in the pretreatment evaluation of patients with clinical FIGO stage IB1 or greater cervical cancer who were scheduled for surgery.

The greatest value of CT scan in the pretreatment evaluation of patients with cervical cancer is in the assessment of advanced disease (stage IB2 and greater) and in the detection and biopsy of suspected lymph node metastases. The treatment plan for patients with locally advanced disease must be modified if retroperitoneal lymph node involvement and/or distant metastases are discovered. A metaanalysis by Schmeler et al. reported a positive predictive value of 61% for CT scan in the pretreatment evaluation of nodal disease in cervical cancer. Moreover, in experienced hands, fine-needle aspiration of retroperitoneal nodes with CT scan guidance has an accuracy rate of 80% to 95%. When the aspiration study unequivocally shows malignant cells, a surgical biopsy need not be performed. This information is most valuable in patients who have metastasis to the paraaortic nodes, because these patients would need the pelvic radiation fields extended to incorporate the involved region if there is no other evidence of distant metastasis.

**SURGICAL TREATMENT OF EARLY-STAGE CERVICAL CANCER**

Based on the pretreatment evaluation of the patient, including the prognostic factors of tumor size, clinical stage of the disease, and risk of pelvic node metastases, a treatment schema can be developed for invasive cervical cancer as shown in Table 47.3. Almost all patients are treated with either primary surgery or primary radiation therapy with concurrent chemotherapy. Some patients are appropriately treated with combinations of all three. The standard management of patients with early cervical carcinoma is surgical removal of the cervix. The extent of resection of the surrounding tissue depends on the size of the lesion and the depth of cervical stromal invasion.

**Stage IA1 Disease**

The exact definition of early-stage cervical cancer has been debated for several decades. This is illustrated by the fact that FIGO changed the definition of early-stage cervical cancer at least five times from 1960 to 1995. In 1985, FIGO defined stage IA cervical cancer as that which invaded the cervical stroma to a maximal depth of 5 mm with no greater than 7 mm of horizontal spread. In 1995, FIGO made its most recent revision in the cervical cancer staging system. After an extensive evaluation of the data in the literature, as well as seeking advice from specialty societies and individuals worldwide, FIGO changed the definition of stage IA1 disease to lesions that invaded the cervical stroma ≤ 3 mm in depth and ≤ 7 mm in width. Stage IA2 includes patients with > 3 mm but < 5 mm invasion and ≤ 7 mm lateral extent.

*For individual patients, recommendations for treatment can vary, depending on the clinical circumstances.

Some authorities recommend modified (class II) radical hysterectomy, bilateral pelvic lymphadenectomy for stage IA2 disease.

Refer to Figure 47.5.

In highly selected cases.

Some authorities recommend simple hysterectomy in addition to castration/chemotherapy for stage IB2 and bulky stage IA disease.

A patient with a stage IVA lesion that extends only in the anterior or posterior direction may be a candidate for pelvic exenteration.

Diagnosis

Microinvasive carcinoma cannot be diagnosed from a punch biopsy because adjacent areas may contain more advanced tumor; conization is required for definitive diagnosis in this situation. The accuracy of the diagnosis depends on the adequacy of the cone and the adequacy of the pathologic examination of the cone. The entire cone should be blocked so that an adequate number of histologic sections can be taken from each block. If the diagnosis is still not certain, more sections should be made. Although some experts can obtain a large tissue specimen with negative margins using loop electrosurgical excision techniques for a satisfactory diagnosis of microinvasive cancer, a traditional cold-knife cone biopsy in the operating
Treat that patients who have squamous cell carcinoma of the cervix have virtually a 100% cure rate when treated with simple hysterectomy or conization alone. However, for patients treated by conization alone, both the internal conization margin and the postconization endocervical curettage must be negative for cancer and dysplasia, because the risk of residual invasive cancer is significantly increased if either the margin or the curettage is positive. The choice of therapy should be influenced by the patient’s desire to maintain fertility. Although LVSI generally is considered to be an adverse prognostic factor in cervical cancer, its prognostic significance in stage IA1 disease is uncertain. Because of this uncertainty, some clinicians suggested that the presence of LVSI in stage IA1 disease might be more appropriately treated with radical hysterectomy or radiation therapy. Recurrence in the vaginal vault usually is the result of failing to accurately define the extent of the lesion and the presence of involvement of adjacent vaginal mucosa. This usually can be prevented with a careful colposcopic examination before hysterectomy. If vaginal fomices are involved, partial vaginectomy is easier to perform with hysterectomy if the operation is done vaginally (Fig. 47.7). Alternatively, if the woman is not a good surgical candidate, radiation therapy (usually in the form of brachytherapy alone) can be selected.

Cancer of the Cervix

In 1996, the National Institutes of Health (NIH) invited an international panel of experts to develop a consensus conference statement on cervical cancer. After an extensive literature review and presentation of the scientific evidence, they concluded that patients with microinvasive adenocarcinoma of the cervix with ≤3 mm stromal invasion and negative conization margins have virtually a 100% cure rate when treated with simple hysterectomy or conization alone. However, for patients treated by conization alone, both the internal conization margin and the postconization endocervical curettage must be negative for cancer and dysplasia, because the risk of residual invasive cancer is significantly increased if either the margin or the curettage is positive. The choice of therapy should be influenced by the patient’s desire to maintain fertility. Although LVSI generally is considered to be an adverse prognostic factor in cervical cancer, its prognostic significance in stage IA1 disease is uncertain. Because of this uncertainty, some clinicians suggested that the presence of LVSI in stage IA1 disease might be more appropriately treated with radical hysterectomy or radiation therapy. Recurrence in the vaginal vault usually is the result of failing to accurately define the extent of the lesion and the presence of involvement of adjacent vaginal mucosa. This usually can be prevented with a careful colposcopic examination before hysterectomy. If vaginal fomices are involved, partial vaginectomy is easier to perform with hysterectomy if the operation is done vaginally (Fig. 47.7). Alternatively, if the woman is not a good surgical candidate, radiation therapy (usually in the form of brachytherapy alone) can be selected.

Increased infection morbidity has been reported with intracavitary irradiation of a recently coned cervix. The cervix must be allowed to heal completely before intracavitary irradiation. The survival rates for microinvasive disease (all treatments) should reach 98% to 99% if patients are adequately studied and properly treated.

Contrary to its squamous cell counterpart, the currently favored treatment for early invasive adenocarcinomas of the cervix is radical surgery or radiation therapy. Only a few studies of microinvasive adenocarcinoma of the cervix have been done. Webb and colleagues recently reviewed the SEER Public-Use Database to identify 131 cases of cervical adenocarcinoma with 3 mm or less stromal invasion. Fifty patients had a radical hysterectomy and pelvic lymph node dissection, and none were found to have lymph node metastasis. Furthermore, there were no deaths among the 54 patients treated with simple hysterectomy alone. Others have reported a 0% rate of lymph node metastasis with depths of stromal invasion of up to 3 and 12 mm. However, bilateral pelvic lymph node metastases have been reported with as little as 2.5 mm of stromal invasion. Furthermore, Elliott and associates reported a case of lymph node metastasis with cervical adenocarcinoma with <1 mm invasion and a second case of recurrence and death after radical hysterectomy and pelvic lymphadenectomy in a patient with 1.8 mm of stromal invasion. More information is needed before sound recommendations regarding conservative treatment options for microinvasive adenocarcinoma can be made.

Hysterectomy after Conization

To evaluate the extent of an early lesion, cervical conization occasionally is required. If simple extrasacral hysterectomy is subsequently chosen as the definitive surgical treatment, the operation should be done within 48 hours of the conization or delayed until the cervix has healed, usually about 4 to 6 weeks later. If the hysterectomy is done after 48 hours and before the cervix has healed, the risk of serious postoperative infectious morbidity is increased. However, a radical abdominal hysterectomy and bilateral pelvic lymphadenectomy can be done at almost any time after cervical conization, even before the cervix is completely healed, without increasing the risk of serious postoperative infectious morbidity. The reason for this difference is not clear, but may be related to the fact that irradiated and possibly infected paracervical and parametrial tissue is actually removed when a radical hysterectomy is done.

Stages IA2, IB1, and Nonbulky (≤4 cm) IIA Disease

The recommended treatment by the NIH Consensus Conference for patients with stage IA2 disease is primary radical or modified radical hysterectomy with bilateral pelvic lymphadenectomy or primary radiation therapy because the risk of nodal metastases is 4% to 10% in these patients. Again, the diagnosis of both stage IA1 and IA2 disease should be based on microscopic examination of removed tissue, preferably a conization or large-loop excision specimen, which must include the entire lesion. For stage IA2 disease, the depth of invasion should not be more than 3 mm taken from the base of the epithelium, either surface or glandular, from which it originates.

The second dimension, the horizontal spread, must be accurately defined by the postconization endocervical curettage. For stage IA2 disease, the depth of invasion must be accurately defined by the postconization endocervical curettage. For stage IA2 disease, the depth of invasion must be accurately defined by the postconization endocervical curettage.
7 mm. Vascular space involvement, either venous or lymphatic, should not alter the staging but should be specifically recorded. The remaining stage I cases should be allotted to stage IB. All grossly visible lesions are defined as stage IB.

For stage IA2 disease, standard treatment is class III radical hysterectomy with bilateral pelvic lymphadenectomy; however, some authors recommend a class II modified radical hysterectomy (Fig. 47.8). The class II hysterectomy removes the medial half of the cardinal and uterosacral ligaments, ligating the uterine artery at the ureter. This more conservative operation has been used by some authors in the past 3 decades to excise small primary tumors while reducing the partial bladder denervation associated with the complete excision of the cardinal and uterosacral ligaments required for a class III hysterectomy. Five-year survival rates of 97% to 98% have been reported for patients with small cervical lesions treated with class II hysterectomy. The role of the class II modified radical hysterectomy was recently evaluated in a randomized, prospective study reported by Landoni and colleagues. Two hundred forty-three patients with FIGO stages IB and IIA were randomized to either class II or III hysterectomy. The recurrence-free and overall survivals were similar between the two groups. Patients treated with type II radical hysterectomy had a statistically significant reduction in operative time and postoperative morbidity, particularly bladder dysfunction. However, given the relatively high care rate for early cervical cancer treated by radical hysterectomy, larger trials are necessary to prove equivalence in survival between the two types of hysterectomy. As stated by Rose, larger trials are required before we can accept these results as the new standard of care. The estimated extent of tissue resection in surgical procedures for early cervical cancer is summarized in Table 47.4.

developed the vaginal radical hysterectomy), Okabayashi, and others, radical surgery was fraught with significant operative morbidity and mortality. The introduction of radium brought irradiation to the forefront of primary treatment for carcinoma of the cervix for the next several decades. In the United States, Joe V. Meigs reintroduced radical hysterectomy as the treatment of choice, publishing a series of 344 cases in 1945. Until formalization of training fellowships in gynecologic oncology in the early 1970s, many outstanding gynecologic surgeons in the United States (Parsons, Ulfelder, Loren, and many others) made important contributions and modifications in the surgical approach that have markedly decreased complications while preserving the cure rate. Today, proficient performance of the radical hysterectomy is the benchmark of the gynecologic oncology surgeon.

**Patient Selection for Radical Hysterectomy**

Simple hysterectomy is not adequate treatment for stage IB cervical cancer. In 1945, Jones and Jones reported a 5-year survival rate of only 41.6% in patients who had been treated for stage I cervical cancer with simple hysterectomy only. Such poor results also have been reported by Schmidt and others. When more than FIGO stage IA1 invasive cervical cancer is a surprise finding in a simple hysterectomy specimen, adjuvant therapy—usually radiation therapy with or without chemotherapy—should be given postoperatively. Suggested indications for radical abdominal hysterectomy are summarized in Table 47.5.

Although radical hysterectomy and pelvic lymphadenectomy occasionally are used to treat patients with adenocarcinoma of the endometrium with involvement of the cervical stroma (stage IB) and, rarely, patients who have a small cervical cancer that persists or recurs in the cervix after primary radiation therapy, in this chapter emphasis is given to the use of the operation as primary treatment for invasive cervical cancer.

Patients with bulky stage IB disease (currently FIGO stage IB2) have traditionally been treated with radical hysterectomy and bilateral pelvic lymphadenectomy or primary radiation therapy with equivalent survivals. However, patients with these larger lesions treated surgically have a very high risk of having lymph node metastasis or close resection margins, which are often reasons for postoperative pelvic radiation treatment. Landoni and colleagues performed a randomized trial of radical hysterectomy and pelvic lymphadenectomy versus pelvic radiation therapy for stage IB to IIA cervical cancer. Patients randomized to the surgery arm who had pathologic risk factors, such as lymph node metastasis, received adjuvant radiation therapy. Of the 55 patients with tumors > 4 cm, 46 (84%) required postoperative irradiation. The disease-free and overall survival for these patients treated with surgery and radiation therapy was the same as that for patients with bulky tumors treated with radiation therapy alone; however, the combination therapy significantly increased morbidity. Subsequently, a randomized trial performed by the GOG has demonstrated the benefit of the addition of cisplatin chemotherapy to pelvic radiation followed by extracervical hysterectomy in this group of patients. Therefore, many experts feel that patients with FIGO stage IB2 and bulky RA cervical cancer are best treated with concomitant cisplatin chemotherapy and radiation therapy followed by extracervical hysterectomy.

In this country, patients with stage IB invasive cervical cancer usually are excluded from primary treatment with surgery. They are usually treated with concomitant radiation therapy and chemotherapy.

The clinical significance of parametral involvement dates from the early studies of Kundrat and Sampson. Kundrat, working in Wertheim’s clinic, studied more than 21,000 serial microscopic sections of the parametrium, finding that the parametrium of one or both sides was involved in 44 of 80 patients. In a similar study at the Johns Hopkins Hospital, Sampson pointed out that the parametrium could feel indurated and yet shows no evidence of cancer. Also, the parametrium can feel normal and yet contain cancer. Sampson emphasized that only by the microscope can the surgeon exclude cancer involvement of the parametrium. More recently, Inoue and Okumura found parametrial extension in 7% of stage IB patients and in only 34% of stage IB patients. Burghardt and Pickel found true parametrial involvement in only 19% of stage IB patients, Matsumura and coworkers found no parametrial cancer in 58% of stage IB patients. These studies were based on careful examination of microscopic sections and reemphasize the difficulty of being certain about parametral extension from pelvis examination alone, emphasizing the shortcomings of a clinical staging system. Inoue and Okumura studied 628 operative specimens from patients treated with radical hysterectomy and lymphadenectomy and found that parametrial extension is an important factor in the number of positive lymph nodes found and in patient survival. If there is suspicion of spread into the parametrial tissues by examination, CT scan, or MRI scan, it is reasonable to offer radiation therapy with concomitant chemotherapy as primary treatment (despite the fact that the official FIGO stage should remain unchanged).

The major point to be emphasized is that the gynecologic surgeon should not attempt to treat a patient with a large cervical tumor with primary radical surgery unless there is reasonable assurance that the operation will result in the complete removal of the central tumor with an adequate margin of tumor-free tissue around it. The surgeon should not operate on patients with the idea that radiation therapy with or without chemotherapy can be used postoperatively to eliminate residual fragments of tumor tissue left behind after incomplete
Squamous cell carcinoma, clear-cell cancer, and undifferentiated adenocarcinoma have a poorer prognosis, regardless of the method of treatment chosen, and therefore are often considered for adjuvant radiation therapy and/or chemotherapy after primary surgery.

Patients considered for radical hysterectomy must be acceptable candidates for an operation and free of serious medical problems that contraindicate extensive surgery. In former years, some institutions limited radical surgery as primary treatment to premenopausal women so that ovarian function might be conserved. As experience has accumulated, it has become apparent that the operation is also well tolerated by older women. In a study of 45 women aged 65 years and older with cervical cancer, Fuchtnner and associates concluded that age alone should not be a contraindication to extensive hysterectomy in the elderly patient with American Society of Anesthesiologists physical status I to III. Kinney and coworkers reported their experience with the Wertheim operation in a geriatric population. Thirty-eight selected women between 65 and 89 years of age (median age, 69 years) were compared with 320 patients younger than age 65. The survival rates were almost identical in the two groups. Perioperative morbidity was minimally increased in the geriatric group. Cohn and colleagues recently reported their results with radical hysterectomy for cervical cancer in 46 obese women. The median body mass index was 36 kg/m² and the median weight was 95 kg. Nine patients (20%) experienced postoperative morbidity, mostly related to wound complications. No patient developed a fistula. Massi and associates have reported that the Schauta-Amreich vaginal hysterectomy can be used as an alternative to the radical abdominal hysterectomy in the presence of obesity or elevated surgical risks.

Studies by Shingleton and Levant compared outcomes after radical hysterectomy for cervical cancer in obese versus nonobese women. They found that survival was not compromised and the incidence of serious complications was not increased in obese patients. However, in obese women, the authors reported that the operative technique is more difficult, the procedure lasts longer, and the surgery is associated with greater blood loss. Cohn and colleagues recently reported their results with radical hysterectomy for cervical cancer in 46 obese women. The median body mass index was 36 kg/m² and the median weight was 95 kg. Nine patients (20%) experienced postoperative morbidity, mostly related to wound complications. No patient developed a fistula. Massi and associates have reported that the Schauta-Amreich vaginal hysterectomy can be used as an alternative to the radical abdominal hysterectomy in the presence of obesity or elevated surgical risks.

According to Shingleton, primary treatment with radical surgery paradoxically also can be riskier in very thin patients because of a higher incidence of fistula. It is speculated that easy exposure and lack of excess fatty tissue in these patients may result in removing essential vasculature around the ureters and bladder, resulting in ischemic necrosis. A thin patient has less fat around the pelvic vessels and in the lymph fields; thus, the surgeon should be satisfied to remove less tissue in an operation that will still be adequate in a thin patient.

The management of the pregnant patient diagnosed with invasive cervical carcinoma is perplexing. First, a decision must be made to either save the pregnancy or treat the cancer. Pregnancy is not a contraindication to primary treatment of stage IB or IA carcinoma of the cervix with radical surgery (Fig. 47.9). In 1974, Sall and coworkers reported on 29 patients with stage IB carcinoma of the cervix in pregnancy treated with radical hysterectomy and pelvic lymphadenectomy. At the time of publication, 28 patients were alive and well, and 23 patients had been followed for more than 5 years. There were no
Advantages of Radical Surgery as Primary Treatment for Invasive Cervical Cancer

The most important considerations in choosing a method of therapy for any cancer are, first, the effectiveness of the treatment in curing the disease and, second, mortality and morbidity rates associated with the treatment plan. For the indications listed previously, the cure rates of primary radiation therapy and primary surgical therapy are about equal. The modern mortality rates also are about equal. Both modalities of therapy have a list of complications unique to each that seem about equal. There are, however, important major and minor advantages of primary radical surgery over irradiation for early-stage disease, some of which are discussed in the following sections.

Accurate Evaluation of Extent of Disease

The findings at operation and from careful pathologic examination of the surgical specimen can be immensely helpful in selecting high-risk patients for adjuvant postoperative radiation therapy, chemotherapy, or both. Most patients with FIGO stages IA2, IB1, and not bulky IA disease are not found to have high-risk factors and thus are spared the potential morbidity associated with whole pelvic radiation therapy. Furthermore, the findings at operation and careful pathologic examination of the surgical specimen can be helpful in determining prognosis and in identifying patients at greatest risk for persistence or recurrence of disease. Such high-risk patients may require additional therapy.

In addition to an accurate assessment of the extent of the cervical cancer, primary surgical treatment allows for discovery of other intraabdominal incidental conditions and diseases entirely unrelated to the cancer. Ovarian malignancies, pelvic tuberculosis, sigmoid diverticulitis, cholelithiasis, and other diseases and conditions may be encountered at the time of operation.

Preservation of Ovarian Function

When primary radiation therapy with or without chemotherapy is used to treat invasive cervical cancer in premenopausal women, premature loss of ovarian function is an unfortunate and inevitable result. When primary surgery is used instead, the function of normal ovaries can be conserved. Sutton and associates analyzed the incidence of ovarian metastasis for 991 patients with stage IB carcinoma of the cervix treated with radical hysterectomy and pelvic lymphadenectomy on a prospective GOG protocol. Ovarian spread was found in 4 of 770 patients (0.5%) with squamous cell carcinoma and in 2 of 121 patients (1.7%) with adenocarcinoma. The difference was not statistically significant. All six patients with ovarian metastases had other evidence of extracervical disease. This study confirmed that ovarian metastasis is rare in patients with stage IB cervical cancer and extremely rare in the absence of other evidence of extracervical disease.

Although the incidence of ovarian metastasis is slightly higher in women with adenocarcinoma of the cervix as compared with squamous cell carcinoma, ovarian conservation should still be considered, especially in young women. Brand and Berek reported no ovarian metastases in more than 60 patients with adenocarcinoma of the cervix treated with radical surgery. Angel and coworkers found no ovarian metastases in 41 patients with adenocarcinoma of the cervix who underwent oophorectomy. Greer and coworkers treated 55 patients with stage IB adenocarcinoma of the cervix with radical hysterectomy and pelvic lymphadenectomy. Ninety-one percent had ovarian preservation, and there was no evidence that this contributed to tumor recurrence. Hopkins and coworkers found that the best cumulative 5-year survival rate (93%) with cervical adenocarcinoma was in patients treated by radical hysterectomy without bilateral salpingo-oophorectomy and concluded that “ovarian conservation seems to be an acceptable alternative to bilateral salpingo-oophorectomy” in young patients.

Some authors have advocated transposing the ovaries into the paracolic gutters at the time of radical hysterectomy in premenopausal women to protect the ovaries from radiation damage. Ovarian function must be conserved. Sutton and associates analyzed the incidence of ovarian metastasis for 991 patients with stage IB carcinoma of the cervix treated with radical hysterectomy and pelvic lymphadenectomy on a prospective protocol. Ovarian spread was found in 4 of 770 patients (0.5%) with squamous cell carcinoma and in 2 of 121 patients (1.7%) with adenocarcinoma. The difference was not statistically significant. All six patients with ovarian metastases had other evidence of extracervical disease. Some authors have advocated transposing the ovaries into the paracolic gutters at the time of radical hysterectomy in premenopausal women to protect the ovaries from radiation damage. All six patients with ovarian metastases had other evidence of extracervical disease.

When primary radiation therapy with or without chemotherapy is used to treat invasive cervical cancer in premenopausal women, premature loss of ovarian function is an unfortunate and inevitable result. When primary surgery is used instead, the function of normal ovaries can be conserved. Sutton and associates analyzed the incidence of ovarian metastasis for 991 patients with stage IB carcinoma of the cervix treated with radical hysterectomy and pelvic lymphadenectomy on a prospective GOG protocol. Ovarian spread was found in 4 of 770 patients (0.5%) with squamous cell carcinoma and in 2 of 121 patients (1.7%) with adenocarcinoma. The difference was not statistically significant. All six patients with ovarian metastases had other evidence of extracervical disease. This study confirmed that ovarian metastasis is rare in patients with stage IB cervical cancer and extremely rare in the absence of other evidence of extracervical disease. Although the incidence of ovarian metastasis is slightly higher in women with adenocarcinoma of the cervix as compared with squamous cell carcinoma, ovarian conservation should still be considered, especially in young women. Brand and Berek reported no ovarian metastases in more than 60 patients with adenocarcinoma of the cervix who underwent oophorectomy. Greer and coworkers treated 55 patients with stage IB adenocarcinoma of the cervix with radical hysterectomy and pelvic lymphadenectomy. Ninety-one percent had ovarian preservation, and there was no evidence that this contributed to tumor recurrence. Hopkins and coworkers found that the best cumulative 5-year survival rate (93%) with cervical adenocarcinoma was in patients treated by radical hysterectomy without bilateral salpingo-oophorectomy and concluded that “ovarian conservation seems to be an acceptable alternative to bilateral salpingo-oophorectomy” in young patients.

impossible. This is especially true of those inferior gluteal nodes can possibly be involved with metastatic tumor is technically eradication at best in that removal of all pelvic lymph nodes that pointed out that pelvic lymphadenectomy is an incomplete op-

eration that included lymphadenectomy. Furthermore, they nary fistulas), a lower operative mortality rate, and a cure patients had fewer postoperative complications (especially uri-

nary fistulas), a lower operative mortality rate, and a cure rates in patients who have undergone radical abdominal hy-
terectomy and bilateral pelvic lymphadenectomy are unusual. These points are especially important when selecting a method of primary treatment for young women.

Psychological Benefits

There are probably important psychological benefits of pri-
mary treatment with radical surgery compared with radiation therapy. Most patients prefer to have the tumor removed and are especially encouraged when the surgeon can report that “the cancer is out” and that no evidence of metastatic dis-

case was found at operation. Radiation therapy carries an un-
fortunate connotation in some patients who feel that it is the treatment of last resort, that the treatments are actually “cook-
ing” the tissues in the pelvis, that the tumor is still there (albeit treated), or that irradiation can cause other cancers. All gyneco-

logic surgeons have heard the disappointment patients express when they are told that they cannot be treated with an opera-
tion. Some patients continue to request an operation even after they have completed radiation therapy.

Justification for Pelvic Lymphadenectomy

Histologically, there was competition between gynecologic sur-
gons who advocated radical vaginal hysterectomy without lymphadenectomy and those who advocated radical abdom-
inal hysterectomy with lymphadenectomy. The advocates of extensive vaginal hysterectomy without lymphadenectomy (the Schauta-Amreich-Navratil operation) argued that their pa-
tients had fewer postoperative complications (especially uri-
nary fistulas), a lower operative mortality rate, and a cure rate that was almost equal to that achieved by an abdominal operation that included lymphadenectomy. Furthermore, they pointed out that pelvic lymph node involvement at best in that removal of all pelvic lymph nodes that can possibly be involved with metastatic tumor is technically impossible. This is especially true of those inferior gluteal nodes that are located in the region of the ischial spine, as pointed out by Reifenstuhl. However, even Navratil stated in 1961 that “indications for the Schauta operation must take the lymph node problem into account.” Later he performed extraperi-
toneal pelvic lymphadenectomy with the Schauta operation in all cases of stage I and II that were locally advanced, as did Mitra.

In recent years, the operative mortality and complication rates in patients who have undergone radical abdominal hys-
terectomy and bilateral pelvic lymphadenectomy have signifi-
cantly decreased. Operative mortality and fistulas occur in <1% and about 2% of patients, respectively. Therefore, one 

pted disadvantage of radical hysterectomy (high mortal-

ity) has essentially been removed, and the surgeon can concen-
trate on the question of whether lymphadenectomy adds any-
thing to the possibility of cure. If a pelvic lymphadenectomy is not done in patients who have a radical hysterectomy for cer-
vical cancer, at least 15% to 20% of patients (those with posi-
tive nodes) will be inadequately treated for their disease (unless perhaps all patients receive postoperative pelvic irradiation). In our judgment, it is better to do a pelvic lymphadenectomy in all patients and then give postoperative radiation therapy selec-
tively than to avoid a lymphadenectomy and give postoperative radiation therapy to all patients.

It is the opinion of some that pelvic lymphadenectomy is of no value in those 80% to 90% of patients who have nega-
tive lymph nodes. We disagree with this view. We believe that lymphadenectomy is helpful in achieving an adequate central dissection around the cervical tumor, the most important part of the operation. This is especially true of that part of the lym-
phadenectomy that involves removal of tissue from around the hypogastric vessels, from the obturator fossa, and from the lower presacral region. Admittedly, dissection of lymph nodes from the common iliac vessels and from the paraaortic region does not add to the completeness of the central dissection.

Removal of these and other nodes, however, is helpful in prognosis and in identifying patients at greater risk for persistent disease who might receive adjuvant postoperative radiation therapy to the pelvis and perhaps to extended fields about the aorta. Al-

though we seldom dissect and remove the highest paraaortic lymph nodes, we do remove the lower paraaortic nodes around and just above the aortic bifurcation. If pelvic lymph nodes in-

olved with tumor are found during the operation, a concerted effort is made to do a more complete paraaortic dissection. Although it is possible for paraaortic nodes to be directly in-

volved without involvement of pelvic nodes, this is extremely rare. For the group of patients who usually would be chosen for treatment with primary radical surgery, routine extensive paraaortic lymph node dissection would not result in a thera-

peutic benefit very often. Podczaski and coworkers found posi-

itive paraaortic lymph nodes in 7 of 52 patients (13.4%) with stage IB and IIA disease. Twenty-eight of the 52 patients, how-

ever, had bulky tumors > 5 cm in greatest diameter. Currently, such patients are considered by many gynecologic oncologists not to be appropriate candidates for treatment with primary radical surgery. Patsner and coworkers performed paraaortic lymph node sampling in patients with small (tumor < 3 cm) stage IB cervical tumor. Only 2 of the 125 patients who under-

went radical hysterectomy, bilateral pelvic lymphadenectomy, and paraaortic node sampling had metastases to the paraaor-

tic nodes. No patient had gross paraaortic nodal involvement, and both patients with microscopic paraaortic nodal metas-
tases had grossly positive pelvic nodal involvement. Therefore, investigators recommended that paraaortic sampling in patients with small stage IB cervical tumors be restricted to patients with suspicious or positive pelvic or paraaortic nodes. The
right common iliac arteries at the fourth lumbar vertebra the vertebral column, where it bifurcates into the left and the tic hiatus of the diaphragm at the lower border of the last the internal iliac) arteries and veins and their various branches the common iliac, external iliac, and hypogastric (also known as lymphadenectomy, the major operative dissection includes the frequently incorporated into the operative field of the pelvic Although the lower portions of the aorta and vena cava are frequently incorporated into the operative field of the pelvic lymphadenectomy, the major operative dissection includes the common iliac, external iliac, and hypogastric (also known as the internal iliac) arteries and veins and their various branches and tributaries. The abdominal aorta emerges through the aortic hiatus of the diaphragm at the lower border of the last thoracic vertebra and descends along the ventral surface of the vertebral column, where it bifurcates into the left and right common iliac arteries at the fourth lumbar vertebra (Fig. 47.10). This is an important anatomic landmark because the bifurcation at L4 lies directly beneath the umbilicus in most cases. Therefore, an abdominal midline incision that provides surgical exposure to the lower aorta needs to be extended somewhat above the umbilicus. The right common iliac artery crosses the upper portion of the left common iliac vein at the aortic bifurcation. This segment of the venous drainage of the left side of the pelvis joins with the right common iliac vein to form the vena cava, which lies directly along the right side of the aorta and on the right lateral side of the bodies of the lumbar vertebrae in its retroperitoneal course through the abdomen.

Both common iliac arteries continue along the medial border of the psoas muscle to the pelvic brim, where they divide into external iliac and hypogastric vessels. As shown in Fig. 47.10, this important vascular division marks the site where the ureters enter the pelvis from the abdomen, usually overlying the terminal end of the common iliac artery on the left and commonly crossing the actual bifurcation of the artery on the right. Both external iliac arteries pass beneath the inguinal ligament to proceed into the leg as the femoral artery. The external iliac artery makes no direct vascular contribution to the pelvis, although there is a fairly constant arterial branch to the ureter from the midpoint of the common iliac artery.

The external iliac vein emerges from beneath the inguinal ligament, where it courses along the lateral pelvic brim on the medial side of the artery until it reaches the proximal segment. Here, the vein passes directly beneath the artery at the bifurcation of the common iliac artery and then passes along the lateral side of the upper half of the artery. It then joins the left common iliac vein to become the inferior vena cava at the fifth lumbar vertebra. In dissecting the lymph nodes along the external iliac vessels, these anatomic landmarks are important to avoid trauma to the wall of the vein as it deviates from the medial to the lateral side of the arterial tree.

The hypogastric artery provides the major blood supply to the pelvic viscera. For descriptive purposes, it is conveniently divided into an anterior and a posterior division. The important branches of the hypogastric artery are shown in Figs. 47.11 and 47.12. A fairly constant arterial branch to the ureter arises from the hypogastric artery near the common iliac bifurcation. This vessel passes medially to the ureter and should be preserved, if possible, during the dissection of the hypogastric vessels. The posterior division of the hypogastric artery continues beneath the coccygeus muscle through the ischiorectal fossa, where it becomes the internal pudendal artery to supply the perineum and vulva.

The major blood supply to the pelvic viscera is derived from the anterior division of the hypogastric artery. Figure 47.11 shows the anterior division, which gives off the uterine artery before continuing along the posterolateral pelvic wall to supply the superior and inferior vesical branches to the bladder. The anterior division then continues as the obliterated umbilical artery as it passes cephalad along the inferior surface of the rectus muscle to the umbilicus. In dissecting along the hypogastric artery in a caudal direction, the uterine artery is the first vessel encountered; it emanates from the medial side of the vessel. Passing more inferiorly and medially is the middle hemorrhoidal artery, which supplies a major segment of the rectum and communicates with the superior hemorrhoidal (from the inferior mesenteric) and the inferior hemorrhoidal (from the internal pudendal) arteries. The hypogastric vein and its tributaries course along the pelvic floor and medial side of the artery to drain the pelvis in close relation to the arterial blood supply. Its extensive anatomic variations and its location along the pelvic sidewall

Arterial and Venous Anatomy

Although the lower portions of the aorta and vena cava are anatomic variations and its location along the pelvic sidewall

pertinent pelvic anatomy

Arterial and Venous Anatomy

Although the lower portions of the aorta and vena cava are frequently incorporated into the operative field of the pelvic lymphadenectomy, the major operative dissection includes the common iliac, external iliac, and hypogastric (also known as the internal iliac) arteries and veins and their various branches and tributaries. The abdominal aorta emerges through the aortic hiatus of the diaphragm at the lower border of the last thoracic vertebra and descends along the ventral surface of the vertebral column, where it bifurcates into the left and right common iliac arteries at the fourth lumbar vertebra
and floor place these tortuous, thin-walled veins in a precarious and vulnerable position for trauma during deep dissection of the pelvis. As shown in Fig. 47.12, the delicate tributaries of the trunk of the hypogastric vein extend into sacral foramina and pass beneath nerve fibers and muscles within the pelvis, so that their identity during the dissection of the pelvis frequently is obscured. The continuation of the hypogastric vein, in association with the artery, beneath the coccygeus muscle is a frequent site of bleeding when dissection is undertaken along the pelvic floor. When this occurs, it is difficult to identify the vessel because it retracts beneath the margins of the muscle.

The profuse collateral blood supply to the ureter is an important anatomic safeguard that protects its pelvic segment from ischemic necrosis as a result of radical hysterectomy (Fig. 47.13). The ureter has the advantage of a multiple-source blood supply. This favorable collateral circulation permits interruption of small arteries and veins deep in the pelvis during extensive dissection of the base of the broad ligament without producing a significant incidence of ischemic necrosis and fistula formation. The freely anastomosing arterial and venous network that courses along the longitudinal surface of the ureter in its adventitial layer is supplied in its superior segment by branches from the renal and ovarian arteries. The middle segment of the ureter derives its blood supply directly from aortic branches and from a vessel from the common iliac artery. As the ureter enters the pelvis and courses along the lateral pelvic wall, it receives arterial branches from the uterine, vaginal, middle hemorrhoidal, and vesical arteries. As it approaches the trigone of the bladder, it has a rich arteriovenous collateral circulation from the arterial branches to the vagina and base of the bladder. Protection of this important vascular network is important for the integrity of the terminal ureter during extensive dissection of the cardinal ligament. Preservation of the lateral aspect of the posterior segment of the

vesicouterine ligament has been recommended to ensure adequate vascularity to the terminal segment of the ureter, but we have encountered no difficulty in removing this tissue and have no hesitation in doing so to enhance the adequacy of the central dissection.

### Lymphatic Anatomy

The lymphatic drainage of the pelvis follows the course of the arterial and venous blood supply. Although there are multiple variations in the lymphatic anatomy of the pelvis, in general, lateral, superior, medial, and inferior lymph nodes and communicating lymphatic channels surround the common iliac, external iliac, and hypogastric vessels. One of the important pathways of the pelvic nodes and thin-walled lymphatics that drain the upper vagina, cervix, and uterus courses along the posterior aspect of the endopelvic fascia. Here, the pelvic nodes pass through the uterosacral ligament area and terminate in lymph nodes along the lateral aspect of the sacrum. These nodes communicate freely with lymphatic channels from the bifurcation of the common iliac artery near the lateral sacral andischiosacral fossae. These can be difficult nodes to resect because they are closely attached to the thin-walled tributaries...

The most direct lymphatic drainage of the cervix and upper vagina is through the lateral parametrium (cardinal ligament) to the hypogastric and obturator lymphatics. Because of the presence of obscure obturator veins and multiple venous tributaries from the hypogastric vein along the pelvic floor, the obturator dissection can be associated with troublesome venous bleeding. Injury also can occur to the obturator nerve, which arises from the anterior division of the second, third, and fourth lumbar nerves; enters the pelvis through the psoas muscle; and runs along the lateral pelvic wall in the obturator fossa to exit the pelvis through the obturator foramen along with the obturator vessels. It is a motor nerve to the adductor muscles of the thigh and is the only motor nerve that arises from the lumbar plexus without innervating any of the pelvic structures. Damage to the obturator nerve produces not only motor impairment to the adductor muscles but also sensory loss along the medial aspect of the thigh (Fig. 47.14). Deep dissection posterior to the obturator nerve can be complicated by bleeding from the tributaries of the hypogastric and obturator veins so that dissection in this area, if necessary, must be done with great care, using clips on the small vessels and compression for troublesome venous bleeding.

Reiffenstuhl, in his classic study of the lymphatics of the female genital organs, describes effluent lymph channels from the cervix to the interilute lymph nodes, the lateral and medial external iliac lymph nodes, the sacral lymph nodes, the subcutaneous lymph nodes, the aortic lymph nodes, the superior gluteal lymph nodes, the inferior gluteal lymph nodes, and the rectal lymph nodes. Of these, the inferior gluteal nodes are not technically possible to remove with the standard approach. This is because the nodes lie around the ischial spine in proximity to the inferior gluteal artery and pudendal artery and nerve. An imposing network of veins also surrounds the inferior gluteal nodes. They are thin walled, easy to damage, difficult to expose, and difficult to control when damaged. Reiffenstuhl’s concepts of the lymphatic drainage of the cervix are partially shown in Fig. 47.15.

FIGURE 47.13. Blood supply of the ureter showing multiple sources of collateral arterial circulation.
**Sentinel lymph node studies** in women with cervical cancer are also adding to our knowledge of the lymphatic drainage in vivo, and identification of sentinel lymph nodes with blue dye and technecium injections is feasible with very low morbidity. These sentinel lymph nodes can be submitted for ultrastaging with immunohistochemistry staining and may help in the post-operative management of cases. Further evaluation is needed to see if sentinel lymph node identification can potentially replace complete pelvic lymphadenectomy. This might reduce the total operative time as well as some perioperative complications and long-term complications, such as the risk of postoperative leg lymphedema, which is occasionally seen in patients undergoing pelvic lymphadenectomy.

**CONCEPT OF RADICAL ABDOMINAL HYSTERECTOMY AND BILATERAL PELVIC LYMPHADENECTOMY**

There are several variations of hysterectomy used in the management of cervical carcinoma. The description of the five

**FIGURE 47.15.** The regional lymph node stations of the uterine cervix. Channels 8, 9, and 10 (indicated by especially heavy lines) lead to those regional lymph node stations most frequently reached by the efferent lymph vessels of the cervix. Nonetheless, it is necessary to remember that carcinoma cells also can reach the pelvic lymph nodes by way of channels 1 through 7, without previous interruption, to (1) rectal, (2) subaortic (promontorial), (3) aortic, (4) medial common iliac, (5) lateral common iliac, (6) lateral external iliac, (7) sacral, (8) superior gluteal, (9) anterior iliac, and (10) internal iliac lymph nodes. (From: Reiffenstuhl G. The lymphatics of the female genital organs. Philadelphia: JB Lippincott, 1964, with permission.)
classes of hysterectomy by Piver and colleagues has found general acceptance. The first three classes are used in the primary treatment of cervical carcinoma, whereas the last two classes are generally reserved for patients with recurrent disease. The class I hysterectomy is a simple extrafascial total hysterectomy. It is used as primary treatment for stage IA1 disease and after concurrent chemotherapy and radiation therapy for stage IB2 and bulky stage IA cervical carcinoma. The class II hysterectomy (Fig. 47.8), also known as a modified radical hysterectomy, removes a more generous vaginal cuff, ligates the ureter on the medial side of the ureter (but does not dissect the ureter from the vesicouterine ligament), and removes the inner one third to one half of the cardinal ligament. As previously stated, some authors recommend the performance of the class II hysterectomy for stage IA2 cervical carcinoma. The class III operation is the classic Meigs procedure, with removal of all of the parametrium and paravaginal tissue in addition to the pelvic lymph nodes (Fig. 47.8). A more extensive procedure is performed in the class IV radical hysterectomy, in which the ureter is completely dissected from the cardinal and vesicoureteric ligaments, the superior vesical artery is sacrificed, and three fourths of the vagina is removed as well as the uterus and parametria, along with a complete lymphadenectomy. A far more extensive procedure is done with the class V radical hysterectomy, in which the terminal ureter or a segment of the bladder or rectum is removed along with the uterus, parametria, adnexa, and pelvic lymph nodes.

Although many techniques emphasize a more or less extensive dissection in one phase of the operation or another, the management of the parametria and the dissection of the pelvic lymph nodes appear relatively uniform. Because the most serious complication of this procedure is related to uterine fistulas and stenosis, many modifications have been undertaken to ensure an adequate blood supply to the terminal ureter. We agree that the terminal ureter must have a good blood supply and believe that this can be accomplished without jeopardizing the adequacy of the central dissection. The classic radical hysterectomy with wide resection of the parametrium, dissection of the terminal ureter from the vesicoureteric ligament, and wide resection of the uterosacral ligaments, upper 2 to 1 cm of vagina, and paravaginal tissues, along with a thorough pelvic lymphadenectomy, constitute the traditional procedure that is used in our institution.

The major focus of the operation is the adequacy of the central dissection. The central cervical tumor must be removed with an adequate margin of uninvolved normal tissue around it. This is the most crucial point in the success of the operation and has been emphasized by many of the famous pelvic surgeons of former years, especially Parsons and Navratil. The central dissection can be facilitated by developing the pelvic spaces and using proper planes for dissection. Correct dissection along natural rather than artificial connective tissue planes and correct development of the pelvic spaces (paravesical, pararectal, vesicocervical, and rectovaginal) avoid unnecessary injury to pelvic vessels, keep blood loss to a minimum, and facilitate an adequate central dissection (Fig. 47.16). The central dissection also is facilitated by a complete removal of the contents of the obturator fossa (except the obturator nerve) so that branches of the hypogastric artery and vein in the cardinal ligament are clearly visible and can be dissected away from their attachments to the lateral pelvic sidewall.

The importance of an adequate central dissection also was emphasized by Gazdar and coworkers. By studying surgical specimens processed according to the giant-section technique of Burghardt and Pickel, parametrial lymph nodes were found in 281 (78%) of the 359 surgical specimens from radical hysterectomies. Metastases to parametrical nodes were found in 63 (22.5%) of these 280 specimens. The lymphatic drainage from the cervix to the pelvic lymph nodes runs through the parametrium, and deposits of tumor often are found there. An adequate central dissection must include removal of a wide margin of parametrial tissue around the central tumor and total removal of the parametria from the bladder, the rectum, and the lateral pelvic wall because positive lymph nodes can be found in the lateral as well as medial parametrium.

When a large vaginal cuff must be removed because of a bulky cervical tumor or involvement of adjacent vaginal mucosa, starting the operation from below may facilitate the central dissection. Sometimes, a large lesion is excised and fulgurated transvaginally. The formation of the vaginal cuff is done in a manner similar to that in the Schauta-Amreich procedure. The vaginal incision is made around the entire circumference of the vagina, mobilizing the vaginal cuff from paravaginal tissue, space, and rectovaginal space from below may be easier than from above.

Superior to the midcommon iliac arteries and in the paraaortic region, lymph nodes are sampled in selected patients (usually stage IB1 and IA2). A special effort is made to remove any nodes that look or feel suspicious. The paraaortic lymph nodes

![Figure 47.16](image-url)
then are sent for frozen section analysis. Approximately 5% to 10% of stage IB patients have paraaortic lymph node metastases. Metastasis to the paraaortic lymph nodes is considered by many gynecologic oncologists as a contraindication to radical hysterectomy. These patients are currently being treated with extended-field radiation therapy with concurrent chemotherapy.

**RADICAL ABDOMINAL HYSTERECTOMY SURGICAL TECHNIQUE**

**Preoperative Evaluation and Preparation**

After the initial history and physical examination have indicated the possibility of primary treatment with radical hysterectomy and pelvic lymphadenectomy, the usual preoperative evaluation common before any extensive operation is indicated. We also recommend a chest x-ray to screen for cardiac or pulmonary disease as well as the very low risk of pulmonary metastases.

Contrary to the frequent practice of doing all possible tests on every patient, it is our practice to be selective and to do only those tests and procedures that are expected to yield useful information. It is not necessary (and indeed may be inappropriate) to subject every patient to a long list of preoperative procedures that are expensive and exhausting and have little, if any, expectation of providing useful information. Indeed, it is most unfortunate when a test or procedure yields questionable or suspicious findings that require one or more additional studies that, after delay, discomfort, and expense turn out to be negative or even perhaps nondiagnostic. Good judgment from an experienced clinician is usually the most helpful.

A young, healthy patient with a small cervical lesion requires an admission history and physical examination, chest radiograph and routine laboratory studies, and anesthesia consultation. If the patient is older, has medical complications, or has a larger or undifferentiated cervical lesion, the preoperative workup and preparation may be more involved and thorough. Although an intravenous pyelogram provides good visualization of the course and number of ureters, if radiologic evaluation of the abdomen and pelvis is being considered, most surgeons obtain a CT scan of the abdomen and pelvis, which also shows the course and number of ureters and also may provide additional information about nodal or other metastases. However, because of the uncertainty of enlarged nodes on CT scan, patients with clinical stage IB1 disease and enlarged pelvic nodes on CT scan would not make us cancel the surgical approach in favor of radiation therapy.

Larger lesions or those more likely to have metastases may be investigated by pelvic and abdominal CT scan or magnetic resonance scans, but we have rarely found those to be helpful in women with small cervical cancers. They may be most helpful when the clinician is undecided regarding whether primary surgery or radiation is the best management option—a clean, normal study may be reassuring that primary surgery is the way to go, whereas suspicious, enlarged nodes in a woman with a 4-cm cervical lesion helps make the decision to recommend radiation. Likewise, cystoscopy or proctoscopy are rarely indicated or helpful in the preoperative evaluation of early-stage cervical cancer. As much as possible should be done on an outpatient basis before admission to the hospital.

**Bowel Preparation**

In our institution, patients are asked to start a liquid diet 24 hours before surgery. They also are given a mechanical bowel preparation and sometimes oral antibiotics if significant peri- toneal adhesions are anticipated or there is a history of previous pelvic surgery or radiation. An intestinal tube for suction is not necessary.

**Positioning and Incision**

Multiple approaches to performing a radical abdominal hysterectomy and bilateral pelvic lymphadenectomy have been described. The traditional transperitoneal approach has been used in our institution for many years with satisfactory results. The transverse Maylard or Chenney incisions are used by some, whereas others prefer midline incisions. Orr and Scribner have reported shorter hospital stays when a Pfannenstiel incision is used. Currie has presented and published a film using a transverse cosmetic incision with vertical fascial entry for selected patients.

After anesthesia is induced, some surgeons prefer that the patient be placed comfortably in stirrups with the buttocks brought to the edge of the “broken” table. Pneumatic compression devices are placed on both lower extremities and the knees are separated about 90 degrees. The thighs are elevated only 15 to 20 degrees relative to the abdomen. Care is taken to avoid pressure on the peroneal nerves in the legs. Propo nents of this position claim several advantages. There is less strain on the patient’s lumbarosacral spine when the thighs are slightly flexed. This is especially important for patients with lumbarosacral back problems. It is possible to have a second assistant stand at the foot of the table between the patient’s legs. His or her participation in the operation is greatly facilitated by being closer to the operative field. Finally, in this position, the urethral orifice, vaginal introitus, and anal orifice are all available for instrumentation in case this is necessary to clarify anatomy.

After the patient is positioned on the operating table, a careful rectovaginal-abdominal pelvic examination is done. This can be followed by cystoscopy or proctosigmoidoscopy if desired. It may be necessary to shave a small amount of the escutcheon, but vulvar hair is not shaved completely. The skin is prepared from the rib margin to the midthigh, with special attention given to the umbilicus, perineum, and vagina. The patient is draped, a transurethral Foley catheter is inserted into the bladder, and the operation is begun.

When operating abdominally, the exposure achieved depends on the choice of incision, the method of retracting, the placement and intensity of overhead lights, and the participation of willing and skilled assistants. Suction should be available to keep the field as dry as possible and is preferred over sponges for two reasons. First, sponges are more traumatic to delicate serosal surfaces and other tissues. Second, a determination of the amount of blood lost can be more accurate if the largest percentage has been suctioned from the operative field into a calibrated bottle and measured.

It usually is possible (and always desirable) to keep the number of clamps in the operative field to an absolute minimum. If the field is cluttered with clamps, the operator cannot see well to operate. There is an unfortunate tendency for gynecologic surgeons to use instruments that are too short. Pediatric clamps, tissue forceps, dissecting scissors, needle holders, and all other instruments must be longer when operating deep in the pelvis and when operating on obese patients. The handles of the instruments must come all the way out and above the level of the base of the table.
Evaluation at Laparotomy

As stated, the operation is initiated through a low transverse (Maylard, Cherney, Pfannenstiel) or a low midline incision. In most patients, the umbilicus identifies the location of the bifurcation of the aorta; therefore, extension of the incision about 2 to 3 cm above the umbilicus is recommended for adequate exposure of this area if a low midline incision is used. The midline incision is protected by a moist pack beneath each arm of the self-retaining retractor to avoid excessive compression of the epigastric vessels that course beneath the rectus muscles. In case of a lengthy operative procedure, the mechanical retractors are released at periodic intervals to improve circulation through the abdominal musculature. The bladder is decompressed by an indwelling catheter throughout the procedure to facilitate exposure and maintain an accurate record of urine output.

Before initiating the pelvic procedure, the abdominal viscera and parietal peritoneum of the abdominal cavity are evaluated meticulously for possible evidence of metastatic tumor. The superior and inferior surfaces of the liver are carefully palpated, as is the region of the celiac plexus. The undersurface of the diaphragm is particularly vulnerable to metastases, especially the right hemidiaphragm, where the paraaortic lymphatics pass from the abdominal cavity into the mediastinum. The mesentry of the large and small bowel and the serosal surface of the bowel along with the omentum should be examined carefully for evidence of metastatic tumor. The kidneys are examined and the retroperitoneal space along the aorta and vena cava is palpated assiduously because these are the major sites of extrapelvic spread of cervical cancer. It is well known that 15% or more of paraaortic node metastases are occult; therefore, even the most unsuspecting node should be removed and evaluated histologically by frozen-section study for possible metastatic tumor. Therefore, it is our practice to sample any paraaortic or paraaortic node that is identifiable before initiating the procedure and send it for frozen section analysis. If there is histopathologic evidence of unsuspected, metastatic tumor in a paraaortic lymph node, we generally do not proceed with a radical hysterectomy and the operation is abandoned. These patients are currently being treated with concurrent chemother-apy and extended-field radiation therapy.

Peritoneal washings for cytologic examination usually are not obtained because the yield is low and the prognostic significance is undetermined.

At this point in the procedure, any adhesions in the pelvis are lysed, and the intestines are placed in the upper abdomen and held there with moist packs. A suitable self-retaining retractor can be used. If Bookwalter, Turner-Warwick, or Balfour retractors are used in a lower midline incision, care must be taken to avoid compression of the femoral nerves by the lateral blades.

Evaluation of the extent of the pelvic tumor is carried out at this time by examining the course of the lymphatic drainage of the pelvis, which is carefully palpated along the pelvic vessels. When enlarged or clinically suspicious nodes are found, they are removed and immediately sent for frozen-section study while further evaluation of the pelvis is undertaken. The paravesical and pararectal spaces are important anatomic landmarks. When developed, they provide an opportunity for thorough exploration of the pararectal and paravesical spaces (Fig. 47.16). Tumor can extend into the base of the broad ligament without detection of anatomic evidence of disease before operation. This step, therefore, is a safeguard in determining the possible extension of tumor beyond the cervix and into the immediate paracervical tissues. When there is evidence of extracervical disease, we may abandon the surgical procedure unless there is clear evidence that the disease can be removed cleanly. In either case, full pelvic irradiation is indicated. Certainly, the lateral pelvic wall must be free of tumor. When the central tumor is clearly resectable, we do not hesitate to complete the operation, even if there is evidence of metastatic disease in the pelvic lymph nodes.

A decision must be made about conservation or removal of the tubes and ovaries before the pelvic planes and spaces are developed. If normal ovaries are conserved in premenopausal patients, the tubes usually are left behind. If the round ligaments are clamped, cut, and ligated, the uterosacral ligaments and medial fallopian tubes are clamped and doubly ligated. The infundibulopelvic ligaments are carefully mobilized, and the adnexal organs are packed out of the operative field with the intestines.

Development of Paravesical Space

The anterior leaf of the broad ligament forms the roof of the paravesical space and blends with the bladder peritoneum medially and the parietal peritoneum laterally. This deep fossa beneath the peritoneal covering is composed of loose connective tissue and fat. It occupies the area between the bladder and the retroperitoneum medially, the pelvic sidewall and obturator muscle forming the lateral boundaries. The superior boundary is formed by the cardinal ligament, whereas the floor is composed of the levator ani muscle. After clamping and ligating the round ligament about midway along its course, the anterior leaf of the broad ligament is opened in an inferior direction, passing well into the pelvis before diverting the incision medially to reflect the bladder peritoneum from the lower uterine segment (Fig. 47.17A). The paravesical space can be entered without difficulty with gentle digital pressure, making certain that the dissection is initiated between the external iliac vein laterally and the obliterated hypogastric artery (lateral umbilical ligament) medially. The dissection is carried all the way down to the levator ani muscle (Fig. 47.17B). There are no major blood vessels in this potential space, although occasionally an aberrant obturator vessel emerges from the inferior epigastric artery and courses along the posterior aspect of the pubic bone to the obturator space. With gentle digital dissection, the pelvic floor can be palpated and the posterior aspect of the space can be identified, including the anterior margin of the cardinal ligament.

Development of Pararectal Space

The pararectal space lies beneath the pelvic peritoneum and extends between the cardinal ligament laterally and the uterosacral ligament medially. It can be entered by extending the incision in the anterior leaf of the broad ligament in a cephalic direction along the lateral margin of the infundibulopelvic ligament (Fig. 47.18A). By retracting the infundibulopelvic ligament and displacing the uterus medially, the uterosacral ligament is placed on a stretch, and the pararectal space is widened. Dissection of this space is much more precarious than that of the paravesical space. Unskilled dissection in this area frequently is associated with troublesome bleeding.

The medial border of the fossa is bounded by the uterosacral ligament and rectum, and the lateral border is formed superiority by the peritoneum of the pelvis and inferiorly by the levator
A FIGURE 47.17. A: Opening the anterior leaf of the broad ligament after ligation of the right round ligament and infundibulopelvic ligament. (Continued)

The sacrum forms the posterior margin of the space, and the ureter is attached to the peritoneum along the roof of the space before entering the medial aspect of the cardinal ligament. The hypogastric artery and vein are located in the deeper aspect of the pararectal space along the levator ani muscle. The cardinal ligament forms the caudal and lateral borders of this important area. Entry into the pararectal space must be made cautiously (Fig. 47.18A) with medial displacement of the ureter and its attached peritoneum. A point between the ureter, which is attached to the medial leaf of peritoneum, and the hypogastric artery is selected. Blunt dissection should be used in this area, and careful handling of tissue is imperative to avoid unnecessary damage to small veins deep in this fossa. When the examining finger reaches the pelvic floor and levator ani muscle, the fossa narrows, and care must be taken to avoid damage to the lateral sacral and hemorrhoidal vessels. The dissection is carried vertically downward for a short distance. The further development of the space then changes to an inferior and caudad direction lateral to the rectum. If the development of the space is difficult, it should be delayed until a later time in the operation. When the paravesical and pararectal spaces have been dissected (Fig. 47.18B), the pelvic floor and cardinal ligament easily can be identified and palpated. In the absence of demonstrable tumor extension, the case is
considered operable, and the lymph node dissection is initiated at this time.

**Pelvic Lymphadenectomy**

Dissection of the lymphatic tissue along the iliac vessels can begin in the region of the bifurcation of the common iliac artery and extend superiority to the bifurcation of the aorta and inferiorly to the inguinal ligament and deep circumflex iliac vein, or it can begin at another point along the course of the iliac vessels. The opening of the posterior peritoneal leaf of the broad ligament must be extended to the area of the pelvic brim, where the ureter is easily identified as it enters the pelvis at the bifurcation of the common iliac artery. This dissection is made easier if the infundibulopelvic ligament has been ligated and divided; however, the ligament and ovarian vessels can be retracted medially if the adnexa are preserved. The ovary and tube also can be detached from the uterine corpus and gently tucked beneath the retractor above. In dissecting the presacral area in the angle of the bifurcation of the aorta, care must be taken to avoid bleeding from the middle sacral vessels as well as from the proximal part of the left external iliac vein, which courses through this retroperitoneal space. It is best to occlude the middle sacral vessels with smaller vascular clips as they are identified, and if traumatized, the venous bleeding can be controlled with positive pressure against the sacrum and with vascular clips. The lymphatic tissue along the common iliac vessels...
FIGURE 47.18. A: Extending the incision in the anterior leaf of the broad ligament in a cephalic direction along the lateral margin of the right infundibulopelvic ligament. B: Paravesical and pararectal fossae, with intervening base of broad ligament attached to pelvic floor and lateral pelvic wall.

is removed by sharp dissection with the points of the Metzenbaum scissors directed upward, while special care is taken to avoid trauma to the ureter (Fig. 47.19). The ureter is reflected medially during the dissection of the common iliac vessels and left attached to the parietal peritoneum to maintain its blood supply.

It is important to remove the loose areolar tissue and fascial sheath from the iliac vessels; however, to avoid trauma to the intima or wall of the vessels (particularly the veins), the surgeon should not attempt to skeletonize the pelvic vessels to the point of producing a pearl-white vascular tree. If there is tumor in the adventitia of the vessel wall, the patient probably will
not be cured by this procedure; consequently, such compulsive surgical efforts produce far more complications than benefits. It is important to rotate the vessels medially and laterally with a vein retractor during the dissection of the common and external iliac trunks to obtain the posterior lymphatic chain behind the vessels along the psoas muscle. The genitofemoral nerve, which is seen lateral to the external iliac vessels, should be preserved, if possible, because damage to this peripheral nerve occasionally produces postoperative discomfort in the groin and medial aspect of the thigh.

The external iliac vessels are carefully dissected down to the point where the deep circumflex iliac vein crosses over the external iliac artery. At this point, care must be taken to avoid injury to the inferior epigastric artery and vein, which arise from the anterior and medial side of the iliac vessels and course along the anterior peritoneum onto the lower abdominal wall. The surgeon also must be cognizant of the anomalous obturator artery and vein, which can arise from the lower portion of the external iliac or inferior epigastric vessels and course over the pelvic sidewall into the obturator space. If accidentally traumatized, they should be ligated at their point of origin from the artery or vein. To avoid bleeding in the obturator space, these vessels are frequently occluded with small vascular clips as they pass through the obturator space, regardless of their origin. Clips also can be used to occlude the lymphatic channels coming into the pelvis from the leg.

The obturator space is entered by reflecting the external iliac vessels medially away from the psoas muscle and freeing the areolar tissue that lies directly between these vessels and the lateral pelvic wall (Fig. 47.20A), usually with blunt dissection. Once the space has been entered and the adjacent tissue cleared from the external iliac vessels, the artery and vein are released and gently retracted laterally with a vein retractor, and the obturator space is clearly exposed. The lymphatic and areolar tissue are dissected from the obturator space to the region of the pelvic floor, with particular care taken to avoid trauma to the obturator nerve and vessels (Fig. 47.20B). The dissection is continued by removing all of the nodes below the bifurcation of the iliac vessels, including the hypogastric nodes and the nodes in the obturator fossa. A lymph node may be encountered in

FIGURE 47.19. Pelvic lymphadenectomy with dissection of right common iliac vessels and their branches, including the external iliac and hypogastric arteries and veins. Note attachment of ureter to parietal peritoneum. The genitofemoral nerve courses along the psoas muscle.
the angle formed by the external iliac and hypogastric arteries and must be carefully dissected out, avoiding trauma to the adjacent hypogastric vein.

Retraction of the common iliac artery and vein medially exposes a group of lymph nodes that should be removed carefully. These lymph nodes are the lateral common iliac nodes. There is danger of venous bleeding in this area. When this area has been cleared, the surgeon can see the obturator nerve entering the obturator fossa through the body of the psoas muscle. The nerve roots of the lumbosacral plexus also are exposed. Particular care must be exercised in the dissection of the lateral sacral and sacroiliac plexus, just medial to the hypogastric artery and vein, near their origin. The rich arcade of small arteries and veins increases the risk of bleeding in this area. When the vessels retract into the sacral foramen, control of bleeding becomes difficult.

The obturator artery can be identified as it courses along the lateral pelvic wall adjacent to the obturator nerve. The nerve, artery, and vein advance toward the obturator foramen, through which they leave the pelvis. Care must be taken to avoid trauma to all of the structures, particularly the obturator veins, which have a rich anastomotic network against the

**FIGURE 47.20.** A: Entry into obturator space by medial reflection of external iliac vessels. B: Dissection of obturator fossa, demonstrating obturator nerve with areolar tissue attached superiorly to external iliac vessels.
lateral pelvic wall and communicate freely with the adjacent hypogastric veins. It is best to ligate or clip the obturator vesical veins from the collateral circulation. In the event that excessive bleeding occurs on one side of the pelvis, dissection can continue on the opposite side in the interim after pressure packing.

### Dissection of Hypogastric Artery, Uterine Artery, Bladder, and Ureter

The hypogastric artery is dissected with identification of the visceral branches of the anterior trunk, which include the uterine; superior, middle, and inferior vesical; and middle hemorrhoidal arteries. The anterior division of the hypogastric artery continues along the paravesical fossa to become the obliterated lateral umbilical ligament beneath the anterior abdominal wall. The hypogastric artery is damaged, it can be ligated without serious compromise to the blood supply of the bladder. At this point, we ligate the ureter artery at its origin from the hypogastric artery. Some authors believe that a more adequate central dissection is achieved by ligating the anterior division of the hypogastric artery just distal to the point of origin of its posterior division rather than ligating the uterine artery individually. Whichever vessel is chosen, after double ligating, the distal branches traversing the cardinal ligament are removed with the specimen. No attempt is made to remove the hypogastric vein. The other, adjacent veins should be ligated to avoid brisk bleeding in this area. The bladder then is reflected off the lower uterine segment by incising the bladder peritoneum from its attachment to the uterus. The fascial adhesions of the base of the bladder are released from the cervix and upper vagina by electrocautery or sharp scissors dissection, and the vesicovaginal space is developed inferiorly and laterally. The ureter tunnels between the anterior fascial bundles of the base of the broad ligament, commonly called the vesicouterine ligament. This fascial tunnel is carefully opened by sliding the Metzenbaum scissors or an Adson right-angle clamp, with concave surface pointed upward, along the anterior and medial surface of the ureter and by gently spreading the blades, as shown in Fig. 47.21A. The ureteric, artery, and vein course along the fascial roof of this ligament. As shown in Fig. 47.21B, the anterior sheath of the vesicouterine ligament is opened by doubly clamping and incising this tissue. Each of the fascial bundles is suture ligated for control of bleeding, and the ureter is dissected free of its attachment to the posterior leaf of the vesicouterine ligament. As with the pelvic veins, care must be taken to prevent damage to the adventitia and muscular wall of the ureter, which contain nutrient vessels from the collateral circulation. In the event that the blood supply to the ureter is compromised by thrombosis or trauma to the veins, fistula formation is a serious and frequent complication. The ureter is gently retracted with an umbilical tape or urethral retractor. If forceps are used to handle the ureter, they should gently grasp only the adventitia.

### Dissection of Cardinal Ligament

The base of the broad ligament (the cardinal ligament) can then be excised from its attachment at the lateral pelvic wall. The technique of clamping and ligating the vascular cardinal liga-

has been shortened by about 2 to 3 cm, is well supported by its attachments to the levator ani muscles and urogenital diaphragm and mainly by the effects of postoperative fibrosis during the healing phase.

At the end of the procedure, some surgeons place suction catheters in the obturator fossae and along the lateral pelvic walls and bring them out through stab wounds in the lower abdomen. After the abdomen is closed, these catheters are connected to intermittent, low-suction drainage units. Traditionally, these drains were thought to be effective in preventing pelvic infection and fistula and lymphocyst formation. However, recent retrospective and prospective studies have demonstrated that the incidence of these complications is minimal and the same whether or not drains are used. Therefore, many gynecologic oncologists no longer use pelvic drains.

No attempt is made to suspend the ureters to the hypogastric artery, as suggested by Green and coworkers, or to place the terminal ureter on the inside of the peritoneal surface, as recommended by Novak. Furthermore, there appears to be no benefit to repertonizing the pelvis as described by Symmonds and Pratt.

If the tubes and ovaries are to be transposed out of the pelvis, a tunnel is dissected beneath the peritoneum laterally and superiorly toward each lateral gutter. An incision in the peritoneum is made as high as possible at the top of the tunnel. The adnexal structures are guided through the tunnel and through the incision at the top of the tunnel, making absolutely certain that the ovarian vessels in the infundibulopelvic ligament are not twisted. Permanent suture material is used to suture the tuboovarian pedicle as high as possible to the peritoneum and underlying muscle. Two large metal clips also are placed across
FIGURE 47.22. A: Clamping and incision of lateral portion of cardinal ligament adjacent to the lateral pelvic wall. B: Excised ligament showing pelvic floor and levator muscles. Dissected obturator nerve is seen in obturator space.

the pedicle to identify later the location of the ovaries with an abdominal radiograph. This ovarian suspension is done when there is a reasonable chance that a patient will need postoperative pelvic irradiation (Figs. 47.26 and 47.27). In most operations, however, the tubes and ovaries can be left in their natural positions in the pelvis.

FERTILITY-SPARING RADICAL ABDOMINAL TRACHELECTOMY

Historically, the recommended surgical treatment for a stage IA2–IB1 cervical cancer is a total radical hysterectomy and
pelvic lymphadenectomy. This operation is very effective at treating early-stage cervical cancer; however, infertility is one of the serious and inevitable consequences of treatment. Partial radical organ resection has been accepted in many solid tumors, such as partial gastrectomy, nephrectomy, pneumonectomy, and colectomy to treat malignancies affecting these organs. In gynecologic oncology, partial organ resection with radical abdominal or vaginal trachelectomy and pelvic lymph node dissection are relatively new techniques used in women with early cervical cancer who wish to retain fertility (Table 47.7). This operation and technique are to be distinguished from the radical abdominal trachelectomy, which is commonly used for resection of cervical stump malignancy following a previous supracervical hysterectomy in the setting in which fertility preservation is not an issue.

**Technique**

A laparotomy and a bilateral complete pelvic lymphadenectomy are performed in a similar manner to patients undergoing a radical abdominal hysterectomy. The limits of nodal

dissection are the deep circumflex iliac vein caudally and the proximal common iliac artery cephalad. Any suspicious lymph nodes were sent for frozen-section analysis. It was our intent to abandon a fertility-sparing approach if positive lymph nodes were identified. Sentinel lymph node biopsy followed by a complete pelvic lymphadenectomy is also a reasonable option and may allow for pathologic ultrastaging of these sentinel nodes. The removal of paraaortic nodes is also considered for lesions stage IB1 or greater.

The intent of the radical abdominal trachelectomy was to resect the cervix, upper 1 to 2 cm of the vagina, parametrium, and paracolpos in a similar manner to a type III radical abdominal hysterectomy but sparing the uterine fundus or corpus (Figs. 47.28 and 47.29).

The procedure is begun by developing the paravesical and pararectal spaces and dissecting the bladder caudal to the midvagina. The round ligaments are divided, and large Kelly clamps are placed on the medial round ligaments to manipulate the uterus. Care is taken not to destroy the cornu or the uteroovarian pedicles. The infundibulopelvic ligaments with ovarian blood supply are kept intact. Care is also taken not to injure the fallopian tubes or disrupt the uteroovarian ligament.

The uterine vessels are then ligated and divided at their origin from the hypogastric vessels. The parametria and paracolpos with uterine vessels are mobilized medially with the specimen, and a complete ureterolysis is performed similar to a type III radical abdominal hysterectomy. The posterior cul de sac peritoneum is incised and the uterosacral ligament divided; similarly, the parametria and paracolpos are divided. Using a vaginal cylinder (Apple Medical Corporation; Marlborough, MA), the desired length of vaginectomy is performed, and the specimen is completely separated from the vagina and placed in the midpelvis, keeping its attachment to the uteroovarian ligaments.

The lower uterine segment is then estimated, and clamps are placed at the level of the internal os (Fig. 47.30). Using a knife, the radical trachelectomy is completed by separating the fundus from the sefthmus or upper endocervix at approximately 5 mm below the level of the internal os, if possible (Figs. 47.31 and 47.32).

The uterine fundus with preserved attachments to the uteroovarian ligaments, placed in the superior part of the pelvis, and the specimen, consisting of radical trachelectomy and parametria with suture marking the vaginal cuff at

**FIGURE 47.28.** Diagrammatic representation of the tissue renewed at radical abdominal trachelectomy.
FIGURE 47.29. The intent of the radical abdominal trachelectomy is to resect the cervix, upper 1 to 2 cm of the vagina, parametrium, and paracolpos in a similar manner to a type III radical abdominal hysterectomy but sparing the uterine corpus.

12 o’clock, is sent for frozen-section evaluation of its endocervical margin. The uterine fundus is inspected and curettage of the endometrial cavity is performed as well as a shave disc margin on the remaining cervical tissue, which is sent for frozen-section analysis (Fig. 47.33). This is performed to ensure that the reconstructed uterus to vagina is disease free. A frozen-section analysis is also obtained on the distal vaginal margin, if clinically indicated.

If all frozen sections tested are benign and at least a 5-mm clear margin is obtained on the endocervical edge, a permanent cerclage with no. 0 Ethibond (knot tied posteriorly) may be placed before the reconstruction (Fig. 47.34). A cerclage was placed in three cases in this series. The uterus is then reattached to the upper vagina with six to eight no. 2–0 absorbable sutures (Figs. 47.35–47.37). No drains are placed. Standard antibiotic prophylaxis and routine postoperative care is prescribed.

An alternative approach would be to separate the fundus from the cervix before the colpotomy, pack the fundus with the intact uteroovarian blood supply in the upper pelvis, place retraction clamps on the cervix, and perform the radical trachelectomy. The role of cystourethroscopy with bilateral temporary ureteral catheterization is optional.

LAPAROSCOPICALLY ASSISTED RADICAL VAGINAL HYSTERECTOMY (SCHAUTA)

History

The “extended” hysterectomy performed vaginally for the treatment of cervical cancer was invented by Schauta in Austria in 1901. A few years earlier, in 1898, also in Austria, Wertheim had reported on the abdominal extended hysterectomy. The
mortality and morbidity of the Wertheim method was initially much higher, but it had the advantage of including a pelvic lymphadenectomy, which is now appreciated as an important and necessary part of the procedure. Because the initial Schauta operation did not include the lymph node assessment, it gradually became less popular. In 1959, Mitra combined the Schauta operation with a retroperitoneal approach for the pelvic lymphadenectomy. This was a clever idea, but it did not gain a lot of acceptance because it necessitated bilateral flank incisions. More recently, in 1987, Dargent revived the Schauta operation by combining it with laparoscopic surgery, allowing thorough and complete pelvic lymphadenectomy. The Schauta operation preceded by a laparoscopic pelvic lymphadenectomy is thus a perfect example of the recent trend toward minimally invasive surgery in gynecologic oncology.

**Technique**

**Laparoscopic Part of the Surgery**

Pelvic Lymphadenectomy. The procedure begins with a complete laparoscopic pelvic lymphadenectomy using a 4-trocar technique as detailed in the laparoscopic surgical staging section below. In the future, if sentinel lymph node mapping proves acceptable to gynecologic oncologists, the extent of the lymphadenectomy may be further minimized to the removal of only the sentinel nodes.

Division of the Uterine Artery. Caudally to the crossing point of the uterine artery, an opening is created bluntly just under the superior vesical artery, which is then retracted laterally in such a way that the uterine vessels lie between the two openings created. Once the uterine artery is divided, the stump can be retracted medially and freed gently from the ureter. This will facilitate the dissection of the uterine artery vaginally. Of note, several collaterals of the uterine artery are frequently encountered and should be clipped, excised, or cauterized individually to avoid bleeding. The vaginal branch of the uterine artery is also frequently seen appearing under the excised uterine artery. It can be divided now or later during the vaginal excision of the parametrial tissue. Lastly, the uterine veins are usually located under the artery and again should be managed individually. On occasion, uterine veins cross over the ureter and can be the source of bleeding during the vaginal part of the surgery.

**Vaginal Part of the Surgery**

The vaginal part of the surgery can be divided into five steps: (i) vaginal cuff preparation, (ii) anterior phase (opening of the vesicouterine space and paravesical space, and mobilization and dissection of the ureter), (iii) posterior phase (opening of the cul-de-sac and pararectal space and excision of the parametrium), (iv) lateral phase (excision of the parametrium), and (v) excision of the specimen and closure.

Vaginal Cuff Preparation. Because the radical vaginal hysterectomy is primarily offered to women with cervical lesions less than 3 cm, it is rarely necessary to remove more than 1 cm of vaginal mucosa. A rim of vaginal mucosa is delineated circumferentially clockwise around the cervix with six to eight straight Kocher clamps placed at regular intervals, about 1 cm below the cervix (Fig. 47.38).

To reduce bleeding from the edges of the vaginal mucosa, a 10- to 20-cc solution of xylocaine 1% mixed with epihinephrine 1:100,000 is injected between each Kocher clamp, then a circumferential incision is made with the scalpel just above the Kocher clamp (Fig. 47.39). The anterior and posterior edges of the vaginal mucosa are grasped with four to six Chrobak clamps to completely cover the cervix.
Anterior Phase (Described for the Patient’s Right Side)

Opening of the vesicouterine space. While pulling the specimen slightly downward with the Chrobak clamps, a single-tooth forceps is used to hold and retract the anterior vaginal mucosa, which usually creates a triangular fold indicating where to cut (Fig. 47.40). The vesicouterine space is opened with Metzenbaum scissors held perpendicular to the cervix in the midline to avoid bleeding from the bladder pillars laterally. The space is further defined and stretched by gentle dissection with the index finger. Care is taken not to enter the anterior peritoneum as in a simple vaginal hysterectomy as it makes identification of the bladder base and ureters more difficult. If entered correctly, the space should be avascular, and the anterior surface of the endocervix and isthmus should be easily identified without resistance. If a resistance is felt, it usually means that the plane of dissection is either too posterior and that the surgeon is digging into the endocervix, or too anterior, which carries a risk of damage to the bladder. For that reason, the bladder base should be carefully delineated. In patients who have had a recent conization, there may be substantial fibrous and scarring between the cervix and the bladder base. The opening of the vesicouterine space may be particularly difficult in those cases. In such situations, a metal bladder catheter introduced into the urethra may be used to locate the bladder base and facilitate its mobilization. Once clearly identified, the vesicouterine space is stretched upward with a narrow Deaver retractor, showing the intact peritoneum (Fig. 47.41).

Reconstruction of the uterine corpus to upper vagina after the cerclage is placed.
FIGURE 47.36. The uterine fundus is reattached to the vaginal apex with six to eight interrupted no. 2-0 absorbable sutures.

Opening of the paravesical space. To open the right paravesical space, the Chrobak clamps are slightly pulled toward the patient’s right side. Straight Kocher clamps are placed onto the vaginal mucosa at 11 and 9 o’clock and stretched out (this is where the 12 o’clock mark made earlier is useful). This maneuver defines a triangle formed by the bladder pillars, the vaginal mucosa, and the Chrobak clamps. An areolar opening is seen just medial and slightly anterior to the 9 o’clock clamp, indicating where to enter to define the paravesical space. The space is blindly entered by opening and closing Metzenbaum scissors, with the tips pointing upward and outward in an oblique axis. If entered correctly, the space should be avascular and the scissors should slide inside easily. Once entered, the space is widened by rotating the scissors under the pubic bone in a semicircular, rotating motion to the patient’s left side. A small Breisky retractor is then placed in the space. This step is unquestionably the most “scary” part of the procedure as it is a blind maneuver. Having defined the paravesical space laparoscopically facilitates the entry of the scissors.

Identification and mobilization of the ureter. To palpate the ureter, the Chrobak clamps are pulled to the left of the patient, and the surgeon’s right index finger is placed in the vesicouterine space while a Breisky retractor (or the back of the scissors) is placed in the right paravesical space. By pulling down and “rubbing” the finger against the Breisky retractor, the “click” of the ureter rolling under the finger should be heard and felt. This maneuver orients the surgeon as to the location of the ureter in relation to the bladder pillars. Next, with the Breisky retractor placed in the right paravesical space and the narrow Deaver retractor placed in the vesicouterine space, the bladder pillars are clearly identified. The knee of the ureter is normally located on the lateral aspect of the bladder pillars (Fig. 47.42).

Once the ureter has been precisely located by palpation, the bladder pillars are excised midway between the bladder base and the endocervix. (Bipolar scissors are useful to decrease bleeding from the bladder pillars.) With the scissors, the medial and lateral pillars of the bladder pillars should be separated first before cutting (Fig. 47.43). The most proximal fibers of the pillars can then be excised, and normally, the knee of the ureter should appear anteriorly. At that point, a Babcock clamp is extremely useful to grab the ureter to allow a good traction on it and to constantly keep it under direct visualization. Once the ureter is clearly identified, the medial and lateral bladder pillars

FIGURE 47.37. The reconstructed fundus with remaining blood supply from the intact uteroovarian ligaments: uterine serosa without evidence of fundal ischemia.

FIGURE 47.38. A vaginal cuff is prepared to remove about 1 to 2 cm of vaginal mucosa.
are safely excised. If the ureter is not seen unequivocally, it should be palpated again to relocate its position before cutting the pillars.

Dissection of the ureter. Once the ureter is clearly identified and placed under traction with a Babcock clamp, it is possible to dissect the ureter. (It is easier if part of the unroofing has been done laparoscopically.) The uterine vessels are usually seen just under the knee of the ureter (Fig. 47.44). With a Kelly clamp, the vessels are pulled down from under the ureter, while at the same time, Metzenbaum scissors are used to free the filmy attachments and allow mobilization of the ureter upward. The uterine artery can be drawn completely into the operative field along with the clips (if they have been used laparoscopically to divide the uterine artery).

Posterior Phase (Described for the Patient’s Right Side) Opening of the cul-de-sac. Chrobak clamps are sharply angulated anteriorly and the posterior cul-de-sac is opened using Metzenbaum scissors as for a simple vaginal hysterectomy. Once entered, the space is stretched laterally to allow placement of a retractor.

Opening of the pararectal space and excision of the uterosacral ligaments. Using Metzenbaum scissors, the pararectal space is defined by opening a space just lateral to the peritoneal folds of the uterosacral ligaments. The medial or rectouterine fibers of the uterosacral ligaments are separated and excised.

Excision of the paracolpos. To complete the posterior phase preparation, the paracolpos is excised. The paracolpos is in fact the inferior border of the parametrium. With the Chrobak clamps rotated to the left, the paracolpos is clamped just medial to the vaginal mucosa, excised, and ligated.

Lateral Phase (Excision of the Parametrium). Before clamping the parametrium, the paravesical space and the ureter should be relocated. The space is verified by palpation with the finger, and a Brescia retractor is replaced in the paravesical space. The ureter should be readily visible and placed under traction with a Babcock clamp. While the Chrobak clamps are pulled and rotated to the patient’s left side, a curved Heaney clamp is placed proximally on the parametrium, then a second clamp is placed higher and more lateral to obtain wider parametrium. The second Heaney clamp should be placed at the contact of the knee of the ureter, which can be further dissected if needed (Fig. 47.45). The parametrial tissue is excised and ligated. Once completed on the other side, the uterus can now be tilted backward and should only be held by the ovarian ligaments (if the adnexae are preserved) or by residual peritoneal attachments. These can be clamped, excised, and ligated. The specimen is removed (Fig. 47.46).

Closure. In general, an attempt is made to include the anterior and posterior pelvic peritoneum along with the vaginal mucosa. Interrupted figures-of-eight of Vicryl 2–0 sutures are used for the closure, starting with the lateral angles. No drains are left in place except for the Foley catheter.
Results

Over the last 2 decades, data have been accumulating in the literature to indicate that the laparoscopically assisted radical vaginal hysterectomy is a safe procedure, with an overall low morbidity rate. Several studies—including those of Jackson and associates, Malur and colleagues, Nam and coworkers, Renaud and associates, Roy and colleagues, and Steed and coworkers—compared laparotomy (LAP) versus laparoscopically assisted vaginal (LAV) route. In general, the data suggest that the operative time is longer for the LAV group, but blood loss, transfusion rate, and hospital stay are significantly lower. The lymph node yield is similar between the two groups. Malur even reported a higher lymph node count in the LAV group. Intraoperative complication rate appears to be higher in the LAV group, probably related in part to the initial learning curve. In the study by Steed and coworkers, most of the complications were related to bladder and ureteral injuries. However, postoperative complications, such as wound infection and bleeding, tend to be higher in the LAP group. Jackson and associates reported the incidence of bladder and bowel dysfunction to be less in the LAV group, whereas Steed and coworkers found the opposite. Renaud and associates reported that the conversion rate to laparotomy is low. Importantly, there does not appear to be a statistically significant difference in recurrence rate and overall survival, suggesting that the radicality of the vaginal approach is adequate. However, Nam and coworkers noted a higher recurrence rate in the LAV group in patients with larger tumor volume and concluded that the vaginal approach should be restricted to patients with small tumor (<2 cm).

For larger-sized lesions, Possover and colleagues and Querleu have described a technique to provide extended radicality comparable to that of a type III radical hysterectomy with the idea that it may reduce long-term lateropelvic recurrences. However, the more radical the hysterectomy, the more side effects there are on the bladder and bowel function. In recent years, attention has been paid to this matter, and laparoscopic nerve-sparing surgical techniques have been developed by Querleu and associates to reduce these side effects. However, this extensive paracervical and parametrial dissection is of limited value in patients with small lesions (measuring <2 cm), as the risk of lateropelvic recurrence is low.

LAPAROSCOPICALLY-ASSISTED RADICAL VAGINAL TRACHELECTOMY (DARGENT PROCEDURE)

History

In 1987, Dargent proposed a modification of the Schauta-Amreich radical vaginal hysterectomy to preserve the body of the uterus and thus the reproductive function. The procedure, the radical vaginal trachelectomy, today known as the Dargent procedure, implies the removal of the cervix along with the proximal portion of the parametrium and is preceded by a complete laparoscopic pelvic lymph node dissection. After
FIGURE 47.43. The ureter is localized by opening the bladder pillars.

nearly 2 decades, the accumulating experience worldwide summarized by Plante and coworkers suggests that the oncologic outcomes with this conservative procedure are comparable to those obtained following a radical hysterectomy for similarly sized lesions. Obstetrical outcomes are also very encouraging. Indications

Eligibility criteria for this conservative procedure were initially proposed by Roy and Plante in 1998 and, for the most part, have remained unchanged thus far.

1. Desire to preserve fertility
2. No clinical evidence of impaired fertility (relative contraindication)
3. Lesion size lesser or equal to 2.5 cm
4. FIGO stage IA1 with presence of vascular space invasion, IA2 and IB1
5. Squamous cell or adenocarcinoma
6. No involvement of the upper endocervical canal as determined by colposcopy or MRI
7. No metastasis to regional lymph nodes

The procedure can be offered to women older than age 40, understanding that the fertility potential is obviously reduced, or to women who already have children, as they may wish to have other children in the future. Sonoda and colleagues reviewed the Memorial Sloan-Kettering Cancer Center experience over the course of 10 years and noted that 43% of their patients who underwent a radical hysterectomy for early-stage cervical cancer were younger than 40 years old, of those, 48% would have met the eligibility criteria for a radical trachelectomy. Therefore, a substantial proportion of young women with cervical cancer are potential candidates for this fertility-preservation alternative.

Technique

Eligibility criteria for this conservative procedure were initially proposed by Roy and Plante in 1998 and, for the most part, have remained unchanged thus far.

1. Desire to preserve fertility
2. No clinical evidence of impaired fertility (relative contraindication)
3. Lesion size lesser or equal to 2.5 cm
4. FIGO stage IA1 with presence of vascular space invasion, IA2 and IB1
5. Squamous cell or adenocarcinoma
6. No involvement of the upper endocervical canal as determined by colposcopy or MRI
7. No metastasis to regional lymph nodes

The procedure can be offered to women older than age 40, understanding that the fertility potential is obviously reduced, or to women who already have children, as they may wish to have other children in the future. Sonoda and colleagues reviewed the Memorial Sloan-Kettering Cancer Center experience over the course of 10 years and noted that 43% of their patients who underwent a radical hysterectomy for early-stage cervical cancer were younger than 40 years old, of those, 48% would have met the eligibility criteria for a radical trachelectomy. Therefore, a substantial proportion of young women with cervical cancer are potential candidates for this fertility-preservation alternative.

The laparoscopic part of the procedure is identical to that of the Schauta except that the uterine arteries are obviously not excised. The first three steps of the vaginal part of the surgery are also identical to the Schauta operation (vaginal cuff preparation, anterior phase, and posterior phase). The initial part of the lateral phase—i.e., excision of the parametrium—is also identical; however, only the descending branch of the uterine artery is excised. The excision of the trachelectomy specimen and closure also differ from the Schauta operation and will be detailed here.

Lateral Phase (Described for the Patient’s Left Side)

Ligation of the Cervicovaginal Artery. As opposed to the Schauta operation, in which the uterine artery is clamped at its origin, pulled down, and unroofed from under the ureter, the cross of the uterine artery is actually preserved in the case of a trachelectomy to maintain optimal vascularization of the uterus in the event of a future pregnancy. Therefore, only the cervicovaginal or descending branch of the uterine artery is excised. So, after precise localization of the isthmus and the cross of the uterine artery, the cervicovaginal artery is clamped with
a right-angle clamp placed at 90 degrees and directly applied to the isthmus (Fig. 47.47); then it is sectioned and ligated.

Excision of the Specimen and Closure. The uterine isthmus and endocervix are precisely located by palpating the uterus anteriorly and posteriorly. The cervix is amputated with a scalpel held perpendicular to the specimen about 1 cm distal to the isthmus (Fig. 47.48). As the specimen is excised, the cervical os appears gradually, and the anterior lip can be grasped with a straight Kocher clamp. Care is taken not to angulate the scalpel to avoid removing too much cervix posteriorly. The specimen is completely excised in one piece to facilitate the pathological evaluation of the margins.

Ideally, the specimen should be at least 1 to 2 cm wide, with 1 cm of vaginal mucosa and 1 to 2 cm of parametrium (Fig. 47.49A-B). When there is no clinical evidence of residual tumor, a frozen-section analysis is not performed. The specimen is kept intact for final analysis and will be processed as a cone specimen. However, in patients with a visible lesion, the trachelectomy specimen is sent for immediate frozen-section analysis to assess the level of the tumor in relation to the endocervical resection margin. At least 8 to 10 mm of tumor-free tissue should be obtained between the level of the tumor and the endocervical resection margin; otherwise, additional endocervix should be removed or the trachelectomy should be completed by a radical vaginal hysterectomy (Schauta). It is thus extremely important to ask the pathologist to do a frozen-section analysis of the cervix with a section made longitudinally from the ectocervix to the endocervix to evaluate the distance between the most cephalad edge of the tumor and the endocervical resection margin. A permanent cerclage is placed at the level of the isthmus using a nonresorbable Prolene or Ethibond 0 suture starting posteriorly at 6 o’clock to have the knot lying posteriorly. The sutures should not be placed too deeply into the cervical stroma, as the cerclage can eventually erode into the endocervical canal and be expelled. When tying the
FIGURE 47.48. Section of the cervix 1 cm below the isthmus. The endocervical canal is visible (arrow).

A cerclage knot, a uterine probe can be placed in the cervical os to avoid tightening the knot too much, as this may cause cervical stenosis (Fig. 47.50).

The Dargent procedure is completed by reapproximating the edges of the vaginal mucosa to the new exocervix. This is accomplished with interrupted figures-of-eight sutures of 2-0 Vicryl. It is easier to begin with the sutures at 12 and 6 o'clock first. The lateral sutures are then placed separately to include the anterior and posterior vaginal mucosa only. Although easy to do, the closure of the vaginal mucosa is an extremely important step of the procedure, and care should be taken not to bury the cervical opening into folds of redundant vaginal mucosa.

FIGURE 47.49. A and B: The specimen with its parametrium. The superior endocervical canal is shown (arrow).

FIGURE 47.50. A cerclage is put in place and ligated posteriorly with a dilator (arrow) in the cervical canal.
mucosa (Fig. 47.51). The new exocervix should remain accessible for monitoring with colposcopic examination and cytology.

At the end of the trachelectomy procedure, laparoscopy is performed to verify hemostasis in the pelvis and the integrity of the pelvic structures. No drains or packings are left.

**Oncologic Outcome**

Data are accumulating worldwide indicating that the oncologic outcome following the radical trachelectomy is comparable to the outcome following a radical hysterectomy for similar-size lesions. Indeed, several large series totaling more than 600 cases consistently report a recurrence rate of less than 4% and a death rate of less than 2% (Table 47.8). Plante and colleagues have noted that the size of the lesion (≥2 cm) and the presence of LVSI seem to be the most important risk factors for recurrences. The recent work of Hertel and coworkers also suggests that adenocarcinomas may carry a higher risk of recurrence.

Morice and associates have noted unusual sites of recurrences, such as in the vesicovaginal septum and in the bladder, which suggests that very meticulous surgical technique should be observed to avoid entering the wrong planes of dissection and potentially disseminating tumor cells at the time of the procedure. Piketty recently reported a recurrence in the ovary in a patient with an adenocarcinoma. Only two recurrences have been reported so far on the residual cervix itself. The first one was reported by Bali and occurred nearly 7 years following the initial surgery. It is unclear whether it truly represents a recurrence or a new primary. The other one was reported by Rader and coworkers; it occurred 6 months postabdominal trachelectomy and was picked up on routine Pap smear. A radical hysterectomy was performed and disclosed a 3-mm recurrence (or persistence) in the cervix. One had a 3.8-cm lesion, and she recurred within 4 months of the surgery with a 6-cm lesion; the other had a 5-cm glassy-cell adenocarcinoma and recurred 14 months after surgery. Strict selection criteria are extremely important to lower the risks of recurrences. Further experience will determine if the abdominal radical trachelectomy is safe in bulky lesions. Another alternative for patients with larger lesions is the use of neoadjuvant chemotherapy to reduce the size of the tumor followed by a fertility-preserving radical trachelectomy. Plante and coworkers have recently published their preliminary experience with three cases. All have had a complete pathologic response to the chemotherapy with no residual cancer in the surgical specimen. Obviously, this approach is currently experimental but has potential merits and deserves further investigation.

Shepherd recommends regular follow-up posttrachelectomies, including a colposcopic examination, cytology, and rectovaginal examination every 3 to 4 months for the first 2 to 3 years, every 6 months for the next 2 years, and yearly thereafter. Unfortunately, colposcopy and cytologies are frequently unsatisfactory after trachelectomy because the squamous columnar junction is often not visualized and the cytology frequently contains only squamous cells. Conversely, atypical glandular cells from the lower uterine segment are commonly picked up on the smear and misinterpreted as suspicious for recurrence. Singh and coworkers have reported their experience with nearly 200 smears posttrachelectomy and concluded that a high proportion of the smears were unsatisfactory; 2% of the smears were reported as suspicious and in fact represented atypical endometrial cells, but two patients recurred and retrospectively had abnormal smears long before the recurrence was diagnosed. Reports of cytology posttrachelectomy should thus be interpreted with caution. Shepherd and coworkers recommend the use of an endocervical cytobrush for the cytology and an MRI at 6, 12, and 24 months postsurgery. The superb work by Sahdev and associates emphasizes the fact that radiologists interpreting those MRIs should be very well aware of the anatomical

changes post-trachelectomy, as some of the changes may be mis-interpreted as cancer recurrences.

**Obstetric Outcome**

The collected data on obstetric outcome are also very promising. As can be seen in Table 47.9, there have been more than 220 pregnancies reported from the same group of investigators. In general, the rate of first-trimester miscarriage does seem to be higher than in the general population, but approximately 16%. It is interesting to note that even though women undergoing radical trachelectomy procedure do so to preserve their fertility, there is a surprising 4% rate of elective pregnancy termination. The rate of second-trimester losses is higher than in the general population (18%). Overall, 66% to 75% of all pregnancies reach the third trimester. Of those, approximately 15% will end with significant prematurity at less than 32 weeks of gestation. Luckily, less than 10% will deliver before 28 weeks, when most of the severe neonatal morbidities and mortalities occur. Of note, multiple pregnancies appear to be at a particularly high risk of severe prematurity post-trachelectomy, and this should be taken into consideration when discussing in vitro fertilization in patients with infertility. Overall, 85% of the pregnancies reaching the third trimester will evolve normally beyond 32 weeks, and the majority will actually deliver at term (>37 weeks of gestation). The work of Klemm and colleagues suggests that there is no evidence that birth weight of newborns delivered from women who had a trachelectomy is lower. They showed that the vascular flow to the uterine artery before and after vaginal trachelectomy is well preserved.

The etiology of the second-trimester losses and the preterm deliveries is thought to be either mechanical and/or infectious. Indeed, the short cervix probably does not offer as much support to the lower uterine segment. As the uterus enlarges and gets heavier, the cervix is more likely to dilate prematurely. However, the main etiology is felt to be infectious. Indeed, the shortened cervix after the trachelectomy procedure seems to prevent the formation of an efficacious mucus plug. The mucus plug is thought to play an important role as a physiological barrier between the vaginal flora and the membranes to prevent ascending infections. Hence, the subclinical chorioamnionitis is thought to be responsible for the premature rupture of membranes and premature labor. Plante and associates have proposed some guidelines for the follow-up of these high-risk pregnancies. A consultation with a specialist in fetal-maternal medicine is recommended. The value of prophylactic antibiotic coverage—as well as steroid injections to accelerate fetal lung maturity near term—is unclear, although Shephard and colleagues strongly recommend it. The work of Berghella and coworkers has shown that serial transvaginal ultrasound is the best modality for the follow-up of cervical length in the general obstetric population and has been used in the follow-up of pregnant women post-trachelectomy. If the pregnancy evolves normally, delivery is planned at 38 to 39 weeks of gestation. Because of the permanent cerclage, women should be delivered by elective cesarean section.

Outcomes of pregnancy following an abdominal trachelectomy also appear promising. Although the numbers are smaller, Ungar and coworkers have reported 10 pregnancies so far, with results comparable to pregnancies after the vaginal approach. There was a concern that ligating the uterine arteries at the time of the procedure might have an impact on the vascularization of the uterus and potentially lead to intrauterine growth retardation. So far, the data seem reassuring in that regard.

**Conclusion**

Based on the collected data available thus far, the radical trachelectomy procedure truly offers a valuable alternative to young women with small, early-stage cervical cancer who wish to preserve their fertility potential. Oncologic outcomes are comparable to standard radical hysterectomy for similar-size lesions, and the complication rate is low. Pregnancies are definitely possible after this procedure, and overall obstetric outcome is good despite the rate of second-trimester loss and premature delivery. In the last 2 to 3 decades, there has been a tremendous shift toward minimally invasive surgical techniques in gynecologic oncology. Laparoscopic and radical vaginal surgeries have revolutionized the surgical management of cervical cancer. The radical trachelectomy procedure (Dargent operation) has also been shown to be effective for the treatment of cervical cancer in women who wish to preserve their fertility potential.

Abdominal radical trachelectomy.
is unquestionably the most important surgical development in the treatment of early-stage cervical cancer in the last century.

**LAPAROSCOPIC RADICAL HYSTERECTOMY WITH PELVIC AND AORTIC LYMPHADENECTOMY**

Laparoscopic radical hysterectomy with pelvic and aortic lymph node dissection was first reported by Nezhat in 1992. This technically challenging procedure initially was received with caution by gynecologic oncologists who have used the abdominal radical hysterectomy as the traditional approach for decades. So far, no randomized trials are available for comparing these two surgical approaches; however, more than 150 patients have been reported with encouraging results. So far, the largest series reported has been by Spirtos and associates, who described 78 consecutive patients, all with early cervical cancer and a Quetelet body mass index <35, who underwent the procedure. In all, 94% of the procedures were completed laparoscopically with an average operative time of 205 minutes and an average blood loss of 225 mL, with only one patient (1.3%) requiring transfusion. There was one ureterovaginal fistula documented. The average lymph node count was 34, with 11.5% of patients having positive lymph nodes. Three patients (3.8%) had close or positive surgical margins, and 5.1% recurred with a minimum of 3-year follow-up. Table 47.10 summarizes reports on laparoscopic radical hysterectomy with pelvic and aortic lymphadenectomy.

manipulation is optional. The pelvic and aortic lymphadenectomy is performed as described in the preceding. Pelvic drains usually are not necessary, and a suprapubic catheter is optional.

## LAPAROSCOPIC SURGICAL STAGING

Currently available clinical staging methods and imaging studies are not completely accurate in the detection of pelvic and aortic lymph node metastasis from cervical cancer, and pathologic evaluation of retroperitoneal lymph nodes remains the gold standard for establishing metastasis. In addition, identifying retroperitoneal nodal metastasis may alter the overall therapeutic approach and affect the patient's prognosis. Laparoscopic surgical staging with pelvic and aortic lymph node dissection for cervical cancer was initially reported by Querleu in France. Since this initial report, many investigators have adopted the laparoscopic pretreatment surgical approach and continue to modify the technical details of the procedure. It is well established at this point that transperitoneal or extraperitoneal laparoscopic pelvic and aortic lymph node dissection for cervical cancer, in experienced hands, is feasible, yields similar results as the open approach, and is associated with low morbidity. Furthermore, this approach may provide valuable information that is not available using clinical staging techniques. Computed tomography was able to detect retroperitoneal nodal metastasis in only 17% to 57% of cervical cancer patients staged laparoscopically. Table 47.11 summarizes selected reports on laparoscopic pelvic and aortic lymph node dissection in the management of stage I to IV cervical cancer.

### Laparoscopic Surgical Staging Technique

The technique of laparoscopic surgical staging continues to evolve as experience with this minimally invasive approach increases. There are two main approaches: the transperitoneal approach and the extraperitoneal approach (popularized by Querleu and Dargent from France). For the transperitoneal approach, four laparoscopic trocars usually are needed (Fig. 47.32): 10-mm trocars in the umbilical and suprapubic regions and 5-mm trocars just medial to the iliac crest on each side. For the aortic nodal dissection, the laparoscope is placed in the suprapubic region, and the monitors are moved cephalad. For the pelvic lymphadenectomy, the laparoscope is placed in the umbilical region, and the monitors are placed caudal. A variety of endoscopic tools may be used with similar results. The selection usually is based on the surgeon's preference and experience. Both monopolar and bipolar currents are available, and a wide variety of endoscopic dissecting instruments, clip appliers, and specimen retrieval devices are available. The 10-mm argon beam coagulator (ABC, Conmed, Utica, NY) is ideal in this setting. It works both as a dissector and a coagulator. A retroperitoneal nodal dissection may be satisfactorily completed in the majority of cases with the aid of a tissue grasper and an endoscopic clip applier. The right aortic nodal tissue is approached via a retroperitoneal incision over the right common iliac artery. The right ureter and ovarian vessels are identified, and the nodal tissue over the iliac vessels is retracted. The left aortic nodal tissue may be approached via the same incision. The inferior mesenteric artery, left ureter, and venae cavae are retracted. The remaining parametria and paracolpos are resected with the ABC and staples. The specimen is removed vaginally with a single tooth tenaculum, and the vaginal cuff is closed laparoscopically with endoscopic sutures of the endostitch. The placement of ureteral catheters or stents to facilitate ureteric manipulation is optional.

PATHOLOGIC EXAMINATION OF THE OPERATIVE SPECIMEN

Considerable useful information about the extent of the disease can be obtained by a careful pathologic examination of the operative specimen. This is helpful in determining prognosis but is also absolutely essential to the identification of patients at greater risk for persistent disease so that additional therapy and close surveillance can be provided. Even though the operator may be fatigued at the end of the operation, he or she should consider accompanying the specimen to the pathology laboratory, where it can be examined with the pathologist before it is placed in fixative and sectioned. Another alternative is to call the pathologist to the operation room for a joint examination of the specimen while the surgical incisions are being closed. The gynecologic surgeon then can point to worrisome parts of the specimen; such information assists the pathologist in taking sections. Critical margins of dissection can be pointed out and stained with India ink so that they can be seen on microscopic slides. The primary cervical tumor should be measured as accurately as possible so that at least an estimate of its size and volume can be recorded. Numerous microscopic sections of the cervix with adjacent vaginal cuff, lower uterine segment, and paravaginal, paracervical, and parametrial tissue should be examined to show the cell type, degree of differentiation, depth of stromal invasion, and presence or absence of invasion of lymphatic and vascular spaces. It is important to know not only the depth of invasion but also the thickness of the uninvolved fibromuscular stroma of the cervix, as pointed out by Kishi and coworkers. These authors found that the nodal metastasis and 5-year cancer death rates were 7% and 8%, respectively, in patients with uninvolved fibromuscular stroma thickness > 3 mm, and 37% and 26%, respectively, in patients with the thickness < 3 mm. Furthermore, GOG has demonstrated that the percentage of invasion of tumor into the cervical stroma is an independent prognostic factor and is used to help determine the need for postoperative adjuvant treatment.

Unfortunately, the exquisite giant-section technique of pathologic examination used by Burghardt and coworkers is not available in any U.S. pathology laboratory. These authors measured ratio of tumor size to the size of the cervix. The incidence of lymph node involvement increased with tumor size, reaching a maximum of 68.3% in the group with a ratio from 70% to 80% of cervical anatomic involvement. Surprisingly, direct spread into the parametrium seldom was found, even when large tumors were found to occupy the entire cervix. This finding is contrary to that of Bleker and coworkers, who found 16.8% unrecognized parametrial tumor involvement in patients with stage IB and IIA lesions. The 5-year survival rate fell with parametrial involvement.

Through examination of the lymphadenectomy specimens must be done. Tumor metastasis to lymph nodes affects patient survival adversely and is an indication for postoperative adjuvant therapy. In patients with positive nodes, the pathologic examination should report whether the metastatic disease is microscopic or macroscopic, single or multiple, unilateral or bilateral. The location of lymph nodes positive for tumor also should be reported because the prognosis is especially poor in patients with positive common iliac or paraaortic nodes. The usual standard technique of pathologic examination of lymphadenectomy specimens involves removal of visible and palpable nodes from fatty tissue, with bisection of each node for microscopic examination. This standard technique may not be adequate for an accurate assessment of lymph node metastases. A significant increase in positive findings can be obtained if special pathologic examination techniques are used, as demonstrated by To and coworkers, Ahrens and Tschoke, and Wilkinson and Huisse. With their technique of dissection of lymph nodes at multiple levels before paraffin embedding, To and coworkers showed that 9% of patients originally reported to have negative nodes actually had positive nodes.

An accurate assessment of the extent of disease by a careful pathologic examination of the operative specimen is imperative in deciding whether additional treatment is needed. Indeed, it is such an important component in the surgical management of patients with cervical cancer that these patients should be operated on only in hospitals where such expert specimen evaluation is available.
Studies have demonstrated that the bladder initially can be hypertonic, with decreased bladder capacity, increased resting pressure, and increased residual urine volume. Many patients have difficulty initiating micturition and experience a loss of sensation of bladder fullness. Using sensitive urodynamic instrumentation, Scott and coworkers found a variety of abnormalities, including obstructive voiding patterns, immediate and delayed loss of compliance, sensory losses, and genuine stress incontinence. Some patients had complete absence of bladder contractions during voiding. Although these findings are quite compelling, Lind and associates recently reported normal preoperative urodynamic findings in only 17% of 210 patients with cervical cancer scheduled to undergo radical hysterectomy.

Mundy and Sasaki and coworkers have suggested that the posterior part of the cardinal ligament (pars nervosa) contains the major part of the parasympathetic and sympathetic nerve supply to the bladder and urethra and that its removal is responsible for postoperative bladder dysfunction. Sasaki and coworkers demonstrated that removal of the anterior cardinal ligament (pars vasculosa) with preservation of the pars nervosa reduces the incidence of postoperative bladder dysfunction. The work of Kadar and coworkers and that of Asmussen and Ulmsten suggests that the nerve supply to the bladder and urethra can be spared without compromising the necessary extensive dissection and tissue removal around the central disease, thus sparing many patients the loss of urethrovescical function. Kuswara and colleagues recently reported a decrease in bladder dysfunction by using a technique of intraoperative electrical stimulation to identify and preserve the vesical nerve branches. These nerve-sparing modifications have not been widely adopted by gynecologic oncologists in the United States because of a concern that this same cardinal ligament tissue also carries lymphatic channels draining the cervix and should be removed in a complete central dissection. However, Trombo and colleagues report the Netherlands, have reported no increase in recurrence or decreased survival in a series of patients treated with nerve-sparing radical hysterectomy.

Techniques of managing the postoperative bladder have varied widely. Duration of catheter drainage, suprapubic versus transurethral drainage, the value of self-catheterization, and the value of cystometric studies have all been debated as described by Bandy and coworkers. These authors also found that patients receiving postoperative adjunctive pelvic radiation had significantly more contracted and unstable bladders than patients treated with surgery alone. Proper management of the bladder in the first several weeks after operation is essential to avoid overdistention. The duration of postoperative bladder catheterization has decreased in recent years. Chamberlin and investigators reported a contemporary median indwelling catheter duration of 6 days compared with 30 days in historical controls with no increase in complication rates.

Although some clinicians leave an indwelling catheter or suprapubic tube in place 2 to 3 weeks, we prefer continuous transurethral catheter drainage until the patient is ready for discharge, which is usually about 4 to 7 days after surgery. Early postoperative intravenous pyelography (IVP) in the absence of intraoperative urinary tract injury or clinical symptoms suggestive of injury is not indicated; moreover, an abnormal early IVP is not predictive of subsequent urinary tract dysfunction. When the patient is ready for discharge, the catheter is removed, and postvoid residuals are checked with a bladder scan or cystometric measurement. Continuous transurethral catheterization also can be used. If the postvoid residual volume is below 50 to 75 mL and the volume of urine spontaneously voided is greater than the postvoid residual, then the patient is allowed to leave the hospital without an indwelling catheter. She must be thoroughly schooled in the importance of not allowing her bladder to become overdistended. Allowing the bladder to overdistend, especially in the early postoperative recovery period, can result in a flaccid bladder from stretching and decomposition of the detrusor muscle, prolongation of bladder dysfunction with high residual urine volumes, and the likelihood of urinary infections. Patients who have unacceptable postvoid residuals are best managed with prolonged indwelling catheter drainage for several weeks before attempting removal. If a serious episode of overdistention of the bladder ever occurs, continuous indwelling catheter drainage should be reinstituted, sometimes for several weeks, with the hope that permanent impairment of bladder function can be avoided. Urinary tract infections can occur in conjunction with bladder dysfunction and should be looked for with periodic urinalysis and culture and treated with appropriate antibiotics. Patients should be encouraged to maintain a urine output above 2,000 mL per day to avoid urinary tract infection.

In most patients, a satisfactory voiding pattern can be established within several months. Urodynamic studies, however, can show some evidence of slight and persistent chronic bladder dysfunction for several years. Fraser stated that 20% of his patients continued to report changes in bladder sensation as long as 5 to 15 years after operation. In many patients who have had properly performed radical hysterectomy and pelvic lymphadenectomy, it is inevitable that bladder function will never be completely normal again. With proper postoperative bladder care and rehabilitation, however, function should be satisfactory in most patients at the end of the first year. According to Fishman and coworkers, 35% of patients continued to express unhappiness at the extent and effect of their postoperative urinary dysfunction.

Vesicovaginal Fistula

In the absence of prior pelvic irradiation, bladder ischemia and vesicovaginal fistula are infrequent complications of this procedure. Vesicovaginal fistulas occur in less than 1% of patients (Table 47.12). Nearly one third of urinary tract fistulas following surgery heal spontaneously, as compared with none if adjuvant radiation therapy is given. The management of vesicovaginal fistulas is discussed in Chapter 39.

Urètre

Clark, working at the Johns Hopkins Hospital, published one of the first descriptions of radical hysterectomy for cervical cancer in 1895. Sampson, working in the same institution during the same time, recognized that injury to the ureter was the most serious problem associated with primary radical surgery for this disease. His publications on ureteral anatomy and blood supply and the relation between the ureter and gynecologic disease are classic and pertinent today. Devascularization and ischemic necrosis of the wall of the terminal ureter has proved to be one of the more serious complications of this operation. Wertheim found this complication to be one of the more serious sequelae. In Menge's clinic, there was a 12.5% incidence of bladder dysfunction with 4% incidence of ureterovaginal fistulas and 4% incidence of ureteral stricture.

For many years, gynecologic surgeons have attempted to lower the rate of ureteral complications with special techniques. Novak, from Yugoslavia, reduced the incidence of ureteral fistulas to 2% after primary radical surgery by placing
the dissected pelvic ureter on the inside (peritoneal surface) of the pelvic peritoneum and by preserving the lateral mesentery to the terminal ureter. Green and coworkers suggested that the terminal ureter should be lifted out of the accumulated fluid in the retroperitoneal space by suturing it to the obliterated hypogastric artery. Ohkawa developed a procedure that attempted to elevate and isolate the ureter from the infected retroperitoneal fluid and also to develop a new blood supply to the terminal ureter by placing it in a peritoneal envelope from the pelvic brim to the bladder. Blythe and coworkers compared this technique with simple retroperitoneal suction drainage first advised by Symmonds and Pratt. They found that ureteral obstruction and ureterovaginal fistulas occurred twice as often and that the operative time was extended 45 minutes to 1 hour with the Ohkawa technique. More recently, Patsner and others have recommended the routine use of the omental J-flap (omentopexy) at the conclusion of radical hysterectomy and pelvic lymphadenectomy as an effective means of minimizing urinary tract fistulas.

Given a normal unirradiated ureter, we believe that the incidence of ureteral fistulas and permanent stenosis can be kept below 1% with meticulous intraoperative management of the ureter by a technically skillful operator who can prevent vascular trauma to the periureteral sheath and injury to the muscularis of the ureter.

Some temporary postoperative changes in ureteral function are an almost inevitable result of radical hysterectomy, as pointed out by Gal and Buchsbaum. Using special static and cinefluoroscopic IVP techniques, these authors found ureteral dilation in 87% of patients in the first week after surgery. In most cases, by 6 weeks after surgery, the dilation had regressed and the pyelograms had returned to normal. Peristalsis was altered in the distal ureter, which appeared as a rigid conduit during the first postoperative week. Peristalsis had returned 1 month later. These changes may explain the increased frequency of urinary tract infections after radical hysterectomy and pelvic lymphadenectomy as an effective means of minimizing urinary tract fistulas.

Table 47.12 shows the frequency of urinary fistulas in a collected series of 7,473 nonirradiated patients treated by radical abdominal hysterectomy as compiled by Shingleton and Orr. The management of ureterovaginal fistulas is discussed in Chapter 39.

### Retropertitoneal Spaces

Traditionally, a closed system of constant suction was placed in the retropertitoneal spaces on each side at the end of the procedure. These drains were thought to be effective for reducing the risk of pelvic infection, fistula, and lymphocyst formation. However, recent retrospective and prospective studies have demonstrated that the incidence of these complications is not decreased in patients who have retropertitoneal drains placed compared with those who do not. Furthermore, the drains may actually increase infectious complications.
Therefore, we do not routinely place drains in the retroperitoneal spaces. Whether drains are placed or not, a small percentage of patients develop lymphoceles. A lymphocoele becomes obvious by symptoms and examination in the weeks after radical hysterectomy and pelvic lymphadenectomy. It may be small and asymptomatic. Most patients with large lymphoceles report lower abdominal discomfort on the lateral pelvic side-wall, where silent thrombosis is common. Prolonged immobilization of the lower extremities during a lengthy operative procedure is responsible for intraoperative venous stasis and clot formation. There is evidence to document that postoperative thrombosis of the lower extremity is a result of the surgical procedure in more than 50% of cases. The prevention, diagnosis, and treatment of venous thromboembolic events is extensively discussed in Chapter 9.

Infection
Historically, patients were treated with antibiotics only if postoperative infection occurred. However, antibiotic prophylaxis has been associated with decreased febrile morbidity and decreased rates of serious infections in women undergoing radical abdominal hysterectomy. Furthermore, Orr and colleagues have demonstrated that a single dose of prophylactic antibiotic is as effective as a multiple-dose regimen and lessens patient exposure and cost. Thus, the prophylactic use of broad-spectrum antibiotics with both aerobic and anaerobic coverage has proved to be a useful addition to the surgical armamentarium.

We initiate single-agent broad-spectrum antibiotic coverage immediately before surgery. The administration of the drug is timed to allow adequate distribution before incision. During an extended operation, if the antibiotic given has a short half-life, a second dose is administered.

When secondary infection occurs despite the use of prophylactic antibiotics, the appropriate cultures are obtained, and bacteria-specific antibiotic therapy is chosen.

Venous Thrombosis and Pulmonary Embolus
Patients who undergo radical pelvic surgery fulfill the components of Virchow’s triad and are at high risk for the development of venous thrombosis of the lower extremities and thromboembolic phenomena. Factors such as postoperative alteration of blood coagulation, trauma to the vein wall, and venous stasis are recognizable features of this type of surgery. In particular, pelvic lymphadenectomy invariably produces some trauma to the vein wall during the mobilization of the vessel and resection of the adherent lymphatic tissue. One of the biologic effects of radical surgery is the occurrence of local tissue necrosis during healing. This results in the release of tissue thromboplastin into the circulation, which contributes to thrombosis. The clotting mechanism (acceleration of the clotting mechanism) is also seen behind the valves of the veins of the lower extremities, where silent thrombosis is common. Prolonged immobilization of the lower extremities during a lengthy operative procedure is responsible for intraoperative venous stasis and clot formation. There is evidence to document that postoperative thrombosis of the lower extremity is a result of the surgical procedure in more than 50% of cases. The prevention, diagnosis, and treatment of venous thromboembolic events is extensively discussed in Chapter 9.

Efforts to decrease the frequency of this complication initially used prophylactic low-dose heparin, 5,000 U subcutaneously, three times daily, beginning 2 hours before surgery, and given every 8 hours thereafter for the subsequent 5 postoperative days. By using perioperative heparin alone, the incidence of deep vein thrombosis in a study by Kakkar and associates was decreased from 24.6% in the untreated control group to 7.7% in the heparin-treated group of surgical cases. More impressive was the observation in a subsequent study by the same investigators that 16 patients in the control group, as compared with only 2 patients in the heparin-treated group, were found on autopsy study to have died of acute, massive pulmonary embolism.

We use intermittent pneumatic calf compression beginning in the operating room and continuing whenever the patient is in bed until she is discharged. These compression boots are used not only in our patients undergoing radical hysterectomy but in all our patients undergoing major gynecologic surgical procedures. In very high-risk patients, we add prophylactic low-molecular-weight heparin. Approximately 3% to 5% of patients with occult venous thrombosis of the lower extremities develop pulmonary emboli. Unfortunately, more than half of the cases of fatal pulmonary embolism occur in patients without evident venous thrombosis and without any clinical evidence of this complication before the acute pulmonary catastrophe. When evidence of venous thrombosis of the lower extremities is verified, full anticoagulation therapy is required for prevention of pulmonary embolism. However, the decision about how soon after radical surgery it is safe to fully anticoagulate a patient may be very difficult. In the rare case that a pulmonary embolus occurs after full anticoagulation has been achieved, it is necessary to prevent further migration of clot to the lung by either inferior vena cava ligation or the use of an intracaval teflon valve. These complications are rare, but the sinister effects of thromboembolism must be carefully evaluated on a daily basis, and a high index of suspicion needs to be maintained in this high-risk group of patients.

Hemorrhage
Intraoperative and postoperative pelvic hemorrhages also are discussed in Chapter 19.

Intraoperative Bleeding
Despite the surgeon’s adequate technical skills and careful dissection, serious hemorrhage can suddenly appear, especially during retroperitoneal dissections on the lateral pelvic sidewalls and around the sacrum. When it happens, it is hoped that the operative field will not be cluttered with clamps; exposure, lighting, and suction will be adequate; the patient’s condition will be stable; and anesthesia will be sufficient to maintain good relaxation. If the bleeding vessel cannot be clamped quickly, the simplest and most effective method of controlling the
hemostasis. In contrast to arterial bleeding, hemorrhage from the pelvic vein has been severely traumatized and has retracted out. The bleeding has been established, in the meantime dissecting is advisable to keep pressure on the vein until full control of the site of bleeding for a similar length of time. In these cases, it is important to use compression of the pelvic floor veins by identifying the site of the lacerated vein. In these circumstances, paraaortic areas are frequent sites of venous bleeding. Therefore, careful positioning of patients in stirrups prevent most nerve injury. Fortunately, most nerve injuries are not associated with serious or permanent disability.

Postoperative Hemorrhage
This condition is a rare complication of radical pelvic surgery. Because all of the blood supply to the pelvis has been skeletonized as part of the operative procedure, it is exceedingly rare for secondary hemorrhage to occur unless there has been uncontrolled bleeding at the completion of the operation. In these cases, the pelvis usually is packed with multiple gauze packs, with one end exteriorized through the open vagina. Tamponade of the pelvis by means of an umbrella or parachute gauze pack and external ring (see Chapter 19) has been advocated by some when there is persistent venous oozing in the pelvis at the completion of the operation. Pelvic packs should be advanced within 24 to 48 hours and removed shortly thereafter to avoid ascending infection from the vagina. In certain cases of postoperative hemorrhage, selective embolization by invasive radiographic techniques can prevent reoperation.

Neuropathies
Nerve injury with radical hysterectomy was reviewed by Hoffman and coworkers, who reported its infrequent occurrence. The most important injuries are to the femoral, obturator, peroneal, sciatic, genitofemoral, ilioinguinal, iliohypogastric, lateral femoral cutaneous, and pudendal nerves. Awareness of the anatomic location of these nerves in the operative field, careful surgical technique in dissection and securing hemostasis, careful placement of self-retaining retractors, and careful positioning of patients in stirrups prevent most nerve injuries. Fortunately, most nerve injuries are not associated with serious or permanent disability.

Rectum
Although much less frequent than bladder dysfunction, both acute and chronic rectal dysfunction may occur following radical hysterectomy. The rectal dysfunction is characterized by difficulty with defecation and loss of defecation urge. Barnes and associates reported that postoperative anorectal manometry studies were abnormal in all patients studied, suggesting disruption of the spinal reflex arcs controlling rectal emptying, possibly secondary to partial denervation of the rectum. Dietary fiber modifications and rectal stimulation with suppositories over several weeks or months are effective in addressing these problems.
ADJUVANT THERAPY IN CONJUNCTION WITH RADICAL SURGERY

Postoperative Pelvic Irradiation

External-beam radiation therapy is used in the postoperative period as an adjunct to radical abdominal hysterectomy and bilateral pelvic lymphadenectomy in selected cases. It is given selectively to patients considered to be at high risk for persistent disease based on operative findings and careful study of the surgical specimens. Previously, if only one or two lymph nodes show micrometastases, postoperative irradiation may not be given. However, when several nodes are involved, the risk of persistent disease is greater, and postoperative irradiation is usually given; it can be extended as high as T12 if proximal common iliac or paraaortic nodes are involved with metastatic disease. However, nodal metastasis is not the only risk factor for recurrence, and other local tumor-related factors may be indicators of high-risk tumors that may warrant adjuvant radiation therapy.

Sedlis and associates—in a GOG randomized trial of pelvic radiation therapy versus no further therapy in selected patients with stage IB carcinoma of the cervix with negative lymph nodes after radical hysterectomy and pelvic lymphadenectomy—evaluated the benefits and risk of adjuvant pelvic radiation therapy aimed at reducing recurrence in this group of patients. In this study, 277 eligible patients were entered with at least two of the following tumor-related risk factors: greater than one third stromal invasion, cervical lymphatic space involvement, or large clinical tumor dimension. Table 47.13 summarizes the eligibility criteria: Of the 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one (15%) in 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment.

Performance of the regimen should be undertaken only with understanding of the toxicities encountered. The data from this randomized trial and the Sedlis trial currently provide practical guidelines for eligibility of patients for adjuvant chemoradiation following primary radical hysterectomy and pelvic lymphadenectomy.

Postoperative Extended-Field Irradiation or Chemoradiation

In selected cases, with multiple positive pelvic nodes, metastases to common iliac nodes, or aortic nodal metastasis, patients are treated with pelvic and extended-field radiation to include the paraaortic lymph chain. To numerous previous studies can be added two studies from Japan that describe the results of paraaortic nodal irradiation in the treatment of cervical cancer. Inoue and Morita (1988) administered extended-field radiation after extensive surgery to 76 patients with paraaortic nodal metastases. Two patients developed severe intestinal complications that required reoperation. Postoperative extended-field irradiation improved the survival rate of patients with four or more positive nodes from 39% to 69%, as well as the survival rate of patients with unresectable nodes from 0% to 44%. The authors concluded that postoperative extended-field irradiation can control the distant spread by way of lymphatic routes and can increase the survival time of patients. In addition, 86 patients with cervical cancer were treated with paraaortic nodal irradiation by Horii and coworkers (1988). None of the patients developed severe complications from the treatment. Based on their selection criteria for paraaortic nodal irradiation, the authors found a statistically significant improvement in the prognosis for the treated group. In 1987, Jones reported on a collected series of 332 patients with paraaortic lymph node metastases who received extended-field radiation. Twenty-six percent were long-term survivors. Although it is true that most patients with positive paraaortic lymph nodes die of their disease (probably because systemic disease is already present), it is also clear that some patients are curable with extended-field radiation or chemoradiation, especially if all the nodes are involved with only microscopic disease. The surgeon must anticipate a 10% incidence of enteric complications even with doses limited to 5,000 cGy. Again, microscopic metastasis is more likely to be eradicated by a dose of 45 Gy of radiation that can be tolerated by the patient. Patients with paraaortic nodes that contain a large volume of tumor are not likely to be cured, even with a dose of paraaortic radiation that exceeds 5,000 cGy, unless the bulky nodes are excised before the irradiation.

Extended-field chemoradiation also may be used. The GOG reported on a multicenter trial of chemoradiation therapy to evaluate the feasibility of extended-field radiation therapy with 5-fluorouracil (5-FU) and cisplatin, and to determine the progression-free interval, overall survival, and recurrence sites in patients with biopsy-confirmed paraaortic paraaortic lymph node metastases from cervical carcinoma. In all, 86 evaluable stage I to IV patients with aortic metastases were reported. Radiation therapy doses were 4,500 cGy to paraaortic nodes, and concomitant chemotherapy consisted of 5-FU 1,000 mg/m2 per day for 96 hours and cisplatin 50 mg/m2 in weeks 1 and 5. Initial sites of recurrence were pelvic alone, 20.9%; distant metastases only, 31.4%; and pelvic plus distant metastases, 19.5%. The 3-year overall and progression-free survival rates were 39% and 34%, respectively, for the entire group. Overall survival was stage I, 50%; stage II, 39%; and stage III/IVA, 38%.

GOG grade 3 and 4 acute toxicity was gastrointestinal (18.6%) and hematologic (15.1%). Late morbidity actuarial risk of 14% at 4 years was primarily involved rectal damage. The authors concluded that extended-field radiation therapy with 5-FU and cisplatin chemotherapy was feasible in a multicenter clinical trial, that a progression-free survival of 33% at 3 years suggests that a proportion of patients achieve control of advanced pelvic disease, and that not all patients with paraaortic metastases have systemic disease. This points to the importance of assessment and treatment of paraaortic metastases.

Adjuvant Postoperative Chemotherapy

Few studies of adjuvant chemotherapy following radical hysterectomy have been done. Wertheim et al. from Memorial Sloan-Kettering Cancer Center (MSKCC) in 1985 reported on a pilot study of adjuvant chemotherapy with cisplatin and bleomycin after radical hysterectomy in patients with cervical cancer at high risk for recurrence after radical hysterectomy and pelvic lymphadenectomy. The continuous disease-free survival rate for the 32 evaluable patients was 84% at a median follow-up time of 28 months. In addition, the complications of this treatment program were not significantly greater than those observed in prior studies using the combination of surgery and adjuvant radiation therapy without chemotherapy. When compared with the results from historical controls in a large series of similar patients at the same institution, the results in this pilot study were encouraging and appeared to justify a randomized prospective clinical trial.

Two randomized trials have attempted to clarify the role of adjuvant postoperative chemotherapy. In 1992, Tattersall and colleagues reported a randomized trial comparing standard pelvic radiation therapy versus three cycles of combination chemotherapy with cisplatin, vinblastine, and bleomycin followed by pelvic radiation therapy. No difference in disease-free or overall survival emerged between the two treatment groups. Relapse was more common in patients with nonsquamous tumors (44%) and in those with metastases in several pelvic lymph nodes.

In 1996, Curtin et al. from MSKCC reported on a prospective multicenter randomized phase III trial of adjuvant chemotherapy versus chemoradiotherapy in patients at high risk for recurrence. The continuous disease-free survival rate for the 32 evaluable patients was 84% at a median follow-up time of 28 months. In addition, the complications of this treatment program were not significantly greater than those observed in prior studies using the combination of surgery and adjuvant radiation therapy without chemotherapy. When compared with the results from historical controls in a large series of similar patients at the same institution, the results in this pilot study were encouraging and appeared to justify a randomized prospective clinical trial.

FOLLOW-UP AFTER RADICAL SURGERY FOR CERVICAL CANCER

Despite carefully planned and executed radical surgery for early-stage cervical cancer, 5% to 20% of patients in various series show evidence of recurrent or persistent tumor. About half occur in the first year after treatment. Almost all occur within the first 3 years. Few occur later. Recurrences many years later are extremely rare after primary surgical treatment and are more likely to be seen in patients treated with primary radiation therapy.

Persistent or recurrent disease after primary radical surgery may represent incomplete resection of the central tumor underdetected at operation or by the pathologist’s examination of the surgical specimen. Microscopic metastatic involvement of lymph nodes may be undetected by incomplete pathologic examination or none of these nodes may be left behind by incomplete lymphadenectomy. Viable tumor cells in small numbers may escape by way of lymphatics or vascular channels to distant sites and overcome host resistance. Probably in as many as 10% of patients with persistent disease, recurrence may result from continued growth of unrecognized intraperitoneal spread of tumor.

After the immediate postoperative recovery is completed, patients are scheduled for regular follow-up examinations, which vary depending on circumstances. Patients who are at greater risk for recurrence should be followed especially closely at frequent intervals. These usually are the same patients who have been given postoperative therapy, including patients with metastatic disease in lymph nodes and/or parametria, close surgical margins, large-volume cervical tumors, deep cervical stromal invasion, and lymphatic and/or vascular channel involvement. The frequency of examination varies somewhat from patient to patient. Most patients are seen every 3 months during the first 3 years after primary treatment, every 6 months during the fourth and fifth years, and every 6 months to 1 year thereafter. Patients are instructed to report any new or persistent symptoms (e.g., vaginal bleeding or discharge, leg swelling, discomfort in the pelvis, disconfort or swelling in the legs, difficulty with urination or defecation, enlarged neck or groin nodes) at any time they appear. Krebs and coworkers, however, reported that 25% of their patients did not have symptoms when persistent disease was diagnosed. In the study reported by Larson and coworkers, 37% did not have symptoms.

A follow-up examination should include palpation of the neck for enlarged lymph nodes, abdominal and pelvis examination, and a speculum and bimanual rectovaginal pelvic examination or these nodes may be left behind by incomplete lymphadenectomy. Viable tumor cells in small numbers may escape by way of lymphatics or vascular channels to distant sites and overcome host resistance. Probably in as many as 10% of patients with persistent disease, recurrence may result from continued growth of unrecognized intraperitoneal spread of tumor.

tissue. A squamous cell carcinoma antigen radioimmunoassay kit, developed by Abbott Laboratories (Abbott Park, Illinois), has been tested, but the role of this antigen in the follow-up of patients with cervical carcinoma is yet to be determined.

Although the early detection of persistence is the primary purpose of and justification for follow-up visits, assessment of urinary tract function also is important. Particular attention should be paid to detecting and alleviating a satisfactory voiding pattern. Urinary tract infection should be diagnosed and treated promptly. If uterine stenosis impairs renal function, early intervention can be successful in avoiding nephrectomy. This is more likely to be seen in patients who receive a combination of radical surgery and irradiation as primary treatment.

Rehabilitation of sexual function after surgical therapy for cervical cancer usually is easily done by the patient and her partner but is more difficult if the vagina and paravaginal tissues have received heavy doses of radiation or if the patient has lost ovarian function as a result of treatment. The gynecologic surgeon should inquire about sexual problems and should give advice and permission when needed. Counseling, including instruction in the technique of alternative means of sexual gratification, may be needed. If ovarian function has been lost as a result of treatment, estrogen replacement therapy should be provided, even though symptoms of hypogonadism are not present. If normal ovaries were conserved, their function should be monitored with periodic follicle-stimulating hormone and estradiol levels so that estrogen replacement can be discussed when ovaries cease functioning in future years. There may be other contraindications to estrogen replacement therapy in patients treated for cervical cancer, but a history of treatment for cervical cancer is not one of them.

And finally, patients who have been treated for cervical cancer are at greater risk for developing other primary cancers at different sites, especially if the treatment included irradiation. Detection of other primary cancers should be part of posttreatment follow-up. This subject has been studied by Hoffman and coworkers, Buchler, and others. Axelrod and coworkers reported that 3.9% of patients with invasive cervical cancer had second primaries. In 1987, Arneson and Kao reported that 61 new primary cancers were detected among 718 patients with invasive cervical cancer who had been studied from 1955 to 1979.

### RADIATION THERAPY

Although radical hysterectomy is generally recommended for women with early-stage cervical cancer who can tolerate the surgery, women with Stage IB or more advanced disease are usually treated with radiation therapy. Radiation is also appropriate for women who are poor surgical candidates because of medical conditions or age.

Ionizing radiation can destroy tumor and cure cancer effectively. Radiation therapy for cervical cancer is usually delivered by two techniques. Intracavitary therapy or brachytherapy is administered by placing a radioactive element—such as radium, cesium, or iridium—in close contact with the tumor. This produces a very effective, high-dose local treatment, but the dose rate delivered falls off very sharply as the distance away from the radioactive source increases. This is called “the inverse square law.” The radiation dose delivered to a given point is equal to 1 divided by the square of the distance away from the radiation source (dose = 1/distance^2). Because of the rapid decrease in the dose, it is necessary to treat potential pelvic lymph node metastases and large primary cervical cancer with external beam radiation. This type of radiation was originally produced by modified diagnostic x-ray machines, but now special high-energy linear accelerators or betatrons are used. These machines are capable of delivering a uniform dose of radiation across the whole pelvis or even an extended field to include the paraaortic lymph nodes.

The use of radiation for the treatment of cervical cancer followed very shortly after the discovery of radium by Marie and Pierre Curie. Beginning in 1903, several methods of intracavitary therapy were developed, including the Stockholm technique from the Radiumhemmet; the Paris technique, designed at the Curie Foundation; and the Manchester technique from England. The Stockholm radium technique consisted of high-intensity central irradiation, repeated two or three times within 3 weeks, whereas the Paris technique used low-intensity central irradiation, continuously delivered over 1 week. The Manchester technique, derived from the Paris method, used low-dosage rates that required at least two separate intracavitary insertions of radiation sources. Other radioactive elements, including cesium and iridium, have replaced radium in central brachytherapy for cervical cancer.

The traditional brachytherapy systems for cervical cancer have been low-dose-rate systems delivering 0.4 to 2 Gy per hour, and typical implants have been of 24- to 72-hour durations. More recently, high-dose-rate systems have been employed capable of delivering dose rates of more than 0.2 Gy per minute, thereby allowing treatments of only a few minutes’ duration and adaptable to the outpatient—rather than the inpatient—setting. A comparison of 5-year survival rates of the two systems by clinical stage documents the usefulness of the newer system (Table 47.14).

With the establishment of the roentgen as a defined unit of radiation exposure (Stockholm, 1921), it became possible to measure the quantity of x-ray radiation delivered to the tissues. Although many clinicians are most familiar with the dosing measured in rads, modern therapy is calculated in grays (Gy) [1 Gy = 100 rads, 1 centigray (1 cGy) = 1 rad]. High-energy, external-beam radiation sources, ranging to 25 MeV for the betatron and linear accelerator, have significantly reduced the complication rates after radiation therapy and have improved the cure rates. An intracavitary pelvic dosage derived from the gamma rays of radium or cesium is complementary to the megavoltage external-beam irradiation to ensure tumoricidal dosages to the cervix, broad ligaments, and lateral pelvic walls. Extended fields of external radiation can deliver therapy to common iliac and aortic nodal tissues.

The balance between enough radiation to destroy the tumor and too much radiation (which results in damage to adjacent normal tissues such as the bladder, vagina, or rectum) is sometimes difficult to achieve. It requires using the correct combination of brachytherapy with external radiation therapy. Treatment planning has been enormously improved in recent years because of the integration of imaging techniques (such as CT scanners) with computer programs that can calculate the dose to the tumor volume and adjacent normal tissues, which helps the radiation oncologist maximize the tumor dose while minimizing the damage to nearby organs.

Survival rates of irradiation and primary surgery can be compared by analyzing the reports from patients treated for stage I cervical cancer. Patients treated by irradiation have an average 5-year survival rate essentially identical to the survival rate for those who undergo radical hysterectomy (Table 47.15).

In the United States, radical hysterectomy generally is recommended for women with stage IA2 and IB1 cervical cancer who are good operative risks, especially if they are...
demonstrated an equal cure rate with primary radical surgery and the potential to retain fertility in carefully selected patients. Microscopic approaches are promising, with comparable cure rates and 5-year cure rates for stage IB1 carcinoma of the cervix are more than 90%. Newer laparoscopic approaches are promising, with comparable cure rates and the potential to retain fertility in carefully selected patients.

Radical vaginal trachelectomy has proven safe and effective for premenopausal women with larger tumors and those who are at risk for surgical complications generally are referred for radiation therapy.

**SUMMARY**

Many improvements have been made in the operative technique of the radical hysterectomy and lymphadenectomy since its original description. The incidence of complications after this procedure has decreased during the past 75 years, and the survival rates have increased. The operation has achieved its peak of clinical usefulness during this period and is now considered to be the principal method of treatment of early invasive carcinoma of the cervix. Among the better surgical institutions, the meticulous execution of this operative procedure has reduced the incidence of complications to an acceptable and infrequent occurrence. In medical centers in which the operation is performed well, the 5-year cure rate for stage IB1 carcinoma of the cervix is more than 90%. Newer laparoscopic approaches are promising, with comparable cure rates and the potential to retain fertility in carefully selected patients. Radical vaginal trachelectomy has proven safe and effective for selected patients with small tumors who wish to preserve their fertility.

Comparative studies with primary radiation therapy have demonstrated an equal cure rate with primary radical surgery in the treatment of early-stage disease. However, the complications of irradiation are far more difficult to manage than are those of primary surgery. In young women, when preservation of ovarian function is important, primary surgery is a preferable choice of treatment.

The major limiting factor in the long-term surgical cure of cervical cancer is related to the spread of the disease at the time of initiation of treatment. Historically, in cases in which pelvic lymph nodes were positive for metastatic tumor, the 5-year cure rate was reduced to about 60%. However, numerous recently reported prospective, randomized trials have demonstrated the benefit of concurrent chemotherapy and radiation therapy in various settings. In the management of high-risk patients after radical hysterectomy and pelvic lymphadenectomy, including those with positive nodes, the reported 4-year disease-free survival is 80%.

It is important to understand that it is the individual surgical expertise that offers the highest cure rate and lowest incidence of complications to the patient with invasive carcinoma of the cervix. One of the greatest errors in clinical judgment made by the gynecologist who attempts a radical hysterectomy and pelvic lymph node dissection without adequate surgical training and experience. Unless the pelvic surgeon is performing this type of surgery regularly in a well-staffed medical center with trained assistants, he or she would be well advised to refer the patient to an established cancer center. From the patient's point of view, the initial treatment, whether primary surgery or irradiation, provides the best chance for long-term cure of this disease. It would be to her advantage to have the treatment conducted in the most expert hands because secondary treatment for recurrent disease offers only limited potential long-term cure.

The gynecologic surgeon who becomes thoroughly familiar with the pathology and natural history of cervical cancer, who appreciates the history of the development of radical hysterectomy and pelvic lymphadenectomy as primary treatment of the disease, and who then thoroughly masters the technical details of performing the operation can feel enormous pride in his or her achievement because there is no greater challenge in gynecologic surgery and no greater personal satisfaction than that which comes to those who are able to perform the operation correctly and save a woman from the intense suffering and undignified death that cervical cancer can cause.
Invasive cancer of the cervix is predominantly of squamous histology. Adenocarcinoma is increasingly common and now accounts for up to 20% of the lesions in some series. Adenocarcinoma, clear-cell, and small-cell neuroendocrine histology are seen infrequently. Tumor grade is not prognostically significant.

Although most women with early-stage cancer are asymptomatic, patients with larger tumors may have vaginal discharge, vaginal bleeding (postcoital, tampon), and eventually pelvic or low-back or hip pain. Leg edema and ureteral obstruction are signs of advanced disease.

A careful and thorough staging workup should be done after a diagnosis is made. This evaluation of the extent of disease is very important for treatment planning and prognosis. FIGO staging should be used, but the metastatic workup should not be limited by FIGO's restrictive guidelines.

Patients with microinvasion (stage IA1) are generally treated with cone biopsy or simple hysterectomy. Patients with stage IA2 disease should be treated by radical hysterectomy with pelvic lymphadenectomy. Most of these patients can be adequately treated by a modified radical hysterectomy (class II), but women with larger tumors and lymph-vascular space involvement may benefit from a traditional (class III) radical hysterectomy.

In the United States, most women with stage IB1 and stage IA2 cervical cancer are treated with radical surgery. Women with larger, higher-stage tumors are usually treated with radiation therapy plus adjuvant chemotherapy. Women who are poor surgical risks are also usually treated with radiation ± chemotherapy. The main advantage of surgery compared with radiation is the preservation of ovarian function, which is most advantageous in younger patients. There is also less risk of upper vaginal stenosis and dyspareunia following surgery. Bladder and rectal dysfunction and, rarely, fistulas occur with both surgery and radiation. Surgical complications tend to occur in the perioperative period, whereas complications and side effects from radiation are often delayed and long lasting.

Radical surgery for cervical cancer requires training, experience, and good ancillary support. This means well-trained operating room personnel, surgical assistants, and anesthesiastaff—as well as adequate radiology, intensive care, and consulting physicians—need to be a regular part of the patient care team.

In a radical hysterectomy for stage IB cervical cancer, we do not routinely do a paraaortic lymphadenectomy, but any palpable nodes are removed and sent for frozen section. The surgical procedure is abandoned if aortic lymph node metastases are identified.

Radical hysterectomy for cervical cancer can be done using the classic abdominal approach, a vaginal approach (Schauta), or a total laparoscopic approach. There are advantages and disadvantages to each of these techniques, but overall survival appears to be similar. The basic technique is the same.

In recent years, a fertility-sparing radical trachelectomy with laparoscopic lymphadenectomy has been described by Dargent. Women with stage IA and early IB1 tumors who wish to preserve fertility have been treated successfully, and the cure rates appear to be comparable to more radical surgery. More than 200 successful pregnancies following Dargent's operation have been reported.

CHAPTER 48 ■ ENDOMETRIAL CANCER

MARTA ANN CRISPENS

DEFINITIONS

Endometrial cancer staging—Consists of pelvic peritoneal washings, hysterectomy, bilateral salpingo-oophorectomy, pelvic and paraaortic lymph node dissection, performed either by laparotomy or by laparoscopy. Hereditary nonpolyposis colon cancer syndrome (HNPCC)—A hereditary cancer syndrome caused by inactivation of one of several DNA-mismatch repair genes. Patients are at increased risk of colon, endometrial, ovarian, uterine, or small bowel cancers. The lifetime risk of endometrial cancer in women with HNPCC is 40% to 60%. In approximately half of women with HNPCC, the endometrial cancer will occur before the colon cancer.

Type I endometrial cancer—Endometrial cancers that are typically of endometrioid pathology, low grade, and diagnosed at early stage and that have an excellent prognosis. These tumors are typically associated with exposure to unopposed estrogen. They account for approximately 90% of endometrial cancers.

Type II endometrial cancer—Endometrial cancers that are typically high grade and often of papillary serous or clear-cell pathology. They tend to be diagnosed at a later stage, but have a poor prognosis even if diagnosed at an early stage. The management of endometrial cancer has changed significantly over the last 40 to 50 years. During the 1970s, endometrial cancer was clinically staged. Patients with early-stage disease were treated with preoperative packing of the endometrial cavity with radiation sources, Heyman's capsules, and followed by hysterectomy. In 1988, the International Federation of Gynecology and Obstetrics (FIGO) approved a surgical staging system for endometrial cancer. This acknowledged the shift to surgery as primary therapy with pelvic radiotherapy being used postoperatively as adjuvant therapy for women at increased risk for recurrence. The last decade has seen a gradual move away from the use of adjuvant pelvic radiotherapy in patients who have been fully surgically staged. Laparoscopic surgery is becoming more important in the treatment of this disease.

The Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute tracks cancer incidence and mortality in the United States. SEER uses a three-tier staging system encompassing localized disease, which is limited to the organ in which the tumor arose; regional disease, which has spread beyond the primary site to nearby organs, tissues, or lymph nodes; and distant disease, which has spread from the primary site to distant organs or tissues. According to SEER data for the years 1993 to 1995, FIGO evaluated the outcomes of 6,260 patients worldwide, of whom 5,694 patients had surgical staging data available. Of these, 3,996 (70%) were stage I, 709 (12%) were stage II, 758 (13%) were stage III, and 231 (4%) were stage IV. The overall 5-year survival for all patients with endometrial cancer was 76.6%. Among surgically staged patients, 5-year survival was 87.4% for patients with stage I disease, 76.3% for patients with stage II disease, 56.6% for patients with stage III disease, and 17.8% for patients with stage IV disease.

EPIDEMIOLOGY

According to American Cancer Society (ACS) estimates, endometrial cancer remains the most common of the gynecologic malignancies in the United States, with 41,200 new cases anticipated in 2006. This makes it the fourth most common cancer occurring in women, behind only breast, lung, and colorectal cancer. It is estimated that there will be 7,350 deaths resulting from endometrial cancer in 2006. That most women with newly diagnosed endometrial cancer can expect a good prognosis is due to the fact that endometrial cancer is usually diagnosed at an early stage, when it is readily treatable with surgery alone. However, there remain a few patients with endometrial cancer who present with high-risk histologic subtypes or advanced-stage disease, in whom the prognosis is more guarded. The current FIGO staging system for endometrial cancer is shown in Table 48.1.

For the years 1993 to 1995, FIGO evaluated the outcomes of 6,260 patients worldwide, of whom 5,694 patients had surgical staging data available. Of these, 3,996 (70%) were stage I, 709 (12%) were stage II, 758 (13%) were stage III, and 231 (4%) were stage IV. The overall 5-year survival for all patients with endometrial cancer was 76.6%. Among surgically staged patients, 5-year survival was 87.4% for patients with stage I disease, 76.3% for patients with stage II disease, 56.6% for patients with stage III disease, and 17.8% for patients with stage IV disease.

The Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute tracks cancer incidence and mortality in the United States. SEER uses a three-tier staging system encompassing localized disease, which is limited to the organ in which the tumor arose; regional disease, which has spread beyond the primary site to nearby organs, tissues, or lymph nodes; and distant disease, which has spread from the primary site to distant organs or tissues. According to SEER data for the years 1993 to 2002 in the United States, 71% of patients had localized disease, 16% of patients had regional disease, 8% of patients had distant disease, and 4% of patients were unstaged. Overall 5-year survival for patients with localized disease was 96%, for patients with regional disease was 86%, for patients with distant disease was 26%, and for patients with unstaged disease was 57%.

In the United States, there is a significant disparity in the survival of African American women as compared with white women with endometrial cancer. According to SEER data, for the years 1994 to 2003, the age-adjusted total U.S. mortality rate from cancers of the uterus was approximately 7 per 100,000 for African American women, but only about 4 per 100,000 for white women. A number of explanations have been proposed for this racial disparity. Some have proposed...
that it is due to limited access to care for African American women. Others have suggested that there is an increased incidence of high-risk histologic subtypes and potential adverse molecular features among African American women as compared with white women.

In a review of data from the National Cancer Data Base from 1988 to 1994 by Hicks and colleagues, endometrial cancer was diagnosed in 32,107 non-Hispanic white and 3,226 African American women. Despite a lower incidence of endometrial cancer among African American women as compared with white women, African American women had a higher mortality rate. For the years 1988 to 1989, the 5-year overall relative survival rate for African American women in this study was 55%, as compared with 86% for white women. Among African American women, the tumors were generally diagnosed at later stage, were higher grade, and were more likely to be of an aggressive histologic subtype. The authors found that African American women were treated less often at every stage and were less frequently treated surgically than white women. This study strongly suggested that the poorer outcomes of African American women with endometrial cancer were due to racial disparities in treatment.

A subsequent review by Randall and Armstrong also demonstrated that African American women had a higher risk of death from endometrial cancer and were less likely to be treated surgically than white women. Even when controlling for tumor and sociodemographic factors, African American women had a hazard ratio for death from endometrial cancer of 1.8.

Other authors have suggested that the difference in survival between African American and white women is, in part, due to differences in tumor biology. Clifford and associates evaluated the incidence of overexpression of p53, a genetic alteration associated with the more aggressive type II endometrial cancers, in women with stage I endometrial adenocarcinoma. They found that p53 overexpression was three times more common among African American women than in white women. Schimp and coworkers have recently confirmed an increased incidence of p53 overexpression among African American women as compared with white women. Although they found that this correlated with an increased rate of type II endometrial cancers among African American women, they saw no difference in survival between African American and white women when adjusting for tumor type. Finally, in a study performed at the Memorial Sloan Kettering Cancer Institute, the gene expression profiles of endometrial cancers from African American and white women were compared. The two groups were matched for stage, grade, and histologic subtype. These investigators found no statistically significant difference in the gene expression profiles between these two groups.

The Gynecologic Oncology Group (GOG) has performed a retrospective analysis comparing the outcomes of 169 African American women to 982 white women with stage III, IV, or recurrent endometrial cancer being treated on one of four clinical trials. These trials evaluated the use of various chemotherapy regimens in the treatment of advanced stage or recurrent endometrial cancer. African American women were more likely than white women to have papillary serous histology, stage IV disease, and higher tumor grade. Even though the two groups of patients received similar treatment, survival among African American women was worse, suggesting some contribution of socioeconomic, biologic, or cultural factors in the poorer outcomes of these women. These data taken together suggest that there are both biologic and sociologic issues involved in the survival disparity noted between African American and white women with endometrial cancer.

### RISK FACTORS

There are no clear risk factors for type II endometrial cancers. Type I endometrial cancers are usually related to exposure to unopposed estrogen, whether exogenous or endogenous. Risk factors for type I tumors are summarized in Table 48.2.

**Histopathology: degree of differentiation**
- Grade 1: 5% or less of a solid growth pattern
- Grade 2: 6%–50% of a solid growth pattern
- Grade 3: More than 50% of a solid growth pattern

**Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or grade 2 tumor by 1.**

Uterine papillary serous carcinomas and clear-cell carcinomas of the endometrium are always high grade tumors, by definition.

**FIGO**, International Federation of Obstetrics and Gynecology.
Endometrial cancer incidence increases with age, until about 70 years, when rates begin to decline. Living in North America or Northern Europe and higher levels of income and education are associated with an increased risk of endometrial cancer. Endometrial cancer incidence is higher among whites than among African Americans, as already discussed.

Reproductive factors can be associated with an increased risk of endometrial cancer. Endometrial cancer risk is increased in women who are nulliparous, infertile, or have menstrual irregularities. Early onset of menarche or late age at menopause is also associated with an increased risk of endometrial cancer.

Estrogen replacement therapy is clearly associated with an increased risk of endometrial cancer. Several studies have shown either a statistically significant decrease or a nonstatistically significant trend toward a decrease in endometrial cancer risk among users of estrogen. This effect may be due to alterations in estrogen metabolism, a reduction in body weight among smokers, or an earlier age at menopause among smokers. However, smoking cannot be recommended as a chemopreventive measure for endometrial cancer.

Of the following are associated with an increased risk of endometrial cancer: higher socioeconomic status, residence in North America or Northern Europe, and higher levels of income and education. There is no increased risk of endometrial cancer associated with the use of aromatase inhibitors.

The ovaries may be a source of unopposed estrogen in women with anovulatory disorders, such as polycystic ovarian syndrome (PCOS). In a retrospective study of 128 patients with endometrial cancer, Pillay and colleagues found that among women younger than 50 years old, PCOS was significantly more prevalent among women with endometrial cancer than among normal controls. They observed no relationship between PCOS and endometrial cancer in postmenopausal women. Premenopausal women with PCOS should be counseled on the risk of endometrial cancer and the importance of hormonal therapy to maintain regular menstrual cycles. The optimal regimen of progesterin treatment is unknown. Estrogen-producing tumors, such as granulosa cell tumors of the ovary, may be another source of endogenous, unopposed estrogen.

Obesity is associated with an increased risk of endometrial cancer. Obesity increases circulating estrogens that are due to peripheral conversion of adrenal androgens to estrogens by the aromatase enzyme in adipocytes. Obesity also causes a decrease in serum sex hormone-binding globulin (SHBG) levels, leading to an increase in the amount of estrogen available to bind to its receptor. Diabetes has been found to be a risk factor for endometrial cancer independent of obesity. The exact mechanism is unknown but may be due to increased estrogen levels in diabetic women, hyperinsulinemia, or elevated levels of insulinlike growth factor-1 (IGF-I).

Conversely, factors that decrease exposure to unopposed estrogens decrease the risk of endometrial cancer. The Cancer and Steroid Hormone Study demonstrated that 12 months of oral contraceptive use decreased the risk of endometrial cancer by 40% and that the effect persisted for at least 15 years after the cessation of use. Smoking also decreases the risk of endometrial cancer. The exact mechanism is unknown. It may be due to alterations in estrogen metabolism, a reduction in body weight among smokers, or an earlier age at menopause among smokers. However, smoking cannot be recommended as a chemopreventive measure for endometrial cancer.

A number of studies have suggested a protective effect of intrauterine device (IUD) use on the risk of endometrial cancer. A large case-control study of 2,418 women in Shanghai, China, demonstrated an approximately 50% reduction in the risk of endometrial cancer among women who had ever used an IUD. Several other studies have shown either a statistically significant decrease or a nonstatistically significant trend toward a decrease in endometrial cancer risk among users of nonmedicated plastic or copper IUDs. The effect of progestin-containing IUDs is unknown.

Some phytoestrogens, weakly estrogenic compounds found in plants, may also decrease the risk of endometrial cancer. These compounds include the isoflavones, which are found in soybeans, and the lignans, which are found in whole grains, seeds, and dried fruit. There are likely multiple mechanisms by which this effect may occur. First, these compounds stimulate the production of SHBG. Estrogen in the circulation that is bound to SHBG is not available to bind to cellular estrogen receptors, resulting in a decrease in the amount of bioavailable estrogen in the circulation. Phytoestrogens also directly bind to the estrogen receptor, which blocks the binding of other estrogens. Phytoestrogens have such a weak estrogenic effect that this binding effectively decreases the growth and proliferation of estrogen-dependent cells. Finally, phytoestrogens may inhibit the aromatase enzyme in adipose tissue. A study by
Goodman and colleagues found that greater consumption of tofu with or without other soy products was associated with a 30% reduction in endometrial cancer risk. Another retrospective, case-control trial found that consumption of isoflavones and lignans was inversely associated with the risk of endometrial cancer.

More generally, a high-fat diet is associated with an increased risk of endometrial cancer. Conversely, diets rich in fruits and vegetables are associated with a decreased risk of endometrial cancer. Some studies have suggested that exercise may reduce the risk of endometrial cancer, even after controlling for the effects of body mass index and caloric intake.

Endometrial cancer is one of the components of the hereditary nonpolyposis colon cancer syndrome (HNPCC). The lifetime risk of endometrial cancer in women with HNPCC is 40% to 60%. This syndrome is caused by inactivation of one of several genes involved in DNA-mismatch repair. A family history of colon, endometrial, ovarian, uterine, or small bowel malignancy should prompt the clinician to consider referral of the patient for genetic counseling and possible genetic testing. Patients with HNPCC may consider chemoprevention with oral contraceptives, increased surveillance with serial endometrial biopsies or transvaginal pelvic ultrasounds, or risk-reducing surgery with hysterectomy and bilateral salpingo-oophorectomy.

### PROGNOSTIC FEATURES

The prognostic features for endometrial cancer have been well defined (Table 48.3). These include race, FIGO stage, depth of myometrial invasion, cervical or adnexal involvement, positive pelvic washings, metastasis to pelvic or paraaortic lymph nodes, histologic subtype, tumor grade, presence of lymph-vascular space invasion, and DNA aneuploidy. Of these factors, FIGO stage is the most important. For women with stage I endometrial cancers, prognosis depends primarily on tumor grade, histologic subtype, and depth of myometrial invasion.

Although positive pelvic peritoneal washings result in upstaging of patients to stage IB, the presence of positive pelvic peritoneal washings in the absence of other sites of metastasis probably does not have any adverse prognostic significance. Kasamatsu and colleagues found that in 280 women with surgically staged endometrial cancer, the presence of positive peritoneal cytology alone did not affect patient outcome. Instead, positive peritoneal cytology probably acts only to worsen the adverse prognosis of patients with other sites of metastatic disease. Thus, many patients with positive peritoneal cytology as their only site of metastatic disease do not receive additional treatment postoperatively.

### SCREENING FOR ENDOMETRIAL CANCER

The 2006 ACS guidelines for the early detection of cancer recommend that for average-risk, asymptomatic individuals, endometrial cancer screening should consist of education of women at the time of menopause regarding the risks and symptoms of endometrial cancer. Women should be strongly encouraged to report any unexpected bleeding or spotting to their physicians. Likewise, routine screening of asymptomatic women for endometrial cancer or its precursors is not recommended by the American College of Obstetricians and Gynecologists (ACOG).

Even women at mildly increased risk for endometrial cancer because of a history of unopposed estrogen therapy, tamoxifen use, late menopause, nulliparity, infertility, anovulation, obesity, diabetes, or hypertension do not benefit from routine screening for endometrial cancer, beyond the reporting of symptoms. The ACS recommends that women at high risk for endometrial cancer, such as women known or at substantial risk to be a carrier of an HNPCC mutation, should begin annual testing for endometrial cancer, usually with an endometrial biopsy, at the age of 35. However, this recommendation is based on expert opinion. There is no scientific evidence that this approach will result in earlier diagnosis or improved outcomes for these women.

Rijcken and associates reported on a screening program using annual transvaginal pelvic ultrasonography in 41 women who had known mismatch repair gene mutations or who were members of high-risk families. Seventeen of 179 transvaginal ultrasonograms were abnormal, leading to the performance of an endometrial biopsy. Three patients were found to have complex endometrial hyperplasia with atypia. One patient with stage IB, grade 2 endometrioid endometrial adenocarcinoma was diagnosed when the patient presented with interval reports of vaginal bleeding 8 months after having a normal ultrasound. In another trial, transvaginal pelvic ultrasound was offered to women with or at risk of having HNPCC. Results were available from 269 women with a total of 825.7 years of risk. Two cases of endometrial cancer were diagnosed, but neither was detected by surveillance scanning. Both patients developed abnormal bleeding and were found to have early-stage endometrial cancers. The findings of these two studies emphasize the importance of patient report and prompt physician evaluation of abnormal uterine bleeding for the early diagnosis of endometrial cancer, particularly in high-risk patients.

### EVALUATION OF THE SYMPTOMATIC PATIENT

Abnormal uterine bleeding is the most common presenting symptom of endometrial cancer. In a review of the pathologic findings among women with postmenopausal bleeding, Gredmark and colleagues found that the risk of adenomatous...
endometrial hyperplasia or cancer in a woman with postmenopausal bleeding is approximately 18%. The risk of malignancy increased with increasing age, with the peak incidence of endometrial cancer occurring in women between 65 and 69 years of age. The most common cause of postmenopausal bleeding was endometrial atrophy, which was identified in 50% of the patients. All patients with postmenopausal bleeding should undergo evaluation for possible endometrial cancer.

Endometrial cancer can also occur in premenopausal women and may present with heavy or irregular vaginal bleeding. Any women age 35 or older with abnormal bleeding should have uterine sampling performed. Young women with risk factors for endometrial cancer, such as obesity or anovulation, should also undergo endometrial sampling. A 25-year-old woman who experienced menarche at age 12, is obese, and has polycystic ovarian syndrome will already have experienced more than 10 years of exposure to unopposed estrogen.

There are multiple options for the evaluation of a woman with postmenopausal bleeding. One approach is to perform an office endometrial biopsy. This is typically accomplished with a Pipelle instrument, which is a disposable plastic catheter that can be placed through the cervix into the endometrial cavity for the aspiration of endometrial cells. Its use may occasionally require the placement of a single-toothed tenaculum on the cervix for countertraction or gentle cervical dilatation.

In a metaanalysis comparing endometrial sampling techniques, the Pipelle was found to be the most accurate. Among postmenopausal women, the sensitivity for detection of atypical endometrial hyperplasia was 81% and for the detection of endometrial cancer was 99.6%. The sensitivity of the device for the detection of endometrial cancer among premenopausal women was 91%. The specificity of the Pipelle device for the diagnosis of endometrial hyperplasia or malignancy was 98%. From 0 to 54% of patients will have failure of endometrial sampling. Farrell and coworkers have reported a 20% incidence of uterine pathology after an “insufficient” endometrial biopsy, with 3% of these patients having malignancy.

Another option for the evaluation of postmenopausal bleeding is transvaginal pelvic ultrasound to evaluate the endometrial stripe thickness. Gupta and associates in a metaanalysis found that among postmenopausal women with an endometrial stripe thickness of 5 mm or less, the risk of endometrial pathology was approximately 2%. These patients can be observed. If the patient has an endometrial stripe thickness of greater than 5 mm, she should undergo endometrial sampling.

Dilation and curettage (D&C) in the operating room has been considered the gold standard for endometrial sampling. However, even D&C fails to sample the entire endometrial cavity. Stock and Kanbour performed prehysterectomy D&Cs and found that in approximately 60% of patients, less than half of the endometrium had been sampled. There are limited data regarding the sensitivity and specificity of D&C for the diagnosis of endometrial hyperplasia and malignancy. However, studies have suggested that D&C may have a false-negative rate of as much as 10%. Thus, women with persistent postmenopausal bleeding despite a negative prior workup should undergo reevaluation.

Authors differ as to whether the addition of hysteroscopy improves the accuracy of D&C in the detection of endometrial neoplasia. Hysteroscopy may aid in the identification of occult uterine pathology, such as polyps or submucous myomas, and in the identification of small, focal lesions. Patients with endometrial cancer who undergo hysteroscopy may be more likely to have positive pelvic peritoneal washings than those who do not undergo hysteroscopy. There is currently no evidence that this results in decreased survival.

The most clinically and cost-effective sequence or combination of tests for the evaluation of postmenopausal bleeding has not been defined. Clark and colleagues performed a decision analysis comparing twelve different strategies for the evaluation of postmenopausal bleeding. They found that initial evaluation with either an office endometrial biopsy or a transvaginal pelvic ultrasound, with a normal endometrial stripe thickness being defined as 4 mm or less, was the most cost-effective strategy.

Based on a review of the literature, Moodley and Roberts recommended that transvaginal pelvic ultrasound should be the first step in the evaluation of postmenopausal bleeding, with an endometrial stripe thickness of less than 4 mm being defined as normal. They recommended office endometrial biopsy for those patients with an endometrial stripe thickness of less than 4 mm who were at high risk for endometrial cancer or who had persistent bleeding and for all patients with an endometrial stripe thickness greater than or equal to 4 mm. D&C was reserved for patients in whom office endometrial biopsy could not be successfully performed or resulted in an inadequate sample (Fig. 48.1).

ENDOMETRIAL HYPERPLASIA

Complex atypical hyperplasia of the endometrium is a premalignant condition. Kurman and coworkers found that 29% of patients with complex atypical hyperplasia who went untreated progressed to cancer. Treatment usually consists of hysterectomy with or without bilateral salpingo-oophorectomy. For young women who wish to retain their fertility or patients with comorbid conditions precluding surgery, treatment with systemic progestin or a progestin-containing IUD can be considered. This approach requires close follow-up and appropriate counseling of the patient regarding the risks. A more thorough sampling of the endometrium by D&C will identify endometrial cancer in approximately 42% of patients with a biopsy diagnosis of complex atypical endometrial hyperplasia.
Further, there are case reports describing progression to metastatic disease in patients with complex atypical hyperplasia being treated with progestin.

**SURGICAL STAGING AND TREATMENT**

**Rationale**

Endometrial cancer is surgically staged and treated. The procedure includes thorough exploration of the peritoneal contents, pelvic washings, hysterectomy, bilateral salpingo-oophorectomy, and bilateral pelvic and paraaortic lymph node dissection. Laparotomy has been the principle surgical approach to hysterectomy and staging for endometrial cancer. As will be discussed in more detail later in this chapter, the last 10 years have seen the increasing use of laparoscopy for endometrial cancer surgery. Because laparoscopic hysterectomy and lymph node dissection techniques are discussed in detail elsewhere in this textbook, the discussion below will focus on open techniques.

Type I endometrial cancers have three main patterns of spread: by direct extension, to regional lymph nodes, and hematogenously. The most common mechanism of spread for type I endometrial cancer is by direct extension, invading into the myometrium or by extension to the adjacent cervix. Hematogenous metastasis tends to occur late in the course of the disease. Type II endometrial cancers, particularly uterine papillary serous carcinomas, may also metastasize within the peritoneal cavity, similar to ovarian carcinomas.

Endometrial carcinoma spreads through three separate lymphatic pathways: Paracervical and parametrial lymphatics drain to the pelvic lymph nodes, ovarian lymphatics drain to the paraaortic lymph nodes, and round ligament lymphatics drain to the inguinal lymph nodes (Fig. 48.2). The lymphatic drainage of the uterine fundus and cervix directs most of the metastases to the pelvic lymph nodes. Although the paraaortic lymph nodes may be primary metastatic sites via spread through the infundibulopelvic ligament lymphatics, it is rare for an endometrial cancer patient to have isolated paraaortic lymph node metastases without concomitant pelvic lymph node metastases. Boronow and colleagues found that the incidence of isolated paraaortic lymph node metastases was only 1.5%.

GOG performed a large, prospective evaluation of the prognostic features associated with lymph node metastases in patients with apparent early-stage endometrial cancers. The presence of these features define a population of patients with endometrial cancers of intermediate risk, who have an approximately 15% to 20% chance of recurrence. This group included patients with grade 3 tumors with invasion of the inner one third of the myometrium, grade 2 or 3 tumors with invasion of the middle one third of the myometrium, cancer of any grade with invasion of the outer one third of the myometrium, presence of lymph-vascular space invasion, and/or extension to the cervix. Until recently, these patients were often treated with postoperative adjuvant pelvic radiotherapy. Although radiotherapy reduces the risk of pelvic recurrence, it has not been shown to improve survival in these patients.

In the past, the need for surgical staging with pelvic and paraaortic lymphadenectomy was determined based on pre- and intraoperative assessment of tumor grade and depth of invasion, as these are the factors most predictive of the risk of lymph node metastasis. Recently, there has been a shift toward the routine staging of the majority of patients with endometrial cancer. This has occurred for two reasons. First, pre- and intraoperative assessment of tumor stage and grade has been demonstrated to be inaccurate. Second, routine performance of lymphadenectomy in patients with early-stage endometrial cancer has been shown to improve survival. Patients with negative pelvic and paraaortic lymph nodes may be able to avoid pelvic radiotherapy and its attendant morbidity.

Many authors have demonstrated the inaccuracy of pre- and intraoperative evaluation of the stage and grade of endometrial cancers. Eltabakh and colleagues performed a retrospective analysis of 182 women with endometrial cancer who had a preoperative endometrial biopsy showing grade 1 disease. Among these patients, 30% had grade 2 or 3 tumors on final pathology, and 12.6% had stage III or IV disease diagnosed at surgery.

In a retrospective series of 153 patients, Frumovitz and associates have reported on the poor sensitivity and specificity of preoperative endometrial biopsies showing grade 1 disease. Among these patients, 30% had grade 2 or 3 tumors on final pathology, and 12.6% had stage III or IV disease diagnosed at surgery.
had no pelvic lymph nodes sampled. Patients undergoing multiple-site lymph node sampling had a survival of approximately 85%, whereas patients in whom pelvic lymph nodes were not sampled had a survival of approximately 6.5%, a statistically significant difference ($p = 0.002$). This survival advantage for patients with multiple-site lymph node sampling persisted even in a subgroup analysis of patients treated with postoperative pelvic radiotherapy.

The impact of routine surgical staging on the treatment of 181 women with a preoperative diagnosis of grade I endometrioid adenocarcinoma of the endometrium was evaluated by Ben-Shachar and coworkers. Surgical staging was performed in 65% of cases and was omitted only when the disease was apparently confined to the endometrium and the surgical risk was high. High-risk uterine features—including greater than one half myometrial invasion, grade 3 tumors, high-risk histologic variants, and/or cervical extension—were identified in 26% of patients. Lymph node metastases were identified in 3.9% of patients. Overall, the findings of the surgical staging procedure significantly affected postoperative treatment decisions in 29% of patients. This includes 12% of patients who were determined to need adjuvant therapy and 17% of patients who were able to forego external-beam whole-pelvic radiotherapy or chemotherapy. The incidence of severe surgical complications in the surgically staged group was 3.2%.

Pelvic and paraaortic lymph node sampling in patients with endometrial cancer is not associated with a significant increase in surgical morbidity. Homerley and colleagues compared the outcomes of 196 patients undergoing hysterectomy with pelvic and paraaortic lymph node sampling for endometrial cancer with those of 104 patients who underwent hysterectomy alone. They found an increased operative time and higher blood loss among women undergoing lymph node dissection, but no difference in overall complication rates. Other complications were found to be primarily related to other factors, such as patient age and weight. Chuang and associates reported a series of 295 patients with endometrial cancer, 193 (65%) of whom had lymph node sampling performed. They noted two intraoperative injuries (one ureteral transection and one major venous laceration) that apparently were repaired without sequelae. They believed that the information gained from the dissection greatly outweighed the operative risk.

Certain medical problems may alter the safety of the pelvic and paraaortic lymphadenectomy. In patients with medical comorbidities, the small added time and blood loss required to perform bilateral pelvic and paraaortic lymph node sampling may be prohibitive. Additionally, in very obese patients, exposure may be compromised. No attempt at lymph node removal should be undertaken if adequate exposure is not possible.

### Preoperative Assessment and Preparation

As noted above, many patients with endometrial cancer may be older and have multiple medical comorbidities. Thus, preoperative preparation is important. All patients should have a thorough history and physical examination. The history should assess the length and severity of the patient’s bleeding or other presenting symptoms. It should also assess for symptoms of metastatic disease, such as abdominal or pelvic pain, changes in bowel or bladder function, lower extremity pain or swelling, abdominal bloating, early satiety, shortness of breath, or cough. Previous medical history and symptoms suggestive of occult cardiopulmonary disease or other medical illnesses should be ascertained. Careful attention should be paid to the family history, as endometrial cancer may develop before colon cancer in 50% of women with HNPCC.

The physical examination should focus on assessment for supraclavicular and inguinal lymphadenopathy, abdominal distension or fluid wave suggestive of ascites, abdominal masses, and lower extremity edema. On pelvic examination, close attention should be paid to possible vaginal or cervical extension of disease. Uterine size and mobility, the presence of adnexal masses, parametrical extension, and cul-de-sac nodularity should be assessed.

Basic laboratory evaluation should include a hematocrit and type and screen. CA-125 testing is not indicated, except in patients with uterine papillary serous carcinoma. A chest x-ray should be performed both to rule out lung metastases and evaluate for concurrent pulmonary disease. An electrocardiogram will be needed in most patients for preoperative assessment for potential cardiac disease. Extensive preoperative radiographic assessment for metastatic disease with computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomography (PET) is not indicated, unless the history or physical examination is suggestive of distant disease. This would be most likely to occur in patients with uterine papillary serous or clear-cell carcinomas. Other preoperative testing should be performed as dictated by the patient’s history and physical findings, and may include complete blood count, electrolytes, and assessment of hepatic and renal function. For patients with multiple medical comorbidities, preoperative cardiac, pulmonary, or other medical consultation may be necessary. In such patients, preoperative consultation with the anesthesiologist may also be of benefit.

Once a patient has completed her preoperative evaluation and has been cleared for surgery, she should be counseled regarding her options for therapy, including surgical therapy; primary pelvic radiotherapy, which is usually reserved for patients who are not good candidates for surgery; and no therapy. Patients should be thoroughly counseled on the indications, risks, and benefits of surgery; that there is no guarantee as to outcome; and that further therapy in the form of additional surgery, chemotherapy, or radiotherapy may be necessary. The patient and her family should be given the opportunity to have all of their questions answered. Written informed consent should be signed.
Preoperative preparation of the patient who is to undergo lymphadenectomy should include a mechanical bowel prepara-
tion to decompress the small bowel. Standard preoperative antibiotic prophylaxis for hysterectomy should be used, typ-
ically with cefazolin 1 to 2 g intravenously given 30 minutes before incision. Metronidazole can be used in patients with a
history of immediate hypersensitivity reaction to penicillin.

The anterior abdominal wall is then incised using a large Richardson retractor. The omentum is
assisted to elevate the anterior abdominal wall at the apex of the incision using a large Richardson retractor. The omentum is

retracted anteriorly with a vein retractor. Blunt dissection is crossed over the external iliac artery. The external iliac vein is tally along the superior vesical artery. The inferior margin of iliac vein, and anterior to the hypogastric artery, extending dis- and medial to the external iliac artery, medial to the external node–bearing tissues in the pelvis. This should include the tis- pararectal space is opened by bluntly dissecting between the pubic ramus, staying lateral to the superior vesical artery. The space can be opened by bluntly dissecting the bladder off the opposite side of the dissection. The peritoneum should be incised to be sure that there has been no injury to the surrounding tissue–figure-of-eight sutures. The pelvis is copiously irrigated, and the vagina is tied. Any remaining open vagina is closed with sutured with Heaney sutures, and the suture in the middle of the vagina and to decrease bleeding. The lateral pedicles are vaginal apex between the two clamps and held, to decrease curved scissors. A figure-of-eight suture is placed through the fallopian tubes, and bilateral ovaries—is now amputated with this is best done with a curved Haney clamp.

the ligaments can be clamped, cut, and ligated separately. Often, to the last pedicle so as not clamp the ureter. The uterosacral ligaments can be clamped, cut, and ligated separately. Often, this is best done with a curved Haney clamp.

When the cervicovaginal junction is reached, either a right- angled Zeppelin clamp or a curved Heaney clamp, depending on the size of the cervix and vagina, is used to clamp across the upper vagina from either side, approximately 1 cm below the uterine cervix. This is performed in addition to any bilateral fallopian tubes, and bilateral ovaries—is now amputated with curved scissors. A figure-of-eight suture is placed through the vaginal apex between the two clamps and held, to decrease contamination of the peritoneal cavity with the contents of the vagina and to decrease bleeding. The lateral pedicles are sutured with Heaney sutures, and the suture in the middle of the vagina is tied. Any remaining open vagina is closed with figure-of-eight sutures. The pelvis is copiously irrigated, and hemostasis is assured. The pelvis should be carefully examined to be sure that there has been no injury to the surrounding pelvic organs, particularly the bladder, rectum, and ureters.

Attention can now be turned to the pelvic and paraaortic lymph node dissection. The bowel will need to be packed to the op- postive side of the dissection. The peritoneum should be incised superio- rly along the white line of Toldt. The colon can then be mobilized bluntly anteriorly and medially. The paravesical space can be opened by bluntly dissecting the bladder off the pubic ramus, staying lateral to the superior vesical artery. The pararectal space is opened by bluntly dissecting between the ureter and hypogastric artery.

The colon and ureter can be retracted with a large Deaver retractor, which should be oriented toward the contralateral shoulder. Sharp dissection with Metzenbaum scissors with hemoclips for hemostasis can be used to excise the fatty, lymph node–bearing tissues in the pelvis. This should include the tis- sues anterior and medial to the common iliac artery, anterior and medial to the external iliac artery, medial to the external iliac vein, and anterior to the hypogastric artery, extending dis- talls along the superior hypogastric plexus. The inferior margin of the dissection is the point at which the circumflex iliac vein crosses over the external iliac artery. The external iliac vein is retractored anteriorly with a vein retractor. Blunt dissection is performed within the obturator space to reveal the course of the obturator nerve. The lymph nodes anterior to the obturator nerve are removed.

The left paraaortic lymph node dissection is extended from the level of the bifurcation of the common iliac artery superiority along the lateral aspect of the aorta. Care must be taken not to extend the dissection too far posteriorly, where the lum- bar arteries arise from the aorta. On the right, the paraaortic lymph node dissection is performed superiority, along the ante- rior surface of the superior vena cava. Small, perforating vessels are numerous on both sides, so careful hemostasis as the dis- section proceeds is important. Because paraaortic lymph node metastases from the uterus usually present direct extension from pelvic lymph node metastasis, it is usually necessary to ex- tend the dissection only to the level of the inferior mesenteric artery.

Special Situations

Uterine papillary serous carcinomas behave in a manner sim- ilar to ovarian cancers, demonstrating spread within the peri- toneal cavity even when the primary tumor is confined to the endometrium. Goff and associates evaluated the patterns of spread in patients with noninvasive uterine papillary serous car- cinomas and found that with complete surgical staging, 36% of patients were found to have lymph node metastases and 43% of patients were found to have intraperitoneal metastases. Chan and coworkers found that 25% of patients with noninvasive uterine papillary serous carcinomas had occult omen- tal disease. Thus, staging of patients with uterine papillary serous carcinoma should include hysterectomy with bilateral salpingo-oophorectomy, peritoneal washings and biopsies, bi- lateral pelvic and paraaortic lymph node dissection, and omen- tectomy, as is typically performed for ovarian cancer.

For patients with stage IB endometrial cancers with a bulky cervix, there is a risk of parametrial extension, as for primary cervical carcinomas. Further, it can sometimes be difficult to distinguish between a primary cervical adenocarcinoma with extension to the cervix versus a primary cervical ade- nocarcinoma that may extend into the lower uterine segment or above. These patients may be treated similarly to cervical cancer patients with a radical hysterectomy and pelvic and paraaortic lymphadenectomy. Five-year survival rates of 90% to 94% have been reported for this treatment strategy.

The alternative is to treat these patients with preopera- tive external beam whole-pelvic radiotherapy and intracavi- try brachytherapy followed by completion hysterectomy with bilateral salpingo-oophorectomy. Completion hysterectomy is nec- essary, as radiotherapy is not as effective in treating disease in the uterine corpus as in the uterine cervix. Reisanger and col- leagues reported a 5-year actuarial survival of 82% in patients with endometrial histology treated with this strategy. Patients with high-risk histologic subtypes had only a 38% 5-year actu- arial survival, with a high incidence of recurrence in the upper abdomen.

In patients with stage III or IV endometrial cancers, tumor debulking may be of benefit. Goff and associates reported on 47 patients with stage IV endometrial cancer. Overall median survival for these patients was 12 months. Among those pa- tients who underwent successful cytoreduction, overall median survival was 18 months as compared with 8 months among pa- tients who did not undergo cytoreduction. Similar survival ben- efits have been reported in a series of 55 patients with stage IV endometrial cancer, overall median survival was 31 months for those whose disease could be optimally cytoreduced to less than
or equal to 2 cm residual disease, 12 months for those whose disease was suboptimally cytoreduced, and 3 months for those whose disease was uncontrollable \( p < 0.001 \). Lamber and colleagues also evaluated the efficacy and safety of cytoreductive surgery in patients with stage III and IV endometrial cancer. They excluded patients with uterine papillary serous carcinomas and clear-cell carcinomas. They found that optimal cytoreduction was greater than or equal to 95% in 51% of patients and only 6.7 months for patients with minimal residual disease was possible in 72% of their patients. Overall median survival was 17.8 months for patients undergoing optimal cytoreduction and only 6.7 months for patients who could not be optimally cytoreduced \( p = 0.001 \). Further, they observed that the proportion of patients having major postoperative complications was actually higher among those who were suboptimally cytoreduced as compared with those who were not, 37.5% versus 7.25%, respectively \( p = 0.005 \). Brostow and coworkers evaluated the survival benefit of lymph node debulking among patients with stage IIIC endometrial cancer. All patients had macroscopic spread to pelvic lymph nodes, and approximately 50% had microscopic involvement of the paraaortic lymph nodes. Disease-specific survival was 37.5 months among patients whose involved lymph nodes could be completely resected as compared with 8.8 months among patients whose involved lymph nodes could not be completely resected \( p = 0.006 \).

Role of Laparoscopy

Multiple surgeons have published data demonstrating the feasibility of laparoscopic staging and treatment of endometrial cancer. These studies consistently demonstrate that the laparoscopic approach is associated with significantly decreased blood loss and shorter hospital stays when compared with open laparotomy. Postoperative complication rates of patients undergoing laparoscopy are typically reported as comparable to or lower than those of patients undergoing laparotomy. The overall cost of laparoscopy has been shown to be equal to or lower than that for laparotomy. Although laparoscopy is associated with increased equipment costs, this is balanced by the increased hospital costs of patients undergoing laparotomy. Short-term quality of life has been shown to be improved in patients undergoing laparoscopy, with decreased need for pain medications postoperatively and faster return to work.

Despite the apparent benefits of laparoscopy, gynecologic oncologists in the United States have been slow to embrace this surgical approach. In fact, most of the United States data regarding the use of laparoscopy for the treatment of endometrial cancer comes from a very limited number of surgeons and centers, who have developed special expertise in this technique. For these individuals, operative times are only slightly longer than for laparotomy, and rates of conversion to laparotomy are comparable to or lower than those of patients undergoing laparotomy. The surgeon must choose the approach that allows him or her to best care for the patient with the least risk of complications. Although for certain surgeons this may be laparoscopy, there are many surgeons for whom laparotomy remains the best and safest approach. On the other hand, it is incumbent on all surgeons to continue to advance our skills throughout our surgical careers so that we may provide the most effective and safest surgical management for our patients.

Radiation Therapy

At the present time, radiation therapy is rarely used as the primary or sole treatment modality for women with endometrial cancer. The goal of postoperative radiotherapy in patients with endometrial cancer is to treat the pelvic lymph node beds with external-beam whole-pelvic radiotherapy and upper vagina with vaginal vault brachytherapy. This has been demonstrated to decrease the risk of local recurrence, but not to improve survival. With the increasing use of surgical staging with pelvic and paraaortic lymph node dissection, the use of adjuvant pelvic radiotherapy has decreased.

Patients with low-risk endometrial cancer, stage IA or IB, grade 1 or 2, require no additional treatment postoperatively. The PORTEC trial was a randomized trial of postoperative radiotherapy versus observation in 714 patients with stage IB, grade 2 or 3 and IC, grade 1 or 2 endometrial cancer who had undergone hysterectomy and bilateral oophorectomy. These patients had not undergone lymph node dissection. At 10 years, the pelvic failure rate was 5% in the patients who received pelvic radiotherapy and 14% among
controls (p < 0.0001). However, there was no statistically sig- nificant difference in survival, with an overall survival of 66% among patients who received pelvic radiotherapy and 73% among controls (p = 0.09).

Straughn and colleagues performed a retrospective review of 613 patients with stage I/endometrial cancer who had under- gone comprehensive surgical staging. Among 325 patients with stage IB disease, 121 (38%) patients received pelvic radiation therapy. Fif- teen (5%) of these patients recurred. All nine local recurrences were salvaged. There were 77 patients with stage IC disease, of whom 53 (69%) did not receive pelvic radiotherapy. Four (8%) patients recurred, and three of them were salvaged. For all stage I patients, the 5-year disease-free survival was 93% and overall survival was 98%. These authors concluded that pelvic radiotherapy is not needed in patients who have under- gone comprehensive surgical staging because of the low risk of recurrence and high salvage rate with subsequent therapy.

In a follow-up to this study, Straughn and colleagues sub- sequently evaluated an expanded cohort of 220 patients with stage IC endometrial cancer. Ninety-nine (45%) patients were treated with radiation therapy—either external beam whole pelvic, vaginal cuff brachytherapy, or both—and 121 (55%) patients were observed. There was no statistically significant difference in the recurrence rate between the two groups. The overall 5-year survival was 92% for the patients who received radiotherapy and 90% for those who were observed. There was noted to be an improved 5-year disease-free survival of 93% among the radiated patients as compared with 75% among those who were observed. The overall salvage rate for patients who recurred was 64%.

In a separate report from the PORTEC trial, there were 99 evaluable patients with stage IC, grade 3 endometrial cancers. All of these patients were treated with pelvic radiotherapy. The 5-year disease-free survival for this group was 58%, which is sig- nificantly lower than that found by Straughn and colleagues among patients with stage IC disease. It is important to re- member that patients in the PORTEC trial did not undergo pelvic and paraaortic lymph node dissection. The difference in survival noted is likely largely due to upstaging of patients with microscopic lymph node metastases in the Straughn se- ries. However, it is important to note that the use of pelvic radiotherapy in the PORTEC trial did not salvage these un- staged patients, again suggesting a therapeutic role for pelvic and paraaortic lymphadenectomy. Because of the higher risk of recurrence among patients with stage IC disease, particularly those with grade 3 disease, these patients are often considered for adjuvant postoperative radiotherapy, even after complete surgical staging.

Pelvic radiotherapy does carry a significant risk of compli- cations. Among the randomized patients in the PORTEC trial, 5-year complication rates were 17% in the radiated patients and 9% in the controls, with all severe complications (3%) occurring in the radiated group.

Patients with pelvic and/or paraaortic lymph node meta- statics are usually treated with postoperative radiotherapy di- rected to the involved nodal basins. Nelson and associates reported a 5-year disease-free survival rate of 72% for pa- tients with pelvic lymph node metastases treated with pelvic or whole-abdominal radiotherapy. Rose and coworkers demon- strated improved survival for patients with paraaortic lymph node metastases who were treated with paraaortic radiother- apy as compared with those who were not treated with paraaar- tic irradiation.

The optimum postoperative treatment for patients with uterine papillary serous carcinoma remains controversial. Both whole-abdominal radiotherapy and platinum-based chemotherapy have been used. The prognosis for this disease is poor, and adjuvant therapy is often recommended, even for patients with early-stage disease.

Patients stage I or II endometrial cancers who are not surgically candidates because of medical comorbidities are sometimes treated with primary pelvic radiotherapy. In a review of the ex- perience at Yale from 1973 to 1992, 4.3% of all patients with stage I or II endometrial cancer were defined medically inop- erable and treated with pelvic radiotherapy alone. The 5-year disease-specific survival rate for inoperable patients with stage I disease was 80%, which was significantly less than that for operable patients at 98%. Notably, the overall 5-year survival of medically inoperable patients was only 30%, as compared with 88% for operable patients, demonstrating that many of these patients succumb to their intercurrent medical illnesses. Another treatment option for selected medically ill patients is vaginal hysterectomy.

SYSTEMIC THERAPY

Patients with advanced or recurrent endometrial cancer are of- ten treated with cytotoxic chemotherapy. A recent GOG trial has demonstrated that for patients with stage III or IV endome- trial cancer, chemotherapy with doxorubicin and cisplatin is su- perior to whole-abdominal radiotherapy. Another GOG trial has demonstrated the superiority of doxorubicin, cisplatin, and paclitaxel (TAP) with filgrastim support over doxorubicin and cisplatin. This multiagent regimen was associated with sig- nificant toxicity, including thrombocytopenia, gastrointestinal problems, and neurotoxicity. A current GOG trial compares this regimen with the less toxic combination of carboplatin and paclitaxel.

Hormonal therapy is also an option for patients with advanced-stage disease. Both progestins and tamoxifen have been used. A recent study by Fiorica and coworkers demon- strated a median overall survival of 14 months in patients with advanced endometrial cancer treated with an alternating regi- men of megestrol acetate and tamoxifen. Hormonal therapy tends to work best in patients with grade 1 endometrioid ade- nocarcinomas, which express estrogen and progesterone re- ceptors. Progestational therapy is sometimes used as fertility- conserving surgery in young patients with complex endometrial hyperplasia with atypia or grade 1 endometrial cancers. Close monitoring is required to assure patients are having an appro- priate response. The major side effect of hormonal therapy is thromboembolic disease.

INCIDENTAL DIAGNOSIS OF ENDOMETRIAL CANCER AT HYSTERECTOMY

For patients who undergo hysterectomy and have the unex- pected diagnosis of endometrial cancer, there are three options: observation, reoperation for staging, or pelvic radiotherapy. Treatment decisions need to be individualized and will depend on the risk of nodal or extratumor spread, which may be esti- mated from the tumor grade, depth of invasion, and evidence of lymphadenopathy on CT of the abdomen and pelvis. The patient’s medical status and her willingness to undergo fur- ther surgery or radiotherapy must also be taken into account. Consultation with a gynecologic oncologist should be strongly considered.
The appropriate follow-up for any malignancy is dependent on the pattern of recurrence. This will differ somewhat for type I and type II endometrial cancers. Adders and associates evaluated 779 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital between 1960 and 1976. Local recurrence was observed in 50%, distant recurrence was observed in 29%, and both local and distant recurrence was observed in 21%. Patients who had received postoperative pelvic radiotherapy were much less likely to recur than those who did not. One third of patients were diagnosed with recurrence within 1 year after the completion of therapy, and two thirds of patients were diagnosed with recurrence within 3 years. There is no single accepted follow-up strategy for patients with endometrial cancer. Physicians have often recommended routine follow-up visits at 3- to 6-month intervals with vaginal cytology at each visit and an annual chest radiograph. Recent studies by multiple groups have demonstrated that this surveillance protocol is neither clinically nor cost effective. These studies demonstrate that 60% to 75% of patients will be symptomatic at the time of recurrence. Most patients with curable recurrences had vaginal bleeding from a vaginal lesion. Curable asymptomatic recurrences were uncommonly detected by routine screening.

Cooper and associates reported that among women with endometrial cancer, 430 Pap tests were required to detect one asymptomatic vaginal recurrence at an additional cost of $15,142 per asymptomatic recurrence detected. Berchuck and colleagues found that the salvage rate for patients with vaginal recurrences diagnosed by vaginal cytology alone was no different than that for women with a visible lesion. They also observed that no patient with an isolated pulmonary recurrence diagnosed by chest radiograph was salvaged. In a similar study from Canada by Shumsky and coworkers, no isolated vaginal recurrence was diagnosed by Pap test alone. Similar to the Duke study, no patients with an isolated pulmonary metastasis diagnosed by chest x-ray was cured.

Despite the limited ability of routine follow-up to improve the outcomes of women with recurrent endometrial cancer, both patients and their physicians continue to favor some form of posttreatment surveillance. As emphasized by Berchuck and colleagues, continuing to be followed for some period of time by her oncologist and having a normal periodic exam likely provides some psychological reassurance to the patient. The focus should be on detection of vaginal recurrences, because most of these patients can be salvaged.

Effective therapy is typically not available for patients who recur at distant sites. Given these observations, routine surveillance for patients with endometrial cancer should include education of patients regarding the symptoms of recurrence, particularly vaginal bleeding, abdominal pain, or back pain, leg swelling, abdominal bloating, cough, or shortness of breath. Symptomatic patients should be instructed to report promptly for evaluation. The recent ACOG Practice Bulletin on the management of endometrial cancer suggests that women with endometrial cancer be seen in follow-up every 3 to 4 months for 2 to 3 years, then every 6 months. Berchuck and colleagues recommend biannual follow-up visits. Most authors agree that patients can return to routine annual well-woman care after 5 years. Each visit should include a thorough review of systems to evaluate for symptoms of recurrence and a focused physical exam, including lymph node survey, abdominal examination, and pelvic examination with speculum exam, bimanual exam, and rectovaginal exam. Routine surveillance with Pap testing and chest radiographs cannot currently be recommended. Other studies should be obtained as dictated by the findings of the patient’s history and physical examination.

Certain groups may require modifications of this follow-up scheme. For example, patients with uterine papillary serous carcinoma are often followed with serial CA-125 determinations, similarly to patients with ovarian cancer. They are much more likely than patients with endometrial cancers to recur with peritoneal carcinomatosis. Patients who have been treated with radiation and/or chemotherapy may need more intensive follow-up to monitor them for long-term complications of their therapy. Again, there are no data to suggest that more intensive follow-up results in improved salvage rates.

FUTURE DIRECTIONS

As with all malignancies, the future will see increasing use of molecular staging to identify patients at risk for recurrence. This should allow for greater individualization of therapy. COG is currently conducting a molecular staging study in endometrial cancer. Laparoscopic and robotic surgical techniques will continue to evolve. Complete lymphadenectomy may decrease in importance if sentinel lymph node techniques can be developed, as in melanoma and breast cancer. Chemotherapy is likely to play an increasing role in the therapy of advanced-stage and recurrent disease.

BEST SURGICAL PRACTICES

- Given that patients with endometrial cancer are often older and have multiple medical comorbidities, preoperative preparation is important. The preoperative history and physical examination should assess both the nature of the patient’s presenting symptom and for occult cardiopulmonary and other medical illnesses. For patients with multiple medical comorbidities, preoperative cardiac, pulmonary, and anesthesiology consultation should be considered. Extensive preoperative assessment for metastatic disease with CT, MRI, or PET is unnecessary.

- When beginning the hysterectomy, the bilateral uterine cornua are grasped with long Kelly or similar clamps, occluding the fallopian tubes. This allows manipulation of the uterus while preventing efflux of malignant cells via the tubes during the course of the hysterectomy. To avoid contaminating the pelvis with malignant cells from the uterus, a tenaculum, Leahy, or other perforating clamp should not be placed on the uterine fundus.

- In clamping the uterine artery and cardinal ligament pedicles, the clamp should be placed just against the cervix and not “rolled off” the cervix. The practicing of rolling the clamp off the cervix may cause the lateral cervix to be caught in the clamp, with risk of leaving residual cervix (and tumor) behind.

- Pre- and intraoperative assessment of tumor stage and grade have been shown to be inaccurate. Pelvic and paraaortic lymphadenectomy has been shown to have a therapeutic effect in patients with endometrial cancer. The results of full staging may change treatment in almost one third of patients. Thus, routine pelvic and paraaortic lymph node dissection should be considered for most patients with endometrial cancer. The use of postoperative,
Laparoscopic hysterectomy and staging has been shown to be feasible for patients with endometrial cancer. CHAPTER 49 ■ OVARIAN CANCER: ETIOLOGY, SCREENING, AND SURGERY

JOHN R. VAN NAGELL JR. AND DAVID M. GERSHENSON

DEFINITIONS

BRCA 1 gene—A tumor suppressor gene located on the long (q) arm of chromosome 17. Germline mutations in this gene are responsible for 80% to 90% of hereditary ovarian cancers.

BRCA 2 gene—A tumor suppressor gene located on the long (q) arm of chromosome 13. Germline mutations in this gene are responsible for 15% of hereditary cancers.

Genetic penetrance—The frequency with which patients with a known genetic abnormality demonstrate a pheno-
typic abnormality.

Hereditary breast-ovarian cancer syndrome (HBOC)—A syndrome characterized by multiple cases of early-onset (<50 years of age) breast and ovarian cancers. It is the most common of the familial ovarian cancer syndromes, making up 75% to 90% of all hereditary ovarian cancers.

Hereditary nonpolyposis colon cancer syndrome (HNPCC) or Lynch II syndrome—A syndrome characterized by early-onset (<50 years of age) proximal colon cancer associated with cancers of the ovary and endometrium. It is caused by a mutation in one of several mismatch repair, most commonly MLH1 and MSH2. It makes up approximately 5% to 10% of all hereditary ovarian cancers.

Hereditary site-specific ovarian cancer syndrome (HSSOC)—A syndrome characterized by multiple cases of early-onset (<50 years of age) ovarian cancer. It makes up approximately 5% of all hereditary ovarian cancers.

Intrapertioneal chemotherapy—Cytotoxic chemotherapy given intraperitoneally rather than intravenously. This is usually given via an intraperitoneal catheter in patients who have undergone optimal cytoreductive surgery.

Neoadjuvant chemotherapy—Chemotherapy given before definitive surgery to chemically debulk cancer with the intention of making future surgical efforts more successful and less complicated. Usually, several cycles of chemotherapy are given to women with advanced ovarian cancer who are poor surgical candidates because of their medical condition or perhaps the extent of disease. At the start of therapy, surgical debulking is planned if there is a response to chemotherapy, although surgery may not occur if the patient does not respond to chemotherapy or her medical condition fails to improve.

Optimal cytoreduction—Survival is related to the volume of residual cancer after initial surgery. It is preferable to remove as much tumor as possible. The definition of op-
timal cytoreduction has continued to change over the years and currently means surgical debulking so that the largest residual tumor mass is less than 1.0 or even 0.5 cm in di-
ameter.

Ovarian tumor morphology indexing—A quantitative analysis relating tumor morphology from sonographically generated images to risk of malignancy.

Proteomics—Analysis of the expression, localization, function, and interaction of the proteins expressed by the genetic material of an organism.

Ovarian cancer is the leading cause of death from gynecologic malignancies in the United States. In 2006, more than 20,000 new cases of ovarian cancer was detected and more than 13,000 women would die from the disease. The lifetime risk for ovarian cancer in American women without a family history of the disease is 1 in 70 (1.4%). Because early ovarian cancer produces few specific symptoms, most women present with advanced-stage disease, for which the cost of treatment is high and the prognosis poor. Approximately 90% of malignant ovarian tumors in adults are of epithelial origin followed by sex cord–stromal tumors (6%) and germ-cell tumors (3%). Good surgery is a blend of good judgment and sound surgical tech-
nique. Much of this chapter is devoted to the natural history and results of various surgical and other treatment approaches for ovarian cancer. This background information provides the surgeon with the basis for clinical decision making concerning patient selection, choice of the right operation, and postop-
ervative treatment recommendations. The operative techniques involved in surgery for ovarian cancer are illustrated in many of the other chapters in this text.

INCIDENCE AND RISK FACTORS

The incidence of ovarian cancer is highest in Sweden (19.6/100,000) and the United States (15.4/100,000), and lowest in Japan (10.1/100,000). In the United States, ovarian cancer incidence rates are highest in Caucasian women, inter-
mediate in African American women, and lowest in Native American women.

Factors associated with an increase in ovarian cancer risk are age, nulliparity, and a family history of the disease. Ovarian cancer is rare before the age of 40, increases steadily thereafter, and peeks at ages 65 to 75. Parity is the most important non-

genetic factor affecting risk for ovarian cancer (Table 49.1).

Incidence of ovarian cancer is the leading cause of death from gynecologic malignancies in the United States. In 2006, more than 20,000 new cases of ovarian cancer was detected and more than 13,000 women would die from the disease. The lifetime risk for ovarian cancer in American women without a family history of the disease is 1 in 70 (1.4%). This background information provides the surgeon with the basis for clinical decision making concerning patient selection, choice of the right operation, and postop-
ervative treatment recommendations. The operative techniques involved in surgery for ovarian cancer are illustrated in many of the other chapters in this text.

The incidence of ovarian cancer is highest in Sweden (19.6/100,000) and the United States (15.4/100,000), and lowest in Japan (10.1/100,000). In the United States, ovarian cancer incidence rates are highest in Caucasian women, inter-
mediate in African American women, and lowest in Native American women.

Factors associated with an increase in ovarian cancer risk are age, nulliparity, and a family history of the disease. Ovarian cancer is rare before the age of 40, increases steadily thereafter, and peeks at ages 65 to 75. Parity is the most important non-

genetic factor affecting risk for ovarian cancer (Table 49.1).
According to this theory, risk for epithelial ovarian cancer is related directly to the number of uninterrupted ovulatory cycles. With ovulation, the surface epithelium is ruptured and then undergoes rapid proliferation and repair. At the time of ovulation, there is invagination of the surface epithelium into the underlying stroma forming inclusion cysts. The epithelium lining these inclusion cysts then undergoes neoplastic transformation under the influence of oncogenic factors. The observation that early age of menarche and late menopause are associated with an increase in ovarian cancer risk is consistent with this theory, because both increase the number of ovulatory cycles.

A second theory of ovarian carcinogenesis is the retrograde menstruation hypothesis. According to this hypothesis, retrograde transportation of carcinogens from the uterus and lower genital tract through the fallopian tube to the ovary occurs at the time of menstruation. The protective effect of oral contraceptives is consistent with this hypothesis, because their use has been associated with a reduction in menstrual blood loss and therefore with decreased retrograde menstruation. Conversely, the observed increase in ovarian cancer risk associated with hormone replacement therapy (Table 49.1) may be mediated through the periods of abnormal uterine bleeding that occur with many hormonal regimens. This hypothesis is also supported by the known decrease in ovarian cancer risk in women who have undergone tubal ligation or hysterectomy, because these procedures prevent the ascent of potential oncogenic factors from the lower genital tract to the ovary.

A final hypothesis concerning the genesis of ovarian cancer is that exposure of ovarian epithelium to persistently high levels of pituitary gonadotropins results in neoplastic transformation. Follicle-stimulating hormone (FSH) has been shown to promote the growth of epithelial ovarian cancer cells in vitro, and this effect can be blocked by luteinizing hormone (LH). A corollary to this hypothesis is that elevated circulating gonadotropin levels promote estrogen biosynthesis in the ovarian stroma, which, in turn, causes abnormal proliferation of the adjacent epithelium. Breast-feeding, which has been reported to lower the risk of ovarian cancer, is associated with reduced serum concentrations of LH and estradiol. Pregnancy and the use of oral contraceptives presumably lower the risk of ovarian cancer by inhibiting prenatal secretion of gonadotropins. This theory also receives support from the observed increased risk of ovarian cancer in women taking fertility drugs because these drugs stimulate ovulation by increasing levels of FSH, particularly in the follicular phase of the cycle.

Perhaps the most important risk factor for epithelial ovarian cancer is a family history of the disease. The estimated odds ratio for the development of ovarian cancer in a woman with one first-degree relative who has ovarian cancer is 3.1 (95% CI = 2.1–4.5). This risk increases even further (OR 4.6 CI = 1.1–18.4) in a woman with two or more primary or secondary relatives who have ovarian cancer. These odds ratios translate to a lifetime risk for ovarian cancer of approximately 5% in a woman with one first-degree relative who has the disease and 7% in a woman with two or more relatives with the disease. It should be mentioned, however, that familial ovarian cancers make up a relatively small proportion of total ovarian cancer cases. Only 5% to 10% of ovarian cancer patients report having a positive family history of the disease.

Three familial ovarian cancer syndromes have been described: hereditary breast–ovarian cancer syndrome (HBOC), hereditary site-specific ovarian cancer syndrome (HSSOC), and the hereditary nonpolyposis colon cancer syndrome (HNPCC). HBOC, the most common of the familial syndromes, is characterized by multiple cases of early-onset (<50 years of age) breast and ovarian cancers. This syndrome accounts for 75% to 90% of all hereditary ovarian cancer cases. HSSOC is manifested only by an increase in cases of early-onset ovarian cancer and makes up about 5% of hereditary ovarian cancers. Women with HSSOC are often younger and more commonly have tumors with serous histology than women with sporadic ovarian cancer. HNPCC, or Lynch syndrome type II, is characterized by a predominance of early-onset proximal colon cancer in association with cancers of the endometrium and ovary. HNPCC is often confirmed by a mutation in one of several mismatch-repair genes, in particular MLH1, MSH2, and MSH6. The estimated lifetime risk of ovarian cancer in women with HNPCC...
is 10% to 12%. These three familial ovarian cancer syndromes are inherited by autosomal dominant transmission through ei-
ther maternal or paternal lineage. Therefore, the children of an affected parent have a 50% risk of inheriting the genetic abnor-
mality. Germline mutations in the BRCA1 or BRCA2 gene appear to account for most hereditary ovarian cancers. BRCA1 was
identified in 1994 and is located on the long (q) arm of chro-
omosome 13. BRCA1 is thought to be a tumor suppressor, because
the normal copy of BRCA1 is always deleted in ovarian cancers
that arise in women who inherit a mutant BRCA1 gene. It is
estimated that germline mutations in BRCA1 are responsible for
80% to 90% of hereditary ovarian cancers. BRCA2 was
identified in 1995 and is located on the long (q) arm of chro-
mosome 13. In a recent report from the Breast Cancer Linkage
Consortium, BRCA1 mutations were identified in 81% of ovar-
ian cancer families, whereas BRCA2 mutations were detected
in 14% of those families. Penetrance is variable (range 10%–
50%) from one individual to another, and it is estimated that
the lifetime risk of ovarian cancer is approximately 39% in
BRCA1 carriers and 11% in BRCA2 carriers.

SIGNS AND SYMPTOMS

Although most reports indicate that patients with early-stage ovarian cancer have few symptoms, a recent national survey of
1,723 ovarian cancer patients provides evidence that many of
these patients actually had symptoms that they or their primary
healthcare providers ignored. The most common symptoms of pa-
tients with stage I or II ovarian cancer were abdominal bloating
or pain, indigestion, urinary frequency, and constipation. Be-
cause the majority of these patients had nonspecific symptoms, patients were unaware that they could be associated with ovarian cancer. As a result, 22% of patients ignored their symptoms entirely, and 30% reported that the wrong diagnosis was made. A pelvic examination was performed in only two thirds of patients, and 45% had a delay in diagnosis of more than 3 months. Patients with advanced disease commonly reported abdomi-
nal swelling, fatigue, and weight loss. In a subsequent study, four target symptoms were significantly more common in ovar-
ian cancer patients before diagnosis than in age-matched con-
trol patients. These symptoms included abdominal pain (fre-
quency 30%, OR 6.0), abdominal swelling (frequency 16.5%,
OR 30), gastrointestinal symptoms (frequency 8.5%, OR 2.3),
and pelvic pain (frequency 5.4%, OR 4.3). These observations emphasize the need for patient and physician education con-
cerning the possible relationship of rather nonspecific abdomi-
nal symptoms to ovarian cancer. A high index of suspicion, coupled with pelvic ultrasound and CA-125 testing, may lead
to the earlier diagnosis of ovarian cancer in selected patients
with these symptoms. Although vaginal bleeding is not commonly associated with ovarian cancer, it may be present in patients with metastatic involvement of the uterus. Likewise, endometrial hyperplasia and abnormal uterine bleeding can be caused by excess estrogen production from ovarian tumors. The frequency of endometrial hyperplasia from metastatic ovarian cancer is more common on the right side and is usually associated with dullness to percussion and decreased bowel sounds. Finally, any patient with a clinically detected pelvic tumor on pelvic examination should undergo careful palpation of both groins to rule out inguinal lymphadenopathy secondary to metastatic disease.

EARLY DETECTION

It is now well documented that pelvic examination is inaccurate in assessing ovarian size, particularly in women who are post-
menopausal or overweight. Most patients with ovarian cancer present with advanced disease, when survival is limited. As a
result, there has been little improvement in overall prognosis of patients with ovarian cancer over the past 2 decades. According
to data from the Surveillance, Epidemiology, and End Results (SEER) program database, the ovarian cancer mortality rate has decreased only from 9.3/100,000 in 1989 to 9.0/100,000 in 2002. Recent efforts to increase early detection of ovarian cancer have focused on screening asymptomatic women to de-
tect ovarian cancer when it is still curable.

For screening to be effective, a disease should have (a) a major cause of mortality, (b) a reasonably high prevalence in the screened population, (c) a preclinical phase detectable by the screening test, and (d) be amenable to therapy, such that the survival rate of patients with early-stage disease is significantly higher than that of patients with advanced disease.

Ovarian cancer fulfills many of the prerequisites of a disease that should benefit from screening. First, it is a major cause of mortality in our population. As has been previously mentioned, more than 15,000 patients would die of ovarian cancer in the United States in 2006, making it the fourth most common cause of cancer death in American women. Although the prevalence of ovarian cancer in the general population is not high, it is more common in older women. According to SEER data, the incidence of ovarian cancer is age related and varies from ap-
proximately 20/100,000 in women from 40 to 50 years of age
to 50/100,000 in women 60 to 70 years. It is even higher in women with a family history of the disease.

Knowledge concerning the duration of the preclinical phase of ovarian cancer is limited at best. Histologic transition from benign to borderline or malignant epithelium has been identified by light and electron microscopy in ovarian mu-
cinous and serous cystadenocarcinomas. Likewise, transition from endometriosis to endometrioid ovarian carcinoma has been
documented. These studies suggest that with time, cer-
tain benign ovarian tumors may undergo malignant trans-
formation. Unfortunately, the frequency with which neoplas-
tic transformation occurs in these tumors is unknown and is probably rare. Theoretically, the identification and removal of premalignant ovarian tumors, particularly in postmenopausal women, should decrease the subsequent occurrence of ovarian cancer.

Finally, there is little doubt that early-stage ovarian cancer is significantly more curable than late-stage disease. The 5-year survival of patients with stage I epithelial ovarian cancer is 85% to 90%, despite optimal surgery and combination chemotherapy. It has been estimated that if the 25% of ovarian cancer patients currently diagnosed with stage I tumors could be increased to 75% through early detection, the number of women dying from this disease could be halved.

The statistical definitions used in ovarian cancer screening are illustrated in Table 49.2. Characteristics of an optimal screening test include high sensitivity, high specificity, high posi-
tive predictive value (PPV), and high negative predictive value (NPV). In addition, the test should be easy to perform, time
efficient, and well accepted by patients. An effective screening test should (a) decrease stage at detection, (b) decrease case-
specific mortality, and (c) cause a statistically significant reduc-
tion in site-specific cancer mortality in the screened population.

Finally, the screening test should be cost-effective, such that its use would reduce the overall cost of health care in the screened population.

At present, the two most effective screening methods for ovarian cancer are transvaginal sonography (TVS) and serum CA-125. TVS is usually performed using a standard ultrasound unit with a 5.0-MHz vaginal transducer. A complete screening examination takes 5 to 10 minutes and is painless. Each ovary is measured in three dimensions, and ovarian volume is calculated using the prolate ellipsoid formula (L × H × W × 0.523). An ovarian volume >20 cm³ in premenopausal women or >10 cm³ in postmenopausal women is defined as abnormal. In addition, any solid or papillary projection from the tumor wall is considered abnormal.

A study evaluating ovarian cancer screening using TVS as the initial screening test was initiated at the University of Kentucky Medical Center in 1987. The current screening algorithm used at this center is illustrated in Figure 49.1. A woman with an abnormal screen is scheduled to have a repeat sono-gram in 4 to 6 weeks. A woman with a persisting ovarian tumor at the time of the second screen is scheduled to have a serum CA-125 determination, tumor morphology indexing, color Doppler sonography, and proteomics. Following these studies, laparoscopic tumor removal is recommended. At the time of laparoscopy, the ovarian tumor is placed in an endocatch bag intraabdominally and removed through a midline subumbilical incision (Fig. 49.2). After removal, frozen section histologic examination is performed on all areas suspicious for malignancy. Patients with ovarian cancer on frozen section or patients with obvious metastatic disease at laparoscopy underwent surgical tumor removal. Forty-four of these patients were found to have primary ovarian cancer. Thirty-six (82%) had stage I or II disease, and all were cured after conventional therapy. The 5-year survival of patients with epithelial ovarian cancer detected by screening was 77%, which was significantly higher than that of patients who were not screened. Annual TVS screening was found to decrease stage at detection and reduce case-specific ovarian cancer mortality. The sensitivity of TVS was 0.850, and the specificity was 0.988. However, the PPV of TVS screening in detecting ovarian cancer was only 13.8%. Therefore, approximately eight benign ovarian tumors were removed for every ovarian cancer detected. Additional tests that can increase the PPV of TVS must be developed. One of the adjuvant methods capable of increasing the PPV of TVS screening is morphology indexing. Morphologic characteristics of ovarian tumors are related directly to the risk of malignancy. Unilocular cystic tumors are usually benign, whereas complex ovarian tumors with solid or papillary components are more often malignant. The addition of morphology indexing to TVS
in postmenopausal women has been reported to increase the PPV of sonographic screening.

CA-125 is an antigenic determinant on a high-molecular-weight glycoprotein recognized by a monoclonal antibody, OC-125. Despite repeated attempts, the gene encoding this molecule has not yet been cloned. CA-125 is expressed by epithelial ovarian cancers and is present in highest concentrations on the tumor cell surface. Although serum levels of this marker are elevated (>35 μg/mL) in as high as 80% of patients with advanced ovarian cancer, they are elevated in only 25% to 50% of patients with clinically detected stage I ovarian cancers. Likewise, serum CA-125 is elevated in patients with a number of benign ovarian conditions, such as endometriomas, inflammatory disease of the ovaries, and serous cystadenomas. Finally, this marker has been reported to be increased in a number of nongynecologic cancers, including cancers of the pancreas, breast, colon, and lung. Because many of the benign conditions producing elevated serum marker levels occur in younger women, the specificity of serum CA-125 is highest in postmenopausal women.

The efficacy of serum CA-125 as a screening method for ovarian cancer was evaluated in 22,000 asymptomatic postmenopausal women in England. Forty-one women (0.2%) had elevated (>30 μg/mL) serum CA-125 levels and underwent surgery. Eleven of these patients had ovarian cancer, but seven had advanced disease (stage III or IV). Eight additional patients developed ovarian cancer despite having a normal serum CA-125. A single serum CA-125 determination in this trial had a sensitivity of 58%, a specificity of 98.5%, and a PPV of 2%. When serum CA-125 was used as the initial screening method, early-stage cancers were missed, and stage at detection was not decreased appreciably. Subsequent studies have indicated that a rising trend in serum CA-125 levels over time is more predictive of ovarian cancer than a single elevated marker determination. Nevertheless, the lack of sensitivity of serum CA-125 in detecting early-stage ovarian cancer and its inability to lower stage at detection has limited its value as a screening method.

The challenge for future ovarian cancer detection trials is to combine TVS with serum markers and morphology indexing in an algorithm that improves the sensitivity, specificity, and
When an ovarian tumor has been identified, it is important to establish its risk of malignancy to properly inform the patient and to plan the most appropriate surgical approach. Approximately 10% to 15% of ovarian tumors in premenopausal women, and 40% of ovarian tumors in postmenopausal women, are malignant. Tumor characteristics associated with malignancy include bilaterality, solid composition, fixation in the pelvis on bimanual examination, and increased size (>10 cm diameter). Interestingly, extremely large ovarian tumors are often benign mucinous or serious cystadenomas. Sonographically determined tumor morphology, serum markers, and color Doppler assessment of tumor vascularity also have been used to predict risk of malignancy. A number of studies have concluded that sonographically generated tumor morphology can be used to differentiate benign from malignant ovarian tumors, particularly in postmenopausal women. Unilocular cystic tumors less than 5 cm in diameter have been shown to have an extremely low risk of malignancy, whereas complex ovarian tumors with solid or papillary projections from the cyst wall have a higher risk of malignancy. Bailey and colleagues, for example, reported no cases of malignancy in 256 unilocular cystic ovarian tumors <10 cm in diameter and recommended that these lesions should be followed with periodic TVS rather than proceeding with operative intervention. Conversely, 7 of 135 complex ovarian tumors <10 cm in diameter were malignant. In a subsequent study, more than 3,000 postmenopausal women with unilocular ovarian cysts <10 cm in diameter were followed with TVS at 6-month intervals for an average of 6 years. Approximately 70% of these cysts resolved spontaneously, and no patient developed ovarian cancer. Using this reasoning, morphology indexes have been developed relating risk of malignancy to specific morphologic findings. The morphology index (MI) presently used in the University of Kentucky Ovarian Cancer Screening Trial was published initially by Ueland and colleagues and is illustrated in Figure 49.3. Both morphologic complexity and tumor volume, as calculated by the prolate ellipsoid formula, were related directly to the risk of malignancy. A point scale was constructed within each category, with total points per evaluation varying from 0 to 10. Risk of malignancy was assessed preoperatively in 442 ovarian tumors using this index. Morphologic abnormalities were easy to categorize, and interobserver variation was minimal. Risk of malignancy varied from 0.3% in ovarian tumors with a MI of <5 to 84% in tumors with a MI ≥8. Using a MI ≥5 as indicative of malignancy, the following statistical parameters were observed: sensitivity 0.981, specificity 0.808, PPV 0.409, and NPV 0.997. Therefore, morphologic indexing is a relatively accurate and cost-effective method to predict risk of malignancy in an ovarian tumor.

Serum biomarker levels have also been used both independently and in conjunction with sonographic findings as a means to differentiate benign from malignant ovarian tumors. Alcazar and colleagues obtained serum CA-125 values on 94 patients with suspicious adnexal masses confirmed sonographically. A serum CA-125 value >35 μ/mL was designated as abnormal. Using this criterion, an elevated serum CA-125 in a postmenopausal woman with a sonographically confirmed ovarian tumor had a PPV for malignancy of 80%. The sensitivity and specificity of an elevated serum CA-125 were highest in postmenopausal women. In patients with an elevated serum CA-125, the presence of abnormal ovarian morphology significantly increased the risk of ovarian malignancy. Recent data suggest that serial biomarker levels may be more effective than a single threshold value in distinguishing benign from malignant ovarian tumors. Generally, serum CA-125 values rise over time in patients with ovarian cancer, whereas they remain stable or decrease in patients with benign ovarian tumors. Using a risk calculation based on progressively rising serum CA-125 levels, Skates and colleagues were able to increase the sensitivity of ovarian cancer detection from 62% to 86%. Therefore, serial CA-125 determinations at 2- to 4-week intervals can be helpful in determining risk of malignancy in a sonographically confirmed ovarian tumor.

The use of color flow Doppler as a method to assess risk of malignancy in ovarian tumors is based on observed differences in resistance to blood flow between vessels supplying normal ovarian tissue and those associated with ovarian neoplasia. With tumor angiogenesis, there is an increase in the number and tortuosity of vessels. These vessels lack muscular intima and generally have low impedance to flow. Transvaginal
In Doppler velocimetry, the flow velocity waveform obtained from a target vessel is evaluated according to standard parameters, pulsatility index (PI), and resistive index (RI). PI is calculated according to the formula: $PI = S - D/A$, where $S$ is the maximum Doppler shift frequency, $D$ is the minimum Doppler shift frequency, and $A$ is the mean Doppler shift frequency during the cardiac cycle. RI is calculated according to the formula: $RI = S - D/S$. A PI of $< 0.5$ and an RI of $< 0.4$ are indicative of low impedance to flow and a high risk of malignancy. Using these criteria, Weiner and colleagues reported that vessels supplying ovarian malignancies had an abnormally low PI in 16 of 17 cases. In contrast, the PI of vessels supplying benign ovarian tumors was normal ($\geq 1.0$) in 35 of 36 cases. Other studies have confirmed that the mean PI and RI are lower in malignant and borderline ovarian tumors than in benign ovarian tumors. However, the overlap in values is such that preoperative color Doppler cannot be used as a reliable preoperative indicator of malignancy.

More recently, contrast-enhanced, three-dimensional power Doppler sonography has been shown to improve the visualization and diagnostic evaluation of tumor vascularity in complex adnexal masses. Intravascular contrast agents are used to enhance depiction of tumor vessels by providing a stronger Doppler signal. Image software systems are used to calculate the total power Doppler intensity for a designated region within each tumor. Preliminary studies suggest that this technology can be used to discriminate benign from malignant ovarian tumors. However, these methods are time-consuming and require sophisticated ultrasound equipment and sonographer skill. At present, Doppler flow studies are used as adjunctive tests in ovarian tumors suspected of being malignant on the basis of morphologic criteria or for serum marker patterns.

Proteomic profiling of serum using mass spectrometry (surface-enhanced laser desorption and ionization) also has been proposed as a method to differentiate benign from malignant ovarian tumors. Basically, a population of proteins can be separated and analyzed to identify unique chemical mass and net electrical charge of the individual proteins. The discriminating proteomic pattern formed by a subset of proteins is defined by peak amplitude at key mass/charge positions along the spectrum. In 2002, Pericon and associates, using this technology, reported a proteomic pattern that could discriminate ovarian cancer patients from normal controls or patients with benign gynecologic disease. Included in the ovarian cancer cases were 15 patients with stage I disease. Unfortunately, these initial results have proven difficult to reproduce, and several investigators have concluded that further work needs to be done before proteomic profiling can provide reproducible data from which to identify ovarian cancer.

Perhaps the most clinically valuable study concerning the differentiation of benign and malignant ovarian tumors was reported by Roman and colleagues. These investigators performed a prospective trial to evaluate the efficacy of pelvic examination, tumor markers, transvaginal gray scale sonography, and Doppler flow sonography in predicting ovarian malignancy. These tests were performed on 226 consecutive women before operative removal of an ovarian tumor. Positive findings included fixed or irregular consistency on pelvic examination, tumor markers, transvaginal gray scale sonography, and color Doppler. If all four criteria were positive, the risk of malignancy was 83%. In contrast, if all indicators were negative, 100% of postmenopausal women had benign ovarian tumors. Logistic regression analysis revealed that sonographically determined ovarian morphology and serum CA-125 were the most significant predictors of malignancy in the ovarian tumors of postmenopausal women. Spectral Doppler analysis of PI and RI did not improve diagnostic accuracy because of the overlap in values obtained between benign and malignant ovarian tumors.

Using morphologic indexing and serum markers, it is now possible to assess risk in an ovarian mass and to plan accordingly. A recent analysis of national data has indicated that the highest survival of women with ovarian cancer occurred when a gynecologic oncologist was involved in their care. Therefore, patients with a high risk of ovarian malignancy on preoperative evaluation can be referred directly to a gynecologic oncologist.

**PREOPERATIVE EVALUATION**

Before operative intervention, each patient should undergo a thorough evaluation designed to determine the anatomic location, size, and morphology of the ovarian tumor, as well as possible sites of metastases. In addition, her general medical condition and ability to undergo a major surgical procedure should be established. All patients should undergo routine hematologic and biochemical testing. A chest x-ray provides valuable information concerning cardiac size, as well as the presence of pulmonary metastases or a pleural effusion. An electrocardiogram is indicated in all women older than age 40 or in a patient with specific signs or symptoms of cardiac disease.

As previously mentioned, TVS is the most accurate test in assessing ovarian tumor size and morphology. In selected patients with large ovarian tumors, it may be necessary to perform abdominal sonography as well as vaginal sonography to determine the full extent of the tumor. TVS is also valuable in identifying intrauterine tumor or occult ascites. A patient with an ovarian tumor and vaginal bleeding should undergo further evaluation to rule out coexisting endometrial cancer or a primary uterine cancer with spread to the ovaries. In patients with an ovarian tumor confirmed by TVS, pelvic/abdominal computed tomography (CT) scanning with contrast may identify ureteral obstruction, retroperitoneal lymphadenopathy, omental disease, and peritoneal metastases. In a patient with ascites but no ovarian tumor, liver function studies should be performed to exclude cirrhosis or liver disease. Rarely, the presence of right heart failure and hepatic congestion will cause ascites. Although paracentesis is contraindicated in a patient with an ovarian tumor confirmed on sonography, it may be useful in a patient who presents with ascites and no evidence of an ovarian abnormality. The characteristics of malignant cells present in ascitic fluid may help identify the primary site of intraabdominal malignancy.

Common sites of nongynecologic cancer that spreads to the ovary include gastric malignancy, colonic carcinoma, and breast carcinoma. A careful history of physical examinations should arouse suspicion of other possible primary malignancies. Any such possibilities should be evaluated with appropriate ongoing studies and diagnostic evaluation, possibly including colonoscopy, upper gastrointestinal endoscopy, and/or mammography. A biopsy of a suspicious finding or easily accessible lymph node may clarify the diagnosis.

Finally, serum markers should be obtained according to the age and clinical findings of each patient (Table 49.3). Serum CA-125 and CEA often are elevated in patients with epithelial ovarian cancer, whereas serum alpha-fetoprotein, human chorionic gonadotropin, or lactate dehydrogenase are more

Commonly increased in younger women with germ-cell ovarian malignancies. Serum inhibin is the most reliable marker in patients with ovarian granulosa cell tumors. The specific marker associated with each type of ovarian cancer is illustrated in Table 49.3. It is important to obtain a baseline serum marker value before surgery so that it can be used to monitor response to therapy.

FIGURE 49.4. Patterns of spread of ovarian cancer.

PATTERNS OF SPREAD

Ovarian cancer spreads by (a) direct extension and exfoliation of tumor cells into the peritoneal cavity, (b) lymphatic metastases to regional and paraaortic lymph nodes, and (c) hematogenous dissemination (Fig. 49.4). The specific pattern of spread depends on the stage, cell type, and histologic differentiation of the tumor.

The earliest method of spread in epithelial ovarian cancer is by exfoliation of tumor cells from the ovarian surface. These cells migrate with the circulation of peritoneal fluid along the surfaces of the pelvic and mesenteric peritoneum. They also are carried cephalad in the paracolic spaces to the omentum and undersurface of the diaphragm. Spread to the right lung occurs through the transdiaphragmatic lymphatics in the right hemidiaphragm, often producing a right pleural effusion. Surface spread to the bowel and bladder is a common finding in advanced-stage ovarian cancer, but involvement of the bowel lumen or bladder mucosa is rare.

Lymphatic drainage from the ovary follows two pathways. The first involves lateral spread through the broad ligament to the pelvic lymph nodes. In patients with advanced-stage disease, there may be retrograde dissemination via the lymphatics of this pathway to the round ligament to the inguinal lymph
nodes. The second pathway of efferent lymphatic drainage follows the ovarian vein to the paracaval and paraaortic lymph nodes. Metastatic spread of ovarian cancer to lymph nodes is well documented even in early-stage disease (Table 49.4) and confirms that there may be separate pathways of dissemination to the pelvic and paraaortic lymph nodes. Caos and coworkers, for example, reported that 14 of 96 patients (15%) with disease visibly confined to one ovary had microscopic lymph node metastases. All 14 patients with nodal spread had poorly differentiated tumors. Isolated ipsilateral lymph node metastases occurred in five patients, and isolated contralateral lymph node metastases occurred in three patients. Pelvic lymph nodes were involved in six patients, paraaortic lymph nodes in five patients, and both in three patients. As expected, the frequency of lymph node metastases is related to stage of disease, cell type, and histologic differentiation of the tumor. Chen and Lee, for example, reported that the frequency of pelvic lymph node metastases increased from 9% in patients with clinically apparent stage I ovarian cancer to 35% in patients with stage IV disease. Similarly, the frequency of paraaortic lymph node involvement increased from 18% in patients with clinically apparent stage I disease to 67% in patients with stage IV disease. These findings are similar to those of Burghardt and colleagues, who noted lymph node metastases in 74% of patients with stage III or IV ovarian cancer. The incidence of lymph node metastases increased from 20% in well-differentiated ovarian cancers to 63% in poorly differentiated tumors and was higher in serious ovarian malignancies than in mucinous or endometrioid cancers.

Hematogenous spread of ovarian cancer to the parenchyma of the liver or lung is fortunately quite rare (<5%) at the time of initial diagnosis, but may occur, particularly in poorly differentiated tumors that become refractory to combination chemotherapy.

EXAMINATION OF OVARIAN TUMOR SPECIMENS AND HISTOLOGIC CLASSIFICATION

Ovarian tumor specimens should be described, fixed, and sectioned according to the guidelines established by the College of American Pathologists (CAP). Tumor should be classified histologically according to the World Health Organization classification and nomenclature of ovarian tumors (Table 49.5). Although there are numerous grading systems for ovarian cancers that use both architectural and nuclear features, it is recommended that four grades be used, with grade 4 (undifferentiated) applied to tumors with minimal or no differentiation. Recommendations concerning the use of special staining techniques or flow cytometry in establishing the correct histologic diagnosis of ovarian tumors are made in the CAP report. Immunohistochemical staining of ovarian tumors for cytokeratin 7 (CK7) and cytokeratin 20 (CK20) is helpful in differentiating primary mucinous ovarian carcinoma from colorectal adenocarcinoma that has metastasized to the ovary. Colorectal adenocarcinomas usually stain positively for CK20 and negatively for CK7. In contrast, ovarian carcinomas usually stain negatively for CK20 and positively for CK7.

Patterns of Care in Ovarian Cancer Surgery

All patients with suspected ovarian cancer should be referred to a gynecologic oncologist for evaluation and possible surgery. Unfortunately, in both Europe and the United States (where most of the outcomes studies have been conducted), too high a proportion of women with ovarian cancer are receiving substandard care. In a Norwegian study, Tingstad and colleagues found that in advanced-stage ovarian cancer, patients who underwent primary surgery at teaching hospitals had significantly improved survival time compared with controls who underwent primary surgery at nonteaching hospitals. Two regional-based studies—one from Utah and the other from Maryland—have also indicated that a significant proportion of women with ovarian cancer are not receiving optimal treatment. Cancer and associates found that less than 50% of women with ovarian cancer are receiving substandard care. In a Norwegian study, Tingstad and colleagues found that in advanced-stage ovarian cancer, patients who underwent primary surgery at teaching hospitals had significantly improved survival time compared with controls who underwent primary surgery at nonteaching hospitals. Two regional-based studies—one from Utah and the other from Maryland—have also indicated that a significant proportion of women with ovarian cancer are not receiving optimal treatment. Cancer and associates found that less than 50% of women with ovarian cancer are receiving substandard care. In a Norwegian study, Tingstad and colleagues found that in advanced-stage ovarian cancer, patients who underwent primary surgery at teaching hospitals had significantly improved survival time compared with controls who underwent primary surgery at nonteaching hospitals. Two regional-based studies—one from Utah and the other from Maryland—have also indicated that a significant proportion of women with ovarian cancer are not receiving optimal treatment.

advanced-stage disease, aggressive cytoreductive procedures, such as intestinal resection and diaphragmatic debulking, were lower in low-volume hospitals. The totality of this information clearly underscores the need for improvement in patterns of referral.

Early-Stage Ovarian Cancer

Comprehensive Surgical Staging

Ovarian cancer is staged according to the International Federation of Gynecology and Obstetrics (FIGO) Staging System (Table 49.6) and is based on a thorough surgical evaluation of the primary ovarian tumor and its potential sites of metastatic spread (Table 49.7). Should preoperative evaluation suggest an area of extraabdominal or intrahepatic metastasis, fine needle aspiration or needle biopsy of this location should be performed. Because ovarian cancer frequently spreads to upper abdominal structures, a vertical midline abdominal incision is recommended. This incision should be extended high enough to remove the primary ovarian tumor and to evaluate the stomach, omentum, liver, and undersurface of the diaphragm. Rupture of a cystic ovarian malignancy is associated with a poorer prognosis, so the incision should be sufficient to allow excision of the primary tumor with its capsule intact. Once the abdomen has been opened, the following steps should be performed for adequate surgical staging:

1. The volume of ascitic fluid should be recorded, and a minimum of 25 mL should be sent for cytologic evaluation.

2. In the absence of ascites, separate saline washings should be obtained from the (a) pelvic cul-de-sac, (b) right paracolic space, (c) left paracolic space, and (d) undersurface of each hemidiaphragm. Approximately 100 mL of saline should

be instilled in each of these areas, recovered, and sent for cytologic evaluation.

3. The ovarian tumor should be inspected, with particular attention to the presence of papillary excrescences on the surface or rupture of the capsule. The contralateral ovary and uterus should be examined for the presence of metastatic tumor. The pathways of ovarian tumor should be removed and sent for frozen-section examination. Removal of the opposite ovary and/or uterus are dependent on several factors and are discussed on the following pages.

4. Careful inspection and palpation of the peritoneal surfaces and intraabdominal viscera should be performed. This evaluation should be approached in a systematic fashion, beginning with the peritoneum of the cul-de-sac and small bowel mesentry. Inspection should continue with the ascending colon, liver, omentum, undersurface of the right and left hemidiaphragms, and stomach. Finally, the transverse colon, spleen, descending colon, and bladder peritoneum should be evaluated.

5. All areas suspicious for malignancy should be biopsied. In the absence of visible disease, biopsies should be taken of the cul-de-sac peritoneum, bladder peritoneum, both lateral pelvic walls, paracolic peritoneum bilaterally, and undersurface of the right hemidiaphragm. An infracolic omental biopsy should be performed in patients with epithelial ovarian cancer and an omental wedge biopsy taken in patients with germ-cell or stromal tumors. Appendectomy should be performed in all patients with mucinous epithelial cancers involving the ovary. Primary appendiceal cancers, although rare, commonly spread to the ovaries and usually require right hemicolectomy as part of initial surgical staging.
6. As has been mentioned, ovarian cancer commonly spreads to both pelvic and paraaortic lymph nodes. Some patients with early-stage ovarian cancer have paraaortic lymph node metastases in the absence of pelvic lymph node spread. Therefore, these lymph node groups should be sampled separately in all patients. It is important that sampling include lymph nodes on the opposite side of the primary ovarian tumor, because isolated contralateral spread has been reported. For this reason, it should be emphasized that operative findings present at staging laparotomy must be carefully documented. Prognosis is related to the site and volume of metastatic tumor spread, as well as the amount of residual disease remaining after surgical debulking. Important data concerning the location and size of tumor metastases are often lost if the details concerning operative staging are not recorded.

7. Fertility-Sparing Surgery

Although the majority of ovarian malignancies occur in older women for whom bilateral salpingo-oophorectomy and hysterectomy are standard treatment, a significant subset of patients is young and can be managed more conservatively (Table 49.8). Conservative management is used here to denote surgery that preserves reproductive potential without compromising curability. With some exceptions, such a strategy may be applicable for women younger than 40 years who wish to bear children.

When contemplating surgery on a young patient with a suspected ovarian malignancy, it is important to discuss with her all possible operative findings and procedures and the long-term implications of the various options. If the patient is a child, the parents need to clearly understand this information. In most instances, young patients have their initial surgery done outside major university hospitals or cancer centers. Common errors in surgical management include incomplete surgical staging and unnecessary bilateral salpingo-oophorectomy. In addition, some patients are mismanaged because of an error in the pathologic diagnosis of a rare ovarian neoplasm.

The optimal candidate for conservative surgical management is a young patient who has stage IA disease. If, on initial inspection, the suspected cancer is confined to one ovary, then unilateral salpingo-oophorectomy is appropriate. If the mass is thought to be benign, then ovarian cystectomy may be preferable. The specimen should be sent for frozen section examination. If malignancy is diagnosed, then appropriate staging biopsies should be performed, as discussed. If the contralateral ovary appears normal, it is recommended that it not be biopsied to avoid potential infertility caused by peritoneal adhesions or ovarian failure.

One should not rely too heavily on frozen section examination in making the decision to perform a hysterectomy and bilateral salpingo-oophorectomy. If the histologic diagnosis is in question, it is always preferable to wait for permanent section results for a young patient, even if this requires a repeat surgery. The advent of in vitro fertilization technology should also have an impact on intraoperative management. Convention has dictated that if a bilateral salpingo-oophorectomy is necessary, a hysterectomy should also be performed. However, current technology for donor oocyte transfer and hormonal support allows a woman without ovaries to sustain a normal intrauterine pregnancy. Similarly, if the uterus and one ovary are resected because of tumor involvement, current techniques allow retrieval of oocytes from the patient’s remaining ovary, in vitro fertilization with sperm from her male partner, and implantation of the embryo into a surrogate’s uterus. Therefore, traditional guidelines concerning surgical management of ovarian cancer may no longer be applicable in selected young patients.

Approximately 50% to 70% of malignant germ cell tumors are stage I. Except for dysgerminoma, in which the incidence of bilaterality is 10% to 15%, bilateral ovarian tumors are exceedingly rare. Such a finding almost always signifies advanced disease with metastatic spread from one ovary to the other or a mixed germ-cell tumor with a dysgerminoma component. Benign cystic teratoma is associated with malignant germ-cell tumors in 5% to 10% of cases and may occur in one or both ovaries. Therefore, unilateral salpingo-oophorectomy, preserving the contralateral ovary and uterus—combined with surgical staging—can be performed in most patients with these neoplasms, even with advanced-stage disease. If the contralateral ovary is enlarged, most likely it represents a benign cystic teratoma that can be managed with an ovarian cystectomy only. With the exception of stage IA pure dysgerminoma or stage IA, grade 1 immature teratoma, these patients require postoperative chemotherapy consisting of the combination of bleomycin, etoposide, and cisplatin (BEP). Several series have documented normal reproductive function in at least 80% of patients as well as pregnancies following fertility-sparing surgery and chemotherapy.

In the past few years, some investigators have advocated the practice of surgery alone for other categories of malignant germ-cell tumors, including stage IA, grade 2 and 3 immature teratomas, and stage IA yolk sac tumors. Such an approach, however, should be taken with caution; many experts would still consider it experimental. Nevertheless, there is a trend toward careful observation following surgery alone for most patients with stage I malignant ovarian germ-cell tumors. The Children’s Oncology Group is currently conducting a clinical trial that includes postoperative surveillance for patients with stage I disease. Chemotherapy is initiated only for serum tumor marker elevation.

Most sex cord-stromal tumors are confined to the ovary. Stage I accounts for >50% (in some series as high as 100%) of granulosa cell tumors. More than 90% of Sertoli-Leydig cell tumors are stage IA. Bilaterality occurs in <5% of cases with either tumor type. Therefore, optimal surgical management of most patients with stromal tumors consists of unilateral adnexectomy combined with appropriate surgical staging. Endometrial biopsy or curettage also should be performed in any young patient whose uterus is preserved because 5% to 15% of patients with granulosa cell tumors develop endometrial cancer or hyperplasia. Postoperative therapy may be indicated for patients with metastatic disease or for selected patients with stage I disease (e.g., poorly differentiated Sertoli-Leydig cell tumor or granulosa cell tumor with rupture). The most commonly used regimens in this setting include either BEP or the combination of paclitaxel and carboplatin.

1319
of borderline or low malignant potential

surgery, and nine patients required subsequent hysterectomy

Schilder and associates reported 52 patients with stage I without chemotherapy. In a multi-institutional retrospective review, lowing treatment with fertility-sparing surgery with or without chemotherapy. In a multi-institutional retrospective review, Schilder and associates reported 52 patients with stage I invasive epithelial ovarian cancer treated with fertility-sparing surgery; 20 patients received adjuvant chemotherapy. Five patients developed recurrence 8 to 78 months after primary surgery, and nine patients required subsequent hysterectomy and contralateral oophorectomy for benign disease. Seventeen patients had 26 term deliveries and 3 spontaneous abortions.

Risk Assessment

To begin making decisions about which patients might benefit from postoperative or adjuvant therapy, one must categorize them based on risk of relapse. The risk of relapse is approximately 1% for patients with stage I borderline ovarian tumors; thus, adjuvant therapy is not recommended.

For women with stage IA or IB sex cord-stromal tumors, no adjuvant therapy is recommended because of the low risk of relapse. For those with stage IC disease, however, the level of risk remains uncertain; some studies suggest that tumor rupture or the presence of ascites is prognostic, whereas others do not.

All patients with early-stage malignant ovarian germ-cell tumors, except those with stage IA dysgerminoma or stage IA, grade 1 immature teratoma, require postoperative chemother-apy. As noted, there is some controversy about whether patients with stage IA yolk sac tumor or stage IA, grade 1 or 2 immature teratoma require adjuvant chemotherapy. Most experts in the United States favor treatment for such patients until such time as more information is available.

For patients with early-stage epithelial ovarian cancer, most experts currently accept a classification system of low and high risk (Table 49.9). Within the stage I category, histologic grade is the most powerful predictor of outcome. Patients with well-differentiated or grade 1 tumors have an excellent prognosis, with a 5-year survival rate of more than 90%. On the other hand, the 5-year survival rates for patients with grade 2 or 3 tumors are approximately 75% to 80% and 50% to 60%, respectively. Other factors that have been found to have prognostic significance include large-volume ascites, dense adherence, and clear-cell histology. Although older studies suggested that capsular rupture or excretences may be associated with a worsened prognosis, more recent studies have found no independent influence of these factors on prognosis. However, the issue of the influence of tumor rupture on prognosis remains controversial.

Therefore, low-risk early-stage epithelial ovarian cancer includes patients with the following factors: (a) stage IA or IB (in- tact capsule, no tumor excretences, and no malignant ascites or negative peritoneal cytology) and (b) grade 1 or 2 disease. The standard treatment for this group of patients is surgery alone, and the 5-year survival is at least 93%. A controversy about whether grade 2 belongs in the low- or high-risk category remains unresolved; it is compounded by the lack of uniformity of grading systems.

Ovarian Cancer: Etiology, Screening, and Surgery

1321

High-risk early-stage epithelial ovarian cancer includes those patients with the following factors: (a) stages IC (ruptured capsule), tumor excurrences, positive peritoneal cytology, or malignant ascites to IL, (b) grade 3 disease, or (c) clear-cell histology. In some classification systems, dense adherence is also included in the high-risk category; however, in the view of many experts, this designation is simply a surrogate for stage II disease. This high-risk subset is thought to have a relapse risk in the range of 40% to 50% and is the focus of adjuvant therapy trials.

Persistent problems with incomplete surgical staging and interobserver variability in assigning histologic grade lead one to the realization that more objective and reliable methods would be desirable for assessment of risk in early-stage ovarian cancer. Currently, there is no universally accepted prognostic molecular biomarker. There are, however, reports of several putative or potential biomarkers. Among these are DNA ploidy, computerized morphometry, Ki-67, p53, and HER-2/neu. Although none of the markers studied yet qualifies as prognostic, as technology advances, future studies will most certainly identify reliable biomarkers. Because there is no universal histologic grading system for epithelial ovarian cancer, investigators at M.D. Anderson Cancer Center recently reported a two-tier grading system for invasive serous carcinomas that emphasizes nuclear atypia rather than architecture, with mitotic count as a secondary feature. There is mounting evidence, both from genomic/molecular studies and clinical reports, supporting this low-grade/high-grade model.

Adjuvant Treatment

For patients with malignant ovarian germ-cell tumors who require adjuvant treatment, standard postoperative therapy consists of a three- versus six-cycle BEP regimen. For patients with high-risk early-stage sex cord-stromal tumors (stage IC or II), there is no standard postoperative treatment. The most commonly used regimens include the BEP combination or the combination of paclitaxel and carboplatin.

Platinum-based chemotherapy has emerged as the standard treatment for patients with early-stage epithelial ovarian cancer. The optimal regimen and duration of therapy remains elusive. Bolis et al. reported the results of two multicenter trials conducted by the Gruppo Italiano Collaborativo in Oncologia Ginecologica. A total of 271 patients were included in these two trials. Trial 1 compared single-agent cisplatin with observation in patients with stage IA and IB, grade 2 or 3. Trial 2 compared single-agent cisplatin with intraperitoneal chromic phosphate in patients with stages IA, grade 2, IB, grade 2, and IC, disease. In both trials, although the cisplatin groups had a better disease-free survival rate, overall survival was not significantly different compared with the other arm. One possible explanation for these findings is that patients in the nonchemotherapy arm crossed over to cisplatin at time of relapse.

The Gynecologic Oncology Group (GOG) reported a randomized trial of cisplatin plus cyclophosphamide for three cycles versus intraperitoneal chromic phosphate in patients with high-risk early-stage ovarian cancer. With 204 evaluable patients randomized, suboptimal resection rates were 77% for the chemotherapy arm and 66% for the P32 arm. After adjusting for stage and histologic grade, the group receiving chemotherapy had a 29% decrement in estimated relapse. Chemotherapy was recommended as standard adjuvant therapy for this subset of patients. Cohen et al. reported on two cycles of paclitaxel/carboplatin and the late bowel toxicity associated with P32. In a subsequent GOG trial, Bell and colleagues compared three versus six cycles of paclitaxel/carboplatin for patients with high-risk early-stage epithelial ovarian cancer. Although the recurrence rate associated with six cycles was 24% lower, the study was powered for a 50% or greater reduction in recurrence rate for six cycles. In addition, there was no difference in overall survival between the arms. In a recently completed GOG trial for early-stage disease, all patients initially received three cycles of paclitaxel/carboplatin and then were randomized between observation and 26 weekly doses of paclitaxel.

Results of this trial are not yet available.

Two large European cooperative group trials in early-stage ovarian cancer were combined for analysis. Both the International Collaborative Ovarian Neoplasm 1 (ICON1) trial and the European Organisation for Research and Treatment of Cancer Collaborators—Adjuvant ChemoTherapy in Ovarian Neoplasm (EORTC-ACTION) trial randomized patients with early-stage epithelial ovarian cancer following surgery to observation versus platinum-based chemotherapy. Both overall survival and recurrence-free survival at 5 years were superior in the chemotherapy arm (82% vs. 74% and 76% vs. 65%, respectively).

Advanced-Stage Ovarian Cancer

Primary Cytoselective Surgery

Cytoreductive or debulking surgery refers to a surgical procedure for which the goal is to reduce the amount of tumor as much as possible in a patient with metastatic ovarian cancer. Early studies suggested a relationship between the completeness of the surgery or the amount of residual tumor and survival. In a landmark paper, Griffiths demonstrated an inverse relationship between residual tumor diameter and survival; patients having residual disease less than 1.5 cm in diameter had a significantly improved survival compared with patients with bulky residual disease. Subsequent reports confirmed these findings. As our philosophy about cytoreductive surgery has evolved over the last 2 decades, optimal debulking has come to denote minimal residual disease less than or equal to 1.0 to 2.0 cm in greatest diameter; suboptimal debulking denotes bulky residual disease greater than 1.0 to 2.0 cm in diameter. Defining the extent of residual disease when dealing with tumor plaques on the peritoneal surfaces remains problematic. Furthermore, there is most certainly a lack of precision in measuring residual disease.

Cytoreductive surgery, of course, must be considered not in a vacuum but rather in the context of responsiveness of residual tumor to postoperative therapies. Both radiotherapy and chemotherapy trials have shown a higher response rate in patients with minimal residual disease. These observations are supported by basic studies that suggest that larger tumor masses have poorly perfused anoxic areas that are not accessible to cytotoxic agents. Furthermore, larger tumors may have a greater proportion of cells in the resting phase. These nonproliferating cells may be less sensitive to cytotoxic agents. Skipper espoused the fractional cell kill hypothesis, stating that the ability of chemotherapeutic agents to eradicate cancer cells depends on both the dose intensity and the biodistribution of the drug. The goal is to design a delivery system that delivers the drug and the other pharmaceuticals directly to the cancer cells present. A given dose of drug kills a constant fraction of cells with each exposure. However, certain factors—such as cell repair mechanisms, tumor heterogeneity, the fraction of cells in G0 phase, and the development of drug resistance—serve to counteract this process. Coleman and Goldman have shown that tumor cells have an intrinsic spontaneous mutation rate; larger tumors that go untreated for an extended period theoretically have a greater probability of containing cell populations...
followed. After evacuation of ascites, if present, and inspection of the abdomen, the initial steps outlined under surgical staging are carried out. Resection of pelvic tumor. If the omentum is adherent to the pelvic peritoneum of the anterior abdominal wall, the pelvic structures, or loops of small intestine, it should be dissected from these structures. Once the omentum is mobilized and lifted cephalad, a dissection plane is developed between it and the serosa of the transverse colon, extending the dissection laterally in both directions (Fig. 49.5A). If the supracolic omentum is heavily involved with tumor and densely adherent to the transverse colon, it also may be necessary to establish a plane between the greater curvature of the stomach and the omentum by ligating the right and left gastroepiploic arteries and entering into a plane between the greater curvature of the stomach and the individual gastric branches (Fig. 49.5B). Entrance into the lesser sac allows traction on the greater curvature of the stomach and facilitates exposure and transection of the gastric branches of the gastroepiploic arch. Occasionally, omental tumors may also involve the spleen or splenic hilum, necessitating splenectomy (see “Splenectomy”).

Resection of pelvic tumor. Any adhesions of small intestine or omentum to the pelvic structures should be lysed. A self-retaining retractor then may be inserted and the bowel packed for adequate exposure. If normal pelvic spaces and planes are obliterated by tumor, then the retroperitoneal approach is preferred (Fig. 49.6). The lateral pelvic peritoneum is incised, and the incision is carried cephalad and caudad. As part of this maneuver, the round ligament is identified and ligated as well. The retroperitoneal space is thus entered and the small residual tumor masses may still contain drug-resistant cells that preclude ultimate cure.

Several reports have described the accomplishment of optimal cytoreductive surgery in a high percentage of patients. The morbidity and mortality associated with cytoreductive surgery also have been analyzed. These studies generally reflect an operative mortality rate of less than 2%, a mean operating time of 3 to 5 hours, and a mean blood loss of approximately 300 to 1,500 mL. There is a wide range of postoperative complications, the most common of which are infection, hemorrhage (at times requiring reexploration), prolonged ileus, and cardiopulmonary problems. The primary question concerning the efficacy of primary cytoreductive surgery is whether improved survival is related more to the biology of the tumor or to the skill and aggressiveness of the surgeon. In other words, are those tumors that can be debulked optimally also tumors that are less invasive, less infiltrative, and more indolent? Earlier studies do not suggest that this is the case. All demonstrated that patients who required extensive surgery to achieve minimal residual disease and those who had minimal disease at the outset had similar survival rates. More recent studies, however, suggest that patients with de novo minimal disease have a superior prognosis to those who are debulked to minimal disease, supporting the prognostic influence of substage categories within the stage III classification. Unfortunately, there are no randomized studies to resolve important issues in this area. Moreover, prospects for such studies are not good because of several factors, including deeply established biases, the multiplicity of associated prognostic factors, and the highly individualized nature of each procedure. In the meantime, the efficacy of cytoreductive surgery remains controversial. Better information will be required ultimately to define its role.

Studies indicate that optimal cytoreductive surgery may confer a survival advantage, even for patients with stage IV ovarian cancer. Four large retrospective reports noted that patients with stage IV disease who were optimally cytoreduced had a statistically superior survival to patients who were suboptimally cytoreduced (Table 49.10).

EFFECT OF DEBULKING ON SURVIVAL IN STAGE IV OVARIAN CANCER

Exploration. The patient is placed in either the supine or semilithotomy or ski position, depending on the likelihood of a rectosigmoid resection. A vertical midline incision is employed for adequate exposure. If normal pelvic spaces and planes are obliterated by tumor, then the retroperitoneal approach is preferred (Fig. 49.6). The lateral pelvic peritoneum is incised, and the incision is carried cephalad and caudad. As part of this maneuver, the round ligament is identified and ligated as well. The retroperitoneal space is thus entered and palpation, the size of the primary tumors(s) and size and extent of metastatic deposits should be noted.

During this initial phase of the operation, the surgeon must make an assessment of the feasibility of cytoreductive surgery. In a typical patient with advanced disease, the omentum may be totally replaced by tumor, and the pelvis may be filled with tumor, making it difficult or impossible for the surgeon to distinguish normal pelvic structures. Findings that may initially dissuade the surgeon from proceeding with aggressive tumor resection include extensive parenchymal hepatic involvement, massive diaphragmatic involvement, extensive infiltration of the small intestinal mesentery, or bulky nodal disease high in the paraaortic chain. On the other hand, even if minimal residual disease cannot be achieved, debulking of omental and pelvic masses may relieve production of ascites, reduce pressure on adjacent organs, and allow the patient increased comfort, at least temporarily. Moreover, intestinal resection still may be indicated for relief of impending or true obstruction.

Omentectomy. It is our preference to perform an omentectomy before focusing on the pelvis if the omentum is largely or completely replaced by tumor. If the omental tumor is adherent to the parietal peritoneum of the anterior abdominal wall, the pelvic structures, or loops of small intestine, it should be dissected from these structures. Once the omentum is mobilized and lifted cephalad, a dissection plane is developed between it and the serosa of the transverse colon, extending the dissection laterally in both directions (Fig. 49.5A). If the supracolic omentum is heavily involved with tumor and densely adherent to the transverse colon, it also may be necessary to establish a plane between the greater curvature of the stomach and the omentum by ligating the right and left gastroepiploic arteries and the individual gastric branches (Fig. 49.5B). Entry into the lesser sac allows traction on the greater curvature of the stomach and facilitates exposure and transection of the gastric branches of the gastroepiploic arch. Occasionally, omental tumor may also involve the spleen or splenic hilum, necessitating splenectomy (see “Splenectomy”).

Decisions regarding the extent of cytoreductive surgery are made based on the presence and extent of metastatic disease. The surgical approach is tailored to the individual patient's needs and situation. The goal is to achieve minimal residual disease, supporting the prognostic influence of suboptimally cytoreduced patients. Studies indicate that optimal cytoreductive surgery may confer a survival advantage, even for patients with stage IV ovarian cancer. Four large retrospective reports noted that patients with stage IV disease who were optimally cytoreduced had a statistically superior survival to patients who were suboptimally cytoreduced (Table 49.10).

Numerous factors contribute to the morbidity and mortality associated with cytoreductive surgery. These include cardiopulmonary problems, the most common of which are infection, hemorrhage (at times requiring reexploration), prolonged ileus, and cardiopulmonary problems. The primary question concerning the efficacy of primary cytoreductive surgery is whether improved survival is related more to the biology of the tumor or to the skill and aggressiveness of the surgeon. In other words, are those tumors that can be debulked optimally also tumors that are less invasive, less infiltrative, and more indolent? Earlier studies do not suggest that this is the case. All demonstrated that patients who required extensive surgery to achieve minimal residual disease and those who had minimal disease at the outset had similar survival rates. More recent studies, however, suggest that patients with de novo minimal disease have a superior prognosis to those who are debulked to minimal disease, supporting the prognostic influence of substage categories within the stage III classification. Unfortunately, there are no randomized studies to resolve important issues in this area. Moreover, prospects for such studies are not good because of several factors, including deeply established biases, the multiplicity of associated prognostic factors, and the highly individualized nature of each procedure. In the meantime, the efficacy of cytoreductive surgery remains controversial. Better information will be required ultimately to define its role.

Studies indicate that optimal cytoreductive surgery may confer a survival advantage, even for patients with stage IV ovarian cancer. Four large retrospective reports noted that patients with stage IV disease who were optimally cytoreduced had a statistically superior survival to patients who were suboptimally cytoreduced (Table 49.10).

Ovarian Cancer: Etiology, Screening, and Surgery

FIGURE 49.6. Retroperitoneal approach with lateral peritoneum incised, demonstrating the proximity of the left ovarian tumor to major pelvic vessels, the ureter, and the rectum.
Resection of Rectosigmoid Colon. A rectosigmoid resection may be performed in approximately 10% of patients during primary debulking (Fig. 49.8). The decision to perform this procedure depends on several factors, including the presence or absence of rectosigmoid obstruction, the amount of tumor infiltration of the lower colon and its contiguity with the ovarian tumor(s), and the probability that such a procedure will render the patient “optimally debulked.” Occasionally, a patient will limit the surgeon’s intraoperative decision-making ability by refusing to consent to possible colostomy. In our experience, resection of the rectosigmoid colon almost always can be accomplished with consequent minimal residual disease in the pelvis; the limiting factor in achieving optimal cytoreduction, however, may be unresectable bulky residual tumor in the upper abdomen or retroperitoneum. In such cases, palliative resection in the absence of obstruction is not recommended. If a rectosigmoid colon resection is performed, in most cases the colon can be reanastomosed using either a suture technique or the end-to-end anastomosis (EEA) stapler. For patients who undergo a reanastomosis, a protective hepatic flexure transverse loop colostomy or loop ileostomy protects the anastomosis for those who have received pelvic radiotherapy, those with unprepared colon, or those whose anastomosis is judged to be suboptimal. Occasionally, a colostomy with a Hartmann’s pouch is necessary.

In 1984, Berek and colleagues reported their experience with 35 patients who underwent a rectosigmoid resection for ovarian cancer, 22 during primary debulking and 13 at secondary debulking. Twenty-four patients underwent a reanastomosis, and 11 had a colostomy without reanastomosis. Seventy-five percent of patients who underwent a reanastomosis did not require a protective colostomy. Optimal cytoreduction (residual tumor <1.5 cm in diameter) was accomplished in 94% of patients undergoing primary surgery and 57% undergoing secondary surgery. Although major morbidity occurred in seven patients (20%), it was temporary in all except one, who developed an anastomotic stricture. There were no postoperative anastomotic leaks or pelvic abscesses.
Soper and associates described 40 women who underwent rectosigmoid colon resection during cytoreductive surgery, 21 (53%) as part of a primary procedure and 19 (47%) as part of a secondary procedure. Residual disease was less than 1 cm in 54% of patients. A permanent colostomy was avoided in 78% of patients. Twenty-five percent of patients experienced major morbidity, including one patient who developed an anas- tomotic dehiscence and pelvic peritonitis necessitating re-exploration and colostomy. One patient (1%) died in the immediate postoperative period. Despite aggressive surgical resection and postoperative therapy, the median survival for the entire group was only 14.5 months. More recent studies have also confirmed the clinical observa- tion that even bloc resection of the rectosigmoid colon during ovarian cancer surgery does result in a high rate of optimal or complete cytoreduction with acceptable morbidity.

Small Intestinal Resection. Although the small intestine is a common site of metastasis, both to the serosa and the mesen- tery, extensive tumor involvement is an uncommon finding at primary surgery. If the small intestine is extensively involved with tumor, it is usually in the terminal ileum. Occasionally, small intestinal obstruction, either partial or complete, is present at diagnosis. As noted, complete surgical staging in- cludes careful examination of the entire length of the small intestine from the ligament of Treitz to the cecum. If, on explora- tion, loops of small intestine are adherent to the pelvic tumor, omental tumor, or other loops of intestine, then these adhesions should be lysed. Indications for small intestinal re- section include obstruction or impending obstruction by tumor infiltrating the serosa and muscularis of a segment or a non- obstructing extensive lesion of the small intestine for which resec- tion would result in minimal residual disease.

If the lesion involves the very terminal portion of the ileum, as is usually the case, or if a portion of the ileum is adherent to the pelvis or cecum, then ileocolic resection, or resection of the ascending colon adjacent to the small intestine may be neces- sary. Care should be taken to avoid the presence of tumor at the points of reanastomosis. The reanastomosis may be per- formed using either the suture or the stapling technique. In our experience and in the literature, small intestinal resection is indi- cated in approximately 5% to 10% of primary operations for ovarian cancer.

Resection of the Urinary Tract. Indications for ureteral resec- tion or partial cystectomy are uncommon during cytoreductive surgery. If ureteral obstruction is noted preoperatively, it is al- most always a result of ureteral compression rather than tumor infiltration. Although adherence of the ureter(s) to masses of ovarian cancer is not an unusual finding, the surgeon can al- most always separate the ureter from the tumor using sharp dissection. If the distal ureter is resected as part of cytoreduc- tive surgery, it usually can be reimplanted into the bladder. More commonly, the ureter may be injured during the course of debulking surgery. Depending on the site of injury, a pri- mary reanastomosis, transureteroureterostomy, or ureteroneo- cystotomy may be indicated. In a report by Berek and as- sociates, 16 of 848 patients (2%) underwent partial ureteral resection. Five patients had transureteroureterostomy, two had reanastomosis, and four had urinary diversion. Twelve of the operations were part of primary cytoreductive surgery, and four were part of secondary surgery. Nine of these 16 patients had evidence of ureteral obstruction on preoperative intravenous pyelograms.

On the other hand, tumor involvement of the peritoneum overlying the urinary bladder is not an uncommon finding dur- ing primary cytoreductive surgery. Occasionally, a partial cy- stectomy may be necessary to achieve optimal cytoreduction. In the series of Berek and associates, eight patients had a partial cystectomy for advanced ovarian cancer. Reconstruction ne- cessitated ureteral reimplantation in two patients and an ileal conduit in one patient. If a partial cystotomy is indicated, we prefer a simple closure with two layers of chromic catgut su- ture, the inner layer as a continuous running suture and the outer layer as interrupted sutures.

In our experience, tumor involvement of the bladder mucosa with ovarian cancer at initial diagno- sis, such patients usually report hematuria in association with obvious massive disease. The definitive diagnosis can be made easily by preoperative cystoscopy.

Splenectomy. Splenectomy is indicated occasionally during pri- mary cytoreductive surgery (Fig. 49.9). Various series report the incidence of splenectomy during primary cytoreductive surgery in 5% to 11% of cases of advanced ovarian cancer. In addition, the indications for splenectomy and the procedure itself have been described in case reports. Most commonly, the hilum of the spleen is involved with ovarian cancer in association with extensive omental involvement. Rarely, isolated splenic caps- ular involvement or even splenic parenchymal involvement may be found. In addition to tumor debulking, splenectomy also may be indicated during cytoreductive surgery because of a traction injury with avulsion of the splenic capsule during omentectomy or mobilization of the splenic flexure of the colon in association with descending colostomy or reanastomosis af- ter rectosigmoid colon resection. If a splenic capsular involvement occurs or access to the lesser sac is limited by the distribution of tumor, the surgeon may prefer to first mobilize the spleen by dividing its peritoneal attachments while compressing the splenic vessels, and then ligate the splenic vessels using a pos- terior approach. The spleen is rotated anteriorly and medially in this technique.

The methods of performing splenectomy during cytoreduc- tive surgery may vary depending on the circumstances. Under controlled conditions (no uncontrolled hemorrhage), the sur- geon may prefer to incise the gastrospenic ligament, gain access to the lesser sac, and identify and ligate the splenic vessels as they run along the superior border of the pancreas. The spleen can then be mobilized by transecting its attachments to the colon, the left kidney, and the diaphragm. If hemorrhage is oc- curring or access to the lesser sac is limited by the distribution of tumor, the surgeon may prefer to first mobilize the spleen by dividing its peritoneal attachments while compressing the splenic vessels, and then ligate the splenic vessels using a pos- terior approach. The spleen is rotated anteriorly and medially in this technique.

Complications associated with splenectomy include hem- orrheage, infection, thromboembolic phenomena, left-sided at- electasis or pneumonia, injury to the tail of the pancreas (with resultant pancreatic pseudocyst), or injury to the stomach (with resultant gastric fistula). Because of the risk of severe infection following splenectomy, the patient should receive perioperative antibiotic coverage and should be vaccinated with polyvalent pneumococcal, quadrivalent meningococcal, and hemophilus influenzae vaccines. We also prefer to insert a drain in the splenic bed postoperatively to diagnose early postoperative hemorrhage and reduce the infection rate.
Resection of Diaphragmatic Tumor. Several reports have described experience with resection of diaphragmatic metastatic deposits in patients with advanced ovarian cancer (Fig. 49.10). To gain access to the diaphragmatic surfaces, the abdominal incision is extended to just below the xiphoid process, and the liver is mobilized by transecting the entire falciform ligament and the coronary and triangular ligaments. After it is adequately exposed, the diaphragmatic tumor may be resected by stripping the peritoneum from the diaphragmatic muscle using sharp dissection with either Metzenbaum scissors or electrocautery. Alternative techniques of debulking in this area are discussed in the following. The anesthesiologist should be notified if the pleural cavity is entered. Defects in the diaphragm may be closed with interrupted sutures. If a large defect cannot be closed primarily or can be closed only under tension, then the defect may be closed using synthetic mesh. If the
pleural cavity is entered, then a thoracostomy tube should be placed.

Possible complications associated with resection of diaphragmatic tumor include pneumothorax, hemorrhage from the phrenic arteries, infection, injury to the pericardial sac, and injury to such structures as the lung, the vena cava, or the phrenic nerves.

Whether aggressive resection of diaphragmatic metastases with associated potential complications is justified is unclear. Montz and coworkers reported that 13 of 14 patients with diaphragmatic tumor could be optimally debulked. The size of resected specimens ranged from $12 \times 7$ cm to $17 \times 11$ cm. Kapnick and colleagues found that tumors that penetrated the entire thickness of the diaphragm to involve the pleura were greater than or equal to 5.0 cm in diameter. Patients with tumors that penetrated the diaphragm had a median survival time of 8 months compared with a median survival time of 26 months for those patients without full-thickness diaphragmatic penetration by the tumor. Therefore, the assessment of the benefit of this procedure must await further studies.

In a review of the Mayo Clinic experience, Aletti and associates found that for the subgroup of 181 patients with ovarian cancer metastatic to the diaphragm, those who underwent diaphragm surgery had improved 5-year overall survival compared with those who did not (53% vs. 15%). In another recent study of 262 patients with stages IIIC to IV epithelial ovarian cancer, Eisenhauer and colleagues found that patients requiring extensive upper abdominal procedures to achieve optimal debulking demonstrated a similar initial response, progression-free survival, and overall survival to patients optimally debulked by standard surgical techniques.

Resection of Retroperitoneal Lymph Nodes. The initial retroperitoneal approach for cytoreductive surgery exposes the node-bearing areas. Lymph nodes are sampled as part of the staging technique, and every effort is extended to remove suspicious retroperitoneal nodes when the peritoneal cavity has been cleared of disease (Fig. 49.11). The benefit of radical resection of extensive retroperitoneal lymph node metastases also remains unclear. Burghardt and associates compared the survival of 70 patients with stage III ovarian cancer who had undergone radical pelvic lymphadenectomy with 40 patients with the same stage of disease treated without lymphadenectomy. The actuarial 5-year survival was superior for the former group: 51% versus 13%, respectively. In the reports of Wu and colleagues and Burghardt and associates, the role of pelvic and paraaortic lymphadenectomy at initial surgery for ovarian cancer is discussed, but there is no particular discussion of debulking of grossly enlarged retroperitoneal nodes. Benedetti-Panici and coworkers reported the findings of a prospective study on the feasibility and morbidity of radical paraaortic and pelvic lymphadenectomy in patients with gynecologic malignancies. They observed acceptable morbidity—principally hemorrhage, lymphocyst formation, and deep venous thrombosis—and no operative mortality. Scarabelli et al retrospectively evaluated the potential benefit on survival of systematic pelvic and paraaortic lymphadenectomy during both primary and secondary cytoreductive surgery in patients with stage IIB or IV ovarian cancer. The previously untreated patients who underwent systematic lymphadenectomy had a significantly improved survival. The authors appropriately recommended a prospective randomized study to determine the efficacy of such an approach.

For patients with malignant germ-cell tumors, especially dysgerminoma, the advantages of debulking metastatic retroperitoneal nodes are even less apparent, because these tumors are generally much more sensitive to chemotherapy than are other ovarian tumors.

Until further information becomes available, it is probably reasonable to consider debulking enlarged retroperitoneal nodes if peritoneal metastases can be cytoreduced optimally, if there is no fixation to blood vessels, and if the surgeon believes that the procedure can be successfully accomplished without undue risk.

**FIGURE 49.11.** Retroperitoneal dissection of paraaortic lymph nodes involved with metastatic ovarian cancer.
Currently, the issue of systematic aortic and pelvic lymphadenectomy has come more to the forefront. Eisenkop and Spjut reported on 106 patients with stage IIC to IV epithelial ovarian cancer who underwent a retroperitoneal lymphadenectomy at the time of primary cytoreductive surgery. Sixty-six percent had positive lymph nodes. Five were microscopically positive, and 64 were macroscopically positive, of which 63% were positive by palpation, 16 (26%) were positive by inspection, and 26 (43%) were positive by dissection. In the other hand, there were 39 patients with negative or only microscopically positive nodes, and 13 of these patients (39%) were thought to have clinically positive nodes by the operating surgeon. The authors concluded that a significant proportion of patients had macroscopically positive lymph nodes that were detectable only after a dissection was in progress, and clinical impression of lymph node status was unreliable.

Morice and colleagues reported on 276 women with epithelial ovarian cancer who underwent systematic bilateral pelvic and paraaortic lymphadenectomy. The overall frequency of lymph node involvement was 44%. Pelvic and paraaortic lymph nodes were involved 30% and 40% of the time, respectively. In patients with apparent stage Ia, Ib, and IC disease, the rates of nodal involvement were 13%, 33%, and 38%, respectively. And, in their report of a large randomized clinical trial (N = 427 patients) comparing systematic pelvic and paraaortic lymphadenectomy versus resection of bulky lymph node nodes only, Benedetti-Panici and colleagues found that systematic lymphadenectomy improves progression-free survival but not overall survival in women with optimally cytoreduced advanced ovarian cancer.

Additional Techniques for Cytoreductive Surgery. In the last few years, several reports have described techniques for debulking: the argon beam coagulator, the Cavitron ultrasonic surgical aspirator (CUSA), and various types of laser therapy. The argon beam coagulator is an electrosurgical device that conducts current to tissue in a beam of inert argon gas. Brond and Pearman reported the use of the argon beam coagulator for debulking in seven patients with advanced ovarian cancer. Areas treated using this device included the diaphragm, stomach, duodenum, small intestine, colon, liver capsule, peritoneum, bladder and ureters, vaginal apex and parametrium, iliac vessels, and abdominal wall. Four of the patients had no gross residual tumor, and three had residual masses of less than or equal to 2 to 3 mm in diameter. Brastow and Monteau reported the use of the argon beam coagulator to facilitate cytoreduction in 31 patients and concluded that it is a useful adjunct to standard techniques and appears to significantly increase the feasibility of achieving optimal cytoreduction.

There have been several reports of the use of the CUSA for cytoreductive surgery. The CUSA combines tissue fragmentation, irrigation, and aspiration while dissecting tumor from blood vessels without injuring them. Adelson and associates described cytoreduction of tumors to less than 0.5 cm in 9 of 10 patients. The authors particularly noted that intestinal resections were avoided because of the use of the CUSA. Deppe et al reported on 11 patients who underwent optimal debulking using the CUSA. In other reports, the same authors described the utility of the CUSA in debulking diaphragmatic metastases and retroperitoneal lymph nodes. In the latter report, the authors were able to optimally resect extensive paraaortic and pelvic lymph node masses in five of six patients with advanced ovarian cancer. Two patients sustained lacerations of the inferior vena cava during the procedure.

Use of the neodymium-yttrium-aluminum-garnet (Nd-YAG) laser for the resection of intraabdominal tumors has been reported. Other reports of laser therapy for metastatic deposits of ovarian cancer undoubtedly will follow during the next few years.

The benefit of any of these new techniques for cytoreductive surgery remains unproved. Further studies will be necessary to elucidate their proper role.

Role of Laparoscopy in the Clinical Management of Ovarian Cancer

At present, the role of laparoscopy in the management of ovarian cancer is evolving. There are several clinical settings in which the potential for this surgical modality has been investigated: (a) primary surgery for early-stage ovarian cancer; (b) restaging of unstageable ovarian cancer; (c) primary cytoreductive surgery for advanced-stage ovarian cancer; (d) assessment of resectability; (e) intraperitoneal catheter placement; (f) second-look surgery; and (g) secondary cytoreductive surgery.

Chi and colleagues compared 20 patients who underwent cytoreductive surgery via a laparoscopic approach with 30 patients who underwent surgical staging via laparotomy for ovarian or fallopian tube cancers. They found no differences in body mass index, omental specimen size, and number of resected lymph nodes. The estimated blood loss and hospital stay were lower for laparoscopy patients, but operating time was longer. LeBlanc and associates performed laparoscopic restaging in 53 patients—42 early after initial surgery for ovarian or fallopian tube cancer and 11 for second-look surgery after primary chemotherapy. Of the 42 early restaging procedures, 41 were completed successfully. An average of 20 paraaortic and paraaortic lymph nodes and 14 pelvic lymph nodes were removed in these procedures. Complications included a hematoma from an inferior epigastric artery injury and two lymphocysts. Eight patients were upstaged: two patients to stage IIa, two patients to stage IIIa, and four patients to stage IIB. In addition, Lecour and coworkers found no difference in survival between patients who underwent surgical staging for stage I epithelial ovarian cancer by either laparoscopy, laparotomy, or laparoscopy converted to laparotomy.

For patients with apparent advanced-stage ovarian cancer, laparoscopic evaluation has been investigated in the context of assessment of resectability. Two recent studies have described this approach. Fagotti and colleagues employed laparoscopy in 64 patients with suspected advanced ovarian cancer before laparotomy for primary cytoreduction. The overall accuracy rate of laparoscopy in predicting optimal cytoreduction was 90%. In a study by Angioli and associates, 87 patients with suspected advanced ovarian cancer underwent diagnostic laparoscopy; of the 53 (61%) patients who were judged to be operable, 96% were optimally debulked.

The major concern regarding the use of laparoscopic surgery in the management of ovarian cancer is the spread of the cancer, particularly port site metastasizes. Ramirez and coworkers estimated the rate of port site metastasis in patients undergoing laparoscopy for gynecologic malignancies as 1% to 2%. Vergote and colleagues reported 173 patients with advanced ovarian cancer who underwent diagnostic laparoscopy. Seventy-one patients underwent complete excision of port sites at the time of primary cytoreductive surgery. Thirty (17%) patients subsequently developed port site metastases. However, only 8 (5%) of these were clinically diagnosed, whereas 22 (31%) were diagnosed on pathologic examination of resected
port sites. All of the port-site metastases resolved during primary chemotherapy, and prognosis was not worsened by this finding.

Therefore, the role of laparoscopy is evolving. At present, the most useful settings for this approach appear to be primary surgery for apparent early-stage disease, restaging of apparent early-stage disease that is unstaged before referral, and assessment of residual or recurrent disease to determine whether primary cytoreductive surgery or neoadjuvant chemotherapy and interval debulking is preferable.

Primary Chemotherapy for Advanced Ovarian Cancer

For patients with advanced-stage malignant ovarian germ-cell tumors, the standard regimen is identical to that for patients with early-stage disease who require chemotherapy—the BEP regimen. The optimal number of cycles remains unknown, but for these patients with a potentially greater tumor burden than those with early-stage disease, four to six cycles may be required in some instances. Generally, administering two cycles following normalization of serum tumor markers may be a reasonable guide, although there are no definitive studies to support this practice.

For patients with advanced-stage sex cord-stromal tumors, platinum-based combination chemotherapy is generally recommended. As noted, the BEP combination regimen or the combination of paclitaxel/carboplatin are the most popular regimens in the United States.

For advanced-stage epithelial ovarian cancer, the combination of cisplatin and cyclophosphamide was the standard postoperative regimen throughout most of the 1980s and until the mid-1990s. Subsequently, based on encouraging results of phase II studies of paclitaxel in patients with refractory ovarian cancer, GOG initiated a randomized trial comparing the standard regimen of cyclophosphamide/cisplatin with the combination of paclitaxel/cisplatin in patients with suboptimally debulked advanced epithelial ovarian cancer. The findings of this study revealed a significant outcome advantage for the paclitaxel/cisplatin regimen in terms of progression-free survival and overall survival. A subsequent similar study conducted by a European consortium confirmed the results of the GOG study. Subsequently, based on the results of a GOG phase I trial, GOG initiated a randomized study comparing paclitaxel/cisplatin with paclitaxel/carboplatin. In the latter regimen, paclitaxel was administered over 3 rather than 24 hours, as in the previous GOG study. Recent data from that study suggest that the paclitaxel/cisplatin regimen is equally efficacious and has a superior toxicity profile compared with the paclitaxel/cisplatin regimen. A study conducted by a German consortium (AGO) demonstrated similar results. Thus, because of its superior therapeutic index, the paclitaxel/cisplatin regimen has become the standard postoperative treatment for patients with advanced epithelial ovarian cancer.

Two other studies, however, have somewhat confused the issue. GOG reported the results of a phase III randomized study in which the 24-hour infusion paclitaxel and cisplatin regimen was compared with single-agent paclitaxel and single-agent cisplatin. Response with single-agent paclitaxel was significantly inferior, but overall survival was identical for all three arms of the study, probably because of significant crossover of patients on monotherapy to the other single agent. In another study conducted by the British Medical Research Council, the paclitaxel/carboplatin regimen was compared with a nonpaclitaxel regimen (either single-agent carboplatin or a combination of cyclophosphamide/doxorubicin/cisplatin). There was no difference in outcome between the two treatment arms with a relatively short follow-up time. However, approximately 20% of the patients in this trial had early-stage disease.

Vasey and colleagues conducted a phase III trial of doxorubicin/cisplatin versus paclitaxel/carboplatin as first-line chemotherapy for stage IC to IV epithelial ovarian cancer and peritoneal cancer. A total of 1,077 patients were enrolled in the study. Although there were no differences in progression-free survival or overall survival between the two groups, the doxorubicin/cisplatin regimen was associated with significantly less neurotoxicity but more myelotoxicity. GOG recently reported the preliminary results of their latest phase III trial in advanced ovarian cancer. This was a five-arm study that introduced three new drugs into first-line therapy as either three-drug combinations or sequential doublets, including liposomal doxorubicin, topotecan, and gemcitabine. The results indicated that no regimen demonstrated superiority to the control arm of paclitaxel/carboplatin.

Intraperitoneal chemotherapy also has been studied as primary treatment for patients with optimally cytoreduced advanced epithelial ovarian cancer. With the recent publication of GOG #172, three GOG studies have now demonstrated the benefits of intraperitoneal chemotherapy over intravenous chemotherapy in the treatment of this subgroup. In an intergroup study, the first such trial, 652 patients with less than 2 cm residual disease were randomized to receive intravenous cisplatin/cyclophosphamide versus intraperitoneal cisplatin plus intravenous cyclophosphamide. The median survival was significantly longer in the group receiving intraperitoneal cisplatin (49 months) than in the group receiving intravenous cisplatin (41 months). In addition, toxicity was worse in the intravenous group. The second GOG intraperitoneal study used intravenous versus intraperitoneal cisplatin as part of initial therapy. Patients on the intraperitoneal arm received an initial two cycles of moderate-dose systemic carboplatin. The results of that study showed a significant improvement in progression-free survival for the intraperitoneal arm but only a borderline effect on overall survival. Because of significant design flaws associated with each of these GOG studies, the role of intraperitoneal chemotherapy in the management of advanced ovarian cancer remains unclear.

In the most definitive trial to date, Armstrong and associates conducted a phase III trial comparing intravenous paclitaxel plus cisplatin versus intravenous paclitaxel and intraperitoneal cisplatin, with intraperitoneal paclitaxel on day 8. The median overall survival was significantly better for the intraperitoneal chemotherapy arm: 66 versus 50 months (p = 0.03). However, short-term quality of life and toxicity—principally fatigue, hematologic, gastrointestinal, metabolic, and neurological—were significantly worse in the intraperitoneal arm. Furthermore, only 42% of patients in the intraperitoneal chemotherapy arm were able to complete all six cycles of planned treatment. Nevertheless, this study has generated much renewed enthusiasm for the intraperitoneal chemotherapy approach, as well as controversy.

An article detailing the intraperitoneal catheter complications in the recent GOG trial was also published. Of the 119 patients in the intraperitoneal chemotherapy arm who were not able to complete six cycles of treatment, 34% discontinued therapy because of catheter-related issues, and 25% continued for noncatheter-related reasons. There also appeared to be an association between sigmoid resection and inability to initiate intraperitoneal chemotherapy.
Neoadjuvant Chemotherapy and Interval Cytoreductive Surgery

Over the past two decades, the concept of neoadjuvant chemotherapy followed by interval debulking (as a primary cytoreductive procedure after a few cycles of chemotherapy) has emerged. This approach began to be reported in the late 1970s for certain subsets of patients: those who were referred to an oncologist after a surgical or nonsurgical biopsy or patients who initially were poor surgical candidates because of a debilitated state related to massive effusions or comorbid conditions. However, this approach was proposed as an alternative for all patients with advanced epithelial ovarian cancer or for certain subsets, such as those predicted to be suboptimally resected. The potential advantage of such an approach is to operate on a patient with an improved nutritional status, a smaller tumor burden, and superior perioperative risk.

Although several studies have explored the concept of a surrogate marker of resectability of advanced ovarian cancer, as evidenced by the outcome of bulky residual disease, this issue remains unresolved. If accurate, such a strategy could potentially avoid a suboptimal debulking with the associated morbidity. The principal focus has been on preoperative serum CA-125 or CT appearance of disease. Unfortunately, to date, neither has been accurate enough to be incorporated into standard care. Diagnostic laparoscopy has also been investigated as a tool for assessing resectability; this approach may ultimately prove to be the most practical and accurate method, but further study is indicated.

A number of retrospective series have reported the feasibility of neoadjuvant chemotherapy and interval debulking. Clinical observations from these reports indicate the following: (a) a high proportion (70%–80%) of patients treated with neoadjuvant chemotherapy have partial or complete responses before interval surgery; (b) a high proportion of patients so treated, possibly higher than with primary cytoreductive surgery, are optimally debulked with minimal residual disease; and (c) the surgical morbidity may be reduced compared with that associated with primary cytoreductive surgery. An European cooperative group is currently studying this approach in a randomized clinical trial. It is hoped that the results of this trial will elucidate the role of neoadjuvant chemotherapy and interval cytoreductive surgery.

SECONDARY SURGERY

Second-Look Laparotomy

Second-look laparotomy for evaluation of disease status following treatment for cancer of the colon was proposed initially by Wilgrensteen and associates in 1948. Beginning in the early 1960s, second-look laparotomy was used extensively in the management of ovarian cancer. The procedure continued to gain popularity as more ovarian cancer patients were treated with chemotherapy and fewer received radiontherapy. Since the mid-1980s, however, there has been increasing skepticism about the benefits of this procedure. Currently, second-look surgery is not part of the routine management of patients with any histologic type of ovarian cancer. Although it remains the most common method of assessing disease status at completion of primary chemotherapy, no study has demonstrated a survival benefit associated with the procedure. In addition to the lack of demonstrated survival benefit, second-look surgery is still not that precise; approximately 50% of patients with negative findings ultimately relapse. However, second-look surgery is still occasionally used if it is part of a clinical trial or if the findings would make a patient eligible for a subsequent clinical trial.

Most experts agree that the term second-look surgery should be restricted to an operation performed on a patient with no clinical evidence of persistent tumor for the purpose of determining disease status after a planned interval of treatment with chemotherapy. The term should not be applied to a surgical procedure performed in patients with clinical evidence of persistent or progressive disease for the primary purpose of debulking or treatment of complications of the disease.

The operative technique of second-look laparotomy has been well described. It is essentially identical to a staging laparotomy, as discussed previously. An adequate vertical midline abdominal incision is made. On entering the abdomen, cytologic washings from the pelvis, bilateral paracolic gutters, and subdiaphragmatic areas are obtained, and the entire contents of the peritoneal cavity are inspected and palpated. If obvious macroscopic tumor is present, then the procedure usually is limited. However, the extent of disease should be carefully determined, and a few biopsies should be taken for documentation of persistent disease (frozen as well as permanent section). If no obvious macroscopic disease is noted, then random biopsy specimens are taken routinely from the peritoneal surfaces, including the cul-de-sac, vesicouterine reflection, bilateral pelvic walls, bilateral paracolic gutters, and surfaces of the diaphragm. Omental biopsies and biopsies of the retroperitoneal lymph nodes also are performed. Lysis of adhesions is not uncommon in the process of performing these biopsies. Sites of previously documented tumor and adhesions should be carefully evaluated and generously sampled. An adequate procedure consists of a minimum of 20 to 30 biopsy specimens.

Of course, laparoscopy rather than laparotomy is an alternative for patients who undergo second-look surgery. Obvious advantages include better visualization of peritoneal surfaces as well as more rapid recovery and significantly reduced time in hospital. Both the “open” and “closed” techniques have been reported.

Findings at second-look surgery are classified as negative (grossly and pathologically negative), macroscopically positive (grossly negative, pathologically positive), and macroscopically positive (grossly and pathologically positive). The clinical variables most consistently associated with findings at second-look surgery and survival afterward are histologic grade, amount of residual disease, and FIGO stage. Patients with minimal residual disease and early-stage disease have a greater probability of having negative findings at second-look laparotomy than do those with bulky residual disease or advanced-stage disease. Other variables found to correlate with second-look findings and subsequent survival in some of these studies are histologic type, type of chemotherapy, amount of disease found at the initial surgery, age, performance status, and peritoneal cytology status.

Findings in approximately 30% to 50% of patients with advanced ovarian cancer (and a smaller percentage of those with early-stage disease) will be macroscopically positive at second-look surgery. Approximately 20% of patients with advanced ovarian cancer who undergo second-look surgery have microscopically positive findings. Negative second-look surgery findings are noted in approximately 30% to 50% of patients with advanced ovarian cancer undergoing this procedure.

There is limited information in the literature regarding second-look surgery in patients with malignant germ-cell tumors and virtually no meaningful information about patients...
with sex cord–stromal tumors. In a review of the experience with second-look laparotomy in patients with malignant germ-cell tumors at M.D. Anderson Cancer Center, findings were negative in 52 of 53 such patients. One patient with negative findings subsequently experienced a relapse and died. Thirteen patients had biopsy-proven evidence of mature teratoma—so-called chemotherapeutic retroconversion—at second-look laparotomy; treatment was discontinued in all patients, and none developed a recurrence. Based on these observations, our group recommended limitation on the use of second-look laparotomy in this patient population as much as possible. Williams et al. reported the GOG experience, in which 117 patients with malignant germ-cell tumors underwent second-look laparotomy after treatment with platinum-based chemotherapy. Based on their findings, the authors concluded that patients with either completely resected tumor or advanced-stage incompletely resected tumor that does not contain elements of teratoma rarely, if ever, benefit from second-look laparotomy. They did recommend second-look surgery for patients with incompletely resected tumor that contains teratoma. However, a significant proportion of this latter subset of patients had clinically detectable tumor before second-look surgery. The procedure is not recommended for those patients with initially detectable levels of serum tumor markers, especially those with early-stage disease. Some patients with advanced disease, particularly those with initially undetectable serum tumor markers, continue to undergo second-look laparotomy. The issue of second-look surgery for patients with incompletely resected tumor that does not contain elements of teratoma remains unresolved. As better therapies are developed and refined, the procedure will inevitably become obsolete, except in unusual situations.

### Secondary Cytoreductive Surgery

The term secondary cytoreductive surgery has no universal definition. It may denote cytoreductive surgery performed in one of several different settings: (a) in patients who are partial responders or nonresponders to primary chemotherapy, (b) in patients who have developed recurrent disease after receiving primary chemotherapy and experience a prolonged disease-free interval off therapy (≥6 months), (c) in patients who undergo a suboptimal debulking initially followed by three cycles of chemotherapy (so-called interval debulking), and, (d) in patients who have persistent macroscopic tumor at second-look laparotomy.

Tumors in these subgroups of ovarian cancer patients may have very different natural histories, principally defined by whether they are platinum resistant or platinum sensitive. For example, patients whose tumor progresses during first-line chemotherapy, whether progression is noted clinically or at second-look laparotomy, are defined as platinum resistant. Patients who have not yet received chemotherapy or are partial responders to chemotherapy (whether the response noted clinically or at second-look surgery) or who have developed recurrent disease after a prolonged interval off therapy may well be platinum sensitive. These subgroups may have very different survival rates based on their responsiveness to second-line chemotherapy after secondary cytoreductive surgery. Therefore, it is extremely important for studies designed to assess the impact of these various secondary procedures on survival rates to carefully define their study populations. Because of the lack of prospective randomized studies in this area, it is difficult if not impossible to draw any firm conclusions about the influence of secondary debulking in these settings. However, the principal setting for secondary cytoreductive surgery is for platinum-sensitive recurrent disease.

### Secondary Cytoreductive Surgery for Recurrent Disease

Several retrospective studies have shown an improved survival for patients secondarily cytoreduced to small residual disease compared with patients who were not optimally cytoreduced. Optimal candidates for such a procedure appear to be those who are platinum sensitive. The longer the interval between completion of primary chemotherapy and the time of recurrence, the better the outcome. Results of published studies on secondary cytoreduction for recurrent ovarian cancer are summarized in Table 49.11. Clearly, the true value of debulking

Gynecologic Oncology

surgery for recurrent ovarian cancer can be assessed only by a prospective randomized study. GOG is in the process of planning such a study in the near future.

Chi and colleagues recently analyzed their experience with 155 consecutive patients undergoing secondary cytoreductive surgery for platinum-sensitive recurrent epithelial ovarian cancer. They confirmed previous observations that the longer the disease-free interval, the longer the survival time after secondary cytoreduction (30 months for disease-free interval of 6–12 months, 39 months for disease-free interval of 13–30 months, and 51 months for disease-free interval greater than 30 months). For patients who had residual disease less than or equal to 0.5 cm, the median survival was 56 months compared with a median survival of 27 months for those patients with residual disease greater than 0.5 cm. The authors further devised a set of recommendations for selection of candidates for secondary cytoreductive surgery based on the disease-free interval, the number of recurrence sites, and evidence of carcinomatosis.

Secondary Attempt at Cytoreductive Surgery after Suboptimal Debulking

The term interval cytoreduction has been used to describe two distinct entities: (a) a true secondary cytoreduction performed after primary cytoreduction that is suboptimal (with bulky residual disease remaining) and three cycles of chemotherapy, or (b) cytoreduction after a biopsy performed at surgery (by laparoscopy or laparotomy), fine needle aspiration, or percutaneous biopsy (usually > 0.5 cm). The latter is really neoadjuvant chemotherapy followed by primary cytoreduction. These two entities have been confused and used interchangeably in the literature. Several reports described secondary cytoreductive surgery as interval debulking after a suboptimal primary surgery and a few cycles of chemotherapy. Van der Burg and associates reported the findings of a large prospective randomized trial in which 278 patients with less than 1 cm residual tumor after primary cytoreductive surgery were enrolled. After three cycles of cisplatin cyclophosphamide chemotherapy, patients were randomized to receive either secondary cytoreductive surgery followed by three more cycles of chemotherapy or three more cycles of chemotherapy alone. Of the 140 patients randomized to the interval cytoreduction arm, 65% still had bulky tumor at the time of this secondary surgery. About 45% of these patients were able to be cytoreduced optimally. Both progression-free survival and overall survival were modestly improved in the interval cytoreduction group. GOG subsequently conducted a study with an identical study design in an effort to replicate the results of this European trial; however, the combination of paclitaxel/cisplatin was used rather than cyclophosphamide/cisplatin. Contrary to the findings of the European study, the addition of secondary cytoreductive surgery to postoperative chemotherapy did not improve either progression-free survival or overall survival. The explanation for the disparate results may lie in the less aggressive initial cytoreductive attempt with resultant larger residual tumor volumes by the European investigators. Based on these findings, this approach is not currently recommended.

MANAGEMENT OF INTESTINAL OBSTRUCTION

Approximately 23% of ovarian cancer patients develop intestinal obstruction in the terminal phase of their illness. One of the major dilemmas facing the gynecologic oncologist is whether to operate on a patient with refractory ovarian cancer and an intestinal obstruction. Although current information provides some guidelines, the decisions concerning the wisdom of surgical intervention and intraoperative management are based more on the art of the discipline and experience of the surgeon than on scientific criteria.

Signs and symptoms of intestinal obstruction resulting from ovarian cancer include nausea and vomiting, abdominal cramping, abdominal distention, and progressive constipation. In patients who have only partial obstruction, these symptoms and findings may be episodic and more subtle. Plain films of the abdomen may support the diagnosis. Dilatation of the small intestine and air fluid levels suggest involvement of the small bowel. Dilatation of the colon may characterize large bowel obstruction. In patients with early, partial obstruction, the radiographic findings may be nonspecific.

Although intestinal obstruction in patients with ovarian cancer may be caused by adhesions, progressive tumor usually is the inciting factor. Of course, if the patient has received abdominopelvic radiotherapy, obstruction that is due to adhesions should be considered. In our experience, and that of others, however, most cases of intestinal obstruction in ovarian cancer patients who have received prior radiotherapy are related primarily to tumor progression.

The site(s) of the obstruction may be solitary or multiple. In 5% to 10% of patients, there is simultaneous obstruction of the small and large bowel. Colon obstruction usually occurs in the area of the sigmoid colon because of growth of pelvic tumor and resultant extrinsic compression; occasionally there may be obstruction of more proximal segments. Small bowel obstruction is usually the result of adherence of loops of bowel by mesenteric or serosal tumor implants. Once the appropriate evaluation is completed and the diagnosis of intestinal obstruction is made, the gynecologist should outline a plan of management. Many factors influence this decision, including age, the nutritional status and general condition of the patient, the amount of tumor present, the presence or absence of ascites, the options for postoperative salvage therapy, the attitude of the physician, and the wishes of the patient and her family. The decision of whether to operate or manage the patient nonoperatively is colored by the fact that surgery for patients with refractory ovarian cancer is associated with significant morbidity and mortality; the obstruction cannot be relieved in almost 20% of those undergoing surgery, and postoperative survival is disappointing. In reported series, the serious complication rate has ranged from 28% to 49%, and the operative mortality rate is in the range of 12% to 16%. The median survival rate for patients who have undergone surgery is in the range of 3 to 5 months.

Although some investigators have used projected survival (usually > 2 months) as a parameter to decide on type of management, such an indicator is too unpredictable. Krebs and Goplerud devised a scoring system for selection of patients for surgery that included patient age, nutritional status, amount of palpable tumor, presence of ascites, previous chemotheraphy, and previous radiotherapy. Outcome seemed to correlate with the prognostic score. Clarke-Pearson and colleagues confirmed the influence of disease status, ascites, and nutritional status.

For initial management of a patient with small bowel obstruction, we prefer the insertion of a nasogastric tube rather than a long tube (Cantor, Miller-Abbott, or Denius) for intestinal decompression. After extensive experience with both, we have found no advantage from the latter. Furthermore, long tubes are associated with considerably greater discomfort.
Long intestinal tubes seem to have the greatest success rate in patients with postoperative adhesions but are fairly ineffective in relieving obstruction resulting from cancer. In the study of Krebs and Coplerud, only 10% of patients had their obstruction relieved by tube decompression. In patients for whom no surgery is planned, we have extensively used the technique of percutaneous gastrostomy since 1984. This procedure has resulted in excellent palliation for terminal-stage ovarian cancer patients, avoiding the discomfort of the nasogastric tube and allowing the patient to be easily cared for at home in most cases. With such a device, the patient may even continue to eat, although the nutritional benefit is essentially nil.

Optimal preoperative preparation is desirable if a patient is judged to be a suitable candidate for surgical intervention. For patients with complete colonic obstruction or perforation of the small or large intestine, a surgical emergency exists unless the patient is in such poor condition that such an intervention is not feasible. In emergency cases, the patient should be stabilized with intravenous fluids and antibiotics before surgery. Emergency surgery is rarely indicated for patients with a small intestinal obstruction. It is preferable to optimize the patient’s condition with nasogastric tube decompression and rehydration. In addition, a barium enema is usually indicated to rule out a coexisting colonic obstruction. If the patient is malnourished, then intravenous hyperalimentation may be indicated preoperatively. Ample information suggests that hyperalimentation places the patient in an anabolic state and reduces the incidence of postoperative morbidity; however, its effect on long-term survival is unclear.

Colonic obstruction usually is treated by performing a colostomy. The selection of the site of colostomy depends on the area of obstruction and the ability to find an adequate bowel segment free of cancer. Most commonly, a transverse loop colostomy is indicated because of the presence of a descending colon or sigmoid colon obstruction. There is increasing experience with the use of colonic stents as a substitute for colostomy. Patient selection is key, because erosion of the colonic wall with perforation is a risk.

A number of options are available for small bowel obstruction, depending on the operative findings. Most commonly, there are multiple sites of obstruction in the terminal ileum, in which case a de-ascending colon bypass or de-transverse colon bypass is preferable. In such situations, it is usually both wise and inappropriate to attempt resection and reanastomosis. If, on the other hand, there is an isolated area of obstruction, then a resection and reanastomosis may be indicated. The anastomosis may be either hand sewn using a two-layer technique or approximated with surgical staplers. We generally prefer the latter because of the time-saving aspect. Frequently, there may be extensive tumor with multiple areas of obstruction, making both bypass and resection impossible. A tube gastrostomy is indicated in such a situation, if possible. Procedures such as these are among the most demanding because of the meticulous, often tedious dissection required. Enterotomies are not uncommon and should be repaired as soon as they are identified. Complications of small intestinal procedures include wound infection, intraperitoneal abscess, sepsis, pneumonia, “blind loop syndrome,” and enterocontaneous fistula.

**BEST SURGICAL PRACTICES**

- In the United States, more than 22,000 new cases of ovarian cancer are detected annually, and more than 16,000 women will die of the disease. The lifetime risk of ovarian cancer for a woman in the United States is 1/70. This risk increases to 5% in a woman with one first-degree relative who has ovarian cancer and to 7% if she has two or more relatives with the disease.
- There are three hereditary familial ovarian cancer syndromes: the hereditary breast-ovarian cancer syndrome (HBOC), the hereditary site-specific ovarian cancer syndrome (HSSOC), and the hereditary nonpolyposis colon cancer syndrome (HNPCC).
- Pelvic examination is inaccurate in assessing ovarian size and morphology, particularly in postmenopausal women and in women who are overweight.
- In a research study, ovarian cancer screening, using a combination of transvaginal sonography and serum biomarkers, results in a decrease in stage at detection and an increase in case-specific survival. However, it is not effective in detecting ovarian cancer in patients whose ovarian volume is normal. With present technology, ovarian cancer screening is not sensitive or specific enough to recommend general population screening. Screening of high-risk women should be individualized.
- Numerous studies have shown improved survival in both early- and advanced-stage ovarian cancer when the initial surgery has been done by a gynecologic oncologist. A careful evaluation of an adnexal mass using transvaginal ultrasound, serum CA-125, and, occasionally, supplemented by other imaging studies will usually identify the patient with a high risk of malignancy who should be referred for surgery by a gynecologic oncologist.
- Surgery for ovarian cancer includes both careful staging to document the extent of the disease and resection or debulking of the tumor. Careful attention to accurate and comprehensive staging is most important in early-stage disease, for which postoperative therapy decisions may depend on the staging findings and histopathologic diagnosis. In patients with advanced disease, maximum surgical debulking to less than 1 cm diameter of residual disease should be the goal.
- In some young women with ovarian cancer, fertility-sparing surgery is possible. In a woman with a lesion apparently confirmed to a single ovary (or rarely both ovaries) who desires future pregnancy, ovarian and uterine conservation should be discussed preoperatively. At surgery, a unilateral oophorectomy and careful staging should be done, but the opposite ovary is not biopsied if it appears normal. If the diagnosis or staging findings are uncertain, it is best to close and await a final review of the permanent sections on the staging studies. Reoperation is preferable to unecessary radicality in a young woman in whom fertility is a concern.
- In women with advanced ovarian cancer, optimal cytoreduction to less than 1 cm residual disease—or even smaller—has clearly been shown to confer a survival advantage. This is true even in patients with stage IV disease. The techniques required to perform radical cytoreduction in ovarian cancer patients and the judgment to know when it is appropriate is a combination of skill and experience and is usually done by gynecologic oncologists operating in hospital with good teams of anesthesiologists, consultants, and critical care experts.
- Laparoscopic surgery for ovarian cancer is currently under investigation. Its role is uncertain at the present time.
- Postoperative chemotherapy is usually required for patients with ovarian cancer; in some cases, chemotherapy may be given before any definitive surgery. This is an important part of the management of ovarian cancer, but it is not addressed in this surgical textbook.

Ovarian Cancer: Etiology, Screening, and Surgery

DEFINITIONS

Anterior pelvic exenteration—Similar to a total exenteration, except the rectum is left intact. This procedure may be used for anterior pelvic recurrences, anterior vaginal cancers, or bladder or urethral tumors.

Posterior pelvic exenteration—Similar to a total exenteration, except the bladder, urethra, and distal ureters are left intact. This procedure may be suitable for posterior pelvic recurrences or some rectal lesions.

Total pelvic exenteration—Surgical removal of all the pelvic organs, including the uterus, cervix, tubes, ovaries, vagina, bladder, urethra, and distal rectum and anus. In most cases, a pelvic and paraaortic lymphadenectomy are also done.

Triad of trouble—Sometimes called the terrible triad, these signs and symptoms are usually indicators of pelvic sidewall involvement with tumor. The triad is composed of (i) unilateral ureteral obstruction, (ii) sciatic nerve pain, and (iii) unilateral leg edema.

Wet colostomy—An old practice of placing the ureters into the bowel just before it exits the abdomen via a colostomy. The urine and feces are passed via a single abdominal stoma. This technique was abandoned because of frequent pyelonephritis, electrolyte abnormalities, and very unpleasant stoma discharge.

It has been more than 50 years since Brunschwig introduced surgical exenteration as an option to control cancers within the pelvic organs. Initially, significant morbidity and mortality rates ranging from 50% to 70% were encountered. These rates have decreased dramatically, allowing the survival rate for those treated to increase substantially. The results of ultraradical pelvic surgery have been enhanced by a number of advances.

Improved surgical techniques and training have decreased operative time and blood loss and limited the extent of disfigurement. Perioperative morbidity has been reduced through the control of infection and the use of blood component therapy, improved anesthetic techniques, parenteral nutrition, and intensive care facilities managed by expert medical teams. Although pelvic exenteration is a formidable procedure, the 5-year survival rate is greater than 50% for appropriately targeted women (Table 50.1). Exenteration has become the treatment of choice for certain types of advanced or recurrent tumors of the pelvis, and it provides another chance at survival for women in whom primary therapy has failed.

Careful patient selection using a thorough and detailed approach to preoperative assessment is essential. Strict guidelines regarding the indications and contraindications for operability must be met. The adaptive ability of patients who survive is dramatic given the magnitude of anatomic and physiologic change associated with exenteration. However, those who die of their disease despite this heroic surgical effort commonly experience intractable pain from intestinal obstruction or distant metastases.

Many modifications of the Brunschwig procedure have been instituted since its introduction in 1948. The most significant modification was introduced in 1950 when Bricker developed and reported his classic ileal conduit technique. This technique provided an isolated conduit for urinary diversion, which became a replacement option for the traditional “wet colostomies” or ureterosigmoidostomy in which both stool and urine exited from a solitary stoma. The separation of urinary and fecal streams represented a huge advance in terms of reducing complication rates from infection. Despite the requirement for two stomas, this technique also achieved greater patient acceptance. Other more recent advances—such as continent urinary diversion, the use of automatic stapling devices for the gastrointestinal portion of the procedure, pelvic floor coverage, vaginal reconstruction, and low rectal anastomosis—also have improved the overall results and rehabilitation of patients.

Total pelvic exenteration encompasses removal of the genital organs (vagina, uterus, fallopian tubes, and ovaries) as well as the bladder and rectum. An isolated segment of bowel is used to construct a replacement urinary reservoir. A segment of small or large bowel or a combination of both may be considered. Modifications of the pelvic exenterative procedure include either an anterior or posterior exenteration or a total exenteration with a low rectal anastomosis. Patients whose cancer is confined to the anterior pelvic structures are candidates for anterior exenteration, which removes the bladder and genital organs while leaving the gastrointestinal system intact. In this situation, a urinary conduit is developed from an isolated segment of bowel into which the ureters are anastomosed. For tumors limited to posterior structures, posterior exenteration can be used to remove the genital organs and rectum, allowing preservation of the urinary system. In selected patients who undergo a total pelvic exenteration, a low rectal anastomosis can be accomplished if the lower 6 to 10 cm of rectum is preserved. The end-to-end anastomosis (EEA) stapling device designed for this purpose is used to reconstruct the rectum low in the pelvis. Low anastomosis often requires a protective colostomy because the anastomosis has been constructed in an irradiated field. The colostomy can be reversed at a later date, eliminating one of the patient’s stomas.

INDICATIONS AND CONTRAINDICATIONS

The decision-making process begins when the physician first sees the patient and takes her history. An initial diagnostic evaluation is obtained. If the patient appears to be a candidate for a pelvic exenterative procedure, she is referred to a gynecologic oncologist who is experienced in the evaluation and treatment of such patients. The best outcomes are achieved in patients who have centrally recurrent squamous cell carcinoma of the

venous pyelogram demonstrating ureteral obstruction, (b) sciatic nerve distribution of pain suggesting neural sheath involve-
ment at or near the lateral pelvic wall, and (c) lower-extremity edema, implying venous or lymphatic compromise of the iliac vessels. If none or one of these features were present, explo-
ration to determine resectability was recommended. If two or more of these abnormalities were present, the patient’s disease was considered unresectable. If there is any doubt whether the lesion can be resected, the patient should undergo exploratory surgery, because exenteration is often the patient’s last oppor-
tunity for curative therapy.

Several diagnostic techniques can aid in assessing resectability in a patient who is believed to have central pelvic disease on clinical grounds. Evaluation of resectability is important from both a technical and psychological standpoint. A preop-
erative study that demonstrates the presence of unresectable disease helps to avoid not only the morbidity of exploratory laparotomy, but also its attendant false hope for cure. There is a tremendous negative psychological impact on the patient when she is prepared preoperatively for the exenterative proce-
dure only to be told postoperatively that she had an inoperable lesion.

Computed tomography (CT) or magnetic resonance imag-
aging (MRI) can be most beneficial in assessing the presence of lateral pelvic wall invasion and unsuspected liver metastases as well as in further evaluation of the retroperitoneal lymph nodes. MRI is especially useful in locating tumor invasion at the pelvic wall.

Exenteration under anesthesia with transvaginal Tru-Cut
needle biopsy can be used to evaluate a palpable pelvic mass at the lateral pelvic wall. These biopsies can differentiate between recurrent neoplasm and postirradiation fibrosis when thick-
ened tissue is encountered throughout the pelvis. Fine-needle aspiration (FNA) of suspicious regional lymph nodes under CT scan guidance can be helpful in confirming unresectable metastases. McDonald and coworkers reported that FNA had an 85% accuracy rate in identifying positive nodes. Because the 5-year survival rate drops to 0% to 14% when the pelvic lymph nodes are positive, pelvic exenteration is unwarranted, and exploratory surgery is not recommended (Table 50.2). It
must be remembered that a negative biopsy does not guarantee that cancer is not present, but merely that no cancer was identified at the focal point of the needle tip.

The final diagnostic decision concerning the operability of disease is made when the patient is examined under anesthesia and as the exploratory laparotomy is performed. Fixation of the tumor in the pelvis caused by recurrent disease extending to the pelvic sidewall, penetration of the tumor into the peritoneal cavity with dissemination of cells intraabdominally, and extrapelvic involvement of regional lymph nodes, omentum, liver, and other structures are all contraindications to the performance of pelvic exenteration with curative intent. These components of the procedure should be delayed until resectability is confirmed. Incomplete resection with positive margins or metastatic disease is not curative and subjects the patient to an extended and difficult postoperative recovery without a realistic chance of long-term survival.

Pelvic exenteration is a relatively therapeutic option for relatively few women with recurrent cancer. About one third of recurrences appear to be central pelvic failure by clinical examination. Of these, one half are excluded from surgical therapy when diagnostic studies reveal unresectable disease. About one half of women who undergo exploration for exenteration are found to have inoperable disease, and the procedure is aborted. Of those who undergo resection by exenteration, about one half obtain long-term survival and apparent cure (Fig. 50.1).

Pelvic exenteration is not considered a treatment of choice for primary disease except in a limited number of patients with carcinoma of the vulva and in selected patients with nonsynergologic lesions that involve the bladder, urethra, or colon. In the past, stage IVA carcinoma of the cervix involving the bladder or rectum was treated in this manner; however, the results were not considered superior to those achieved by full-course pelvic radiotherapy. Exenteration has been abandoned as primary therapy for this lesion since Rutledge and Burns treated stage IV lesions with radiation therapy and showed an acceptable 28% survival rate. The same concept exists in regard to primary carcinoma of the vagina, for which radiation therapy is the preferred initial treatment. Current chemoradiation protocols with or without conservative surgery appear to provide results equivalent or superior to those obtained with exenteration for advanced tumors of the cervix, vulva, and vagina. Consequently, primary exenteration has become a rare operation.

Disease-free interval—the time from primary diagnosis to recurrence—is highly predictive of survival following exenteration. In all series, there is a direct relation between time from primary treatment to time of recurrence and survival: 5-year survival rate of greater than 90% has been reported when the disease-free interval was greater than 10 years, compared with a survival rate less than 50% when this interval was 1 year or less.

Pelvic exenteration occasionally may be indicated to manage severely damaged irradiated tissue in the pelvis. Many patients with radiation necrosis experience intractable pain, copious amounts of foul-smelling discharge, and both urinary and rectal fistulas from tissue necrosis. In many cases, symptoms can be relieved with urinary and/or bowel diversion procedures alone. Palliative exenteration should be considered only in extreme cases in which more conservative approaches have failed.

Traditionally, the presence of recurrent or persistent adenocarcinoma of the female pelvic organs was a relative contraindication to exenterative therapy. These glandular lesions are more likely to disseminate through the hematologic or lymphatic routes and bypass the traditional, more orderly mode of spread seen with squamous tumors. However, small recent series suggest that exenteration can provide curative therapy for 30% to 50% of women with isolated central recurrence of adenocarcinoma of the endocervix and endometrium (Table 50.3). A diligent search for unresectable metastases must be performed before and during the operation. High tumor grade and short disease-free interval are correlated with decreasing chance of survival. Locally advanced or recurrent pelvic sarcoma, although rare, occasionally may be managed by pelvic exenteration.

Age, religious orientation, obesity, and medical and psychological alterations must be evaluated as potential contraindications to exenteration. Although life expectancy beyond 70 years for women who undergo this procedure steadily diminishes, this factor alone is not an absolute deterrent to this procedure. A number of patients older than 70 years have been treated successfully with return to fully functional status. Religious orientation is seldom a contraindication; however, the high likelihood of blood replacement requires that the patient be willing to accept transfusion of blood and blood products.
Pelvic Exenteration

### Preoperative Preparation

The initial planning for pelvic exenteration begins in the outpatient office. A full discussion is undertaken with the patient before definitive surgery is planned. The complete operation—including the removal of the bladder, vagina, and rectum and the possible necessity of two ostomies—is fully outlined. Occasionally, patients cannot psychologically adjust to the concept of the operation and refuse further evaluation. Such decisions should be honored, and ongoing supportive care of the patient should be offered. For the patient who can psychologically commit to the removal of her pelvic viscera, a further discussion is undertaken to assess her desire for vaginal reconstruction, creation of a continent urinary diversion, and, potentially, low rectal reanastomosis.

Patients are admitted the day before surgery for bowel preparation and intravenous hydration and to be marked by the stomal therapist for ostomy placement. Arterial blood gas analysis is obtained routinely. For patients whose oxygen saturation is adequate, pulmonary function testing is not routinely performed. A central venous catheter should be placed during anesthetic induction to provide appropriate vascular access. Preoperative total parenteral nutrition is not used routinely unless the patient has a nutritional deficit. Intravenous prophylactic antibiotics are given on call to the operating room, and the patient is shaved just before surgery. Venous prophylactic antibiotics are given on call to the operating room, and the patient is shaved just before surgery. Intravenous prophylactic antibiotics are given on call to the operating room, and the patient is shaved just before surgery.

The patient is positioned for surgery using Allen stirrups. This position allows simultaneous access to the abdominal and perineal areas for bimanual assessment of the lesion intraoperatively and to facilitate the “double team” approach to operating transabdominally and transvaginally simultaneously. A two-team approach should be considered in all cases to shorten anesthetic time, reduce blood loss, and minimize fatigue of the surgical team. Rotation of members of the operative team in and out of the operating room allows for rest and refreshment and minimizes the chance of fatigue-related operator errors during the critical reconstructive phase of the operation.

### Intraoperative Exploration

The abdomen is opened using a vertical midline incision. Although a transverse incision allows greater pelvic exposure and facilitates the lateral pelvic wall assessment, it limits the upper abdominal evaluation, aortic node dissection, and creation of continent urinary diversion (Fig. 50.2). On entry into the peritoneal cavity, the surgeon should carefully palpate all organs, surfaces, and lymph node areas. The liver is examined for evidence of metastatic disease. Cytologic washings and ascitic fluid, if present, can be recovered and sent for immediate cytologic analysis. Any areas that appear abnormal on the preoperative diagnostic studies are examined. Any questionable areas are biopsied and samples sent for frozen-section analysis. Abnormal nodal findings are similarly analyzed, with a specific focus on the pelvic, high common iliac, and paraaortic lymph nodes. Frozen-section support by a pathologist experienced in the evaluation and diagnosis of gynecologic cancers and eradicated tissue changes is absolutely essential.

Obesity is a relative contraindication to surgery. Most patients with recurrent cancer of the cervix have a protracted disease course and are rarely overweight. These patients present technical problems that further complicate an already difficult procedure, and they must be evaluated individually. Stomal construction can be difficult in these patients, operating time is prolonged, infection rates are increased, and pulmonary function may be compromised during the postoperative period.

Medical condition and psychological state are important factors in deciding whether some patients should undergo operation. Surgical risks must be weighed against the benefit of the procedure. The patient’s willingness to actively participate in her recovery and her ability to adapt psychologically are key components to the success of resection. In most settings where exenteration is offered, there is no favorable alternative therapy. The patient must clearly understand the implications of her decision to seek or refuse exenteration. Although small, the risk of perioperative mortality with this operation is definite. Complications of some type are seen in 30% to 50% of cases.

The preoperative medical and anesthetic assessments of the cardiorespiratory, renal, and nutritional status of the patient must be thorough. Consultants with expertise in these areas must be available during the perioperative period. All patients require close surveillance in an intensive care unit postoperatively. Patients must also be psychologically prepared for the significant alterations in their excretory systems and their sexual function. These patients often benefit from counseling by an enterostomal therapist, psychologist, or psychiatrist before the operation. The consultant’s aid in preparing the patient may be as important as the surgery itself. An informal discussion with another patient who has satisfactorily adjusted to the alterations of exenteration frequently is beneficial and should be considered.

The surgeon who undertakes pelvic exenterative therapy has responsibilities beyond the performance of surgery. The surgeon must consider the quality of life remaining for the patient if it is not.
FIGURE 50.2. Use of the low lithotomy position and Allen stirrups allows three operating surgeons to have direct visual access to the abdominal cavity. This position also provides access for a second team to perform the perineal portion of the resection and the vaginal reconstruction while the upper team creates the urinary conduit and colostomy.

Paraortic lymph node dissection is performed by initially incising the peritoneum over the lower aorta (Fig. 50.3) or right common iliac vessels. The area is carefully evaluated by visual and tactile examination. The lymph node dissection is begun at or just below the bifurcation of the aorta and proceeds cephalad. The lymphatic tissue is carefully freed from the aorta; hemoclips are used to ligate the small perforating vessels. Using gentle upward traction and sharp dissection, the surgeon can isolate the nodes to about the level of the inferior mesenteric artery. The uppermost pedicle is tied or ligated with an appropriate hemoclip. A similar dissection is performed over the anterior wall of the inferior vena cava to obtain lymph nodes located on the right side of the aorta. Squamous cell carcinoma of the cervix spreads in a stepwise manner; thus, extensive paraaortic node dissection to the level of the renal artery is not necessary. If the lower paraaortic tissue is negative for metastatic disease, none is found at a higher level. The high common iliac and pelvic lymph nodes are dissected similarly and evaluated. Dissection to the level of the renal vessels should be performed in patients with adenocarcinoma of the cervix or endometrium whose tumors have a less predictable pattern of lymphatic spread.

When this evaluation is completed and there are no contraindications to proceeding, the round ligaments are divided and the pararectal and paravesical spaces are opened. The paravesical space is developed by bluntly sweeping the bladder away from the pubic symphysis in the space of Retzius and continuing the dissection laterally, sweeping the bladder medially off the pelvic sidewall until the fibrovascular pedicles are encountered at the 4- and 8-o’clock positions. These fibrovascular pedicles, commonly referred to as “the web,” contain the uterine artery and vein, the ureter, the base of the broad ligament extending from the upper vagina and cervix to the pelvic sidewall, and the superior hemorrhoidal vessels. One pelvic sidewall at a time should be evaluated. The round ligament is ligated and divided, and the peritoneum is incised over the iliopectineus muscle. This exposes the pararectal space, which is developed by bluntly freeing the medial leaf of the peritoneum with the attached ureter from its areolar attachment to the pelvic sidewall structures. When the pararectal space is fully developed, the fibrovascular pedicle can be palpated between the operator’s thumb and index finger, allowing for evaluation of the pelvic sidewall. Any nodular or suspicious area in this region is biopsied and frozen section is obtained (Fig. 50.4). At this early stage in the operation, the mass of neoplasm should be movable. Free spaces should be present between the neoplasm and the pelvic sidewalls in both the paravesical and pararectal spaces. If the tumor mass is not freely movable, lateral invasion is likely, and a more extensive evaluation of resectability should be undertaken. Biopsy of the cardinal ligaments or lateral tumor spread at the pelvic sidewall should be taken for frozen section.

At this point in the operation, the patient has not been committed to an exenteration because neither the bowel nor the ureter has been transected. Once disease resectability has been confirmed and the decision to perform an exenteration is made, the specific type of procedure—total, posterior, or...
Pelvic Exenteration

Figure 50.4. The pararectal and paravesical spaces have been developed. Thickened or suggestive areas of tumor extension to the sidewalls are sampled for frozen section analysis. The uterine artery is divided at its origin from the internal iliac and is tied with 2-0 silk.

Retention of the Specimen

An en bloc dissection of the pelvic tissue is undertaken by clamping and dividing the web of tissue at the pelvic sidewalls. Large pedicle clamps are used to clamp the tissue and control the bleeding from this area. The tissue is divided and ligated with suture, using either suture ligatures or large hemostatic clips. We prefer to clamp, divide, and ligate the uterine artery at the top of the web lateral to the ureter separately, allowing the dissection to continue along the pelvic sidewall. The ureters are freed from the medial leaf of the peritoneum with sharp dissection, clipped with large hemoclips, and transected as distally as possible. The proximal ureters distend during the remainder of this part of the procedure, facilitating their later anastomosis into the urinary conduit.

The sigmoid colon is divided using the gastrointestinal anastomotic (GIA) stapler. Before this division, small epiploic vessels are divided and tied. A free space is developed in the bowel mesentery just beneath the bowel wall. This allows introduction of either a bowel clamp or the staple. The peritoneum overlying the mesentery is incised, exposing the vessels to the sigmoid colon. These are cross-clamped and tied. Transillumination of the vascular arcade leading to the bowel allows for preservation of the major blood supply, which consists of the sigmoidal and superior hemorrhoidal arteries arising from the inferior mesenteric artery, the middle hemorrhoidal arteries coming bilaterally from the hypogastric vessels, and the inferior hemorrhoidal vessels from the pudendal arteries. The sigmoidal artery usually is preserved, whereas the superior hemorrhoidal vessel is ligated.

When the sigmoid colon is divided and the superior hemorrhoidal vessel is clamped and divided, the sigmoid is detached from the sacrum, and a free space becomes apparent (Fig. 50.5). This is an avascular plane, and the dissection should be directed toward the colon and away from the sacrum. Using blunt dissection, the colon can be freed posteriorly to the levator ani muscles that compromise the lateral pelvic diaphragm. Care must be taken not to damage the sacral veins when dissecting the colon free in this area. If these sacral veins are torn, the resulting hemorrhage is often difficult to control. Attempts to clamp and ligate the sacral vessels are uniformly unsuccessful. Fine, absorbable figure-of-eight sutures or packing with the use of absorbable hemostatic substances may be more beneficial in these instances. Sterile thumbtacks placed directly into the sacrum also can be used to control this bleeding. The middle hemorrhoidal vessels are clamped, further freeing the pelvic specimen. These pedicles, entering from the 4- and 8-o'clock positions, are ligated with suture (Fig. 50.6).

As the pelvic diaphragm is approached abdominally, the second surgical team begins the perineal phase of the operation. The incision around the urethra, vagina, and rectum is outlined, and the dissection proceeds cephalad toward the pelvic diaphragm from below. These muscles are transected circumferentially, and the specimen is removed in toto through the pelvis. The pelvis is copiously irrigated, and hemostasis is achieved. The perineum is supported by approximating the levator muscles with absorbable sutures. If a bilateral myocutaneous graft is to be used for vaginal reconstruction, the second team begins “harvesting” the grafts while the team operating in the abdomen begins construction of the urinary conduit.
Conduit Formation

We prefer either the continent urinary reservoir or the ileal conduit. About 15 cm of the terminal ileum is selected as the urinary conduit; it is divided with the GIA stapler. It is important to carefully estimate the length of the conduit segment. If the conduit is too short, stomal retraction and stenosis follows. An excessively long conduit can lead to stone formation or metabolic complications from fluid and electrolyte absorption across the bowel mucosa. In the obese patient, measurements for the conduit should be taken during the preoperative planning phase. In general, the conduit length should be 15 cm plus the thickness of the anterior abdominal wall when the patient is in the supine or standing position to account for the thickness of the patient's pannus. Alternatively, a segment of

FIGURE 50.5. Ureters have been tied and divided. The colon has been isolated and divided with the gastrointestinal anastomotic stapler. The superior hemorrhoidal vessels have been clamped and divided previously. The colon is swept free by gentle blunt dissection from the sacrum. Similarly, the bladder is swept free from the symphysis pubis (arrows).

FIGURE 50.6. The fibrovascular pedicle (the "web") is progressively clamped and divided down to the pelvic floor. The perineal dissection is simultaneously performed with isolation and removal of the pelvic mass in toto.
The ileal conduit is created by isolating a 15- to 20-cm segment of ileum as needed for the conduit. If there is significant radiation injury to the bowel in the pelvis, a transverse colon conduit can be constructed.

The ureters are further freed along their routes using blunt and sharp dissection. Care should be taken to select an area of the ureter for anastomosis that is relatively free of radiation damage. The left ureter should be freed superiorly and tunneled through an avascular window in the bowel mesentery to reach the isolated segment of ileum. After an appropriate site is selected to ensure a tension-free anastomosis, the ureters are sutured to the bowel segment (Fig. 50.7). This site usually is 2 to 3 cm from the proximal end of the conduit. The site is opened sharply for about 1 cm. Some surgeons choose not to use stents; however, we routinely place a Silastic pediatric feeding tube through the lumen of the bowel and through the selected anastomotic site into the ureter. The stent is sutured to the bowel with fine absorbable suture passing through the bowel wall and the feeding tube. The ureter is then spatulated to the bowel with fine absorbable suture passing through the mucosa of the ureter to the antimesenteric border for a distance of about 4 to 5 mm. A full-thickness mucosa-to-mucosa anastomosis of the ureter to the bowel is performed using fine interrupted absorbable sutures. The feeding tube is then sutured to the bowel segment (Fig. 50.7). This site usually is 2 to 3 cm from the proximal end of the conduit. The site is selected to ensure a tension-free anastomosis, the ureters are sutured to the bowel segment (Fig. 50.7). This site usually is 2 to 3 cm from the proximal end of the conduit. The site is opened sharply for about 1 cm. Some surgeons choose not to use stents; however, we routinely place a Silastic pediatric feeding tube through the lumen of the bowel and through the selected anastomotic site into the ureter. The stent is sutured to the bowel with fine absorbable suture passing through the bowel wall and the feeding tube. The ureter is then spatulated for a distance of about 4 to 5 mm. A full-thickness mucosa-to-mucosa anastomosis of the ureter to the antimesenteric border of the isolated segment of bowel is then performed using fine (3-0 or 4-0) absorbable suture. Six to ten interrupted sutures are used for the anastomosis. The ureter is anchored with long-acting absorbable suture to the underside of the conduit about 2 cm from the anastomosis to further reduce tension on the anastomosis. When the conduit is completed, the distal end is brought through the preselected site on the abdominal wall and, once positioned, is sutured to the peritoneum for stability. A “rosebud” stoma is fashioned to allow for ease of care and application of the urinary appliance. The proximal end of the conduit can be anchored to the sacral peritoneum to stabilize the unit.

The sigmoid colon may be used. If a colostomy is to be done, this saves a small bowel anastomosis because an isolated segment of ileum is not needed for the conduit. If there is significant radiation injury to the bowel in the pelvis, a transverse colon conduit can be constructed.

The ureters are further freed along their routes using blunt and sharp dissection. Care should be taken to select an area of the ureter for anastomosis that is relatively free of radiation damage. The left ureter should be freed superiorly and tunneled through an avascular window in the bowel mesentery to reach the isolated segment of ileum. After an appropriate site is selected to ensure a tension-free anastomosis, the ureters are sutured to the bowel segment (Fig. 50.7). This site usually is 2 to 3 cm from the proximal end of the conduit. The site is opened sharply for about 1 cm. Some surgeons choose not to use stents; however, we routinely place a Silastic pediatric feeding tube through the lumen of the bowel and through the selected anastomotic site into the ureter. The stent is sutured to the bowel with fine absorbable suture passing through the bowel wall and the feeding tube. The ureter is then spatulated for a distance of about 4 to 5 mm. A full-thickness mucosa-to-mucosa anastomosis of the ureter to the antimesenteric border of the isolated segment of bowel is then performed using fine (3-0 or 4-0) absorbable suture. Six to ten interrupted sutures are used for the anastomosis. The ureter is anchored with long-acting absorbable suture to the underside of the conduit about 2 cm from the anastomosis to further reduce tension on the anastomosis. When the conduit is completed, the distal end is brought through the preselected site on the abdominal wall and, once positioned, is sutured to the peritoneum for stability. A “rosebud” stoma is fashioned to allow for ease of care and application of the urinary appliance. The proximal end of the conduit can be anchored to the sacral peritoneum to stabilize the unit.

The continent urinary conduit has gained increasing acceptance and now provides a legitimate alternative to the ileal conduit. This modification of the urinary diversion procedure requires serial catheterization but eliminates the need for an external appliance. Construction of the continent conduit is more complex but is a preferred option for appropriate patients.

The continent conduit is formed from the right colon and the proximal portion of the transverse colon as well as a distal part of the terminal ileum. The details of this technique are provided in Chapter 51. Once the continent urinary conduit has been developed, the terminal ileum is brought through the abdominal wall. This site should be preselected, and care must be taken to bring the terminal ileum straight through the layers of the abdominal wall so that catheterization is not impeded postoperatively. A kink or turn in the ileum may cause the patient to have difficulty with catheterization. Ureteral stents are placed at the time of ureteral implantation; these are brought through separate stab incisions in both the cecum and the abdominal wall. A Foley or 14 F red Robinson catheter is placed through the stoma, and the conduit drains dependently for about 10 to 20 days.

For all urinary diversions, an intravenous pyelogram or loopogram is obtained about 10 to 14 days postoperatively. If there is no urinary leakage, the ureteral stents can be removed. The patient is instructed on methods of appliance application (ileal conduit) or self-catheterization and irrigation (continent conduit).

The sites for urinary and fecal stomas, which are selected preoperatively by the stomal therapist, are marked on the abdomen using scratch marks or sterile methylene blue injections before the patient is draped. The urinary conduit is brought through the abdominal wall in the right lower quadrant, midway between the umbilicus and the anterior superior iliac spines, where a flat skin surface is available for attachment of the prosthesis. The sigmoid colostomy site is located in the left lower quadrant.

The abdominal wall aperture is prepared by removing a round segment, 2 to 3 cm in diameter, through its entire thickness to the level of the fascia. Skin, subcutaneous fat, and external oblique fascia must all be excised so that the flow of urine from the conduit is not obstructed. The urinary conduit is brought through the abdominal wall, and the serosa of the bowel is sutured to the peritoneum. The bowel mucosa is everted, creating a raised “rosebud” stoma, which projects over the abdominal wall. The stoma is fashioned with interrupted sutures of 3-0 delayed-absorbable suture, which passes initially through the dermis at the skin edge, then through the serosa and musculature of the adjacent bowel wall, and finally through the free margin of the bowel mucosa. When the sutures are tied, the mucosa is everted over the serosa of the bowel to produce a raised stoma that directs the urine away from the skin surface, thus reducing the chance for stricture and skin irritation.
FIGURE 50.8. Technique for creating a bowel stoma that is elevated from the skin surface. This “rosebud” stoma is developed by excising a 3-cm circumferential segment of abdominal wall (A), anchoring the skin margin with the adjacent wall of the exteriorized bowel (B), and approximating the mucosal edge of the bowel to the skin (C). The cross-sectional view demonstrates how the bowel wall is anchored to the skin margin to prevent retraction (D).

Application of the urinary stoma bag also is facilitated by the raised opening.

The fecal stream is diverted through the left abdominal wall in a similar manner (Fig. 50.8). The free end of the sigmoid colon is brought through the abdominal wall to the skin through the previously marked site. If anatomically feasible, the colostomy bud should be placed below the waistline so that the colostomy bag is not constantly pulled on by the waistband of the patient’s clothing. Stoma construction is accomplished as described in the preceding.

Pelvic Floor Coverage

Attention is then directed to the pelvic floor. If vaginal reconstruction has been done using myocutaneous flaps, these effectively fill the pelvis and bring in new blood supply. Coverage of this raw surface enhances hemostasis and minimizes the risks of bowel adhesions and subsequent obstruction. If no vaginal reconstruction is done, an omental J-flap is used for this purpose with satisfactory results. The omental attachment to the greater curvature of the stomach is isolated, transected, and ligated (Fig. 50.9). Hemostasis must be meticulous. The operator must preserve the blood supply from the left gastroepiploic artery as the major blood supply to the omentum. The omental flap can be laid into the pelvic basin as a carpet and sutured in place with absorbable interrupted sutures. The omental coverage of the pelvic floor provides “new” blood supply to the surgical site and enhances healing. Some type of pelvic floor support should be provided to minimize the possibility of vaginal evisceration. Usually, this can be accomplished by suturing the remnants of the levator muscles together in the midline.

Anterior Exenteration

Anterior exenteration is a modification of total exenteration that leaves the rectosigmoid colon and posterior vagina intact. After the ureters are isolated and divided, the rectum must be taken down from the posterior vagina. This is accomplished by incising the peritoneum along the rectovaginal peritoneal reflection. When this free space has been entered, the rectum can be bluntly dissected from the upper portion of the posterior vagina. It is freed laterally from the uterosacral ligament.
Pelvic Exenteration 1349

FIGURE 50.9. An omental “J-flap” can be developed by separating the right-sided portion of the omentum from the stomach and transverse colon. This pedicle then is positioned over the pelvic defect and loosely sutured in place.

uterosacral ligaments are clamped, divided, and ligated with sutures as close to the sacrum as possible. The procedure is carried down the pelvic sidewalls, similar to the procedure for total exenteration. Great care is taken to ensure that the rectum and its blood supply are not damaged. When the perineal phase is performed, the vagina is entered in its midportion and dissection connected into the upper portion of the rectovaginal septum. An ileal conduit is constructed as described. Alternatively, a continent reservoir can be created. A single gracilis myocutaneous flap can be used to replace the anterior vaginal wall.

Posterior Exenteration

Posterior exenteration is most often used for vulvar cancer and is also a modification of total exenteration. In this procedure, the uterovesical peritoneum is incised and the bladder is freed, using sharp and blunt dissection, from the cervix and vagina. After the uterine artery is ligated, the ureter must be dissected free down to the bladder. This is performed in a manner similar to that used for a radical hysterectomy. This allows for visualization of the ureter and frees it from the vagina. The web can be divided in a manner similar to that used for total exenteration. The ureter and bladder are preserved under direct visualization of these structures. The perineal phase retains the anterior vagina adjacent to the base of the bladder in the lowermost portion of the pelvis. The upper and posterior vagina are resected along with the rectosigmoid colon. An end sigmoid colostomy is created. A single gracilis myocutaneous flap can be used to replace the posterior vaginal wall and fill the surgical defect (Fig. 50.10). This is particularly useful because bladder prolapse is common following loss of the posterior support structures.

Total Exenteration with Low Rectal Resealostomosis

The lower 6 to 10 cm of rectum may be preserved in selected patients undergoing total pelvic exenteration. This depends on the location of the recurrent tumor. When this lower portion of the rectum is preserved, the sigmoid colon can be brought down and anastomosed to the rectal stump. This is greatly facilitated by use of the EEA stapler. In these patients, the colon has been previously divided using a GIA stapler proximally across the sigmoid and a TA-50 or reticulating stapler across the rectum. The staple line is cut off the sigmoid, and a running suture of 2-0 nylon or Prolene, starting on the outside, is placed on the open end of the sigmoid colon. The anvil of the EEA stapler is placed in the sigmoid, and the purse string is tied. The EEA stapler is introduced through the rectum and centered so that the spike can be advanced through or just above the staple line. The spike is removed, and the stem of the anvil is inserted. When the stapler is properly oriented, the two ends of the bowel are approximated, and the stapler is fired. When the stapler is removed, a “doughnut” of tissue from each end of the bowel should be present in the removed EEA stapler. The anastomosis is reinforced with interrupted sutures. A temporary diverting colostomy usually is necessary if the patient has been previously irradiated. Bowel continuity can be restored via colostomy closure in 3 to 6 months. This technique is illustrated in Chapter 43.
FIGURE 50.10. A single gracilis myocutaneous flap can be used for reconstruction when anterior or posterior exenteration is performed. The single flap can be harvested from either thigh, rotated into position, and sutured to the remaining vagina.

Gynecologic Oncology

VAGINAL RECONSTRUCTION

Split-Thickness Skin Graft Vaginoplasty

The skin graft is taken from the buttocks or the posterior thigh as a split-thickness graft 10 to 15 cm in length at about 0.013 to 0.017 of an inch in thickness, using the air-powered dermatome. A vaginal stent is selected from commercially available supplies or fashioned from a foam obturator, the graft is sewn together over the obturator, and the visible end is sutured to the introitus. This technique is illustrated in Chapter 51. The patient is confined to bed for 3 days, and ambulation is allowed on the fourth or fifth day. The obturator is removed for the first time on about the fifth day, but may be left in place for up to 10 days. The patient leaves the obturator in place continuously for 4 to 6 months, removing it for cleaning and vaginal irrigation every day or so. It is worn at night for another 4 to 6 months to minimize the risk of stricture of the skin graft. The obturator can be fashioned inexpensively by shaping a piece of foam rubber and covering it with a condom. The patient can attempt intercourse about 6 weeks after surgery. Skin grafts can provide an excellent result for vaginal reconstruction. Beemer and coworkers reported that 90% of their patients achieved satisfactory coitus.

Myocutaneous Gracilis Graft

The myocutaneous gracilis graft also can be used for creation of a neovagina. Some surgeons use the rectus abdominis myocutaneous graft to construct the neovagina. However, I believe that its abdominal donor site complicates stoma placement and so use the gracilis as our procedure of choice. Construction at the time of initial exenteration surgery is required. The advantages include immediate reconstruction of the vagina, and the tissue mass itself helps to fill the pelvic defect as well as introduce a new blood supply to the area. An obturator is not required to maintain patency. When this approach is chosen, it is best to have a second operating team harvest the grafts and construct the neovagina while the primary surgical team completes the urinary diversion. Myocutaneous grafts are constructed by obtaining bilateral full-thickness muscle, adipose, and skin flaps. The initial incision is made in an elliptical manner along a line extending from the superior aspect of the symphysis pubis to the medial condyle of the femur. The overlying skin is sutured to the skin paddle. The muscle is mobilized toward the symphysis. The perforating vessels on the underside of the muscle are about 10 cm from the symphysis and should be dissected with the myocutaneous unit. When the muscle and overlying skin are fully mobilized, they are brought through a subcutaneous tunnel to the perineal defect. The posterior edges of the grafts from both sides are sutured together with absorbable interrupted sutures, followed by a similar approximation of the anterior edges. This graft is introduced (or inserted) into the pelvic cavity and sutured to the sacral periosteum or levator remnants with long-acting absorbable sutures. The opening to the new vaginal tube is sutured to the introitus with interrupted absorbable sutures (Fig. 50.11). The leg incisions are closed with skin staples. Jackson-Pratt drains are placed in the bed of each harvest site as well as in close proximity to the graft in the pelvis.

Postoperative Care

Patients are routinely admitted to the intensive care unit on completion of a pelvic exenteration. The continued oozing from the operative site with sequestration of fluids in the extravascular spaces causes significant fluid shifts; therefore, central venous pressure monitoring is essential. When left heart function and pulmonary function are adequate, a Swan-Ganz catheter is not routinely used. When ureteral stents are used, there is little chance of conduit obstruction from mucous plugging, and the urine output should accurately reflect kidney function. During the initial 24 hours after surgery, volume usually is replaced with crystalloid and blood products.
Electrolytes and coagulation studies must be closely monitored, as well as calcium and magnesium levels. By the second to fourth postoperative day, the patient usually is ready to leave the intensive care unit. Hyperalimentation, which is started on the first postoperative day, is continued until the patient begins to have spontaneous bowel function. Intravenous antibiotics are continued for about 5 days. If vaginal reconstruction has not been performed or the perineum has not closed, the pelvic packing is changed daily after being left in place for the first 3 to 5 postoperative days.

Complications

The incidence of postoperative complications following pelvic exenteration is significant; complications occur in 30% to 50% of patients undergoing this procedure. The most common major complications after this operation primarily involve the urinary or gastrointestinal tracts and their reconstructions. Other complications include bleeding, infection, thromboembolism, and, some time later, stoma problems, such as stenosis, prolapse, and hernia.

The occurrence of ureteral stricture and urinary leakage at the ureterointestinal anastomotic site has significantly decreased with current techniques. Ureteral stricture, especially if ureteral obstruction coexists, must be corrected surgically without delay or a percutaneous nephrostomy done to preserve renal function. Most anastomotic leaks heal spontaneously without requiring surgical repair. Renal calculus formation does occur but can be reduced by avoiding exposed staple lines and permanent sutures in the conduit.

Intestinal obstruction occurs both as an early and a late complication of exenteration and continues to be a serious problem in 10% to 15% of cases. The incidence of this complication has been reduced by use of the omental J-flap to cover the raw pelvic surface at the level of the pelvic diaphragm. Most paralytic ileus problems seen in the postoperative period can be treated conservatively with traditional nasogastric decompression. Enteral fistulas are seen uncommonly but are more common when omental flap or vaginal reconstruction is not used. These fistulas may heal spontaneously with bowel rest and hyperalimentation.

Septicemia, which often originates as a urinary tract infection, usually responds to antibiotic therapy. Thromboembolic disease has become a less frequent postoperative complication since the use of low-dose heparin or XCDs began, even in the presence of a large demuded pelvic vault and exposed vessels. For wound and pelvic abscesses, CT-guided drainage, if feasible, is preferred to laparotomy.

The operative mortality rate related to pelvic exenterative surgery has improved dramatically since the 1970s. Earlier series reported a peroperative mortality rate ranging from 7% to 17%. In modern series, the reported mortality rate is less than 5% (Table 50.1).

BEST SURGICAL PRACTICES

■ Pelvic exenteration is a technically challenging surgical procedure; but just as important, the postoperative care of these patients is extremely difficult from both a medical and psychological aspect. This operation and the care of these patients should be undertaken only by a well-trained and experienced team of specialists in a hospital staffed and equipped to manage the complex problems associated with the multiple organ systems involved in the ultraradical surgery, recovery, and rehabilitation.

■ The main indication for pelvic exenteration is centrally recurrent cervical cancer after failure of primary radiation therapy. Occasionally, patients with vulvar, vaginal, or uterine cancer—and some patients with urologic or rectal cancer—may also be candidates. Women with cancer extending to the pelvic sidewall precluding a clear resection margin or those with metastatic disease are not candidates for exenteration. Occasionally, a patient with only anterior or posterior tumor involvement will be a suitable candidate for an anterior or posterior rather than the usual total pelvic exenteration.

■ A very complete preoperative evaluation is necessary with all appropriate imaging studies to evaluate resectability. In addition, the patient must be evaluated medically and psychologically to be sure she can tolerate this extensive surgery
and will be able to deal with the stoma and altered body image postoperatively.

■ Two or even three surgical teams may be used to reduce surgeon fatigue and operative time. There are three somewhat different phases of the surgical procedure that naturally lend themselves to the assignment of different surgical teams: (i) the pelvic extirpative part; (ii) the perineal and vaginal extirpative part and, where indicated, the vaginal reconstruction; and (iii) the construction of the urinary and colonic diversions.

■ The initial phase of the operation is to evaluate the patient for resectability. Are there intraabdominal metastases? Positive washings? Pelvic or paraaortic lymph node metastases? Does the tumor extend to the pelvic walls?

■ The choice of the urinary diversion is complex. There are several options, including an ileal or colon conduit or various modifications of a continent urinary pouch. The final decision will be based on the patient's desire and ability to manage a continent pouch or a conduit, as well as the patient's anatomy, prior treatment, and the preference and experience of the surgical team.

■ Vaginal reconstruction is another area in which there is considerable choice. In some women, vaginal reconstruction is not desired. In other patients, reconstruction of a functional vagina is an important psychological asset in their recovery. Various techniques, including gracilis myocutaneous flaps, transverse rectus abdominis myocutaneous (TRAM) flaps, and split-thickness skin grafts, have been used. I prefer the gracilis myocutaneous flap, which also brings additional tissue and blood supply into the previously radiated, empty pelvis. It can be constructed at the same time the urinary diversion is being done so that the operative time is not increased.

■ In many cases, the postoperative recovery phase is as challenging as the surgical procedure. An experienced team of intensive care experts is needed to manage the many immediate and delayed complications that we encounter in these patients. Long-term follow-up is important.

CHAPTER 51  ■  SURGICAL RECONSTRUCTION OF THE PELVIS IN GYNECOLOGIC CANCER PATIENTS

Luis E. Mendez and Manuel Penalver

DEFINITIONS

Gluteal thigh flap—This flap is based on the gluteal muscle and the overlying skin. The vascular supply is mainly from the superior gluteal artery. It is first sutured to the sacral promontory posteriorly, and pelvic walls laterally to form a pelvic lid.

Rectus abdominis myocutaneous flap—A flap based on the rectus abdominis muscle and overlying skin. The muscle belly is supplied by minor vascular pedicles from the superior epigastric artery. It is first sutured to the sacral promontory posteriorly, and pelvic walls laterally to form a pelvic lid.

Omental J-flap—A technique for revascularizing the pelvis after exenteration. The omentum is detached from the greater curvature of the stomach and brought down as a flap based on the left (or occasionally right) gastroepiploic artery. It is first sutured to the sacral promontory posteriorly, the public symphysis anteriorly, and pelvic walls laterally to form a pelvic lid.

Sigmoid neovagina—Use of an isolated sigmoid segment to construct a vagina after total pelvic exenteration. The omentum is detached from the superior epigastric artery and is taken from the supraumbilical portion of the laparotomy incision (vertically oriented). A unilateral rectus abdominus myocutaneous (RAM) flap is usually sufficient to repair large vulvar defects or create an adequate-sized neovagina. The horizontal diameter of the skin should be at least 10 to 12 cm wide to make a vagina that is about 4 cm in diameter.

Gluteal thigh flap—This flap is based on the gluteal muscle and the overlying skin. The vascular supply is mainly from the superior gluteal artery. It is first sutured to the sacral promontory posteriorly, and pelvic walls laterally to form a pelvic lid.

VAGINAL RECONSTRUCTION

Vaginal reconstruction has become a regular option presented to patients undergoing radical pelvic procedures. Vaginitectomy, whether simple or radical, can be a primary procedure or a part of a more extirpative procedure, such as a pelvic exenteration. In addition, nonsurgical techniques such as radiation therapy can produce severe fibrosis or stenosis with the result of an essentially nonfunctional vagina.

With the advent of improved perioperative care and survival for radically resected patients, thoughts must extend to afford- ing the patient acceptable sexual options. The loss of sexual gratification and function may be a devastating consequence to a woman even in the presence of a surgical cure. The oncologist has no way of knowing unless specific questions are pre- sented to the patient as part of the routine preoperative history. The possibility of restoring a functional vagina may provide a woman with a tremendous source of psychological motivation in approaching her cancer therapy. It may alleviate some of the fears that she has toward her future psychosexual well-being as well as the domestic relationship with her partner. Physical sexual function, even though attempted, is never always successful. Depending on the procedure chosen and the commitment of the patient to maintain the neovagina, success rates of 80% are considered reasonable.

Besides its beneficial effects on psychosexual factors, recon- struction of the vagina after total pelvic exenteration has been shown to have a beneficial effect on wound healing, preven- tion of enteropelvic fistulae, and absence or pelvic collection formation. The insertion of nonirradiated tissue in the previ- ously radiated pelvis obliterates a great deal of dead space and provides a healthy vascular pedicle in an area with borderline blood supply resulting from extensive pelvic irradiation and radical resection.
Description of a neovagina using skin grafts attached to the colon posteriorly and bladder anteriorly supported by vaginal forms and stents was popularized by McIndoe and Banister as early as 1938. Techniques were also modified to use portions of the remaining viscera after less radical operations to fashion a neovagina. However, with the advent of ultraradical pelvic operations and the theory of en bloc resections to improve survival, it was evident that new efforts in reconstruction were needed. Classic reconstructive techniques that simply use skin grafts, as in the McIndoe procedure, are insufficient, because the supportive fasciae, rectum, bladder, and even pelvic floor have usually been extirpated.

Today there are various techniques to reconstruct the vagina. Some techniques, such as the pudendal thigh flap or the gluteal thigh flap, can be used for neovaginal construction. These are addressed in the section on vulvar reconstruction, where they are more commonly used. This section discusses the omental J-flap with skin graft, sigmoid neovagina, gracilis myocutaneous flap (GMF), and rectus abdominis flap.

**Techniques for Vaginal Reconstruction**

**Gracilis Myocutaneous Flap**

In the past, the GMF has been the workhorse of neovaginal reconstruction in patients who have had radical resections. The GMF was introduced by McGraw and colleagues in 1976 and had the immediate impact of decreasing perioperative morbidity and providing a potential for restoring coital function. The GMF is a versatile flap and has also been used for neovaginal and neovulvar reconstructions. However, it has not been without its problems. Initially, the GMF had rates of flap necrosis and prolapse as high as 65%. Techniques to anchor the neovagina and the trend to use smaller flaps have reduced this rate significantly to 13% to 37%. Infection is a problem and can complicate up to 37% of cases, but infection responds well to antibiotic therapy and local debridement if needed. Sexual adjustment has lagged and is reported to be significantly impaired in these women for various reasons, including the appearance of large inner thigh scars.

The GMF operation is begun with the patient in the dorsal supine position. The hips are abducted 45 degrees and flexed 30 degrees for exposure of the vulva, the knees are extended, and the feet are placed in gynecologic stirrups. This extended-knee position provides maximum visualization of the gracilis muscle and the overlying cutaneous skin.

The approximate upper limit for flap viability is 8 x 20 cm (Fig. 51.1). After determining the length and width of flap needed, the gracilis muscle is palpated from its origin on the pubic ramus to its insertion on the medial aspect of the knee. The extension of the knee aids in the palpation of the gracilis muscle and reduces the possibility of mistaking the sartorius muscle for the gracilis muscle. A line is drawn along the length of the gracilis muscle, and the skin island is marked carefully because only a 2- to 3-cm length of skin from the muscle edge will be supported (Fig. 51.2). The vascular supply is mainly based on the medial circumflex artery proximally. The distal muscle belly is supplied by minor vascular pedicles from the superficial femoral artery that can be sacrificed. Innervation is from the obturator nerve branches, resulting in a sensate flap.

An incision is made through the skin and subcutaneous tissue distally along the anterior border of the flap, down to the adductor longus fascia. It is extended along the line of the skin, outlining the paddle-shaped flap. Distally, at the edge of the flap, the gracilis is transected. We prefer to secure the muscle belly to the dermis with 3-0 synthetic absorbable suture to avoid shearing the flap. The vascular pedicle of the gracilis muscle is invested by the fascial layer that separates the adductor longus and adductor magnus muscles (Figs. 51.3 and 51.4). The surgical approach to the gracilis neurovascular bundle is made by reflecting the fascia to the adductor longus muscle. When the fascia is reflected, the adductor longus, adductor brevis, and the gracilis muscles are identified, exposing the vascular bundle of the gracilis muscle about 7 to 10 cm from the pubis. The gracilis muscle is isolated and divided at its origin on the pubic bone. The gracilis vascular pedicle is located by sterile Doppler ultrasound. Repeated use of sterile Doppler ultrasonography confirms the location of the blood supply to the muscle and ensures its protection. When the flaps from both legs have been adequately dissected and are ready for rotation, 1 to 3 g of intravenous fluorescein is administered. The flaps are exposed to an ultraviolet Wood’s light in a darkened room.
Nonviable areas of the flaps are demonstrated by their failure to fluoresce, and these areas are excised (Fig. 51.4). Each flap is rotated into position (or tunneled under a skin bridge if no vulvar defect is present) and either secured to cover one half of a vulvar defect or sutured together, tubularized, and inserted into the pelvic cavity to form the neovagina (Figs. 51.2, 51.5, and 51.6).

The remaining subcutaneous tissue of the defect is sutured to the subcutaneous tissue of the flap with interrupted 3-0 synthetic absorbable sutures if a vulvar defect is present. Otherwise, the flaps are tubularized and inserted into the empty pelvic cavity. Closed suction drains should be used at the harvest sites and the skin closed primarily. Sexual activity can commence after 6 to 8 weeks of recovery.

Omental J-Flap with Split-Thickness Skin Graft
By modifying the omental flap that is normally used to close off the pelvic inlet after exenteration (Fig. 51.7A), with or without low coloprostectomy, the surgeon can create an omental cylinder, providing anterior, posterior, and lateral walls for the neovagina. When the cylinder is sutured to the introitus and lined with a skin graft (split or preferably full thickness) and expanded in the postoperative period by a soft rubber vaginal form, a satisfactory functional neovagina can be created (Fig. 51.7B–D). The works of Morley and DeLancey as well as Wheless have shown that a split-thickness skin graft for the neovagina may no longer be needed. Full-thickness skin grafts work well for all neovaginal reconstructions. The full-thickness skin graft survives equally well as the split-thickness graft but has reduced the tendency to contract postoperatively compared with the split-thickness skin graft.

In Figure 51.7C, the skin graft is laid out on a vaginal form. The form is fashioned from foam rubber and stuffed into a contraceptive latex condom. The split-thickness skin graft is folded over the vaginal form, and the edges of the graft are

sutured with a running 4-0 synthetic absorbable suture. The completed operation is shown in Figure 51.7D.

In Figure 51.7D, a sagittal section shows a patient who has undergone a total pelvic exenteration. The rectal stump was retained, and the descending colon was mobilized and brought down into the pelvis for a very low (below 6 cm) coloproctostomy. The omentum has been detached from the greater curvature of the stomach and brought down as a flap based on the left gastroepiploic artery. It is first sutured to the sacral promontory posteriorly, the pubic symphysis anteriorly, and pelvic walls laterally to form a pelvic lid. In patients who have insufficient omentum to form both the pelvic flap lid and walls of the neovagina, the omentum making the pelvic lid can be supplemented by the use of a sheet of synthetic, absorbable mesh.

The omentum, innervated by the vagus nerve, forms the wall of the neovagina. Normally, tugging or pulling on the omentum does not produce a sensation of pleasure that is associated with sexual intercourse; however, about 40% of the patients who have undergone this operation report that they experience sexual orgasm. Another possible physiologic change is the development of estrogen hormone receptors in the skin graft. The graft, taken from the skin on the buttocks or thigh, normally has no demonstrable hormone receptors. Once the skin
is placed in the neovagina, the graft eventually becomes almost indistinguishable from normal vaginal mucosa on histologic examination. After the development of estrogen receptors, the maturation index from cells of the graft can be influenced by the administration of systemic estrogen similar to normal vaginal mucosa.

If construction of the neovagina is performed immediately following total pelvic exenteration, it is important to ensure that hemostasis in the pelvis is complete before applying the skin graft. If hemostasis is uncertain, the omental pocket for the neovagina should be packed with gauze. When hemostasis is secure and serous drainage has stopped, the packing can be removed and the graft can be taken and applied to a vaginal form and placed in the omental pocket.

After the skin graft is inserted, the neovagina must remain dilated with a vaginal form until healing is complete. For a period of 6 months thereafter, a soft Silastic vaginal form should be worn at all times except during intercourse and douching. After 6 months, the vaginal form is worn only at night if the patient is not sexually active.

Studies have demonstrated that this type of reconstruction works well and has minimal morbidity. Kusiak and Rosenblum have reported a series of 20 patients in whom all grafts have taken, and there has been no postoperative morbidity as a result of the neovagina. Up to 80% of patients have reported satisfactory vaginal function.

**Sigmoid Neovagina**

A third procedure that can be used to fashion a neovagina uses the distal sigmoid colon. As early as 1955, Alexandrov reported on the use of a colon segment to create a new vagina. An impressive 89% success rate was reported. Kindermann subsequently published his experience with this technique for construction of neovaginas, also with good results.

The cardinal feature for use of an isolated segment of rectosigmoid colon is the integrity of the vascular supply of the colon via the superior hemorrhoidal artery (Fig. 51.8). Unlike secretions of the small bowel, the secretions of an isolated (10- to 12-cm) segment of sigmoid colon are not copious. Thus, the inconvenience to the patient of a copious vaginal discharge from the neovagina is reduced. An additional anatomic advantage of the rectosigmoid colon over the use of isolated segments of small bowel is the unique anatomic feature of the marginal artery of the colon. This allows the surgeon to reverse the peristaltic direction of the colon to obtain greater mobility by transecting the mesentery medial to the marginal artery. The superior hemorrhoidal artery provides the appropriate vascular supply to the colon segment. The sigmoid neovagina must prolapse through the introitus.

be, a synthetic mesh can be used to eliminate tension on the closures. Closed suction drains can be used if indicated. The vaginal form is removed from 5 to 7 days postsurgically, and the patient can attempt intercourse after 6 weeks. The RAM family of myocutaneous flaps is becoming the procedure of choice for vulvovaginal reconstructive procedures in gynecologic oncology. Long-term sequelae of RAM flaps are few, and prolapse is greatly reduced. Carlson and colleagues reported on a pilot series in 1993 with 100% flap viability. Data are now available on longer-term follow-up of these patients. The authors published a 78% satisfaction rate of patients who underwent RAM reconstructions after pelvic exenteration.
Researchers at Duke University also found a 62% coitus rate 12 months after reconstruction in a similar cohort. Nonetheless, reports exist of squamous carcinomas of RAM neovaginas and perioperative complications, demanding that the utmost care be taken in developing this type of flap and in selecting the appropriate patient who will benefit from this extensive reconstructive procedure.

VULVAR RECONSTRUCTION

In the 1940s, the work of Taussig and Way demonstrated the efficacy of en bloc removal of the vulva, mons pubis, and inguinal lymph nodes from the anterior iliac spine to the adductor canal in patients with squamous cell carcinoma of the vulva. By using a more extensive dissection, pelvic surgeons have removed more tissue and thereby enhanced the probability of increased survival. This type of radical excision, however, has been complicated by problems associated with closure of large wounds—that is, difficulties involving postoperative necrosis of the suture line over the mons pubis and the inguinal and lateral vulvar skin (Fig. 51.14). Attempts have been made to redesign the incisions for radical vulvectomy to allow for adequate surgical margins and, at the same time, provide better primary healing of the incision with reduced necrosis. This includes the use of “separate incisions” to approach the primary tumor and the inguinosfemoral lymph nodes. Nonetheless, resection of the primary tumor can result in defects necessitating extensive plastic reconstruction. Although these modifications of the original Way incision have allowed some improvement in the incidence of necrosis and pelvic contraction, many patients have had significant wound breakdown, requiring a split-thickness skin graft to cover the area that has become necrotic during the postoperative period. The hospital stay of these patients has been prolonged, awaiting acceptable healing of the wound. In addition, patients have developed severe perineal contractures with significant distortion of the bladder neck and urethra, resulting in incontinence of urine, perineal pain, pressure, and, in some cases, difficulty walking.

The ideal method of perineal reconstruction after a radical resection of the vulva should provide an immediate anatomic restoration and primary healing at the time of tumor resection. The neovulva should have as many of the anatomic characteristics of the original vulva as possible. The donor tissue ideally should be expendable from the donor site and transferable with minimal patient morbidity. Most radical vulvectomy operations can be closed primarily. Others can be closed with the assistance of the Z-plasty pedicle flaps advocated by Julian and Woodruff (Fig. 51.14) and by the other techniques described below. There are occasional perineal resections, however, that are so extensive that none of the cited techniques is adequate for primary closure. In these patients, myocutaneous flap is a means of primary closure. Efforts to reconstruct a radically resected vulva have been ongoing for decades. Many different techniques have been introduced, and each has a particular risk/benefit profile. With the refinement of surgical therapies for vulvar carcinoma, emphasis has shifted to the use of fasciocutaneous and local flaps for reconstruction. Nonetheless, in certain cases, the volume resected can only be reconstructed with a myocutaneous flap. This section describes split-thickness skin grafts, Z-plasty closures, the SURE Closure, V-Y advancement flaps, and the pudendal thigh flap. The gracilis and RAM flaps are discussed in the section on vaginal reconstruction. The myocutaneous flaps, however, continue to be the mainstay for vulvar reconstruction of very large defects.

Techniques for Vulvar Reconstruction

Split-Thickness Skin Graft

The use of the split-thickness skin graft for reconstruction of the vulva is not extensively described here. Most radical vulvar procedures resect deep to the perineal fascia, requiring a reconstruction that needs to provide greater thickness than that of a simple graft. However, in the case of an extensive simple or “skinning” vulvectomy, this technique alone can be adequate. The procedure for harvesting a graft is available in standard surgical texts. In brief, it involves taking a 0.35-mm (12/1,000 inch) split-thickness skin graft from an acceptable donor site with a dermatome and applying the split-thickness graft to the denuded area of the vulva. The margin of the graft is sutured to the margin of the defect with fine sutures, and a moist stent pack is used to ensure that the split-thickness skin graft is adequately pressed against the wound. Small pockets of serum can be aspirated by needle to allow the graft to lie flat over the denuded area. We have found the use of meshed grafts to be of particular value in large wounds in which the potential for infection and subgraft seroma collection can be significant. The small defects in the mesh allow adequate drainage of the wound while epithelialization takes place. The physiologic and
logistic advantages of covering large, open wounds are well
documented and are preferable to the long and costly process
of granulation. Immobilization of the graft is an important key
to success of the transplant.

**Z-Plasty Full-Thickness Pedicle Flap**

In cases in which primary closure of the vulvar wound cannot
be performed without tension, the use of a pedicle flap, as ad-
vocated by Julian and Woodruff, has proven efficacious (Fig.
51.14). The flap is relatively easy to perform but must be well
designed before making the actual incision for the flap. Partic-
ular attention should be given to the width of the base of the
flap to ensure an adequate blood supply to the distal points of
the flap. A general rule to follow is that 2 cm of base should
be present for each 1 cm of length of the flap. After measuring
the defect and translating these measurements into the appro-
priate size of flap needed, the future flap is marked along the
designated lines with a surgical marker before the incisions are
made. The incision should be full thickness, including epider-
imis, dermis, and subcutaneous fat, down to the fascia. The flap
is rotated into position and sutured to the midline of the per-
ineum without tension. Generally, it is difficult to rotate the flap
beyond the midperineal line. If additional tissue is needed to
close the contralateral vulvar defect, a flap is elevated from the
opposite side and similarly sutured in the midline. The flap is
sutured to the underlying fascia, covering the pubic rami, and
to the incision line on the opposite side. Preferably, 3-0 syn-
thetic absorbable suture is used. The suture in the skin margin
should be fine synthetic monofilament suture, such as nylon or
fine delayed absorbable suture. The medial margin of the flap
is sutured to the margin of the vaginal mucosa with interrupted
2-0 synthetic absorbable sutures. A soft Silastic closed suction
drain is placed under the flap, sutured into place, and placed to
low suction. The remaining skin adjacent to the flap is brought
into position to close the donor site and is sutured with a
subcutaneous row of interrupted 3-0 synthetic absorbable sutures and 4-0 nylon sutures in the skin. The cardinal feature of successful healing of these flaps is positioning without tension. If they are under tension, separation occurs.

Modification of full-thickness pedicled flaps includes the gluteal thigh flap, which can incorporate a much larger skin paddle, depending on the inferior gluteal artery, and can range up to 8 × 20 cm. It should not be performed in a patient with a previous bilateral hypogastric artery ligation because compromise may occur.

**Mechanical Skin Stretcher (SURE Closure)**

A technique for closure of skin defects or to obtain a full-thickness skin graft for neovagina construction from donor site on the body is the mechanical skin stretcher (SURE Closure, Life Medical Sciences, Inc.) (Fig. 51.15). The skin, because of its viscoelastic properties, can be stretched significantly. (For example, the abdominal skin of a woman who is 40 weeks pregnant is significantly stretched.) Through the extensive work of Hirshowitz and Lindenbaum and through the mechanical engineering of the Life Medical Sciences, Inc., it is possible to stretch skin in about 1 hour in the operating room to cover most defects (Fig. 51.16). This device can have a significant role in pelvic surgery.

Large abdominal wall defects and certain vulvar defects may be closed without rotational flaps and split-thickness skin grafts. The application of the skin-stretching device to each margin of the large open abdominal defect allows stretching of the skin in about 1 hour in the operating room to cover most defects (Fig. 51.16). This device can have a significant role in pelvic surgery.

Large abdominal wall defects and certain vulvar defects may be closed without rotational flaps and split-thickness skin grafts. The application of the skin-stretching device to each margin of the large open abdominal defect allows stretching of the skin in about 1 hour in the operating room to cover most defects (Fig. 51.16). This device can have a significant role in pelvic surgery.

**V-Y Advancement Flap**

A simple sliding design for a skin flap that is dependent on random perfusion of perforating musculocutaneous arteries can reconstruct even moderately large vulvar defects. The upper inner thigh is the usual donor site for vulvar defects. Circulation to that area has been reported distally via a rich suprafascial plexus from gracilis and adductor musculocutaneous perforators and proximally from the external pudendal. Bilateral triangles can be drawn while the patient is in the dorsal lithotomy position. The incision is carried down to include subcutaneous fat. After mobilization, the flap is “slid” toward the defect and secured to the remaining vaginal mucosa or to each other, if needed. The original “V” incision is then closed as a “Y” (Fig. 51.17). With a good blood supply and adequate mobilization, the incidence of wound dehiscence is small. Closed suction drains should be placed and left for 7 to 10 days. Ambulation may begin after 3 days. In the interim, prophylactic antibiotics and thromboprophylaxis should be administered, as with most moderately extensive vulvar flaps.

The V-Y flap can be used for even larger reconstructions, as described by Tateo and associates, by transecting the gracilis toward the insertion and making it a type of sliding musculocutaneous flap after mobilization.

**Gracilis and Rectus Abdominis Myocutaneous Flaps**

The gracilis and RAM flaps are extremely versatile flaps, as described in the section on vaginal reconstruction. The same principles hold true for vulvar reconstruction in terms of elevating, rotating, and securing these flaps. The principal difference is that unilateral gracilis flaps can be used, depending on the vulvar defect, and no tubularization is necessary. Similar breakdown rates are seen with vulvar reconstruction as with vaginal reconstruction. We believe that the RAM flap continues to be a superior flap for all myocutaneous vulvovaginal reconstructions.

**OPERATIONS TO PRESERVE URINARY CONTINENCE**

Fecal and urinary diversions have been an essential part of total pelvic exenteration surgery. The early pioneer work of Brunschwig in total pelvic exenteration surgery used
FIGURE 51.16. A: Photograph of an open abdominal wound to be closed with a skin stretcher instrument. B: Midline skin closed without tension. The transverse incision is stretched with the instrument before it is sutured.

ureterosigmoidostomy for urinary diversion (a “wet colostomy”). Reflux of fecal contaminated urine resulted in unacceptable rates of pyelonephritis and secondary renal deterioration. In 1950, Bricker introduced the isolated ileal loop urinary diversion. Later, the colonic loop modification was preferred by some operators. These two techniques have been the preferred techniques for urinary diversion for more than 40 years. Long-term follow-up of patients with isolated intestinal loop urinary diversion, however, has revealed a high incidence of ureteral stenosis and upper renal tract deterioration, especially in those patients who have had pelvic irradiation for gynecologic malignancies. In addition, negative quality-of-life issues secondary to the required urostomy bag—including its odor, reduced self-image, and reduced sexuality—make an alternative technique without a bag desirable. This section discusses the Kock pouch, which introduced the idea of a continent reservoir, and the Miami pouch, which is a newer continent ileocolonic reservoir that has become popular in gynecologic oncology. Each patient should be evaluated individually as to the type of reservoir best suited for her needs. The surgeon should consider the various types but should always perform the procedure that he or she is most comfortable with and that is best suited for the patient.

Continent Urostomy Operations

There are unique pathologic and physiologic changes in pelvic organs after irradiation for gynecologic malignancies. The same levels of perioperative irradiation are not usually required for most urologic malignancies, such as carcinoma of the prostate and bladder. The pathophysiologic changes of irradiation-induced endarteritis, resulting in ischemia and later fibrosis, are not present in urinary diversions required for congenital anomalies. In selecting a continent, nonrefluxing urostomy that meets the physiologic requirements, several features must be considered. The ureteral intestinal anastomous...
must be as free as possible from potential stricture formation that would result in hydro pneumosis and eventual upper re-
nal unit deterioration. Techniques that require the irradiated 
ureter to be buried in the muscular layers of irradiated colon to 
achieve the nonrefluxing feature of continent ureterostomy may be 
associated with a risk of stenosis and secondary hydro pneumo-
sis that is higher than acceptable. The integrity of the upper 
renal tracts remains to be evaluated in prospective, randomized 
trials between the continent ureterostomy and the ileosappend-
colonic variety of these operations. All continent ureterostomy 
procedures should have similar physiologic characteristics, includ-
ing a low pouch pressure of less than 40 cm H2O pressure, even 
at volumes greater than 500 mL. This reduces the incidence of 
ureteral reflux and reduces the incidence of reflux incontinence. Re-
flux and incontinence are reduced because, in the Kock pouch 
ureterostomy, pressures are 90 cmH2O. The use of small 
segments of irradiated large bowel in continent ureterostomies—
that is, the Indiana pouch—may lead to unacceptable levels of 
pressure. This finding needs careful study with long-term 
follow-up.

The compliance of large bowel, especially after irradiation 
therapy, is less than that of small bowel. A larger segment of de-
tubularized colon—that is, the entire ascending and proximal 
transverse colon (Miami pouch)—may overcome this problem 
and allow pressures within the pouch to remain at acceptable 
low levels. Patients could catheterize their continent pouches 
at least four times per day.

The continent ureterostomy is favored in gynecologic oncol-
ogy patients for two reasons. First, medically, the continent 
ureterostomy should help prevent contaminated urine from re-
fluxing into the kidney. This contaminated urine reflux sets up 
a chronic pyelonephritis. After a prolonged period of time, 
there could be deterioration of the upper renal units commonly 
associated with both the ureteral loop and ileal loop ileostomies. Second, quality of life is improved by elimination of the urinary bag with its atten-
dant problems of awkwardness, odor, reduced self-image, and 
reduced sexuality.

**Continent Urostomy with Ileal Reservoir (Kock Pouch)**

The Kock pouch, developed by Nils Kock in 1982, was de-
volved as a continent nonrefluxing ureterostomy. Modifications by 
Skinner improved the surgical technique and reduced the post-
operative complications of the original Kock technique. This 
alternative to ileal or colonic loop urinary diversion should be 
considered by gynecologic oncologists. Skinner and coworkers 
have shown that construction of an internal reservoir suitable 
for urinary bladder replacement must provide (a) retention of 
500 to 1,000 mL of fluid, (b) maintenance of low pressure af-
ter filling, (c) elimination of intermittent pressure spikes that 
produce reflux, (d) true continence day and night, (e) ease of 
catheterization, and (f) prevention of reflux.

The mucosa of the ileum in the wall of the pouch appears 
to adapt well to urine. The height of the villi of the ileal mu-
cosa gradually decreases, and, in time, the mucosa becomes 
neither flat, thereby proportionally reducing the absorption of 
electrolytes from the urine.

Prerequisites for constructing a continent ureterostomy include 
reasonable renal function (creatinine level < 3.0 mg/dL), an 
adequate length of small bowel so that use of 80 cm of ileum 
taken out of the digestive tract does not result in significant 
short bowel syndrome, and a patient and her surgeon who are 
prepared to understand and accept the inherent risks (in irradiated bowel, an 8%–16% incidence of malfunction of the continent valve mechanism, necessitating additional surgery). When the pouch procedure is performed in conjunction with total pelvic exenteration, resection of the pelvic organs is performed first. For the conversion of an ex-
isting ileal or colon conduit to a continent ureterostomy, all the 
intradominal adhesions of the intestine must be taken down 
and the bowel inspected for enterostomies before initiating the 
Kock pouch continent ureterostomy.

**Technique for Kock Pouch Continent Urostomies: Skinner Modification**

As seen in Figure 51.18, knowledge and understanding of the 
anatomy of the terminal ileum and ascending colon and of the 
blood supply to these structures is essential for the success of 
the operation. The terminal ileum is transected about 16 cm 
from the ileocecal junction in the area of the avascular plane of 
Treves. To ensure mobility of the pouch, an incision is carried 
up the avascular plane of Treves for 25 to 30 cm. The ileocolic 
artery must be lateral to this incision, with the branches of the 
superior mesenteric artery medial to the incision.

The pouch requires 17 cm of ileum for the efferent nipple 
valve and bowel limb, two 22-cm segments of ileum for the 
pouch itself, and one 17-cm segment of ileum for the afferent 
bowel limb and nipple valve. As seen in Figure 51.19, 5 cm 
of proximal ileum is sacrificed to allow greater mobility of the 
completed pouch. The anterior wall of the pouch is opened with 
electrocautery. The posterior wall is sutured with two layers of 
synthetic absorbable suture (Fig. 51.19A).

The nipples are constructed by intussusception of the small 
intestinal (Fig. 51.19B). Stapling the nipple intussusception with 
a TA-55 4.8-mm stapler to prevent deintussusception is a vital 
step in this procedure (Fig. 51.19C). The walls of the pouch are 
folded over and sutured in place to complete the pouch (Fig. 
51.19D). The ureters are anastomosed to the afferent bowel 
limb over Silastic stents (Fig. 51.19D). The efferent bowel limb is 
tapered and brought through a defect in the umbilicus. The 
afferent bowel limb is anchored with suture near the promon-
tory of the sacrum. The pouch itself is positioned in the pelv-
inlet. The efferent bowel is tapered to the size of a 20-French 
catheter with a gastrostominal anastomotic (GIA) stapler be-
fore it is exteriorized (Fig. 51.19F).

The efferent system of the pouch requires a 30-French Medena catheter placed through the stoma and passed through the efferent nipple into the pouch for drainage of urine and intestinal mucus (Fig. 51.19G).

During the postoperative phase, all continent ureterostomies 
are protected by an adjacent, closed-suction drain placed in the 
area of the pouch. Leakage from pouch suture lines has been 
frequent, and, if not drained, a urinoma with septic abscess 
may occur. The catheter in the efferent limb and nipple and the 
closed suction drain can be removed 3 weeks postoperatively. 
Thereafter, the patient is trained by the enteroctomal therapist 
in the technique of catheterizing the pouch. Three weeks post-
operatively, endoscopy is performed on the pouch, the Silastic 
stents are removed from the ureters, and the pouch is tested 
for reflux of urine as well as continence by filling the pouch 
with 200 mL of radioactive contrast. An abdominal radiograph 
is obtained to observe reflux into the kidney. An intravenous 
pyelogram should be obtained after removal of the ureteral 
stents for baseline assessment of the kidney. Slight pyeloluc-
tasis (grade I) is not unusual in the postoperative period. For 
the first 3 weeks postoperatively, while the stents are in place, 
the patient is placed on a broad-spectrum antibiotic regimen.

Results of this procedure have been encouraging. In highly 
irradiated bowel, there is a lower incidence of ileal or sigmoid 
necrosis compared with the Kock and Skinner series that were 
preponderantly made up of nonirradiated patients. Long-term 
evaluation of upper renal tract deterioration in patients with
ileal and colonic loops compared with upper renal tract deterioration in patients with continent urostomies awaits further study. Early results reported by Skinner indicate a protective effect on the upper renal tracts secondary to a reduction of contaminated urinary reflux and its associated subclinical chronic pyelonephritis.

**Ileocolic Continent Urostomy (Miami Pouch)**

Another procedure for continent urostomies following removal of the bladder is the use of a small portion (10–15 cm) of terminal ileum, the ascending colon, and proximal transverse colon. Earlier series of patients having a modification of this procedure—that is, the Indiana pouch—using irradiated bowel were discouraging because the amount of colon used was small (ascending colon only). The smaller segment of irradiated colon may result in higher pouch pressures and, therefore, greater ureteral reflux and incontinence. In a technique described at the University of Miami, modifications that used a larger segment of colon that included the entire ascending colon as well as the proximal portion of the transverse colon resulted in reduced pouch pressure, less reflux, and reduced incontinence (Fig. 51.20). The Miami pouch was developed by Bejany and Politano and was reported in 1988. The intention of the pouch was to improve the rate of urinary continence, allowing for both increased flexibility in reimplantation of the ureters and an adequate storage system. The alternative to the intussuscepted segment to prevent ureteral reflux was a nontunneled ureterocolonic anastomosis. Continence was achieved by reinforcing the ileocecal segment with three circumferential silk sutures, placed in a purse-string fashion, and tapering the distal segment of the ileum over a 14-French catheter. This technique created a low-pressure reservoir, high-pressure outlet to maximize continence.

The ileocolic continent urostomy (Miami pouch) does not require the intussusception of bowel to create the continent mechanism for the efferent system. A combination of the intact ileocecal valve, as well as reduction in the diameter of the lumen of the terminal ileum by tapering, elevates the pressure in the efferent system to about 80 to 90 cmH₂O. The pressure in the efferent system is higher than the pressure in the central pouch, which should be less than 40 cmH₂O. It is unclear whether patients who are continent after an ileocolic continent urostomy are continent secondary to an intact (competent) ileocecal valve or from the tapering of the terminal ileum. Furthermore, it is unclear which ureterocolic technique is the best for achieving a nonrefluxing anastomosis of the ureters to the colon. Further data are required to determine whether the traditional technique for achieving antireflux (i.e., embedding the ureter in the wall of the colon) prevents reflux because there is a naturally higher ureteral pressure compared with pouch pressure or because embedding the ureter in the wall of the colon elevates ureteral pressure to a level greater than the pouch. Stenosis at the ureteral anastomotic site can result in hydroureter and hydronephrosis. A benefit of the ileocolic continent urostomy technique is the elimination of the need for intussusception of the small bowel, as in the Kock pouch, to produce the continent afferent and efferent systems. Construction of an ileocolic

B: Nipples are constructed by intussusception of the small intestine. C: The TA-55 4.8-mm stapler is used to staple the nipples at the 2- and 10-o’clock positions to prevent deintussusception. D: The completed pouch shows the efferent and afferent nipples constructed with their respective efferent and afferent bowel limbs. Strips of polyglycolic acid mesh have been inserted through the mesentery to be sutured adjacent to the intussusception to further reduce the incidence of deintussusception. The walls of the pouch are labeled B, E, A, A’, C, and C’. These letters are connected to form the pouch. E: The ureters are anastomosed to the afferent bowel limb over the Silastic stents. F: The diameter of the lumen of the terminal ileum was reduced by applying the gastrointestinal anastomotic stapler over a number 14-French catheter used as a sizer. G: The completed pouch is positioned in the pelvic inlet. The efferent system of the pouch requires a number 24-French Medena catheter placed through the stoma and passed through the efferent nipple into the pouch for drainage of urine. The stoma is exteriorized at the umbilicus.

Surgical Reconstruction of the Pelvis in Gynecologic Cancer Patients 1367
The ileocolic pouch requires a larger volume of colon. The small bowel is transected about 10 to 15 cm from the ileocecal valve. Incision is carried up the avascular plane of Treves. The transverse colon is transected to provide an equal segment of transverse colon to the right colon. Care is taken to preserve the middle colic artery.

Continent urostomy (Miami pouch) is technically simpler. It also lends itself to the use of a Polysorb (synthetic absorbable) surgical stapler for closure of the margins of the pouch walls, thereby reducing overall operative time. Finally, there is the potential decreased morbidity by sparing a large segment of small bowel absorptive function that can be seen with small bowel continent reservoirs.

Technique for Ileocolic Continent Urostomy (Miami Pouch)

The distal ileum is transected 10 to 15 cm proximal to the ileocecal valve. The cecum and the segment of ascending colon are mobilized up to the right colic flexure, and the transverse colon is transected just distal to the middle colic artery (Fig. 51.21). Continuity of the bowel is restored with an ileotransverse colon anastomosis. If an appendectomy has not been performed, it should be done during the procedure. The colon is opened with cautery along the tenia and folded onto itself to create a U-shaped intestinal plate (Fig. 51.22). The legs of the “U” are anastomosed in a side-to-side fashion with absorbable staples or interrupted absorbable sutures to form the posterior wall of the reservoir (Fig. 51.23). This detubularizes the segment of bowel and reduces the potential for high pressure in the colon segment.

The left ureter is passed through the sigmoid mesocolon before entering the reservoir, unless the sigmoid colon has been removed. A mucosal incision is made to create a sulcus in which the ureters will be anastomosed. The distal ends of the ureters...
are spatulated and, with 4-0 polyglycolic acid sutures, anastomosed to the submucosal layers of the colon. The muscular wall of the colon and the low-pressure reservoir provide the antireflux mechanism. Extraluminally, the ureteral adventitia is fixed to the bowel serosa. The ureters are stented with 7-French single-J ureteral diversion stents that are secured distal to the ureterocolonic anastomosis with absorbable sutures; alternatively, double-J indwelling catheters may be used. The nonstented ureterocolonic anastomosis has worked well for us in the colon. Incidence of reflux and obstruction has been similar to that recorded with other forms of intestinal anastomosis.

Tapering the segment of distal ileum and placing purse-string sutures at the level of the ileocecal valve helps create the continence mechanism. A 14-French rubber catheter is placed into the distal ileum. The ileum, with the rubber catheter in place, is clamped using four Babcock clamps on the mesenteric side. Allis clamps are placed on the antimesenteric border of the ileum and pulled to provide mild traction. A stapling instrument is applied to the ileum longitudinally between the Babcock and the Allis clamps to reduce the lumen diameter down to the underlying 14-French catheter (Fig. 51.24). This tapering is done to increase the pressure of this ileal segment and to provide continence by having a higher pressure than the colonic reservoir. Three purse-string sutures (0.5 cm apart) of 2-0 silk or polypropylene are placed in the seromuscular layer of the ileal segment at the level of the ileocecal valve to increase the final closure pressure and achieve urinary continence (Fig. 51.25). The tapered ileal segment is exteriorized as a stoma to the right lower quadrant of the abdomen for future self-catheterization by the patient.

The anterior wall of the reservoir is then closed with absorbable staples or suture in an interrupted fashion. The
The second procedure to maintain continence when constructing a Miami pouch is tapering of the distal ileum. The ileal segment is tapered over a 14-French catheter. Care must be taken to taper the antimesenteric side so as not to disrupt blood supply. (From: Estape R, Mendez L, et al. Urinary diversion in gynecologic oncology. Surg Clin North Am 2001;81:788, with permission.)

Reinforcing the ileocecal valve is considered essential for maintaining continence. The ileocecal junction normally acts as a valve, thus preventing reflux of colonic contents into the lumen. If a urinary reservoir becomes distended, the ileocecal valve alone may not be sufficient to prevent leakage. By tapering the segment of the distal ileum and placing purse-string sutures at the ileocecal valve, the pressure of this segment of bowel exceeds the reservoir pressure at all times, thereby resulting in full continence.

Approximately 2 weeks after surgery, a contrast study of the reservoir and an intravenous urogram are performed to evaluate for leakage, reflux, or upper tract obstruction. If the radiographs show normal findings, the ureteral stents are removed, and the patient is taught to irrigate and catheterize the pouch. Initially, the patient catheterizes the stoma every 2 to 4 hours and irrigates it four times a day. The patient gradually decreases the frequency of catheterization and irrigation if continence and/or obstruction of the catheter by mucus is not a problem. Patients describe a feeling of fullness or slight cramping in the right lower quadrant, indicating the need to empty the reservoir. The average frequency of catheterization is five to six catheterizations in 24 hours. The time needed for emptying the reservoir is about 3½ minutes. The amount of urine for each catheterization averages 365 mL (range, 250–500 mL). Urodynamic evaluation of the reservoir reveals that the basal pressure fluctuates between 10 and 20 cm of water, whereas in the tapered ileum it varies between 50 and 60 cm of water.

We have reviewed the incidence and management of the urinary complications related to the creation of the Miami pouch at the Division of Gynecologic Oncology of the University of Miami. The majority of the patients who had urinary diversion—68 of 90 (76%)—underwent pelvic exenteration for recurrent cervical cancer, and the majority of these (93.5%) were previously irradiated. The most common complications of the 90 patients evaluated were urinary tract infection/pyelonephritis (40%), ureteral stricture/obstruction (20%), difficult catheterization (18%), and pouch leakage (14%). It is now clear that most of the complications related to the urinary diversion can be safely treated conservatively. Conservative treatment was efficacious in most of the urinary complications related to the creation of the Miami pouch. In this study, ureteral strictures were encountered in 10 patients (13%). All strictures were noted at the level of the ureterocolonic anastomosis. Conservative management includes balloon dilation, stent placement, and nephrostomy placement. Conservative treatment was successful in 8 of the 10 patients. Ureteral obstruction that was caused by stone formation was treated with lithotripsy in one patient; the other required...
surgical revision because of the dimension of the stones. Another five patients presented with ureteral obstruction, four of which cases were successfully managed conservatively. The total number of patients with stones was four (52%), only one, as previously mentioned, required surgical revision. Five patients developed a fistula with the Miami pouch; three of these cases were also managed conservatively.

We have recently reported our 15-year experience performing the Miami Pouch with favorable results. There was a 40% urinary tract infection rate and a 20% ureteral structure rate; however, the rate of urinary continence in these patients was 93%

Although complications related to the creation of the Miami pouch are not infrequent, early detection and conservative management are now recommended to manage the majority of these patients safely. Conservative management should be attempted whenever possible, but surgical intervention should not be delayed when indicated. The optimal management of these complications consists of multidisciplinary approach with active participation of endoscopists, urologists, and radiologists.

In summary, the Miami Pouch continues to be an excellent choice for urinary reconstruction after radical resection for gynecologic cancer in the properly selected patient. With the advent of minimally invasive surgery being applied to radical pelvic resections and in certain cases even urinary reconstructions, we can expect the quality of life and recovery of these patients to continue to improve.

**TECHNIQUES TO RESTORE RECTAL FUNCTION**

In many gynecologic malignancies, resection of the rectosigmoid colon may be indicated to achieve optimal cure rates. In diseases ranging from primary ovarian cancer to recurrent cervical cancer, the rectosigmoid may need resection even with the aim for proper surgical management. In cases in which the anus is resected, the patient has few options except en bloc colostomy. However, efforts have been made in patients who have rectal and anus-sparing procedures to improve the technical and functional results by reanastomosis. Metastasis of ovarian cancer to the anus and lower rectum is rare. In 1954, Javert reported that the number of metastases of cervical carcinoma to the anus from the cervix was as low as 1.4 cm from the anal verge. A statistically significant difference in the number of patients having fecal frequency was noted between the group with end-to-end anastomosis versus those having construction of a rectal J-pouch reservoir. A total of 60% of those with a J-pouch reservoir had one to two bowel movements per day versus 33% of those with an end-to-end anastomosis procedure has spared many patients an undesirable end colostomy. This technique is described in Chapters 43 and 50.

The straight end-to-end colorectal anastomosis is not without its critics. Functional studies have revealed poor results with defecation disorders (leakage, urgency) in as many as 30% of patients, usually related to residual rectal length. Whereas reported in 1987 on incontinence and dysfunction in gynecologic patients undergoing very low colorectal anastomoses, an unacceptably high 70% of patients reported more than four bowel movements per day, even 2 years after surgery. Some physiologic studies seem to indicate that the incontinence is due to damage of the internal anal sphincter. Intercourse of any instrument transanally should be done with the utmost caution.

Frequency disorders, on the other hand, are a result of loss of rectal storage function. Many patients tend to improve over time, probably from an increased reservoir function of the remaining rectal stump; however, this adaptive period may last up to 2 years. For this reason, surgical options to improve functionality in patients undergoing rectosigmoid colon resection and anastomosis have been introduced with good results.

### Colonic J-Pouch Reservoir for Very Low Coloproctostomy

Patients in whom a very low anterior resection of the colon was performed were frequently left with an end sigmoid colostomy and low Hartmann pouch. Historical attempts to reestablish continuity of the fecal stream in patients requiring very low anastomosis (<5 cm from anus) of the colon to the rectum at or below the level of the levator sling met with discouraging results.

Tenesmus and fecal frequency are common side effects of very low end-to-end coloproctostomy after very low rectosigmoid resection. The creation of a rectal J-pouch reservoir, even in irradiated colon and rectum, appears to restore the rectal ampullae bulb reservoir and is an effective method of substantially decreasing these troublesome symptoms. As shown in Figure 51-27, the sigmoid colon is folded on itself with 5 to 7 cm extending into the affrent and efferent segments. A defect is opened in the bottom of the J-pouch, and the 10-cm in-line stapler with 4.8-mm staples is placed in both loops of the colon and fired. The end-to-end anastomosis (EEA) stapler is inserted through the rectum after two purse-string sutures are placed in the rectal stump and the bottom of the J-pouch. The EEA stapler is fired and the anastomosis is completed. The integrity of the anastomosis is tested by inserting a sigmoidoscope per anus, pumping air through the sigmoidoscope into the J-pouch, and observing all stapled suture lines for air leaks under saline placed into the pelvis. The problem of tenesmus and fecal frequency in very low anastomosis has been addressed by Lazorthes and coworkers in a study of 63 patients who underwent low anterior resection of the colon for rectal carcinoma. Forty of the 65 patients underwent end-to-end anastomosis at a mean distance of 2.3 cm from the anal verge, and 20 had construction of a rectal J-pouch reservoir with anastomosis to rectum at a mean distance of 1.4 cm from the anal verge. A statistically significant difference in the number of patients having fecal frequency was noted between the group with end-to-end anastomosis versus those having construction of a rectal J-pouch reservoir. A total of 60% of those with a J-pouch reservoir had one to two bowel movements per day versus 33% of those with an end-to-end...
FIGURE 51.27. A: Cutaway view of the completed rectal J-pouch is shown positioned over the anus and rectal stump with the end-to-end anastomosis stapler inserted through the anus up the rectum. The anvil of the stapler has been inserted into the pouch, and two adjacent purse-string sutures are applied and tied around the central rod. The stapler is closed and activated. B: Completed rectal J-pouch coloproctostomy.

anastomosis. Fecal frequency in these patients is due to the surgical removal of the rectal ampulla, which acts as a low-pressure pouch that does not produce tenesmus until it is full. This improvement was ascribed to a manometrically confirmed and statistically significant higher maximum pressure and tolerable fecal volume in the neorectum of those patients with a neoreservoir (J-pouch) versus those having direct end-to-end anastomosis.

This is especially true in gynecologic oncology patients with irradiated rectosigmoid colons whose compliance is reduced. Therefore, the radius of the end-to-end anastomosis is small, and, under Laplace’s law, the pressure becomes high. In the J-pouch, the radius is larger; therefore, the pressure is lower. There is little tenesmus, and fecal frequency is significantly reduced. A confirmatory study was published by Parc and colleagues, who reported on 30 patients who underwent low anterior resection and rectal J-pouch coloproctostomy. After surgery, the mean number of bowel movements in this group was 1.1 per day, and no patients reported tenesmus.

The use of this technique in patients undergoing surgery for gynecologic malignancy, particularly those whose condition has been previously treated with total pelvic irradiation and brachytherapy, has not been extensive. Some suggestion has been made that with the J-pouch there is a better blood supply, leading to a decreased incidence of anastomotic breakdown in patients with a history of pelvic radiotherapy.

The colonic J-pouch is not without complications itself. The principal shortcoming is incomplete emptying. Several studies have been directed at the limb length of the J-pouch. To minimize this problem, the consensus seems to be to construct a useful reservoir the limb length of 5 to 7 cm.

The issue of a protective colostomy or ileostomy when performing a colorectal anastomosis usually rears its ugly head at about this time. The literature at this time is unclear. Data in the colorectal literature suggest it is beneficial. However, data from our institution suggest, for patients undergoing pelvic exenteration, that the major risk factor for fistula formation or anastomotic breakdown is a history of pelvic radiotherapy, independent of the presence of a protective diversion. Indeed, 33% of previously irradiated patients will have an anastomotic breakdown (even with a proximal diversion) versus 7.5% in those with no history of radiotherapy.

In summary, colon J-pouches significantly improve the quality of life for patients, especially those patients who have irradiated bowel and in whom significant portions of the small bowel have been removed. It should be considered by all who perform gynecologic oncology surgery.

BEST SURGICAL PRACTICES

- Radical resection of pelvic malignancies or tissue injury from radiation may produce significant structural and functional pelvic or vulvar defects that need to be repaired by the gynecologic surgeon.
- Vaginal reconstruction: Gracilis myocutaneous flaps are the standard reconstruction technique for vaginal reconstruction after pelvic exenteration because they are bulky and fill the pelvic cavity with tissue and bring in new blood supply. An omental flap with a split-thickness skin graft can also be used, but this requires use of a vaginal stent or mold (for at least 6 months) to maintain patency. Rectus abdominis
flaps have also been used, but they cannot be constructed at the same time as the urinary and bowel diversions; thus, this technique prolongs the exenterative operation.

Vulvar reconstruction: In most cases, even large vulvar defects can be closed primarily because of the loosen skin of the vulva, thigh, and buttocks. The Z-plasty full-thickness pedicle flap is very useful and relatively easy to perform. The design of the flap is the most critical part of the procedure. As a rule, for every centimeter of flap length, the base must be 2 cm wide. Use of V-Y advancement flaps split-thickness skin grafts and various myocutaneous flaps may be helpful in some defects.

Urinary tract reconstruction: Although an ideal conduit provides a relatively rapid technique with few complications for bladder replacement after exenteration, continent urinary reservoirs result in a more normal quality of life for the postoperative patient. We have had considerable experience with the Miami pouch, which uses a longer segment of colon to increase the size of the reservoir and a tapered segment of distal ileum resulting in good continence rates.

Rectal reconstruction: When the anus and distal rectum can be preserved, several techniques to reestablish rectal continuity exist. The use of end-to-end stapling devices has allowed much more distal anastomoses than was possible with hand-sewn anastomoses. In some patients, the loss of rectal storage function of the healthy sigmoid colon may lead to perineal, urgency, and incontinence. A rectal Y-pouch may solve this problem in all cases of low rectal anastomosis in a previously radiated pelvis, a temporary protective colostomy should be strongly considered.

Bibliography

ACKNOWLEDGMENT

We would like to acknowledge Clifford R. Wheelless Jr., MD, for his contributions to the current and prior editions of this chapter. Dr. Wheelless is a pioneer in the field of reconstructive gynecologic surgery, and his work has continued the rich tradition of the true pelvic surgeon.

CHAPTER 2

1. A legal document reflects that an adequate informal consent process has taken place.
   a. True
   b. False

2. An ethically valid informed consent requires that it be obtained through the voluntary authorization by a patient for a medical intervention.
   a. True
   b. False

3. An adverse surgical outcome is synonymous with negligence.
   a. True
   b. False

4. The surgeon should document in the chart the alternatives to a selected procedure and indicate that they were each discussed with the patient before the procedure.
   a. True
   b. False

5. Competence of the patient is one of the core components required in the decision-making process.
   a. True
   b. False

6. An incorrect entry in a patient’s chart should be corrected by a second entry without crossing out and initialing the erroneous entry.
   a. True
   b. False

7. Standard of care refers to a level of care that is generally thought to represent the norm.
   a. True
   b. False

8. The National Practitioners Data Bank receives and makes available data regarding infraction of practice standards.
   a. True
   b. False

9. The Health Insurance Portability and Accountability Act (HIPAA) establishes minimal national standards to ensure confidentiality of protected health information.
   a. True
   b. False

10. The Nuremberg Code establishes the need for voluntary consent of the patient.
    a. True
    b. False

11. Surgeons who choose to respect the wishes of a competent Jehovah’s Witness patient to refuse blood products in the face of imminent exsanguination are, in general, protected from wrongful death liability.
    a. True
    b. False

12. A durable power of attorney for health care is a legal document in which a patient designates a specific individual to make health care decisions in the setting of loss of decisional capacity.
    a. True
    b. False

CHAPTER 3

1. Select the professional who should be responsible for answering patient’s questions before she undergoes surgery:
   a. Office nurse who works with preoperative patients
   b. Ancillary personnel who has taken a course called “Preparing the Patient for Surgery”
   c. The patient’s surgeon
   d. A trusted friend who has recently had the same procedure

2. In which of the following patients is an obliterator procedure indicated?
   a. A patient who is not sexually active
   b. An octogenarian
   c. An elderly widowed or divorced patient
   d. None of the above; age should not be a determinant

3. Which of the following questions should be answered for the patient before surgery?
   a. How will surgery affect my sexuality?
   b. When can I safely resume sexual intercourse?
   c. What hormonal changes should I expect after surgery?
   d. Can I have ovarian cancer after my ovaries are surgically removed?
   e. Will I need hormone replacement therapy (HRT)?
   f. Is HRT safe?
   g. All of the above

4. What is a complete physician?
   a. A physician who has mastered and maintained his or her skills in the surgical arena
   b. One who keeps up to date by acquiring new skills
   c. One who is most well known in his community as a skilled surgeon
   d. A skilled surgeon who addresses his patient’s psychological as well as physical needs

5. Which of the following should be considered “special needs” patients who require extra attention?
   a. Teenagers
   b. Patients from another culture
   c. A depressed patient
   d. The cancer patient
   e. The senior woman
   f. All of the above

6. Shaving the perineum preoperatively is:
   a. Always indicated before vaginal surgery
   b. Always indicated before abdominal surgery
   c. Decreases postoperative infections
   d. Indicated in the older patient

1375
Questions

1. An outdated procedure that should no longer be performed routinely
2. Alleviating preoperative stress does the following:
   a. Releases endogenous opiates
   b. Has little or no effect on postoperative morbidity
   c. Has been shown to decrease the requirement for analgesics after surgery
   d. Wastes the time of the physician and personnel in the modern office

CHAPTER 4

1. The Standard of Care requires in most states in the United States that physicians must render the degree of care exercised by physicians under the same or similar circumstances in the:
   a. Community
   b. State
   c. Region
   d. Nation
2. An indirect cause-and-effect relationship must exist between the breach in the Standard of Care and the adverse outcome for malpractice to legally occur.
   a. True
   b. False
3. The ethical principles generally involved in providing adequate informed consent include:
   (1) Autonomy (2) Beneficence (3) Nonmaleficence (4) Justice
   a. 1 and 4
   b. 1 and 2
   c. 3 and 4
   d. 1, 2, 3, and 4
4. The primary purpose of a well-documented medical record is to:
   a. Protect the physician from a malpractice claim
   b. Provide adequate information to the patient’s insurance company
   c. Communicate with members of the health care team
   d. Meet hospital requirements
5. The words ______ are medicolegally correct words to be use in describing, in a progress note or an operative note, an adverse event that might have occurred during an operative procedure:
   1. Unintentionally
   2. Inadvertently
   3. Accidentally
   4. Unfortunately
   a. 1 and 4
   b. 1 and 3
   c. 2 and 4
   d. None of the above
6. When a language barrier exists between the patient and physician, the physician is relieved of the ethical requirement to provide reasonable communication in providing informed consent.
   a. True
   b. False
7. The physician is protected from being sued for malpractice for an adverse outcome when the physician’s managed care plan has denied the physician’s patient access to studies or treatments recommended by the physician.
   a. True
   b. False
8. In preparation for and during a deposition, it is generally prudent for a physician to:
   1. Be unfamiliar with the office and hospital policies so that the plaintiff’s attorney cannot question the physician about those areas
   2. Not attempt to educate his or her attorney about the medical facts of the case, because the insurance carrier would only use attorneys who are very knowledgeable about all the medical aspects of the case
   3. Always demand to be able to read and sign the deposition
   4. Be unfamiliar with the alternative forms of therapy that you might have used so that the plaintiff’s attorney is unable to question you about them
   a. 1 and 2
   b. 1 and 4
   c. 3
   d. 2 and 4
9. During a trial, it is prudent for the physician to:
   1. Attend only those sessions where he or she has to give testimony to convey to the jury lack of concern about the matter
   2. Explain in complex medical terms the facts of the case so that the jury can be impressed with his or her medical knowledge
   3. Give the best educated guess to questions of which he or she is not completely sure of the answer
   4. Dress in a manner to convey to the jury that he or she is a rich and very successful physician
   a. 1 and 3
   b. 2 and 4
   c. 2 and 3
   d. None of the above
10. The emotional stress of a malpractice case has:
    a. Been equated to the loss of a loved one
    b. Resulted in symptoms of major depression in 40% of sued physicians
    c. Resulted in 8% of sued physicians having the onset of physical ailments of which one fourth were life threatening
    d. All of the above

CHAPTER 5

1. Common electronic health record errors include which of the following?
   a. Entering and retrieving information
   b. Failure of software
   c. Communication and coordination of patient care processes
   d. Inability for physicians to learn how to navigate the programs
2. For resident education, Brazil requires which of the following?
   a. Weekends off
   b. 30 consecutive days off per year
   c. One day off in 5
   d. 10% of total work hours dedicated to educational activities
3. Regarding hospitalist programs, which of the following are true?
   a. The majority of clinical trials demonstrate decreased length of stay.
   b. These providers only work in hospitals.
   c. There are multiple models and work paradigms.
2. Choose the incorrect statement pertaining to the pudendal artery and nerve.
   a. The pudendal nerve provides only sensory innervation to the perineum.
   b. The pudendal nerve arises from the sacral plexus.
   c. The pudendal artery originates from the anterior division of the internal iliac artery.
   d. The nerve and vessels have three branches: clitoral, perineal, and inferior hemorrhoidal.
   e. The perineal branch of the pudendal artery is the largest of the three branches.

3. Choose the incorrect statement.
   a. Vulvar lymphatic channels lie medial to the labiocutaneous fold, establishing this as the lateral border of surgical resection.
   b. The clitoris never drains directly into the deep pelvic nodes.
   c. The superficial inguinal nodes lie in a T-shaped distribution 1 cm below the inguinal ligament.
   d. The deep inguinal nodes are found beneath the fascia cribrosa.
   e. Within the femoral triangle, the most medial structure is the femoral vein.

4. Choose the incorrect statement.
   a. The perineal membrane is a triangular sheet of fibromuscular tissue spanning the anterior half of the pelvic outlet.
   b. The perineal membrane attaches medially with the urethra, walls of the vagina, and the perineal body.
   c. The internal anal sphincter is indistinguishable from the external anal sphincter, and it lies just outside the external anal sphincter.
Questions

d. The levator ani muscles and their fascia are called the pelvic diaphragm.
e. The urogenital hiatus allows passage of the urethra, vagina, and rectum through the pelvic diaphragm.

5. Which of the following is a vaginal structure?
   a. Anterior and posterior columns
   b. Urethral carina
   c. Anterior and posterior fornices
   d. Lateral vaginal sulci

6. Choose the incorrect statement.
   a. The four portions of the fallopian tube from medial to lateral are the isthmus, interstitium, ampulla, and fimbriated end.
   b. The ovary connects medially to the uterus with the uteroovarian ligament.
   c. The normal ovary measures 7 cm long during reproductive life.
   d. The anterior portion of the uterine cervix is covered by squamous to columnar epithelium.

7. Choose the correct statement.
   a. The fallopian tubes are approximately 15 cm long.
   b. The muscle fibers of the uterine corpus are arranged in a complex diagonal crisscrossed pattern.
   c. The cervix is divided into two portions: the portio vaginalis and the portio supravaginalis.
   d. The distal end of the fallopian tube is attached to the ovary by the fimbria ovarica.

8. Choose the incorrect statement.
   a. The ovary attaches medially to the pelvic sidewall with the infundibulopelvic ligament, which contains the ovarian vessels.
   b. The ovary is anterior and posterior fornices.
   c. The normal ovary measures 7 cm long during reproductive life.
   d. The ovary attaches to the broad ligament through the mesovarium.
   e. Ovarian follicles, corpora lutea, and corpora albicantia are found within the ovarian cortex.

9. Choose the incorrect statement.
   a. The blood supply of the upper adnexal structures comes from the ovarian arteries that arise from the aorta below the renal arteries.
   b. The ovarian veins drain into the vena cava on the left and the renal vein on the right.
   c. The uterine artery, which usually originates from the internal iliac artery, is a branch of the main left iliac artery, may have a common origin with the internal pudendal or vaginal arteries.
   d. The uterus attaches to the base of the uterine cervix.
   e. The vagina receives blood supply from the uterine artery, vaginal artery, and the pudendal vessels.

10. Choose the incorrect statement pertaining to the ureter.
    a. The ureter descends into the pelvis after passing over the bifurcation of the internal and external iliac arteries.
    b. The ureter lies in a special connective tissue sheath within the medial leaf of the broad ligament.
    c. The ureter crosses under the uterine artery in its course through the cardinal ligament.
    d. The ureter lies approximately 3 cm from the anterolateral surface of the cervix.
    e. The ureter receives blood supply from the common iliac, internal iliac, uterine, and vesical arteries.

CHAPTER 8

1. A preoperative evaluation of a patient with an uncomplicated gynecologic history and an uncomplicated medical or surgical status should include all of the following laboratory tests EXCEPT:
   a. Electrocardiogram if older than 40 years
   b. Pregnancy test if reproductive age, sexually active, not using contraception, or if using questionably effective contraception
   c. Blood type and screen if the potential exists for a more than minimal surgical blood loss
   d. Chemistry panel
   e. Hematocrit or hemoglobin if older than 6 months

   2. During the preoperative history, herbal therapy and dietary supplements should be questioned because of their potential adverse effects on surgical outcomes. These potential adverse effects may include:
      a. Effect of anticoagulation
      b. Effect on glycemic control
      c. Blood type and screen if the potential exists for a more than minimal surgical blood loss
      d. Chemistry panel
      e. None of the above

   3. Pelvic surgery should always be preceded by a recent cyto logic study of the cervix because:
      a. A negative Papanicolaou smear always excludes the possibility of cervical, endocervical, or endometrial neoplasm.
      b. Most preclinical malignancies of the cervix demonstrate significant gross lesions indicating the need for cytologic evaluation.
      c. Patients with abnormal Papanicolaou smears showing repeated dysplasia should be evaluated by colposcopy and suspicious lesions biopsied before pelvic surgery.
      d. A sampling of cells taken from the portio of the cervix is simple, inexpensive, and is indicative of cervical and endocervical pathology.
      e. A finding of abnormal glandular cell dysplasia requires only an endocervical curettage for a complete evaluation.

   4. In regards to the planning and accomplishment of gynecologic surgery on senior patients, which of the following statements is INCORRECT?
      a. Senior gynecologic patients present with significantly greater health care problems.
      b. Senior gynecologic patients are at increased risk during surgery.
      c. Age is a relative contraindication for gynecologic surgery.
      d. With appropriate evaluation and management, the risks of gynecologic surgery on senior patients can be reduced to a level not much greater than for premenopausal patients.
      e. Age is not always an accurate indicator of organ function or malfunction.

   5. Preoperative prophylactic antibiotics are recommended in which of the following gynecologic surgical procedures?
      a. Ovarian cystectomy
      b. Cervical pregnancy
      c. Uterine myomectomy
      d. Tubal ligation
      e. Vaginal and abdominal hysterectomy

   6. Patients who are found during their preoperative examination to have bacterial vaginosis should be treated with:
      a. Oral metronidazole for 7 days
1. All of the following statements regarding preoperative patient preparation are true EXCEPT:
   a. A full bowel prep should be carried out on all gynecologic surgeries.
   b. Pelvic cleansing should be accomplished before all pelvic or abdominal surgeries.
   c. Universal precautions should be used in all gynecologic surgeries.
   d. Hepatitis B vaccination is recommended for all physicians accomplishing gynecologic surgeries.
   e. In those gynecologic surgeries in which hair removal is deemed necessary, hair clipping, rather than hair shaving, is recommended before surgery.

2. Which form of pharmacologic venous thromboembolism (VTE) prophylaxis has the lowest rate of heparin-induced thrombocytopenia (HIT)?
   a. Low molecular weight heparin
   b. Fondaparinux
   c. Dabigatran
   d. Oral anticoagulants
   e. None of the above

3. In regards to the planning and accomplishment of gynecologic surgery on senior patients, which of the following statements is INCORRECT?
   a. Senior gynecologic patients present with significantly greater health care problems.
   b. Senior gynecologic patients are at increased risk during surgery.
   c. Age is a relative contraindication for gynecologic surgery.
   d. With appropriate evaluation and management the risks of gynecologic surgery on senior patients can be reduced to a level not much greater than for premenopausal patients.
   e. Age is not always an accurate indicator of organ function or malfunctions.

4. What are the five basic pathophysiologic mechanisms that cause hypoxemic respiratory failure?

5. Preoperative prophylactic antibiotics are recommended in which of the following gynecologic surgical procedures?
   a. Ovarian cystectomy
   b. Ectopic pregnancy
   c. Uterine myomectomy
   d. Tubal ligation
   e. Vaginal and abdominal hysterectomy
Questions

6. Patients receiving prophylactic antibiotics before gynecologic surgery should be given the antibiotic:
   a. 6 hours before surgery
   b. 1-2 hours before surgery, repeated once if the surgery lasts longer than 3 hours
   c. 1-2 hours before surgery, repeated at 3 and 6 hours after the start of surgery
   d. 6 hours before surgery, repeated again 1-2 hours before surgery
   e. 6 hours before surgery, repeated every 6 hours for 2 days

7. A rectal examination, in combination with the abdominal-pelvic examination, offers all of the following EXCEPT:
   a. A more complete assessment of the broad and uterosacral ligaments
   b. A more effective assessment of the posterior bladder wall
   c. A more complete assessment of the cul-de-sac of Douglas
   d. A more effective assessment of the adnexa
   e. A more effective assessment of the anal sphincter, anal canal, and lower rectum

8. All of the preoperative management actions are suggested in the preoperative care of gynecologic patients EXCEPT:
   a. Discontinue the use of birth control pills 2 to 4 weeks before the planned gynecologic surgery
   b. Immediate preoperative examination by the gynecologic surgeon and anesthesia assessment by an individual anesthesiologist or in the anesthesia preoperative clinic
   c. Cleansing of the lower colon by a preoperative enema
   d. Use of vaginal estrogen cream in postmenopausal women undergoing vaginal surgery
   e. Use of gonadotropin-releasing hormone agonist for 2-3 months before hysteroscopic resection of submucous uterine leiomyoma

9. All of the following statements regarding preoperative patient preparation are true EXCEPT:
   a. A full bowel prep should be carried out on all gynecologic surgeries
   b. Pelvic cleansing should be accomplished before all pelvic or abdominal surgeries
   c. Universal precautions should be used in all gynecologic surgeries
   d. Hepatitis B vaccination is recommended for all physicians accomplishing gynecologic surgeries
   e. In those gynecologic surgeries in which hair removal is deemed necessary, hair clipping, rather than hair shaving, is recommended just before surgery.

CHAPTER 11

1. Closing the subcutaneous space decreases the rate of superficial wound infection.
   a. True
   b. False

2. A 40-year-old woman is diagnosed by ultrasound with a left tubalovarian complex (6 × 6 cm). An open left salpingo-oophorectomy is performed without complications. On postoperative day 2, the patient reports pain at the incision site, and her temperature is noted to be 38.1°C (100.6°F). Examination and gentle probing of the wound show purulent drainage with an intact fascia. Along with antibiotic therapy, the next appropriate step in the management of this postoperative infection is:
   a. Return to the operating room for a thorough examination of the wound and fascial plane under general anesthesia.
   b. Open the wound widely to allow drainage and debridement of necrotic tissue, then cleanse the wound thoroughly with povidone-iodine before reclosing the wound.
   c. Open the wound widely and debride necrotic tissue, then insert a Penrose drain at the infected site before reclosing the wound.
   d. Open the wound widely to allow drainage and debridement of necrotic tissue, then apply wet-to-dry packing until the wound closes by secondary intention.

CHAPTER 12

1. Adult respiratory distress syndrome is characterized by:
   a. Narrowing of the alveolar-arterial O2 gradient
   b. Supplemental oxygen usually able to maintain systemic oxygen saturation (arterial PaO2 over 65 mm Hg)
   c. Intrapulmonary shunting
   d. For platelet counts below 100,000
   e. Oliguria

2. Initial manifestations of early reversible shock include:
   a. Reduced cardiac output
   b. An increase in the systemic vascular resistance
   c. Cold, clammy skin
   d. Disorientation
   e. Oliguria

3. Platelet transfusion is indicated:
   a. For every 4 units of packed red cells transfused
   b. Whenever the platelet count falls below 50,000 µg/dL
   c. For persistent bleeding consistent with coagulopathy
   d. For platelet counts below 100,000 µg/dL before surgery
5. Which of the following characterizes dobutamine?
   a. Maximizes cerebral, coronary artery, and renal blood flow
   b. α-adrenergic effects predominate
   c. β1-adrenergic effects predominate
   d. β2-adrenergic effects predominate
   e. Inotropic and vasoconstrictive effects

6. Following an uneventful total abdominal hysterectomy for symptomatic uterine leiomyomata, a 47-year-old, otherwise healthy patient is seen on morning rounds 24 hours after surgery. The estimated operative blood loss was approximately 1,500 mL. Current vital signs reveal that she is afebrile, has a blood pressure of 110/80 (consistent with her preoperative blood pressure); she does not appear to be in distress. Orthostatics reveal a positive tilt test. Her post-op hemoglobin, checked 24 hours after surgery, is 8 mg/dL. The best management initial treatment for this patient is:
   a. Packed red blood cells (1–2 units)
   b. Crystalloid infusion (1–2 L)
   c. Collodion solution (50–100 mL 25% albumin)
   d. Control venous catheterization
   e. Observation

7. A 22-year-old G0 presents to the emergency room with symptoms of diffuse abdominal pain. She reports that she was treated last year for pelvic inflammatory disease. On admission, her temperature is 38.4°C, her blood pressure is 100/65 mm Hg, and her heart rate is 90. Orthostatics reveal minimal change in blood pressure sitting and reclining. Abdominal examination reveals diffuse tenderness without rebound or guarding, and a bimanual exam reveals a left-sided mass. Laboratory investigation reveals a negative β-hCG titer; a white blood cell count is 21,000 with 90% mature segmental neutrophils. There is a 5-cm complex adnexal mass on ultrasound and no cul-de-sac tent. Of the following, which is the most appropriate next step?
   a. Immediate exploratory laparotomy
   b. Immediate intravenous antibiotics
   c. Urine-plasma creatinine (40 mEq/L/24 hr)
   d. Fractional excretion of sodium
   e. Observation

8. Oliguric prerenal azotemia is characterized by:
   a. Hypotensive hyperchloremic metabolic alkalosis
   b. Urine-plasma creatinine (40 mEq/L/24 hr)
   c. Urine sodium excretion (20 mEq/L/24 hr)
   d. Administration of an erythropoietic stimulating agent.

9. A 46-year-old woman underwent a difficult abdominal hysterectomy and bilateral salpingo-oophorectomy for endometriosis, and the estimated blood loss was 950 mL. Twenty-four hours later, she is anemic. Vital signs reveal a heart rate of 110 that increases to 125 on sitting, and her reclining blood pressure, 110/80 mm Hg, is 105/70 mm Hg in the sitting position. Over the past 8-hour shift, her urine output was 250 mL. These findings are most consistent with which class of shock?
   a. Class I
   b. Class II
   c. Class III
   d. Class IV
   e. Class V

10. Classically, the order of organ system loss in patients with multiorgan failure syndrome is:
    a. Lung, liver, gastrointestinal (GI), kidney
    b. Liver, lung, GI, kidney
    c. GI, kidney, liver, lung
    d. Kidney, GI, lung, liver
    e. Increased sympathetic activation causes renin release.

11. Which of the following statements characterize the mechanism of action of an intact renin-angiotensinogen system?
    a. Angiotensin I is an active polypeptide.
    b. Angiotensin II is a potent vasoconstrictor.
    c. Aldosterone along with antiadrenergic hormone promotes water and sodium excretion.
    d. Angiotensin II decreases venous return, stroke volume, and cardiac output.
    e. Inotropic and vasoconstrictive effects

12. A 58-year-old woman was admitted with fever and severe neutropenia 10 days after chemotherapy. Approximately 48 hours later, she continues to have a low-grade fever (37.9°C) and an absolute neutrophil count (ANC) of 500 mm³. She has an indwelling vascular catheter, with no appreciable erythema or discharge around the catheter site. She is asymptomatic otherwise, and physical examination is unremarkable. Blood cultures are positive for Gram-positive cocci. What is the next logical step in her care?
    a. Empiric therapy with cefepime, ceftriaxone, and imipenem
    b. Removal of the indwelling catheter
    c. Identification of etiology of the anaerobic organism before modifying antibiotic treatment
    d. Vancomycin antibiotic therapy
    e. Piperacillin-tazobactam antibiotic therapy

13. A 59-year-old patient 12 weeks after surgical staging, hysterectomy, and bilateral salpingo-oophorectomy is receiving cycle 2 of carboplatin and paclitaxel chemotherapy for stage III, grade 3 endometrial adenocarcinoma. Pretreatment complete blood count (CBC) reveals a serum Hb of 8.8 and hematocrit of 27 mg%. The patient has well-controlled hypertension and diabetes. Her blood pressure and pulse are in the normal range. She is able to perform most activities of daily living but acknowledges chronic fatigue. In this clinical setting, the best first step in the management of her anemia is:
    a. Transfuse with 2 units of packed blood cells.
    b. Discontinue chemotherapy and begin pelvic radiation therapy.
    c. Initiate supplementation with oral folic acid and monthly B₁₂ injections.
    d. Administer an erythropoietin stimulating agent.
    e. Give iron supplementation.

Questions 1381
CHAPTER 14

1. Which transverse abdominal incision is a muscle-cutting incision?
   a. Pfannenstiel
   b. K"ustner
   c. Maylard
   d. Gridiron

2. The posterior rectus sheath, below the arcuate line, increases the strength of the anterior abdominal wall.
   a. True
   b. False

3. Which aponeuroses contribute to the posterior rectus sheath?
   a. External and internal obliques
   b. External oblique and transversalis
   c. Internal oblique and transversalis
   d. Transversalis and linea alba

4. If one used a Pfannenstiel incision to enter the abdomen for a gynecologic surgery, but found that the incision was inadequate for completion of that surgery, which is the best surgical option to improve visualization?
   a. Transect the rectus muscles, similarly done when performing a Maylard incision.
   b. Transect the rectus muscles at their insertion, similarly done when performing a Cherney incision.
   c. Make a vertical incision, in the midline of the abdomen, bisecting the transverse skin incision and separating the rectus muscles.
   d. Separate the anterior abdominal wall fascia from the overlying subcutaneous fat to the level of the umbilicus and make a vertical incision in the fascia, separating the rectus muscles.

5. Which of the incisions listed below is not routinely used for an extraperitoneal approach to access the retroperitoneal structures?
   a. Sunrise
   b. J-shaped incision
   c. Gridiron
   d. Maylard

6. On average, how many days postoperatively does an evisceration occur?
   a. 2
   b. 4
   c. 6
   d. 8
   e. 10

7. An inferior epigastric artery arises from which major vessel?
   a. Internal iliac artery
   b. External iliac artery
   c. Femoral artery
   d. Hypogastric artery

CHAPTER 15

1. To reduce the risk of unintentional burn when using monopolar electrosurgical devices, one should:
   a. Use an energy current with a highly interrupted sinusoidal wave pattern (COAG).
   b. Use a contemporary electrosurgical generator that uses a “floating ground” circuitry system.
   c. Use a return electrode (ground) of large contact area to ensure a low-current density.
   d. Use a higher voltage to concentrate the energy onto the intended tissue site.

2. To minimize risks of electrosurgical injury during laparoscopic surgery, all of the following practices are recommended EXCEPT:
   a. If metal laparoscopic trocars are used, a plastic insulating collar should be used.
   b. When changing from a flat-puddle electrode to a needlepoint electrode, the power should be decreased.
   c. With bipolar instruments, the CUT current should be used.
   d. An in-line ammeter should be used with bipolar instruments to insulate that coagulation of the tissue in the grasping is complete before the tissue bundle is cut.

3. While coagulating a small diameter bleeder clamped in a hemostat during an emergency laparotomy, the assistant surgeon’s hand is burned where she holds the hemostats. This was due to:
   a. Using CUT instead of COAG
   b. A small hole in the assistant’s glove
   c. Using a return electrode with a low-current density
   d. Activating the current before making contact with the clamp

4. Compared with desiccation, fulguration:
   a. Is a desirable electrosurgical modality for venous bleeding, such as oozing from a muscle
   b. Produces less necrosis and deep-tissue injury
   c. Generates an energy current that avoids “spraying” of the tissue with electricity and injury to the adjacent structures
   d. Is better for coaptive coagulation of an isolated bleeding vessel

5. When using a wire loop for a loop electrosurgical excision procedure (LEEP), all of the following are true EXCEPT:
   a. Larger loop electrodes should be used with higher power settings to provide the same tissue effects as a smaller diameter loop.
   b. Faster movement of the wire through the cervical tissue causes more thermal injury and makes it more difficult for the pathologist to interpret.
   c. The power should be applied to the loop electrode before touching the cervical tissue.
   d. During coagulation of bleeders in the cone bed, the ball electrode should not touch the tissue, allowing the sparks to arc to the surface.

CHAPTER 16

1. The following lasers can be transmitted through quartz fibers except:
   a. Nd:YAG
   b. CO2
   c. KTP
   d. Ho:YAG
2. As the orbital distance of the electron from the nucleus of an atom increases, the energy level decreases.
   a. True
   b. False

3. Q-switching a laser produces the following except:
   a. Increase in pulse time
   b. Increase in peak power
   c. Minimalization of adjacent tissue effect
   d. Cutting of tissue with lower water content
4. One joule equals 1 watt applied for 10 seconds.
   a. True
   b. False

5. Vaporization of tissue with laser occurs:
   a. Between 57°C and 100°C
   b. Above 100°C
   c. Above 100°F
   d. By conduction of the heat away from the laser impact site

6. Laser energy is unique in that it is uniform throughout the cross section diameter of the beam.
   a. True
   b. False

7. The most vulnerable organ to be damaged by laser is:
   a. Skin
   b. Eye

8. The best carbon dioxide laser backstop is:
   a. Glass
   b. Pyrex
   c. Quartz
   d. Water

CHAPTER 17

1. The most cost-effective trocar/sleeve system is which of the following?
   a. Reusable
   b. Disposable
   c. Reposable
   d. Suposable

2. The term laser is an acronym for light amplification by spontaneous emissions of radiation.
   a. True
   b. False

3. The inferior epigastric artery is a direct branch of what major blood vessel?
   a. Internal iliac artery
   b. External iliac artery
   c. Femoral artery
   d. Aorta

4. Which nerve injury is most commonly associated with placement of lateral trocars during laparoscopy?
   a. Obturator nerve
   b. Iliosinguinal nerve
   c. Sciatic nerve
   d. Lateral femoral cutaneous nerve

5. A 52-year-old woman presents to your office 1 week status post a difficult laparoscopic sacral colpopexy requiring 6 hours of surgery. A thorough history and physical exam reveal that she has an inability to dorsiflex or evert her foot. In addition, she has a loss of sensation to the lateral calf and dorsum of the foot. You find that she does have sensation in her toes and the plantar surface of her foot. Her injury is most consistent with which of the following?
   a. Injury to femoral nerve, excessive flexion of the hips with Allen stirrups
   b. Compression of the common peroneal nerve, compression by Allen stirrups
   c. Compression of the tibial nerve, compression by Allen stirrups
   d. Entrapment of pudendal nerve, sutures entrapping the nerve

6. The coagulation button on the cautery is actually an extremely “damped” or modified form of the cutting wave current.
   a. True
   b. False

7. The open technique for laparoscopy has been shown to result in a statistically significant decrease in deaths during laparoscopy when compared with the Veress needle technique.
   a. True
   b. False

CHAPTER 18

1. Choose the incorrect statement.
   a. Hysteroscopes are available with 0-degree straight on or 30-degree fore-oblique views.
   b. The telescope is composed of the eyepiece, the barrel, and the objective lens.
   c. Three types of light generators are available: tungsten, metal halide, and xenon.
   d. The tungsten light source is superior to other sources.

2. Choose the incorrect statement.
   a. The diagnostic hysteroscope is 4 to 5 mm in diameter.
   b. The operative hysteroscope is 15 mm in diameter.
   c. The operating electrodes include a ball, barrel, and cutting loop.
   d. Most resectoscopes are equipped with a 30-degree telescope.

3. Which of the following are available as accessory instruments for hysteroscopy?
   a. Grasping forceps
   b. Scissors
   c. Biopsy forceps
   d. Monopolar electrode
   e. All of the above

4. Which of the following is the distending medium of choice for office hysteroscopy?
   a. Carbon dioxide
   b. Hyskon
   c. Normal saline
   d. Glycine 1.5%

5. Which of the following should not be used with monopolar cautery?
   a. Carbon dioxide
   b. Hyskon
   c. Normal saline
   d. Glycine 1.5%
Questions

7. Because of its hypoosmolarity, while using which of the following should caution be taken when a fluid deficit of greater than or equal to 500 mL occurs?
   a. Carbon dioxide
   b. Hyskon
   c. Normal saline
   d. Glycine 1.5%

8. Choose the incorrect statement.
   a. Hysteroscopy should be performed during the luteal phase for best visualization of the endometrial cavity.
   b. Routine cervical dilatation should be avoided at the time of hysteroscopy.
   c. Uterine position should be determined by pelvic examination before beginning hysteroscopy.
   d. The hysteroscope should be advanced into the uterine cavity under direct visualization.

9. Simultaneous laparoscopy should be performed with all of the following hysteroscopic procedures EXCEPT:
   a. Metroplasty
   b. Resection of uterine synchiae
   c. Cannulation of the fallopian tube
   d. Endometrial ablation

10. Which is the most common complication of operative hysteroscopy?
    a. Infection
    b. Uterine perforation
    c. Carbon dioxide embolism
    d. Bleeding

CHAPTER 19

1. All of the following conditions increase the risk of intraoperative hemorrhage EXCEPT:
   a. Obesity
   b. Hepatitis B
   c. von Willebrand disease
   d. Pelvic malignancy

2. Which of the following is not recommended when trying to control significant bleeding in the area of the uterine artery at the time of hysteroscopy?
   a. Use large figure-of-eight sutures so the suture will not cut through the tissue.
   b. Obtain good exposure with retraction, suction, and good lighting.
   c. Control the bleeding with pressure until adequate preparations have been made to identify and control the bleeding.
   d. Do a cystoscopy or open the bladder after controlling the bleeding to be sure the ureter has not been compromised.

3. Which of the following agents or techniques are not used to control pelvic bleeding?
   a. Microfibrillar collagen
   b. Fibrin glue
   c. Thumbtacks
   d. Lamellar platelets

4. The risk of which infection is greatest with blood transfusion?
   a. Hepatitis B
   b. Hepatitis C
   c. Human immunodeficiency virus (HIV)
   d. Human T-lymphotropic virus (HTLV)

5. Hyogastric artery ligation helps control pelvic bleeding by:
   a. Ligating the feeder vessels of the pelvic blood supply
   b. Reducing the pulse pressure
   c. Increasing pelvic thrombokinase
   d. Infarction of the uterus

6. The risk of fetal growth restriction is doubled in a pregnancy that occurs after bilateral hyogastric artery ligation.
   a. True
   b. False

7. In a 150-lb. woman (68 kg), a 15% blood loss would be approximately 680 cc.
   a. True
   b. False

8. When using hyogastric artery ligation to control pelvic hemorrhage, all of the following are true EXCEPT:
   a. The right-angle clamp should be passed from lateral to medial under the artery.
   b. The hyogastric artery should be tied but not cut.
   c. Only the posterior division of the hyogastric artery should be ligated.
   d. The hyogastric arteries should be ligated bilaterally.

9. The risk of HIV infection due to blood transfusion in the United States is currently about:
   a. 1 in 2000
   b. 1 in 20,000
   c. 1 in 200,000
   d. 1 in 2 million

10. Venous bleeding is usually more easily controlled than arterial bleeding.
    a. True
    b. False

CHAPTER 20

1. What is the best therapy for a couple reporting infertility whose only finding is painless endometriosis in the female partner?

2. In a couple found to require in vitro fertilization (IVF) because of a male factor, it is found that the female partner age 35 has six intramural fibroids, the largest of which is 4 cm in diameter. Is pre-IVF treatment needed for these fibroids?

3. In a couple reporting infertility, it is found that the male partner has a sperm count of 1.5 million with 4% normal forms by the strict morphology classification. The female partner age 31 is found to have bilateral asymptomatic hydrosalpinges 2 cm in diameter. What therapy is required?

4. A female age 27 without children is found to have Hodgkin disease requiring intensive chemotherapy. What advice can a gynecologist offer her about options for preserving future reproduction?

CHAPTER 21

1. What is the most commonly isolated organisms in patients with pelvic inflammatory disease (PID)?
   a. Escherichia coli
   b. Chlamydia trachomatis
   c. Neisseria gonorrhoeae
   d. Mycoplasma hominis
2. Which of the following is NOT a contraindication to hysterosalpingography (HSG)?
   a. Possible pregnancy
   b. Undiagnosed uterine bleeding
c. Lower genital tract infection
d. Known tubal obstruction

3. Which of the following conditions can be managed by tubal cannulation?
   a. Tubal plugs
   b. Obliterative fibrosis
c. Mild synchie
   d. Cornual spasm

4. Patients with tubal factor infertility may achieve pregnancy through reconstructive surgery and/or IVF. Which is NOT an advantage of reconstructive surgery?
   a. To use cautery during dissection to facilitate hemostasis
   b. To prevent foreign body contamination of the peritoneal cavity
c. To minimize adjacent tissue damage
d. Reduced risk of ectopic pregnancy

5. What is NOT a principle of microsurgical technique that minimizes tissue trauma?
   a. To use cautery during dissection to facilitate hemostasis
   b. To prevent foreign body contamination of the peritoneal cavity
   c. To minimize adjacent tissue damage
   d. To identify proper cleavage planes

6. Salpingostomy for cases of mild and moderate distal tubal disease is associated with excellent intrauterine pregnancy rates. What factor is considered in classifying tubal disease as mild, moderate, or severe?
   a. Proximal tubal thickness
   b. Endosalpingiosis of ampulla
c. Presence of peritubal adhesions
   d. Nature of the tubal endometrium

7. What is a predictor of intrauterine pregnancy after tubal reanastomosis for reversal of sterilization?
   a. Duration of infertility
   b. Length of reconstructed tube
c. Parity of woman
d. History of PID

CHAPTER 22

1. Which of the following have been proposed as possible mechanisms for development of endometriosis?
   a. Retrograde menstruation and direct implantation
   b. Coelomic metaplasia
   c. Vascular dissemination
d. Alterations in cellular immunity
e. All of the above

2. Choose the incorrect statement.
   a. Laparoscopy provides inferior visualization of the posterior cul-de-sac compared with laparotomy.
b. Conservative resection of endometriosis by laparotomy is most valuable in cases of extensive pelvic adhesions or endometriomas larger than 3 cm.
c. Preoperative sigmoidoscopy and intravenous pyelography (IVP) are recommended in patients with symptoms suggestive of deeply invasive endometriosis.
d. Surgery is successful in relieving pain symptoms in a high percentage of women and offers a better prognosis for pregnancy in cases of advanced disease.

3. Choose the correct statement.
   a. The classic triad associated with endometriosis includes infertility, dyspareunia, and dysmenorrhea.
b. Pain typically does not correlate to steroid hormone fluctuations.
c. Pain associated with endometriosis is only weakly associated to the depth of infiltration of the peritoneal surfaces.
d. Surgical castration does not decrease pain in most patients.

4. Choose the correct statement.
   a. The rate of recurrence of pelvic pain and dysmenorrhea is equivalent for patients whose endometriomas are managed by cytectomy as compared with those undergoing fenestration and coagulation.
b. Uterine suspension is efficacious as an adjunct in the treatment of endometriosis-associated pelvic pain.
c. Presacral neurectomy, or division of the superior hypogastric plexus, is useful as an adjunctive procedure to reduce midline pelvic pain and dysmenorrhea in women with endometriosis.
d. There is no difference in pain persistence or recurrence following laparoscopic resection or unipolar cauterization of endometriotic implants less than 1 cm in depth.

5. Which is NOT a principle of microsurgical technique that minimizes tissue trauma?
   a. To use cautery during dissection to facilitate hemostasis
   b. To prevent foreign body contamination of the peritoneal cavity
   c. To minimize adjacent tissue damage
   d. Reduced risk of ectopic pregnancy

6. What is NOT a principle of microsurgical technique that minimizes tissue trauma?
   a. To use cautery during dissection to facilitate hemostasis
   b. To prevent foreign body contamination of the peritoneal cavity
   c. To minimize adjacent tissue damage
   d. Reduced risk of ectopic pregnancy

7. What is a predictor of intrauterine pregnancy after tubal reanastomosis for reversal of sterilization?
   a. Duration of infertility
   b. Length of reconstructed tube
c. Parity of woman
d. History of PID

CHAPTER 23

1. Match the diagnosis in Column A with the clinical finding in Column B.
   A B
   1. Granuloma inguinale a. Bubos
   2. Chancroid b. Chlamydia trachomatis
c. Donovan bodies
d. Pox virus

2. Choose the incorrect statement.
   a. Ultrapotent corticosteroid ointment (Clobetasol 0.05%)
b. Topical testosterone cream (2%)
c. Partial vulvectomy
d. Total simple vulvectomy

3. A 58-year-old woman presents with the symptom of burning vulvar pain. Her exam shows an erythematous area involving the left posterior vulva, and biopsy confirms the diagnosis of Paget disease. You would recommend what therapy initially?
   a. Ultrapotent corticosteroid ointment (Clobetasol 0.05%)
b. Topical testosterone cream (2%)
c. Partial vulvectomy
d. Total simple vulvectomy

4. A 35-year-old woman has a small 1.5-cm red area on the right anterior vulva. A 4-mm Key’s punch biopsy is read as
vulvar intraepithelial neoplasia (VIN). Which of the following treatments is not appropriate?

a. CO2 laser vaporization
b. Calvertson Ultrasonic surgical aspirator (CUSA)
c. Simple vulvectomy
d. Wide local excision

CHAPTER 24

1. The hymen:
   a. Is usually imperforate during embryonic life
   b. Becomes patent when canalization of the most caudal portion of the vaginal plate at the urogenital sinus occurs
   c. Most frequently has a folded shape with an eccentric orifice in the newborn
   d. Is found to be imperforate in 1% of newborns

2. Choose the incorrect answer:
   a. Ambiguous external genitalia are remarkably constant in appearance regardless of etiology.
   b. Most patients have a high [suprasphincteric] urethral vaginal connection.
   c. Reconstruction must be timed properly to allow easy identification of all structures while preventing psycho-logic stress to the patient.
   d. Most hermaphrodites reared as girls do have a vagina or vaginal pouch.

3. Choose the incorrect answer:
   a. In the group of patients undergoing reconstruction of the external genitalia, 87% required further vaginal reconstructive surgery to allow intercourse.
   b. The most common long-term problem following reconstruction procedures is intravaginal stenosis.
   c. Vaginoplasty should be performed in infancy to prevent vaginal stenosis.
   d. In patients who underwent clitoridectomy, 29% reported no orgasms.

4. Classic bladder exstrophy is characterized by all of the following EXCEPT:
   a. Male-to-female ratio of 2:1
   b. Absence of anterior abdominal wall
   c. Absence of the posterior wall of the bladder exposing the ureteral orifices
   d. Wide separation of the pubic symphysis

5. Other possible anomalies associated with bladder exstrophy include:
   a. Bifid clitoris
   b. Rectal prolapse
   c. Imperforate anus
   d. Renal agenesis
   e. All of the above

6. Choose the incorrect statement about vaginal carcinoma.
   a. The average age at presentation is 35 years.
   b. Vaginal carcinoma must meet specific International Federation of Obstetrics and Gynecology (FIGO) criteria to be considered a primary vaginal carcinoma.
   c. Vaginal carcinoma composes less than 2% of gynecologic malignancies.
   d. Clinicians must find the urethra, cervix, and vulva to be histologically negative to diagnose primary vaginal carcinoma.

7. Choose the incorrect statement about diethylstilbestrol (DES).
   a. DES is a nonsteroidal estrogenic hormone that was used in patients with a history of recurrent pregnancy loss until 1970.
   b. The incidence of vaginal adenocarcinoma in young women exposed to DES in utero is 0.14 to 1.4 per 1,000.
   c. Seventy-five percent of women exposed to DES in utero have anatomic abnormalities.
   d. Vaginal adenosis has been found in 34% to 90% of women exposed to DES in utero.

8. Choose the incorrect answer pertaining to vaginal carcinoma.
   a. Stage 0 disease can be treated with surgery, carbon dioxide laser, or 5-fluorouracil cream.
   b. Stage 1 disease lesions can be treated with radiation therapy or total abdominal hysterectomy.
   c. Stage 2 or 3 lesions are treated with radiotherapy.
   d. Stage 4 lesions are treated with pelvic exenteration or radiotherapy.

9. Which of the following is not a possible cause of urethral diverticulum?
   a. Neisseria gonorrhoeae infection
   b. Trauma associated with childbirth
   c. Urethral stone
   d. Surgical trauma
   e. Infection of the Bartholin gland

10. Choose the incorrect answer:
    a. Dysuria, frequency, urgency, and hematuria occur in 85% to 90% of patients with urethral diverticula.
    b. Urethral diverticula frequently cause a palpable lump in the vagina.
    c. Most urethral diverticula are located in the proximal urethra.
    d. Urethral diverticula can be diagnosed with cystourethroscopy, positive pressure urethrocystography, or voiding cystourethrography.
4. Evaluation of patients with müllerian agenesis should include all of the following EXCEPT:
   a. Psychologic support
   b. Genetic evaluation
   c. Ultrasonography or magnetic resonance imaging (MRI)
   d. Complete physical examination
   e. Laparoscopy

5. Which of these important issues in successful nonsurgical creation of a neovagina is true?
   a. Nonsurgical creation of a neovagina is not appropriate as a first-line approach.
   b. Greater than 90% of patients have been shown to achieve anatomic and functional success by vaginal dilation.
   c. A “buddy” support system is not helpful in achieving success with vaginal dilation.
   d. Vaginal dilation should be initiated in any age patient, even in prepubertal girls.

6. According to Sir Archibald McIndoe, the important principles in successful surgical creation of a neovagina include all EXCEPT:
   a. Dissection of an adequate space between the rectum and bladder
   b. Inlay split-thickness skin grafting
   c. Continued and prolonged dilation during the contractile phase of healing
   d. Adequate preoperative dilatation

7. Which of the following is true regarding cervical dysgenesis?
   a. Cervical agenesis is the most common müllerian anomaly.
   b. There is only one type of cervical dysgenesis.
   c. Creation of a passage between the uterus and vagina is a simple, highly successful procedure.
   d. Conservative management, with hormonal suppression of endometrial stimulation, is appropriate for young patients.

8. Lateral fusion disorders of the müllerian ducts include all of the following EXCEPT:
   a. Bicornuate uterus
   b. Septate uterus
   c. Didelphic uterus
   d. Rokitansky syndrome

9. The müllerian anomaly associated with the most reproductive success is:
   a. Septate uterus
   b. Bicornuate uterus
   c. Didelphic uterus
   d. Unicornuate uterus

10. Benefits of hysteroscopic resection of a uterine septum include all of the following EXCEPT:
    a. The potential for a vaginal delivery with future pregnancies
    b. A prolonged postoperative recovery period
    c. Similar success as an abdominal metroplasty
    d. That transcervical lysis may also be used to repair a complete septate uterus

---

CHAPTER 26

1. The most likely etiology of perimenarchal abnormal uterine bleeding is:
   a. Endometrial polyp
   b. Anovulatory bleeding

2. Acute control of heavy abnormal uterine bleeding can be accomplished by all of the following except:
   a. Oral contraceptive pills
   b. Intravenous estrogens
   c. Oral progestins
   d. Gonadotropin-releasing hormone (GnRH) analog injection
   e. Dilatation and curette

3. Sonohysterography is best performed:
   a. During menstruation
   b. In the follicular phase
   c. Near ovulation
   d. In the luteal phase
   e. In anovulatory cycles

4. Hemostasis in a bleeding endometrium depends on which of the following?
   a. Thrombus plugs in superficial vessels
   b. Vasoconstriction of spiral arterioles
   c. Endometrial collapse with compression of bleeding vessels
   d. All of the above

5. A 26-year-old female patient reports menometrorrhagia unresponsive to oral contraceptive therapy. The best next step in her evaluation is:
   a. Endometrial biopsy
   b. Dilatation and curette
   c. Sonohysterography
   d. MRI of pelvis
   e. Laparoscopy

---

CHAPTER 27

1. Techniques to reduce the likelihood of complications when the Veress needle is inserted into the abdominal cavity include all of the following EXCEPT:
   a. Directing the insertion of the needle in the midline toward the hollow of the sacrum or uterine fundus
   b. Elevating the abdominal wall before insertion
   c. Inserting the needle with the port closed
   d. Infiltration and aspiration of sterile fluid through the needle after insertion
   e. Elevating the abdominal wall after insertion to demonstrate negative intraperitoneal pressure

2. Which of the following methods of laparoscopic tubal occlusion would be most appropriate for a woman with thickened fallopian tubes or dense pelvic adhesions?
   a. Bipolar coagulation
   b. Spring clip application
   c. Filshie clip application
   d. Silicone rubber band application

3. Which of the following techniques for bipolar coagulation is least helpful in reducing the likelihood of pregnancy after the procedure?
   a. Bipolar coagulation
   b. Spring clip application
   c. Filshie clip application
   d. Silicone rubber band application

4. Which of the following methods of laparoscopic tubal occlusion would be most appropriate for a woman with thickened fallopian tubes or dense pelvic adhesions?
   a. Bipolar coagulation
   b. Spring clip application
   c. Filshie clip application
   d. Silicone rubber band application

5. Which of the following techniques for bipolar coagulation is least helpful in reducing the likelihood of pregnancy after the procedure?
   a. Avoiding coagulation of the proximal 2 cm of tube
   b. Coagulation of at least three contiguous areas
   c. Direct observation of tubal blanching and swelling
   d. Use of an optical flow meter
   e. Use of the cutting waveform
4. Which of the following conditions is less common in a woman who has undergone tubal sterilization than in a woman whose partner has undergone vasectomy?  
   a. Ectopic pregnancy  
   b. Hysterectomy  
   c. Ovarian cancer  
   d. Regret that sterilization was performed

CHAPTER 28

1. Gonadal primordia are of what embryologic developmental layer?  
   a. Ectoderm  
   b. Mesoderm  
   c. Endoderm  
   d. Trophoblast  

2. Which of the following is true regarding testicular determining factor?  
   a. It is an HY cell surface antigen.  
   b. It is located on the X chromosome.  
   c. It is a growth factor.  
   d. The bipotential gonad develops into a testicle through a default pathway because of the absence of testis-determining factor (TDF).

3. Meiosis begins at what gestational age (weeks)?  
   a. 10  
   b. 12  
   c. 16  
   d. 24

4. Which of the following is correct regarding ovarian nerve supply?  
   a. It is parasympathetic only.  
   b. It is sympathetic only.  
   c. It contains both motor and sensory parasympathetic and sympathetic nerves.  
   d. It is autonomic only.  

5. Based on the Rotterdam Consensus for polycystic ovarian syndrome (PCOS), which of the following is true regarding PCOS?  
   a. It is a clinical diagnosis.  
   b. Criteria to establish the diagnosis include oligospermia, clinical evidence for hyperandrogenemia, and polycystic-appearing ovaries on ultrasound.  
   c. It begins in adolescence.  
   d. All of the above

CHAPTER 29

1. When a patient reports pain in response to a gentle touch, this is an example of:  
   a. Hyperalgesia  
   b. Neuropathic pain  
   c. Allodynia  
   d. Myofascial pain

2. The prevailing theory of pain perception today is:  
   a. Cartesian theory  
   b. Neuromatrix theory  
   c. Gate control theory  
   d. Neuroplasticity theory

3. Irritable bowel syndrome, interstitial cystitis, and vulvar vestibulitis may all be examples of:  
   a. Psychosomatic disorders  
   b. Neuropathic pain  
   c. Somatosensory disorders  
   d. Immune deficiency disorders

CHAPTER 30

1. The Centers for Disease Control and Prevention (CDC) recommended treatment for patients hospitalized with pelvic inflammatory disease (PID) include:  
   a. Intravenous metronidazole plus gentamicin  
   b. Intravenous clindamycin plus gentamicin  
   c. Intravenous ceftriaxone plus metronidazole  
   d. Intravenous ceftriaxone plus oral ciprofloxacin

2. A young female patient with pelvic pain without an elevated white count or a fever cannot have PID.  
   a. True  
   b. False

3. The most common bacteria isolated from pus collected from the cul-de-sac in a woman with acute salpingitis is:  
   a. Neisseria gonorrhoeae  
   b. Chlamydia trachomatis  
   c. Trichomonas vaginalis  
   d. A polymicrobial mixture of aerobes and anaerobes

4. The CDC-recommended outpatient treatment regimens for PID include:  
   a. Oral ciprofloxacin plus metronidazole  
   b. Oral clindamycin plus doxycycline  
   c. Intramuscular ceftriaxone plus oral metronidazole  
   d. Oral ofloxacin plus metronidazole

5. Laparoscopic confirmation of PID does not need to be discussed or offered if a patient has had a previous appendectomy.  
   a. True  
   b. False

CHAPTER 31

1. Typical characteristics of uterine leiomyomata include all of the following EXCEPT:  
   a. Typical locations are subserosal, submucosal, and intramural in nature.  
   b. The most common change is hyaline degeneration.  
   c. Red or carcinosarcoma is never seen during pregnancy.  
   d. A subserosal, pedunculated myoma may outgrow its blood supply.

2. Which degenerative changes are the least common?  
   a. Hyaline degeneration  
   b. Red or carcinosarcoma degeneration  
   c. Necrosis  
   d. Sarcomatous degeneration

3. Which of the following is true regarding intravenous leiomyomatosis?  
   a. The condition is quite common and may be found in as many as 50% of patients with leiomyoma.  
   b. The tumor behaves clinically as a benign entity.  
   c. The condition is often involves the only the ovarian veins.  
   d. The most common site of metastases is the brain.

4. In describing the clinical features of leiomyomata, it is important to remember that:  
   a. Most leiomyomata are asymptomatic and may not require any treatment.
b. If the uterine size is believed to be greater than 12 weeks, a hysterectomy is recommended.

c. Most women will have an increase in symptomatology after menopause.

5. Hormonal management options for patients with a myomatous uterus may include all of the following EXCEPT:
   a. Mifepristone (RU486)
   b. Danazol
   c. GnRH analogues
   d. Oral contraceptives (30 to 35 pg ethinyl estradiol)

6. Which of the following is a true statement regarding hysteroscopic resection of submucous myomata?
   a. By combining the procedure with endometrial ablation, pregnancy rates are increased.
   b. Menorrhagia is only rarely controlled.
   c. It is recommended to combine laparoscopic guidance with the hysteroscopic procedure.
   d. Success rates are not dependent on the experience or skill of the surgeon.

7. Appropriate candidates for a laparoscopic myomectomy include which of the following?
   a. A postmenopausal patient with incidentally detected myomata on an annual examination
   b. A 34-year-old woman desiring future fertility with two intramural myomas each measuring 3 cm in diameter
   c. A 34-year-old woman desiring future fertility with two submucosal myomas each measuring 3 cm in diameter
   d. A 40-year-old woman who has completed childbearing with a 20-week-size uterus with multiple myomata

8. Methods to control intraoperative blood loss during an abdominal myomectomy may include all of the following EXCEPT:
   a. Preoperative treatment with oral contraceptive pills
   b. Local injection with vasoconstrictive agents
   c. Controlled induced hypotension
   d. Use of a uterine tourniquet

9. Postoperative morbidity commonly associated with an abdominal myomectomy includes all of the following EXCEPT:
   a. Significant blood loss
   b. Intraperitoneal adhesion formation
   c. Febrile morbidity
   d. Pulmonary embolus

10. Which of the following statements is true regarding uterine artery embolization?
   a. Most patients report an improvement in menorrhagia and bulk-related symptoms.
   b. The overall success rate with an experienced team of providers is only about 25%.
   c. Less than 1% of patients develop postembolization syndrome with fever and malaise.
   d. The major complication rate approaches 50%.

CHAPTER 32A

1. Common indications for abdominal hysterectomy include all of the following EXCEPT:
   a. Endometriosis
   b. Leiomyoma
   c. Prolapse
   d. Malignancy
   e. Abnormal bleeding

   2. The most common technique for hysterectomy in the United States is:
      a. Abdominal hysterectomy
      b. Vaginal hysterectomy
      c. Laparoscopically assisted vaginal hysterectomy
      d. Total laparoscopic hysterectomy

3. Which hysterectomy technique is associated with the fewest complications and most rapid return to full activity?
   a. Abdominal hysterectomy
   b. Vaginal hysterectomy
   c. Laparoscopically assisted vaginal hysterectomy
   d. Total laparoscopic hysterectomy

4. Compared with total abdominal hysterectomy, the documented advantages of supracervical (subtotal) hysterectomy include (check all that apply):
   a. Better postoperative sexual function
   b. A lower incidence of vaginal prolapse
   c. Shorter operative time
   d. Decreased risk of postoperative stress urinary incontinence

5. Bilateral oophorectomy at the time of hysterectomy reduces the risk of breast cancer.
   a. True
   b. False

6. To minimize bleeding, the bladder is dissected off the anterior cervix after the uterine vessels are clamped and ligated.
   a. True
   b. False

7. Ureteral injury is most commonly associated with all of the following EXCEPT:
   a. Previous tubal ligation
   b. Cervical fibroid
   c. Ovarian endometrioma
   d. Bleeding from the uterine artery pedicle

8. The risk of pelvic infections following abdominal hysterectomy has been shown to be reduced by which of these procedures? (Check all that apply):
   a. Vaginal douche with Betadine the night before surgery
   b. Shaving the pubic hair in the operating room before prepping the patient
   c. Prophylactic intravenous antibiotics within 1 hour before surgery
   d. Mechanical bowel prep the night before surgery
   e. Leaving the vaginal cuff open for drainage

9. In a subtotal abdominal hysterectomy, the uterine fundus is amputated after the uterine vessels have been ligated.
   a. True
   b. False

10. The mortality rate for abdominal hysterectomy in the United States is approximately:
   a. 1/100 hysterectomies
   b. 1/10,000 hysterectomies
   c. 1/100,000 hysterectomies
   d. 1/1,000,000 hysterectomies

CHAPTER 32B

1. Patients experience lower morbidity, less pain, more rapid recovery, more rapid return to normal activities, and consumption of fewer health care dollars and resources with what hysterectomy method?
   a. Laparoscopic assisted vaginal hysterectomy (LAVH)
   b. Abdominal hysterectomy
c. Total laparoscopic hysterectomy (TLH)
d. Laparoscopic supracervical hysterectomy (LSH)
e. Vaginal hysterectomy

2. The most limiting factor in selecting the vaginal approach to hysterectomy is:
   a. Uterine size >280 g
   b. Nulliparity
   c. Iliac artery diameter (8 cm)
d. Comfort and preference with abdominal hysterectomy
   e. Previous C-section

3. Skilled vaginal surgeons have reported successful vaginal oophorectomy associated with hysterectomy what percent of the time?
   a. Less than 10%
   b. 15%–25%
   c. 50%–65%
   d. More than 90%

4. Adopting the National Guideline Clearinghouse guidelines for determining the route of hysterectomy for benign indications has increased the use of vaginal hysterectomy to what level?
   a. 10%
   b. 20%
   c. 50%
   d. 90%

5. All of the following techniques are recommended for decreasing the risk of ureteral injury during vaginal hysterectomy EXCEPT:
   a. Dividing the uterine vessels
   b. Dividing the cardinal ligament
   c. Retracting the bladder anteriorly
   d. Downward traction on the cervix

CHAPTER 32C

1. Prospective, randomized studies have shown that laparoscopic hysterectomies have which of the following significant advantages over total abdominal hysterectomy?
   a. Fewer transfusions
   b. Shorter operative time
   c. Fewer complications
   d. Shorter hospital stay

2. The difference between a laparoscopically assisted vaginal hysterectomy (LAVH) and a vaginally assisted laparoscopic hysterectomy (VALH) is:
   a. The VALH is started vaginally.
   b. The uterine vessels are secured laparoscopically in a VALH.
   c. The uterus is removed vaginally with a VALH.
   d. The tubes and ovaries cannot be removed with a VALH.

3. Studies have shown which of the following advantages for laparoscopic subtotal hysterectomy (compared with LAVH)?
   a. Shorter operative time
   b. Less postoperative urinary incontinence
   c. Better sexual satisfaction postoperatively
   d. Less vaginal prolapse postoperatively
   e. All of the above

4. Maintenance of the pneumoperitoneum after colpotomy during a total laparoscopic hysterectomy (TLH) can be accomplished by all of the following techniques EXCEPT:
   a. A McCartney tube®
   b. KOH colpotomizer system®
   c. The Vagiballoon®
   d. Moistened laparotomy sponges

5. A large cervical fibroid might be a good indication for a vaginally assisted laparoscopic hysterectomy (VALH).
   a. True
   b. False
3. Which of the following complications are not increased with elective peripartum hysterectomy?
   a. Transfusion rate
   b. Bladder injuries
   c. Operation time
   d. Rate of infection

4. At the time of cesarean delivery for placenta accreta, the placenta is not removed.
   a. True
   b. False

5. At the time of a forceps delivery, an episiotomy reduces the risk of:
   a. Rectal sphincter tear
   b. Rectal mucosal injury
   c. Fetal brain injury
   d. Hemorrhage
   e. None of the above

6. Compared with a midline episiotomy, a mediolateral episiotomy is associated with all of the following EXCEPT:
   a. An increased risk of rectal sphincter tear
   b. More blood loss
   c. A higher level of postpartum pain
   d. A decreased risk of a fourth-degree laceration
   e. A more difficult repair

7. Current thinking suggests that dehiscence of an episiotomy should be repaired within 2 weeks of occurrence.
   a. True
   b. False

CHAPTER 35B

1. The most common ovarian neoplasm in pregnancy is:
   a. Papillary serous adenocarcinoma
   b. Embryonal carcinoma
   c. Dysgerminoma
   d. Benign cystic teratoma

2. The best management of a luteoma of pregnancy found at cesarean delivery is:
   a. Unilateral oophorectomy
   b. Biopsy only, no further surgery
   c. Unilateral oophorectomy, washings, staging biopsies
   d. Bilateral salpingo-oophorectomy, biopsies, hysterectomy, washings, staging biopsies

3. All of the following ovarian tumors can cause virilization in pregnancy EXCEPT:
   a. Hyperreactio luteinalis
   b. Sertoli-Leydig cell tumors
   c. Dysgerminoma
   d. Benign cystic teratoma

4. A 26-year-old patient at 19 weeks of gestation has a pelvic ultrasound showing a 6-cm left adnexal complex mass with a pulsatility index of 1.4. There are no other abnormalities. The best management plan is:
   a. Repeat the ultrasound in 4 weeks.
   b. Schedule the patient for an ultrasound-guided cyst aspiration.
   c. Schedule the patient for a diagnostic laparoscopy.
   d. Schedule the patient for laparotomy with left oophorectomy and frozen section.

5. Evaluation of an adnexal mass during pregnancy should be evaluated by which of the following tests or exams?
   a. Serum CA-125
   b. Pelvic ultrasound
   c. Abdominal and pelvic computed tomography (CT) scan
   d. Positron emission tomography (PET scan)

CHAPTER 36A

1. The pelvic diaphragm is composed of all of the following muscles EXCEPT:
   a. Iliococcygeus
   b. Puborectalis
   c. Transversus perinei
   d. Pubococcygeus

2. The primary goal of defect-specific pelvic reconstructive surgery is to identify and reattach damaged endopelvic connective tissue to what central pelvic structure?
   a. Arcus tendineus fascia pelvis
   b. Sacropinous ligament
   c. Levator plate
   d. Pericervical ring

3. Of the following factors, which is considered to be most important in the development of pelvic organ prolapse?
   a. Low estrogen levels
   b. Vaginal delivery
   c. Straining with defecation
   d. Coughing as a result of chronic lung disease

4. In both the Pelvic Organ Prolapse Quantification and Baden-Walker Halfway systems, what fixed anatomic reference point is used for measurements and grading?
   a. Ischial spine
   b. Vaginal introitus
   c. Cervix or apical vaginal vault
   d. Hymenal ring

5. Pelvic organ prolapse primarily affects:
   a. Longevity
   b. Quality of life
   c. The degree of pain a patient experiences

CHAPTER 36B

1. Anterior vaginal compartment defects include:
   a. Cystocele
   b. Paravaginal defects
   c. Urethrocele
   d. All of the above

2. Paravaginal defects create an abnormal connection between the:
   a. Vesicocervical and vesicovaginal spaces
   b. Vesicovaginal and paravesical spaces
   c. Vesicocervical and pararectal spaces
   d. Vesicocervical and presacral spaces

3. Cystoceles are caused most frequently by:
   a. A general weakening of the pubocervical joint
   b. A transverse anal defect between the pericervical ring and the pubocervical septum
   c. Pressure from uterine prolapse
   d. Failure to perform Kegel exercises

CHAPTER 36C

1. Generally, where is the easiest place to identify the arcus tendineus fascia pelvis?
   a. The ischial spine
   b. Medial to the obturator foramen
   c. A bump on the pubic area
   d. At the lateral edge of the buttock

2. Which of the following is not a common complication of peripartum hysterectomy?
   a. Transfusion rate
   b. Bladder injuries
   c. Operation time
   d. Rate of infection

3. At the time of cesarean delivery for placenta accreta, the placenta is not removed.
   a. True
   b. False

4. At the time of a forceps delivery, an episiotomy reduces the risk of:
   a. Rectal sphincter tear
   b. Rectal mucosal injury
   c. Fetal brain injury
   d. Hemorrhage
   e. None of the above

5. Current thinking suggests that dehiscence of an episiotomy should be repaired within 2 weeks of occurrence.
   a. True
   b. False

6. Compared with a midline episiotomy, a mediolateral episiotomy is associated with all of the following EXCEPT:
   a. An increased risk of rectal sphincter tear
   b. More blood loss
   c. A higher level of postpartum pain
   d. A decreased risk of a fourth-degree laceration
   e. A more difficult repair

7. Evaluation of an adnexal mass during pregnancy should be evaluated by which of the following tests or exams?
   a. Serum CA-125
   b. Pelvic ultrasound
   c. Abdominal and pelvic computed tomography (CT) scan
   d. Positron emission tomography (PET scan)
1. At the attachment to the pubocervical fascias near the pelvic sidewall
2. The bladder should not be dissected off the anterior vaginal wall during an open paravaginal defects repair because:
   a. The bladder will lose support.
   b. Troublesome bleeding may result.
   c. The bladder will be denervated.
   d. A midline defect in the anterior pelvic support will be created.
3. On examination, loss of the anterior, lateral vaginal sulcus is a sign of a paravaginal support defect.
   a. True
   b. False
4. In a vaginal repair of a paravaginal defect, sutures are:
   a. Placed individually starting near the ischial spine
   b. Absorbable to reduce the risk of infection
   c. Tied individually starting with the suture nearest the vaginal apex
   d. Placed through the sacrospinous ligament for support
5. Which of the following structures contributes to the “white line”?
   a. Fascia of the iliopsoas muscle
   b. Fascia of the puborectalis muscle
   c. Fascia of the transversus perineal muscle
   d. Fascia of the obturator internus muscle

CHAPTER 36D

1. After performing a hysterectomy, to what ligament(s) should the vaginal apex be attached to minimize the risk of vaginal vault prolapse?
   a. Round ligament
   b. Cardinal and uterosacral ligaments
   c. Uteroovarian ligament
   d. Sacrospinous ligament
2. Which one of the following structures is at risk of injury during a McCall culdoplasty?
   a. Sciatic nerve
   b. Rectum
   c. Internal iliac vein
   d. Pudendal nerve
3. Which of the following structure(s) lie posterior to the ischia spine?
   a. Pudendal nerve/vessels
   b. Sciatic nerve
   c. Hypogastric venous plexus
   d. Inferior gluteal vessels
4. One of the late complications following sacrospinous ligament fixation is:
   a. Uterine prolapse
   b. Dyspareunia
   c. Anterior vaginal wall prolapse
   d. Medial thigh pain
5. All of the following procedures are performed as part of an abdominal sacral colpopexy EXCEPT:
   a. Dissecting the peritoneum off the vagina
   b. Attaching the mesh or graft to the vagina with nonabsorbable sutures
   c. Suturing the mesh to the longitudinal ligament over the sacral promontory
   d. Suturing the round ligaments to the anterior graft with nonabsorbable sutures

CHAPTER 36E

1. Pessaries are effective in the treatment of pelvic organ prolapse and should be considered for most patients.
   a. True
   b. False
2. Which of the following patient characteristics is associated with failure of successful pessary use?
   a. Degree of pelvic organ prolapse
   b. Vaginal mucosal atrophy
   c. Wide vaginal introitus
   d. Size of the genital hiatus
3. Which of the following pessaries is compatible with normal vaginal intercourse?
   a. Gellhorn
   b. Donut
   c. Cube
   d. Ring
4. All of the following are potential complications of pessary use EXCEPT:
   a. Increased difficulty with bowel movement
   b. Vaginal erosion
   c. Vaginal cancer
   d. Incarceration of the cervix

5. What is the most common reason a woman stops using her pessary?
   a. It keeps falling out.
   b. It does not improve her symptoms
   c. It hurts.
   d. It is difficult to remove.

---

CHAPTER 37

1. The dominant structure altering cause of stress urinary incontinence is thought to be:
   a. straining at stool
   b. obesity
   c. smoking
   d. *childbearing
   e. chronic cough

2. The most common pathophysiologic cause of stress incontinence is:
   a. hypermobile bladder neck
   b. intrinsic (urethral) sphincter deficiency
   c. combined hypermobile bladder neck and low urethral closure pressure
   d. *combined bladder neck hypermobility and intrinsic sphincter deficiency
   e. combined intrinsic sphincter deficiency and low leak point pressure

3. The basic evaluation for urinary incontinence requires all but one of the following:
   a. history
   b. urinalysis
   c. urolog summary (voiding diary)
   d. residual urine determination
   e. *cystometrogram

4. The following must be completed prior to initial management of stress urinary incontinence:
   a. cystometry
   b. urine culture
   c. *basic evaluation
   d. urodynamics
   e. Q-tip test

5. What is the least effective therapy for initial conservative management of pure stress urinary incontinence?
   a. pelvic floor muscle exercises
   b. bladder drills
   c. pessary
   d. *antimuscarinic medication
   e. biofeedback

6. What test is used to rule out detrusor overactivity incontinence?
   a. pressure voiding study
   b. uroflowmetry
   c. *cystometrogram
   d. leak point pressure
   e. urethral closure pressure profile

7. Which of the following procedures is the best recommendation for a primary approach for stress urinary incontinence?
   a. paravaginal defect repair
   b. perirethral collagen injection
   c. Kelly plication with anterior repair
   d. Pereyra procedure
   e. *suburethral sling

8. What is the main difference between a tension-free tape and a suburethral sling as performed today?
   a. indication for surgery
   b. cure rate
   c. *placement at midurethra
   d. placement without tension
   e. use of cystoscopy during placement

9. The 'gold standard' surgery for surgical correction of stress urinary incontinence is:
   a. sling procedure
   b. tension-free tape
   c. *retropubic urethropexy
   d. anterior colporrhaphy
   e. needle urethropexy

---

CHAPTER 38

1. The most common site of ureteral injury during pelvic surgery is:
   a. As the ureter transverses the tunnel of Wertheim
   b. Dorsal to the infundibulopelvic ligament near or at the pelvic brim
   c. At the cardinal ligament when the ureter passes under the uterine artery
   d. In the intramural portion of the ureter
   e. *mobile bladder neck

2. The most important means to prevent ureteral injury is:
   a. Surgical knowledge of the location and anatomy the ureter
   b. Preoperative intravenous pyelogram
   c. Administration of intravenous indigo carmine during surgery
   d. Prophylactic ureteral stint placement

3. Following partial ureteral ligation, the preferred method of inserting a ureteral stint is:
   a. Ureterostomy
   b. Cystostomy
   c. Cystocele
   d. None of the above; no ureteral stint is indicated

4. The most common gynecologic surgical procedure during which the ureter is injured is:
   a. Total vaginal hysterectomy
   b. Bladder neck suspension
   c. Total abdominal hysterectomy
   d. Total laparoscopic hysterectomy
   e. None of the above; no ureteral injury is indicated

5. Uncomplicated total transection of the distal third of the ureter should be managed with:
   a. Primary repair over a ureteral stint
   b. Ureteroureterostomy
   c. Cystocele
   d. Needle urethropexy
   e. *ureteroureteral transposition over ureteral stint
CHAPTER 39

1. Factors that may contribute to the formation of vesicovaginal fistula include all of the following except:
   a. Obstructed labor
   b. Pelvic radiation
   c. Tribal “gishiri” cuts to the vagina
   d. HIV infection
   e. Hysterectomy

2. Which of the following techniques of hysterectomy is most likely to result in vesicovaginal fistula?
   a. Laparoscopic
   b. Vaginal
   c. Abdominal
   d. Supracervical

3. Prolonged indwelling Foley catheter can predispose a patient to urethrovaginal fistula.
   a. True
   b. False

4. Vesicovaginal fistula as a complication of hysterectomy is most likely to be located:
   a. In the trigone near the ureteral orifices
   b. Superior to the interureteric ridge in the posterior bladder
   c. In the bladder dome
   d. At the bladder base proximal to the urethra

5. You are evaluating a patient in your office who had a TAH secondary to large uterine fibroids performed 4 years ago by one of your former partners who has since retired. She has occasional episodes of severe dysuria followed by hematuria that resolve after a few days without treatment. You review her operative note from her TAH, which notes that she sustained an intraoperative cystotomy that was repaired by mobilization of the tissue and tension-free multilayer closure with 3-0 silk suture. Her current symptoms are most likely secondary to:
   a. Recurrent urinary tract infections
   b. Poorly healed cystotomy with chronic intermittent wound separation
   c. Stone formation
   d. An occult vesicovaginal fistula

6. You are seeing a patient in the office 3 weeks after a laparoscopically assisted vaginal hysterectomy for small uterine fibroids and irregular bleeding. She reports an intermittent, watery discharge for the past 2 weeks. Exam of the vaginal apex shows no fistula, but a small amount of clear fluid is present. You fill the bladder with a dilute indigo carmine/saline solution and note no leakage on visualization of the vaginal apex with a speculum. Your next diagnostic test would be:
   a. Cystourethroscopy
   b. Intravenous urogram
   c. Insert a tampon in the vagina and have the patient walk around for 15 minutes
   d. Test the fluid for creatinine

CHAPTER 40

1. Vaginal birth may contribute to development of anal incontinence through damage to:
   a. The puborectalis muscle sling
   b. Pelvic eversion
   c. The anal sphincter complex
   d. a and c
   e. a, b, and c

2. The use of which of the following obstetrical practices are associated with anal sphincter disruption at the time of vaginal birth?
   a. Midline episiotomy
   b. Perineal massage
   c. Forceps delivery
   d. a and c
   e. a, b, and c

3. Which of the following anatomic structures are important in the woman to maintenance of continence of fecal material?
   a. External anal sphincter
   b. Puborectalis muscle
   c. Internal anal sphincter
   d. a and c
   e. a, b, and c

4. Which of the following testing modalities is the most cost-effective, accurate, and best tolerated by anally incontinent patients being investigated for the presence of a segmental anal sphincter defect?
   a. Pudendal nerve terminal motor latency (PNTML) testing
   b. Magnetic resonance imaging (MRI)
   c. Anal manometry
   d. Endoanal ultrasound
   e. Defecography

5. Patients undergoing sphincteroplasty and perineal reconstruction for anal incontinence should have a reasonable expectation of total continence postoperatively.
   a. True
   b. False

CHAPTER 41

1. Can the BRCA gene be transmitted from the paternal side of the family?

2. If the BRCA gene test is negative, does the patient need additional follow up?

3. If the patient has a normal mammogram in the face of a persistent mass, is it true that she doesn’t need additional follow-up?

4. What prevention options are available to women at high risk?

5. What are the risk benefits of core needle biopsy (CNB) versus fine-needle aspiration (FNA)?

6. What risk-assessment model is most applicable in clinical practice?

7. What are the benefits of breast cancer risk assessment?

8. Stage II breast cancer includes tumors measuring 2 cm.
   a. True
   b. False

9. The majority of women with breast cancer have identifiable risk factors.
   a. True
   b. False

CHAPTER 42

1. Which of the following statements regarding the statistical nature of appendicitis is incorrect?
   a. The mortality rate of appendicitis with appropriate and timely treatment is less than 1%.
   b. Individuals have a 7% lifetime risk of developing appendicitis.
   c. With acute appendicitis, there is a 20% mean incidence
4. A 28-year-old G2P2 presents to the emergency room with right-sided abdominal pain and nausea. On exam, she is tender to palpation at McBurney’s point with voluntary guarding, and her pelvic exam elicits pain on palpation of her right adnexa without note of an obvious mass. Her temperature is 99°F, her pulse is 88, and her blood pressure is 126/74. Labs reveal a WBC count of 9,400. CT scan suggests an appendiceal abscess. Given the below options, the best treatment plan at this point is:

a. Immediately, take the patient to the operating room for an emergency exploratory laparotomy and appendectomy.

b. Start intravenous fluids and a first-generation cephalosporin antibiotic, and consent the patient for a laparoscopic appendectomy to be performed in the morning.

c. Start intravenous fluids and broad-spectrum antibiotics with enteric organism coverage, keep the patient NPO, and keep the patient under close observation for progression of her illness.

d. Send the patient home with appendicitis precautions and a 14-day course of Levaquin and metronidazole.

e. A 26-year-old with systemic lupus erythematosus (SLE) who has end-stage renal disease

2. Which of the following definitions regarding diagnostic signs of appendicitis is incorrect?

a. McBurney’s point: located at the junction of the middle and medial thirds of a line drawn from the umbilicus to the anterior superior iliac spine

b. Rovsing sign: pain in the right lower quadrant when pressure is applied to the left lower quadrant

c. Psoas sign: increased pain in the abdomen as the right leg is extended at the hip when the patient is in the left lateral decubitus position

d. Obturator sign: increased pain in the right lower abdomen when passively flexing the hip

e. Because the increasing girth of the gravid uterus, infection of the appendix would be more difficult to detect given the compression it experiences from the surrounding structures

3. A patient undergoing laparoscopy for removal of right-sided tuboovarian abscess

d. A patient undergoing laparoscopy for removal of right-sided tuboovarian abscess

CHAPTER 43

1. An 18-year-old nulliparous woman presents to your clinic for her annual exam. On exam there is a right adnexal mass that is about 5 × 3 cm. Ultrasonographically it is consistent with a dermoid cyst. Although without pain for the past several weeks, she has a history of right lower quadrant pain that has occurred intermittently over several years, and she has had guaiac positive stool in the past but none currently. She is taken to the operating room where she is found to have a dermoid, as expected, but is also found to have a diverticulum 9 cm in length arising from the antimesenteric border of the ileum 13 inches from the ileocecal valve. There is a slight thickening of the tip of the diverticulum, but the tissue otherwise appears totally healthy. Which of the following statements about the management of this case of Meckel’s diverticulum is true?

a. The patient’s symptoms have now resolved and the dermoid has been removed, so there is no need to remove the diverticulum, which likely will remain asymptomatic the patient’s entire life.

b. The diverticulum should be removed because the patient has a history of symptoms that it may have caused, and it has slightly atypical features.

c. The diverticulum should be removed because any time a Meckel’s diverticulum is discovered incidentally, it should be removed to prevent future complications.

d. The diverticulum should not be removed at this time, but if the patient has recurrent symptoms, she should be referred to general surgery for removal.

e. A 16-year-old alcoholic with cirrhosis

2. In which of the following patient(s) would sodium phosphate probably not be a good choice for a bowel prep?

a. A 26-year-old with systemic lupus erythematosus (SLE) who has end-stage renal disease

b. A 54-year-old alcoholic with cirrhosis

c. A 64-year-old with stage IIB ovarian cancer

d. A 48-year-old well services worker

e. A 35-year-old with diabetes with a hemoglobin A1C of 6.7

3. A patient undergoing a laparoscopic tubal ligation. Upon insertion of the laparoscope, intraluminal bowel mucosa is seen, as well as reflux of enteric contents. Which of the following would be the best course of action?

a. Remove the trocar, convert to an open laparotomy, and repair the injury.

b. Leave the trocar in place, convert to an open laparotomy, and repair the injury.

c. Insert another trocar to confirm that bowel injury has occurred, then attempt to repair the injury laparoscopically.

d. Withdraw and repossession trocar so that the injury is visible with the laparoscope, and then decide if laparoscopic repair is feasible.

e. A 37-year-old patient undergoing a laparoscopy for fulguration of endometriosis and is discharged the same day. Which of the following presentations would be most consistent with an electrosurgical injury that was unrecognized during surgery?

a. The patient presents to the ER 3 days postoperatively reporting nausea, vomiting, and fever.

b. The patient becomes hypotensive and tachycardic in the recovery room but responds to fluid boluses.

c. The patient presents to the ER 24 hours postoperatively with abdominal pain and fever.

d. The patient becomes hypotensive and tachycardic on the operating table.

e. A 26-year-old with systemic lupus erythematosus (SLE) who has end-stage renal disease
Questions

c. The patient presents to the ER on postop day one reporting worsening abdominal pain, fever, and constipation.
d. The patient calls the clinic 1 week postoperatively reporting nausea, vomiting, and diarrhea but denies fever.
e. The patient presents to clinic 1 month postoperatively reporting irregular bowel movements since surgery and continued abdominal pain.

5. Which of the following statement(s) regarding early feeding in patients who have undergone a bowel anastomosis are true?

a. The rate of ileus is significantly higher in patients who are fed before passing flatus.
b. The rate of anastomotic complications is significantly decreased by delaying feeding.
c. Return of bowel function generally occurs at the same rate regardless of early or delayed feeding.
d. Early feeding decreases the probable length of hospital stay.
e. None of the above

6. Which of the following are the three most common reasons for bowel obstruction?

a. Adhesions
b. Intestinal polyps
c. Volvulus
d. Hernias
e. Malignancy

7. A 62-year-old patient undergoes a bowel resection. Because there is only 5 cm of rectum conserved, the decision is made to create a sigmoid J-pouch. Which of the following regarding the J-pouch is true?

a. The patient is less likely to suffer from frequency, urgency, and incontinence of stool.
b. The patient is less likely to have a sense of incomplete evacuation after bowel movements.
c. Slight tension on the J-pouch will resolve over time and need not be a source of concern.
d. Enemas should be avoided in patients who have had a J-pouch created.

8. A 34-year-old patient undergoes a TAH-BSO for leiomyomata. During the surgery, the small bowel sustains a thermal injury requiring resection of 4 cm of small bowel. The remaining bowel appears healthy. Which of the following types of anastomosis should probably not be used because of the higher potential for excessive luminal narrowing?

a. End-to-end hand-sewn anastomosis
b. Side-to-side hand-sewn anastomosis
c. (True) end-to-end staple anastomosis
(d. Side-to-side staple anastomosis (functional end-to-end anastomosis)

9. A 38-year-old patient with a history of severe endometriosis who is known to have extensive adhesive disease presents to the ER with abdominal pain. Physical exam and radiologic imaging lead to the diagnosis of small bowel obstruction. During surgery, which of the following characteristics of her injured bowel indicate viability most reliably? (Choose two.)

a. Tissue color
b. Bleeding from a cut edge
c. Extent of edema
d. Peristalsis
e. Fluorescence of bowel wall under Wood's lamp 10 minutes after IV fluorescein

10. Designate whether each of the following statements is true or false.

a. Intraluminal fluid collection in a complete obstruction is unlikely to exceed 2 L.
b. Less than 20% of bowel injuries during gynecologic surgery occur during lysis of adhesions.
c. Absent bowel sounds are usually indicative of ileus.
d. Peristaltic waves causing pain every 12 minutes indicate a relatively high obstruction.
e. Sodium phosphate generally provides better bowel prep for colonoscopy than polyethylene glycol.
f. Stair-step air fluid levels from RLQ to LUQ is most consistent with adynamic ileus.
g. The tissue edges on a bowel anastomosis should be everted.
h. Colonic dysfunction following surgery usually resolves within 6 to 8 hours.

CHAPTER 44

1. How often do patients with documented colorectal cancer have a negative fecal hemoccult test?

a. 10%  
 b. 30%  
 c. 50%  
 d. 80%

2. The most common pelvic retroperitoneal mass related to the urinary tract is a:

a. Lower ureteral carcinoma  
 b. Urinoma  
 c. Pelvic kidney  
 d. Bladder diverticulum

3. Patients on broad-spectrum antibiotics and/or prolonged bowel preparations may have a prolonged prothrombin time.

a. False  
 b. True

4. Nongynecologic conditions most often seen by the gynecologist arise from what system or organ?

a. Gastrointestinal  
 b. Urinary tract  
 c. Lymphatic system  
 d. Orthopedic (muscle, bone)

5. Which is the most common neurogenic tumor that can arise in the pelvis and be mistaken as a gynecologic problem?

a. Neurofibromas  
 b. Asterocytoma  
 c. Glioblastoma  
 d. Schwannoma

6. At laparotomy, the finding of thickened mesentery with growth of mesenteric fat (“fat wrapping”) around the circumference of atheretra fibrotic bowel is pathognomonic of:

a. Crohn disease  
 b. Ulcerative colitis  
 c. Tuberculosis  
 d. Adenocarcinoma of small bowel

7. Of cancers metastatic to the ovary, which is the most common primary site?

a. Colon  
 b. Stomach  
 c. Breast  
 d. Uterus
CHAPTER 45

1. Which of the following is a recognized risk factor for vulvar malignancy?
   a. Diabetes
   b. Cigarette smoking
   c. Obesity
   d. Immunosuppression

2. You may consider omitting lymphadenectomy as part of the operative treatment for squamous cell vulvar carcinoma when:
   a. Lesion 1.5 cm diameter, less than 5 mm invasion
   b. Unilateral lesion, less than 5 mm invasion
   c. Any location, less than 1 mm invasion
   d. Unilateral lesion 1.3 cm diameter, 3 mm invasion

3. Which factor predisposes patients to develop local recurrence with squamous cell vulvar carcinoma?
   a. Midline location
   b. Enlarged inguinal nodes
   c. Close resection with margin less than 1 cm
   d. Poorly differentiated histology

4. The use of preoperative radiation therapy in patients with squamous cell vulvar carcinoma is most appropriate for:
   a. Patients with suspicious groin nodes
   b. Locally advanced disease or lesions encroaching on midline structures for which surgical removal is accompanied by significant morbidity
   c. Poorly differentiated histology type in stage 1 disease
   d. Multifocal lesions in stage 1 disease

5. When a woman has a Bartholin mass, what features would prompt you to consider biopsy or excision?
   a. Age younger than 40
   b. History of previous Bartholin abscess
   c. Failure to improve promptly with conservative therapy
   d. Negative culture
   e. Bilateral masses

6. The recurrence-free survival of patients with invasive squamous cell carcinoma of the vulva correlates most closely with:
   a. Tumor differentiation
   b. Tumor location
   c. Radiation tumor dose
   d. Pathologic status of the inguinal lymph nodes
   e. Age of the patient

7. Which of the following histologic types of vulvar cancer has the most favorable prognosis?
   a. Squamous cell carcinoma arising from a Bartholin gland
   b. Paget disease with an underlying apocrine gland adenocarcinoma
   c. Melanoma 4 mm in thickness
   d. Basal cell carcinoma
   e. Merkel cell carcinoma

8. Which of the following histologic variants of vulvar cancer is most likely to metastasize to the inguinal lymph nodes?
   a. Verrucous carcinoma
   b. Basosquamous carcinoma
   c. Warty carcinoma
   d. Carcinoma in situ with early stromal invasion
   e. Basal cell carcinoma

CHAPTER 46

1. Human papillomavirus (HPV) is the cause of at least 99% of all cervical cancers.
   a. True
   b. False

2. Based on studies of college-aged women in the United States, what percent of young women test positive for a cervical HPV infection during a 3- to 5-year interval?
   a. 10%
   b. 25%
   c. 50%
   d. 80%
   e. 100%

3. Effective screening for cervical cancer has been reported using each of the techniques EXCEPT:
   a. Cervical cytology
   b. Visual inspection with acetic acid
   c. Lugol’s staining
   d. Colposcopy
   e. Computer-assisted cytology

4. A single Pap test, on average, would be able to pick up low-grade squamous intraepithelial lesion (LSIL) or worse in a screened patient what percent of the time?
   a. >95%
   b. 90%
   c. 80%
   d. 70%
   e. 50%

5. Recommended treatment for a 26-year-old woman in her first pregnancy at 24 weeks who has a colposcopically directed biopsy showing severe dysplasia at 1 o’clock is:
   a. Cryotherapy
   b. LEEP as an outpatient
   c. Cone biopsy in the operating room
   d. Cesarean section with cone biopsy at 36 weeks
   e. Follow-up with no treatment during pregnancy

6. How often will women with a biopsy diagnosis of mild cervical dysplasia resolve spontaneously with no treatment if followed for 24 months?
   a. 10%
   b. 25%
   c. 50%
   d. 75%
   e. 90% or more

7. All of the following are terms for abnormal colposcopic findings EXCEPT:
   a. Mosaic
   b. Metaplasia
   c. White epithelium
Questions

8. Which of the following is the main advantage of LEEP over cryotherapy for the treatment of cervical intraepithelial neoplasia (CIN)?
   a. It produces a specimen for histologic study.
   b. It does not require expensive equipment.
   c. It does not require general anesthesia.
   d. It has a lower risk of premature labor in future pregnancies.
   e. It requires less surgical skill and training.

9. HPV testing has been shown to be clinically effective for all of the following EXCEPT:
   a. Triage of ASC-US Paps
   b. Follow-up after LEEP
   c. Core biopsies with Pap for screening in women older than age 30
   d. Identification of which patients with mild dysplasia need treatment

10. Traditional cold-knife cone biopsy under anesthesia is recommended by experts for which of the following two scenarios?
    a. Cervical glandular lesions
    b. Grossly visible cervical lesions
    c. Lesions that extend into the canal
    d. Suspected microinvasive lesions

CHAPTER 47

1. A 3-cm cancer of the cervix with no signs of spread is probably:
   a. Stage IA2
   b. Microinvasive disease
   c. Stage IB
   d. Stage IIB

2. The most important determinant of prognosis of cervical cancer is:
   a. Depth of invasion into the cervix
   b. FIGO stage
   c. Presence of lymph node metastasis
   d. Histologic differentiation

3. The best rationale for choosing radical surgery over radiation treatment for early-stage carcinoma of the cervix is:
   a. Better survival with surgery
   b. Fewer complications
   c. Preservation of ovarian function
   d. Decreased short-term recurrence

4. Which of the following is not permitted for FIGO staging of cervical cancer?
   a. Intravenous pyelogram
   b. CT scans of abdomen and pelvis
   c. Lymphangiogram
   d. PET scan

5. Which of the avascular pelvic spaces lies immediately posterior to the cardinal ligament?
   a. Space of Retzius
   b. Pararectal space
   c. Paravesical space
   d. Rectovaginal space

6. In a classic type III radical hysterectomy, the uterine artery is ligated at which point?
   a. Its origin from the hypogastric artery
   b. Where it crosses over the ureter
   c. 1 cm lateral to the uterus
   d. As it enters the parametrial “web”

7. The most common late sequelae of radical hysterectomy and pelvic lymphadenectomy is:
   a. Vesicovaginal fistula
   b. Numbness of the medial thigh
   c. Leg edema
   d. Bladder dysfunction

8. The most common symptom of early cervical cancer is:
   a. Vaginal bleeding
   b. Pelvic pressure/pain
   c. Hematuria
   d. Unilateral leg edema

9. In a radical vaginal hysterectomy, which step of the procedure is performed “blindly”?
   a. Entry into the posterior cul de sac
   b. Entry into the pararectal space
   c. Entry into the paravesical space
   d. Entry into the vesicouterine space

10. Following a radical vaginal trachelectomy for cervical cancer, what percentage of pregnancies reach the third trimester?
    a. 25%–35%
    b. 45%–55%
    c. 65%–75%
    d. More than 90%

CHAPTER 48

1. All of the following increase the risk of endometrial cancer EXCEPT:
   a. Infertility
   b. Tamoxifen use
   c. Obesity
   d. Cigarette smoking
   e. Increasing age

2. A 65-year-old woman presents to your office with symptoms of vaginal spotting for the last 3 months. The next best step in her management is:
   a. Office endometrial biopsy
   b. D&C
   c. Hysterectomy
   d. Vaginal estrogen

3. A 53-year-old obese woman with diabetes and hypertension is diagnosed with grade 1 endometrioid adenocarcinoma of the endometrium. Her preoperative evaluation should include:
   a. CA-125
   b. CT of abdomen and pelvis
   c. MRI of pelvis
   d. PET scan
   e. None of the above

4. Which of the following statements regarding surgery for endometrial cancer is correct?
   a. Surgical staging for patients with uterine papillary serous carcinoma includes peritoneal washings and biopsies, pelvic and paraaortic lymph node dissection, and omentectomy.
   b. When clamping the cardinal ligaments, it is important to include the lateral cervical tissues to decrease the risk of bleeding.
c. The survival of patients treated with laparoscopic surgery is significantly shorter than that of patients who undergo laparotomy.
d. The fundus should be grasped with a tenaculum for manipulation of the uterus.
e. Debulking surgery does not improve survival in patients with advanced-stage endometrial cancer.

5. A 59-year-old woman presents for postoperative surveillance following surgery for stage IB, grade 1 endometrioid adenocarcinoma of the endometrium. Recurrent disease is most likely to be diagnosed by which of the following:
   a. History and physical examination
   b. Vaginal cytology
   c. Chest x-ray
   d. CT scan of abdomen and pelvis
   e. CA-125

CHAPTER 49

1. A 23-year-old patient is diagnosed with a stage IA malignant ovarian germ-cell tumor. Which of the following would be the standard treatment?
   a. Unilateral oophorectomy
   b. Bilateral oophorectomy and hysterectomy
   c. Bilateral salpingo-oophorectomy without hysterectomy
   d. Transvaginal pelvic ultrasound

2. A 3-year-old patient is diagnosed with stage IB serous ovarian adenocarcinoma of the endometrium. Recurrent disease is most likely to be diagnosed by which of the following:
   a. History and physical examination
   b. Cul-de-sac aspiration cytology
   c. BRCA1 genetic testing
   d. Ovarian biopsy followed by chemotherapy

3. Which of the following factors has not been shown to have prognostic significance in epithelial ovarian cancer?
   a. History of oral contraceptive use
   b. Age of menarche (15)
   c. Native American ethnicity
   d. Nulliparity

4. You are consulted intraoperatively by a colleague who has now has a 3-cm mass at the vaginal apex. Biopsy shows carcinoma of the anterior upper third of the vagina. She occurred.

5. Several large studies have found that early ovarian cancer can be detected successfully using which of the following screening techniques?
   a. Serum CA-125
   b. Cul-de-sac aspiration cytology
   c. BRCA1 genetic testing
   d. Transvaginal pelvic ultrasound

6. Which of the following tumor markers is most often elevated in patients with ovarian granulosa cell tumors?
   a. Serum inhibin
   b. CA-125
   c. AFP
   d. β-hCG

7. Which of the following findings on color flow Doppler are consistent with a benign mass (as opposed to a possible malignant mass)?
   a. Peripheral vascularity
   b. Increased diastolic blood flow
   c. Resistive index of >1
   d. Pulsatility index of 0.2

8. A 56-year-old G3P3 patient presents for her annual exam with no symptoms. She experienced menopause at the age of 51 and has no complaints. She has been on combination hormone replacement therapy. Her mother died of metastatic cancer (unknown primary) at the age of 68. She is found on exam to have a mobile, firm, nontender adnexal mass. Her bimanual and rectal exam have no other abnormal findings. An ultrasound shows a simple, unilocular cyst of the right ovary measuring 4 × 3 × 5 cm. Which of the following would be the best course of action?
   a. Check a CA-125 level, and if normal, repeat the ultrasound in 3 months to determine if any change has occurred.
   b. Assure the patient that everything looks all right and that she should return for her next annual exam in 1 year.
   c. Recommend laparoscopy with laparoscopic RSO if the ovarian cyst looks benign.
   d. Order a CT scan to reevaluate the findings seen on ultrasound.

9. What percentage of ovarian tumors in premenopausal women are malignant?
   a. >10%
   b. >10%–15%
   c. 25%–50%
   d. >75%

10. A 65-year-old G1P1A1 of Native American descent presents reporting bloating and weight loss for 6 months. Her mother is alive and well in her 80s. Her maternal aunt died of breast cancer at the age of 43. Her single pregnancy ended in spontaneous abortion at 10 weeks of gestation, and she was on birth control pills for 8 years over her life. Menarche had been at the age of 15 and menopause at the age of 51 and has no complaints. She has been on combination hormone replacement therapy. Her mother died of breast cancer at the age of 51 and has no complaints. She has been on combination hormone replacement therapy. Her mother died of breast cancer at the age of 43. Her single pregnancy ended in spontaneous abortion at 10 weeks of gestation, and she was on birth control pills for 8 years over her life. Menarche had been at the age of 15 and menopause at the age of 51.

   a. History of oral contraceptive use
   b. Age of menarche (15)
   c. Native American ethnicity
   d. Nulliparity

CHAPTER 50

1. Which of the following is not a candidate for total pelvic exenteration?
   a. A 36-year-old woman treated 1 year ago for stage IIIIB cancer of the cervix with pelvic radiation and chemother-apy who now has a vesicovaginal and a rectovaginal fistula. Biopsies, exam, and imaging studies show no evi-dence of cancer.
   b. A 65-year-old woman treated 20 months ago with pelvic radiation and chemotherapy for stage II squamous cell carcinoma of the anterior upper third of the vagina. She now has a 3-cm mass at the vaginal apex. Biopsy shows
1400 Questions

5. Use of a myocutaneous flap for vaginal reconstruction during a pelvic exenteration has all of the following advantages EXCEPT:
   a. It brings in new blood supply to the pelvis.
   b. It fills in the pelvic defect.
   c. Adequate blood supply
   d. Wound breakdown

2. Which of the following factors is not a relative contraindication to pelvic exenteration?
   a. Obesity
   b. Jehovah's Witness who will not accept blood products
   c. Inability to stress or care for herself because of mental or physical impairment
   d. Age older than 70
   c. Increased risk of recurrence

3. All of the following clinical findings suggest that a patient's tumor will be unresectable EXCEPT:
   a. Unilateral leg edema
   b. Tumor causing a vesicovaginal fistula
   c. Sciatic nerve pain
   d. Unilateral ureteral obstruction

4. During a pelvic exenteration, all of the following pelvic spaces are used EXCEPT:
   a. Pouch of Douglas
   b. Space of Retzius
   c. Paravesical space
   d. Presacral space
   e. Pararectal space

5. Use of a myocutaneous flap for vaginal reconstruction during a pelvic exenteration has all of the following advantages EXCEPT:
   a. It brings in new blood supply to the pelvis.
   b. It fills in the pelvic defect.
   c. Adequate blood supply
   d. Wound breakdown

CHAPTER 51

1. One technique for vaginal reconstruction after vaginectomy includes the omental J-flap with split-thickness skin graft (STSG). Which of the following is not considered a benefit of this technique?
   a. Psychosexual factors/satisfactory intercourse
   b. Prevention of enteroperineal fistula
   c. Abscess collection
   d. Urinary incontinence

2. Incorporating which vessel is crucial to ensuring success of the sigmoid neovagina procedure?
   a. Inferior hemorrhoidal artery
   b. Superior hemorrhoidal artery
   c. Pubendal artery
   d. Dorsal clitoral artery

3. When identifying the structure for the gracilis myocutaneous flap, which muscle can be confused for the gracilis?
   a. Adductor longus
   b. Adductor brevis
   c. Adductor magnus
   d. Sartorius

4. When performing a rectus abdominis myocutaneous (RAM) flap, what is an absolute contraindication to the procedure?
   a. Previous Maylard incision
   b. Diabetes
   c. Obesity
   d. Previous radiotherapy

5. All of the following are considered disadvantages of the traditional vulvectomy except:
   a. Perineal contractions
   b. Distortion of the bladder neck/urethra leading to incontinence
   c. Increased risk of recurrence
   d. Wound breakdown

6. To ensure adequate closure with a Z-plasty pedicle flap, each of the following should be included EXCEPT:
   a. Adequate blood supply
   b. A flap length 2 cm long and a base of 1 cm
   c. Full-thickness skin graft
   d. Rotation of the flap to the midperineal line

7. Physiologic characteristics of a continent urinary pouch are designed to prevent reflux, infection, and incontinence. Which describes the ideal situation for a continent urinary pouch?
   a. 40 cm H2O pressure, 500 mL volume
   b. 80 cm H2O pressure, 500 mL volume
   c. 80 cm H2O pressure, 1,000 mL volume
   d. 40 cm H2O, 1,000 mL volume

8. The Kock pouch is suitable for urinary bladder replacement because it possesses features necessary for maintaining continence. These include all of the following except:
   a. Maintenance of low pressure after filling
   b. Prevention of reflux
   c. Retention of 1,000 to 1,500 mL of fluid
   d. Elimination of intermittent pressure spikes (promoting reflux)

9. Variations of the original Kock procedure have been designed that do not require intussusception of the bowel. One of these is the Miami pouch. In what way is it different from the Kock procedure?
   a. The distal terminal ileum is transected proximal to the ileocecal valve.
   b. Appendectomy is performed.
   c. The ureters are anastomosed directly into the muscular wall of the colon.
   d. Reinforcing the ileocecal valve by tapering the distal segment is essential for maintaining continence.

10. Rectosigmoid colon resection (RSC) can lead to several defecation disorders, including all of the following EXCEPT:
    a. Fecal incontinence
    b. Constipation
    c. Fecal urgency
    d. Tenesmus
ANSWERS

CHAPTER 2

1. b. False  
2. a. True  
3. b. False  
4. a. True  
5. a. True  
6. b. False  
7. a. True  
8. a. True  
9. a. True  
10. a. True  
11. a. True  
12. a. True

CHAPTER 3

1. c. The patient’s surgeon  
2. d. None of the above; age should not be a determinant  
3. g. All of the above  
4. d. A skilled surgeon who addresses his patient’s psychological as well as physical needs  
5. f. All of the above  
6. c. An outdated procedure that should no longer be performed routinely  
7. a. Releases endogenous opiates and c. Has been shown to decrease the requirement for analgesics after surgery

CHAPTER 4

1. d. Nation  
2. b. False  
3. d. 1, 2, 3, and 4  
4. c. Communicate with members of the health care team  
5. d. None of the above  
6. b. False  
7. b. False  
8. c. 3

CHAPTER 5

1. a. Entering and retrieving information c. Communication and coordination of patient care processes  
2. b. 30 consecutive days off per year d. 10% of total work hours dedicated to educational activities  
3. a. The majority of clinical trials demonstrate decreased length of stay. c. There are multiple models and work paradigms.  
4. a. More effective when there is greater incentive b. More effective when the incentive applies to a larger percent of patients in the provider’s practice c. Currently being evaluated by Center for Medicare and Medicaid Services (CMS)  
6. a. Financing b. Establishing new workflows that optimize use of the HER c. Having adequate technical support d. Establishing a culture in the implementation setting that will allow for the necessary change  
7. b. Total duty hours should not exceed 80 hours when averaged over 4 weeks d. At least 10 hours of off time between worked shifts  
8. b. Gives a “B” recommendation when the data are based on limited or inconsistent scientific evidence d. Is commonly used in obstetrics and gynecology for evaluating peer-reviewed literature

CHAPTER 6

1. e. Decreased use of conservative medical management has increased the number of major surgical cases.  
2. c. All of the above  
3. c. Significantly increased ob/gyn knowledge base
CHAPTER 7

1. e. Anus
2. a. The pudendal nerve provides only sensory innervation to the perineum.
3. b. The clitoris never drains directly into the deep pelvic nodes.
4. c. The internal anal sphincter is indistinguishable from the external anal sphincter and it lies just outside the external anal sphincter.
5. e. All of the above
6. a. In a woman of reproductive age, the uterine cervix is larger than the uterine corpus.
7. d. The distal end of the fallopian tube is attached to the ovary by the fimbria ovarica.
8. c. The normal ovary measures 7 cm long during reproductive life.
9. b. The ovarian veins drain into the vena cava on the left and the renal vein on the right.
10. d. The ureter lies approximately 3 cm from the anterolateral surface of the cervix.

CHAPTER 8

1. d. Chemistry panel
2. d. All of the above
3. c. Patients with abnormal Papanicolaou smears showing repeated dysplasia should be evaluated by colposcopy and suspicious lesions biopsied before pelvic surgery.
4. c. Age is a relative contraindication for gynecologic surgery
5. e. Vaginal and abdominal hysterectomy
6. d. a, b, or c
7. b. 1–2 hours before surgery, repeated once if the surgery lasts longer than 3 hours
8. b. A more effective assessment of the posterior bladder wall
9. a. Discontinue the use of birth control pills 2 to 4 weeks before the planned gynecologic surgery
10. a. A full bowel prep should be carried out on all gynecologic surgeries.

CHAPTER 9

1. Low-molecular-weight heparin
2. 8%
3. Advanced age, obesity, intraperitoneal infections, prolonged anesthesia time, nasogastric tube placement, and a history of smoking
4. 1. Hypoventilation
2. V/Q abnormalities
3. Venous admixture
4. Diffusion limitation
5. Low inspired fraction of oxygen

CHAPTER 10

1. d. Chemistry panel
2. d. All of the above
3. c. Patients with abnormal Papanicolaou smears showing repeated dysplasia should be evaluated by colposcopy and suspicious lesions biopsied before pelvic surgery.
4. c. Age is a relative contraindication for gynecologic surgery
5. e. Vaginal and abdominal hysterectomy
6. d. a, b, or c
7. b. 1–2 hours before surgery, repeated once if the surgery lasts longer than 3 hours
8. b. A more effective assessment of the posterior bladder wall
9. a. Discontinue the use of birth control pills 2 to 4 weeks before the planned gynecologic surgery
10. a. A full bowel prep should be carried out on all gynecologic surgeries.

CHAPTER 11

1. b. False
2. d. Open the wound widely to allow drainage and debridement of necrotic tissue, then apply wet-to-dry packing until the wound closes by secondary intention.
3. a. Index finger of the left hand of the surgeon
4. a. Metronidazole
5. c. Heparin and antibiotics for total of 7 to 10 days; no need for long-term anticoagulation therapy.

CHAPTER 12

1. c. Intrapulmonary shunting. Clinically, adult respiratory distress syndrome is characterized by intrapulmonary shunting, widening of alveolar-arterial O₂ gradient, and reduced pulmonary compliance and functional residual capacity. Although supplemental oxygen is used, arterial PaO₂ typically remains less than 65 mm Hg. In patients with significant pulmonary injury, hypoxemia is progressive despite adequate oxygen supplementation, and assisted mechanical ventilation is required.
2. e. Oliguria. For both hypovolemic and septic shock, oliguria is a manifestation of early reversible shock and is also a clinical finding for patients with irreversible shock. Characteristics of late irreversible shock include a reduction in cardiac output, systemic vascular resistance, and cardiac index. Cold, clammy skin is present because of poor peripheral circulation, and disorientation or obtundation from decreased cerebral perfusion is present. In contrast, early reversible septic shock is characterized by an increase in cardiac output that is due to compensatory cardiac dilatation and sympathetic response; tachycardia is also present. Systemic vascular resistance is decreased but may be normal in the absence of hypotension. The skin is usually warm, secondary to an increase in cardiac output and peripheral vasoconstriction and to the febrile response.
3. c. For persistent bleeding consistent with coagulopathy. Platelet transfusion is indicated intraoperatively whenever there is persistent bleeding consistent with coagulopathy. In general, 1 unit of platelets will increase the platelet count by 5000 to 10,000/mL. It is recommended that when
blood loss exceeds 25% of the total intravascular volume and is ongoing, or when there is bleeding consistent with coagulopathy, packed red blood cells are indicated in a 4:1 ratio with fresh frozen plasma. There are isolated reports of satisfactory outcome in asymptomatic patients with solid tumors who did not receive platelet transfusions in the absence of bleeding, unless the counts were below 10,000/μL. Depending on the bleeding risks, currently accepted indications for preoperative and intraoperative platelet transfusions include platelet counts of less than 50,000/μL.

4. c. Inotropic and vasoconstrictive effects. Dopamine stimulates dopamine, β-adrenergic and β-adrenergic receptors. Dopamine is unique in that it stimulates these receptors in a dose-dependent fashion. At low doses (1–3 mg/kg/min), dopamine receptors are mainly affected. This results in preferential cerebral, renal, and mesenteric arterial vasodilatation. The net effect is an increase in urine output and blood flow to the brain and gastrointestinal tract without increasing the heart rate or significantly affecting blood pressure. In moderate doses (5–12 mg/kg/min), both β- and β-adrenergic receptors are affected. The effects are inotropic; that is, the effect is an increase in myocardial contractility, sinoatrial rate, impulse conduction, and cardiac output. With increased myocardial contractility, myocardial oxygen consumption is increased with no compensatory increase in coronary blood flow. In a patient with a history of coronary artery disease, this effect could lead to myocardial ischemia. At high doses (20 mg/kg/min) β-adrenergic effects predominate, resulting in severe generalized vasoconstriction, and the severity of vasoconstriction is similar to the effects of epinephrine or norepinephrine. Dopamine has little β2-adrenergic activity.

5. b. Dopamine is a direct-acting inotropic agent that stimulates β1- and β2-adrenergic receptors. Its β2-effects reduce afterload and its β1-effects increase heart rate. The major clinical distinction between Class I and Class II is generally characterized by blood loss of less than 750 mL, Class II with volume losses of 750 to 1,500 mL, and Class III with uncompensated blood or volume loss of more than 1,500 mL. Any volume loss may be associated with tachycardia, which can be a sympathomimetic response to pain or anxiety. In patients with less than 1,500 mL of volume loss, renal perfusion and urine output is typically maintained. The major clinical distinction between Class I and Class II hypovolemic shock is the presence of postural hypotension.

6. b. Crystalloid infusion (1–2 L). The most common types of shock in obstetrics and gynecology are hypovolemic and septic. A healthy, young patient who is otherwise asymptomatic and is tolerating a hemoglobin of 8 mg/dL may be managed adequately with crystalloid and oral iron as soon as she is able to begin oral feeding. Blood transfusion is not indicated in this patient at this time. Although colloids such as 5% and 25% albumin and synthetic colloid preparations have been used in the past for volume replacement, the majority of studies have found no advantage of colloids over crystalloids in this clinical setting.

When hemorrhagic shock is identified, the initial management consists of placement of a large-bore peripheral intravenous catheter and infusion of 1 to 2 L of an isotonic electrolyte solution. The rate of fluid administration is proportional to the caliber and length of the catheter; thus, placement of a central venous catheter will not improve the rate of fluid administration. Furthermore, central venous catheterization carries a risk of pneumothorax and other life-threatening complications and is unnecessary in an otherwise healthy patient.

7. c. Blood and cervical cultures. In all probability, this patient has a tuboovarian abscess. In this young, nulliparous patient, to preserve fertility, aggressive intravenous antibiotic therapy specific for genital tract pathogens (chlamydia and anaerobes) is recommended. When the diagnosis of tuboovarian abscess is suspect, antibiotic therapy in the hospitalized setting is warranted, regardless of concerns for future fertility. Before initiation of intravenous antibiotics, a pelvic examination with appropriate cultures for gonorrhoea and chlamydia should be performed. All aerobic cultures obtained in a patient who is febrile and has a significant leukocytosis. Because this patient has no evidence of a perforated viscus, plain films for free air are not indicated at this time. If the patient does not respond to antibiotic therapy, exploratory laparotomy may be indicated, but the initial management should be intravenous antibiotics after obtaining appropriate cultures.

9. c. Urine sodium excretion <30 mEq/L/24 hr; oliguric pre-renal azotemia is an early reversible injury. It is characterized by urine-plasma creatinine ratio greater than 40 mEq/L/24 hr, a urine sodium excretion of less than 20 mEq/L/24 hr, a fractional excretion of sodium less than 1%, and a high urine osmolality (>500 mOsm). Patients can have normal, increased, or reduced serum sodium, depending on volume replacement and intake. Contraction alkalosis is characteristic of prolonged diuretic use. Characteristics of acute tubular necrosis, which results from prolonged hypoperfusion and cellular damage, is typically characterized by the loss of ability to concentrate urine. Osmolality of the urine is usually less than 350 mOsm.
13. e. Give iron supplementation. Anemia is a common complication of cancer and cancer therapy. Because of alterations in tissue perfusion as well as immunological responses, significant anemia profoundly affects normal cellular and vascular physiology, impairing response to therapy and quality of life. Anemia preoperatively and postoperatively is an independent risk factor for postoperative infection, longer hospital stays, and death in noncardiac surgical patients. In several tumor models, anemia is a poor prognostic factor associated with poorer local control of disease and lower survival rates. Anemia leads to an increase in the tumor hypoxic fraction, with relative radioreistance resulting from impaired tumor oxygenation. The two most common reasons for anemia are iron deficiency and anemia of chronic disease. The patient described above is likely to have both true iron deficiency and inflammatory anemia. The best next step in the management of this patient is to determine relative iron stores; if serum ferritin levels are less than 30 nanograms per mL, iron therapy should be initiated. Although additional B12 and/or folate acid supplementation would be indicated for measurable deficits, vitamin deficiency is an uncommon cause for anemia in the adult patient with an intact gastrointestinal tract and a normal diet. Erythropoietin is the principal hematopoietic growth factor that regulates erythroid lineage proliferation and differentiation. Erythropoietin is a pleiotropic cytokine that is proangiogenic, with broad tissue-protective effects in diverse nonhematopoietic organs. Multiple trials demonstrate recombinant erythropoietin effectively reduces transfusion requirements and improves quality of life in cancer patients. However, erythropoietin does not reduce transfusion risks or correct anemia in the absence of sufficient iron stores. Therefore, administration of erythropoietin stimulating agents in conjunction with iron-vitamin supplements is indicated for patients with anemia of chronic disease and mixed anemia. Red cell transfusion is indicated for acute symptomatic anemia, especially when blood loss is ongoing, for patients with comorbid conditions in which anemia increases the risk of ischemia, and in chronic symptomatic anemia unresponsive to erythropoietin and iron therapy. The choice of therapy (chemotherapy, radiation therapy, or both) is usually predicated by the stage of disease and tumor type. Changes in treatment are usually made based on response and toxicity.

CHAPTER 13

1. c. Polyglandin 910 Rapide. The well-vascularized, rapidly healing tissues of the vagina need support for only a short period of time after injury, suggesting the need for a rapidly absorbed suture. Multiple studies are now available that show significantly less postoperative pain after repair with synthetic absorbable sutures compared with catgut sutures. This is believed to be caused by the intense inflammatory response produced by the gut sutures. Although use of longer delayed suture is also associated with less pain than catgut, the presence of suture material and knots has been associated with dyspareunia and pain after the postpartum period.

2. c. Suture pulling through fascia. Fascial dehiscence can be caused by multiple factors, including suture breakage, knot failure, and suture pulling through fascia, but the most common factor appears to be suture pulling through fascia. Wound infection may play a contributing factor in fascial dehiscence but is not a primary cause.

CHAPTER 14

1. c. Maylard
2. b. False. There is no posterior rectus sheath below the arcuate line.
3. c. Internal oblique and transversalis. The aponeuroses of the transversalis and the split aponeurosis of the internal oblique come together to form the posterior sheath of the rectus muscles above the arcuate line.
4. b. Transect the rectus muscles at their insertion, similarly done when performing a Cherney incision. Although one could use a Maylard, the risk of injury to the inferior epigastric vessels would be greater. Further, one would have to suture the muscle edges to the fascial edges to reapproximate the rectus muscle bellies. Given all of these pitfalls, the best option would be to transect the rectus muscles at their tendinous insertion into the pubic symphysis. Care must be taken to reattach the muscles to the tendon—not the periosteum of the pubic symphysis—at the completion of the procedure.
5. d. Maylard. The Maylard incision is used to enter the abdomen in a transperitoneal approach.
6. d. 8. Eviscerations usually occur from day 5 to 14 after the operation, with a mean of 8 days.
7. b. External iliac artery. The inferior epigastric artery arises from the external iliac artery. The superficial epigastric artery arises from the femoral artery. The hypogastric artery is another name for the internal iliac artery.

CHAPTER 15

1. c. Use a return electrode (ground) of large contact area to ensure a low-current density.
2. a. If metal laparoscopic trocars are used, a plastic insulating collar should be used.
3. d. Activating the current before making contact with the clamp.
4. a. Is a desirable electrosurgical modality for venous bleeding, such as oozing from a punch-out.
5. b. Faster movement of the wire through the cervical tissue causes more thermal injury and makes it more difficult for the pathologist to interpret.
3. a. Increase in pulse time
4. b. False
5. b. Above 100°C
6. b. False
7. b. Eye
8. d. Water

CHAPTER 17
1. a. Reusable
2. a. True
3. b. External iliac artery
4. b. Ilioinguinal nerve
5. b. Compression of the common peroneal nerve, compression by Allen stirrups
6. a. True
7. b. False

CHAPTER 18
1. d. The tungsten light source is superior to other sources.
2. b. The operative hysteroscope is 15 mm in diameter.
3. e. All of the above
4. a. Carbon dioxide
5. c. Normal saline
6. b. Hyskon
7. d. Glycine 1.5%
8. a. Hysteroscopy should be performed during the luteal phase for best visualization of the endometrial cavity.
9. d. Endometrial ablation
10. d. Bleeding

CHAPTER 19
1. b. Hepatitis B
2. a. Use large figure-of-eight sutures so the suture will not cut through the tissue.
3. d. Lamellar platelets
4. a. Hepatitis B
5. b. Reducing the pulse pressure
6. b. False
7. a. True
8. c. Only the posterior division of the hypogastric artery should be ligated.
9. d. 1 in 2 million
10. b. False

CHAPTER 20
1. In vitro fertilization (IVF)
2. Yes
3. IVF with intracytoplasmic sperm injection (ICSI), salpingectomy before IVF
4. If married, cryopreservation of preembryos. If single, cryopreservation of oocytes or ovarian tissue; both procedures must be considered experimental.

CHAPTER 21
1. b. Chlamydia trachomatis
2. d. Known tubal obstruction
3. b. Obliterative fibrosis
4. d. Reduced risk of ectopic pregnancy
5. a. to use cautery during dissection to facilitate hemostasis
6. d. Nature of the tubal endoderm
7. b. Length of reconstructed tube

CHAPTER 22
1. e. All of the above
2. a. Laparoscopy provides inferior visualization of the posterior cul-de-sac compared with laparotomy.
3. a. The classic triad associated with endometriosis includes infertility, dyspareunia, and dysmenorrhea.
4. c. Presacral neurectomy, or division of the superior hypogastric plexus, is useful as an adjunctive procedure to reduce midline pelvic pain and dysmenorrhea in women with endometriosis.
5. b. The ASRM defines complete cul-de-sac obliteration as when no peritoneum is visible below the uterosacral ligaments.

CHAPTER 23
1. 1-c; 2-a; 3-d; 4-b
2. c. Partial vulvectomy
3. a. True
4. c. Simple vulvectomy

CHAPTER 24
1. b. Becomes patent when canalization of the most caudal portion of the vaginal plate at the urogenital sinus occurs
2. b. Most patients have a high (suprasphincteric) urethral vaginal connection.
3. c. Vaginoplasty should be performed in infancy to prevent vaginal stenosis.
4. c. Absence of the posterior wall of the bladder exposing the ureteral orifices
5. e. All of the above
6. a. The average age at presentation is 35 years.
7. c. Seventy-five percent of women exposed to DES in utero have anatomic abnormalities.
8. b. Stage 1 disease lesions can be treated with radiation therapy or total abdominal hysterectomy.
9. e. Infection of the Bartholin gland
10. c. Most urethral diverticula are located in the proximal urethra.

CHAPTER 25
1. b. Septate uterus
2. a. The vagina develops from both the mullerian ducts and the urogenital sinus.
1406 Answers

3. c. Impaired ovarian function
4. e. Laparoscopy
5. b. Greater than 90% patients have been shown to achieve anatomic and functional success by vaginal dilation.
6. d. Adequate preoperative dilatation
7. d. Conservative management, with hormonal suppression of endometrial stimulation, is appropriate for young patients.
8. d. Rokitansky syndrome
9. c. Didelphic uterus
10. b. A prolonged postoperative recovery period

CHAPTER 26

1. b. Anovulatory bleeding
2. d. GnRH analog injection
3. b. In the follicular phase
4. d. All of the above
5. c. Sonohysterography

CHAPTER 27

1. c. Inserting the needle with the port closed. Careful attention to safety measures will reduce the likelihood of complications with Veress needle insertion. The needle should be inserted in the midline toward the hollow of the sacrum to avoid the major vessels laterally. The anterior abdominal wall should be elevated to avoid the dorsal vascular structures. The needle should be inserted with the port open and held to avoid occlusion of the spring mechanism of the inner safety obturator. Several techniques, including infiltration and aspiration of sterile fluid through the needle, can help to identify correct placement.
2. a. Bipolar coagulation. Both types of clips and the silicone rubber band are most likely to be effective if applied to normal fallopian tubes. Dense pelvic adhesions will decrease the likelihood that the tubes can be adequately mobilized for proper application of these methods. The presence of thickened or edematous tubes decreases the likelihood that the clip or band can adequately occlude the tube and increases the likelihood of tubal transaction.
3. c. Direct observation of tubal blanching and swelling. Bipolar coagulation is highly effective with proper technique. Because thermal injury to the seromuscular layer of the tube can occur without adequate coagulation of the endosalpinx, visual end points for adequate coagulation are unreliable. The use of a cutting waveform with the power output at least 25 W against a 100-V load increase the likelihood of complete coagulation, and use of an optical flow meter assists in determining when coagulation has been adequate. Coagulation of at least three contiguous areas will enhance the likelihood that a sufficient amount of tube has been occluded, and avoiding the proximal isthmus is thought to decrease the risk of tuboperitoneal fistula formation.
4. c. Ovarian cancer. Women who undergo tubal sterilization are more likely than women whose partners undergo vasectomy to later experience an ectopic pregnancy and to undergo hysterectomy. They appear to be equally likely to experience regret after the procedure. For a reason that remains unclear, sterilized women are less likely to develop ovarian cancer than their nonsterilized counterparts.

CHAPTER 28

1. b. Mesoderm
2. a. It is an HY cell surface antigen.
3. b. 12
4. c. It contains both motor and sensory parasympathetic and sympathetic nerves.
5. d. All of the above

CHAPTER 29

1. c. Allodynia
2. b. Neuromatrix theory
3. c. Somatosensory disorders

CHAPTER 30

1. b. Intravenous clindamycin plus gentamicin
2. b. False
3. d. A polymicrobial mixture of aerobes and anaerobes
4. d. Oral ofloxacin plus metronidazole
5. b. False

CHAPTER 31

1. c. Red or carneous degeneration is never seen during pregnancy.
2. d. Sarcomatous degeneration
3. b. The tumor behaves clinically as a benign entity.
4. a. Most leiomyomata are asymptomatic and may not require any treatment.
5. b. Danazol
6. c. It is recommended to combine laparoscopic guidance with the hysteroscopic procedure.
7. b. A 34-year-old woman desiring future fertility with two intramural myomas each measuring 3 cm in diameter
8. a. Preoperative treatment with oral contraceptive pills
9. d. Pulmonary embolus
10. a. Most patients report an improvement in menorrhagia and bulk-related symptoms.

CHAPTER 32A

1. a. Prolapue
2. a. Abdominal hysterectomy
3. b. Vaginal hysterectomy
4. c. Shorter operative time
5. a. True
6. b. False
7. a. Previous tubal ligation
8. c. Prophylactic intravenous antibiotics within 1 hour before surgery
9. a. True
10. b. 1/1,000 hysterectomies

CHAPTER 32B
1. e. Vaginal hysterectomy
2. d. Nulliparity
3. d. More than 90%
4. d. 90%
5. a. Dividing the uterine vessels

CHAPTER 32C
1. d. Shorter hospital stay
2. b. The uterine vessels are secured laparoscopically in a VALH.
3. a. Shorter operative time
4. c. The Vagiballoon™
5. a. True

CHAPTER 33
1. d. All of the above. They are all appropriate management plans for the hemodynamically stable patient with incomplete abortion or missed abortion. Surgical management is more likely to result in completion than medical management, and medical management is more likely to result in completion than expectant management, but the inverse is true of costs incurred. Patient satisfaction can be seen with any of these management plans. Certainly in the face of severe anemia, hemodynamic instability, or infection, surgical evacuation should be performed. Without these, patient preference should be strongly considered.
2. b. 7 weeks. The FDA has approved mifepristone 600 mg orally followed by misoprostol orally 48 hours later up to 7 weeks for early medical abortion. Recent literature supports an alternative regimen that can be effective up to 9 weeks.
3. b. False. All abortions, spontaneous or induced, can result in Rh sensitization in an Rh-negative woman. All women with an abortion should be given anti-D immune globulin. 30 μg is sufficient before 12 weeks of gestation; 300 μg is necessary thereafter.

CHAPTER 34
1. b. Ampullary, interstitial, interstitial
2. d. All of above

CHAPTER 35A
1. b. An increase in pulmonary reserve
2. c. An increased risk of placenta accreta
3. d. Rate of infection

Answers
1407

CHAPTER 35B
1. d. Benign cystic teratoma
2. b. Biopsy only, no further surgery
3. c. Dysgerminoma
4. a. Repeat the ultrasound in 4 weeks.
5. b. Pelvic ultrasound

CHAPTER 36A
1. c. Transversus perinei
2. d. Pericervical ring
3. b. Vaginal delivery
4. d. Hymenal ring
5. b. Quality of life

CHAPTER 36B
1. d. All of the above
2. c. Vesicovaginal and paravesical spaces
3. b. A transverse apical defect between the pericervical ring and the pubocervical septum

CHAPTER 36C
1. d. The posterior aspect of the pubic bone
2. b. Troublesome bleeding may result.
3. a. True
4. a. Placed individually starting near the ischial spine
5. d. Fascia of the obturator internus muscle

CHAPTER 36D
1. a. The change to site-specific defect repair
2. d. All of the above
3. d. In recurrent cases in which native pelvic tissues are weak
4. c. Mesh exposure
5. d. It is one of the most common surgeries performed in women older than age 50 and has an unacceptably high failure rate.

CHAPTER 36E
1. b. Cardinal and uterosacral ligaments
2. b. Rectum
3. a. Pudendal nerve/vessels
4. c. Anterior vaginal wall prolapse
5. d. Suturing the round ligaments to the anterior graft with nonabsorbable sutures
CHAPTER 36F

1. a. True
2. c. Wide vaginal introitus
3. d. Ring
4. a. Increased difficulty with bowel movement
5. b. It does not improve her symptoms.

CHAPTER 37

1. d. Act to decrease intraurethral resistance
2. b. Has a retropubic passage
3. a. 85%
4. b. Q-tip straining angle of >40°
5. d. All of the above
6. d. Must perform a cystotomy to complete the procedure(s)

CHAPTER 38

1. c. At the cardinal ligament when the ureter passes under the uterine artery
2. a. Surgical knowledge of the location and anatomy the ureter
3. b. Cystotomy
4. c. Total abdominal hysterectomy
5. c. Ureteroneocystomy with psoas hitch

CHAPTER 39

1. d. HIV infection
2. a. Laparoscopic
3. a. True
4. b. Superior to the interureteric ridge in the posterior bladder
5. c. Stone formation
6. c. Insert a tampon in the vagina and have the patient walk around for 15 minutes

CHAPTER 40

1. c. a, b, and c
2. d. a and c
3. c. a, b, and c
4. d. Endoanal ultrasound
5. b. False

CHAPTER 41

1. Yes. Unlike sporadic breast cancers, which may be associated with primarily maternal family-history risk factors, BRCA can be transmitted from the paternal side of the family as well. This means that the patient may be at an increased risk to develop breast cancer in male relatives as well as other nonreproductive cancers. The carrier relative may also be unaffected with disease at the time of review.
2. Yes. As inherited breast cancer (at this point) only accounts for 5% to 10% of breast cancers, once the gene is negative, the patient still remains at risk for the other 90% to 90% of sporadic breast cancers. We also have limited knowledge of other possible sources (undiscovered genes) for hereditary susceptibility to breast cancer. Thus, the patient should have, at minimum, mammographic, self-breast, and clinical breast examination (CBE) surveillance based on her age. And if familial breast cancer remains a concern, additional scrutiny may be warranted, including increased CBE, MRI testing is also currently showing promise in high-risk women, but additional studies are ongoing.
3. No. As mammograms have a 10% to 15% false-negative rate, a negative mammogram should not deter additional evaluation. Furthermore, the increased breast density noted in younger women portends an even higher false-negative rate.
4. Currently chemoprevention, prophylactic mastectomy/ oophorectomy, lifestyle modification, and increased surveillance are risk-reducing options in women with high-risk characteristics. Decreased use of alcohol and tobacco in addition to early childbearing are options for women pursuing lifestyle modification. Initial prevention data indicating a nearly 50% reduction in breast cancer was based on tamoxifen prophylaxis. As tamoxifen has additional side effects (including but not limited to an increased risk of endometrial cancer and venous thromboembolism), raloxifene was reviewed, with promising information released in the Study of Tamoxifen and Raloxifene (STAR) trial indicating a similar risk-reduction benefit for raloxifene without the increased risk of endometrial cancer. The risk of venous thromboembolism (VTE), however, was increased, thus indicating the need for additional studies. Aromatase inhibitors are being studied in pending trials including STELLAR (Study of Letrozole and Raloxifene—accrual to begin in late 2006 or 2007) in postmenopausal women. Oral contraceptives have also been shown to decrease a woman’s risk for the development of ovarian cancer. This creates a quandary for women at increased risk for both ovarian and breast cancer.
5. CNBs provide a histologic sample rather than the cytologic sample of FNA. Thus, invasion past the basement membrane cannot (as a rule) be delineated, thereby decreasing one’s ability to differentiate carcinoma in situ (CIS) from invasive cancer. Pathologists with significant experience in cytologic interpretation, however, may narrow this gap.
6. The Gail, Claus, and BRCAPRO are the most frequently used models in clinical practice. Of these, the Gail model is the only one that has been clinically validated. The risk for young women may be underestimated in both the Gail and Claus model. BRCA mutation carriers and those with paternal family history of breast cancer are underestimated in the Gail model. Moreover, the Gail model has not been validated in minority patients. The BRCAPRO model specifically focuses on genetic mutation risk. Thus, although each model has its advantages and limitations, it appears (from studies) that the Gail model may be most applicable. Also, it is assessable on the National Cancer Institute Web site.
7. Assessing an individual’s risk for the development of breast cancer likely encourages awareness of breast cancer and breast cancer screening recommendations, provides a forum
for discussion and clarification of risk management (as women often overestimate their risk), and improves the overall quality of care as information is being released indicating differential effects of tamoxifen and breast-feeding in BRCA1 versus BRCA2 carriers. Thus, stratification is necessary to provide accurate information regarding risk reduction.

8. b. False. Tumors equal to 2 cm are considered stage I (i.e., tumor < 2 cm). Another often-missed component is that tumors measuring 5 cm are considered stage II. Only those greater than 5 cm are considered stage III.

9. b. False. Actually, the majority of women with breast cancer have no identifiable risk factor other than sex and age.

CHAPTER 42

1. d. The greatest incidence of appendicitis occurs in the third and fourth decades of life.
2. a. McBurney’s point: located at the junction of the middle and medial thirds of a line drawn from the umbilicus to right anterolateral spine
3. c. Start intravenous fluids and broad-spectrum antibiotics with enteric organism coverage, keep the patient NPO, and keep the patient under close observation for progression of her illness.
4. b. Premature labor and delivery are among most serious fetal risks, with up to 30% fetal mortality reported if perforation occurs.
5. b. A patient undergoing standard repeat cesarean section with tubal ligation

CHAPTER 43

1. b. The diverticulum should be removed because the patient has a history of symptoms that it may have caused, and it has slightly atypical features.
2. a. A 26 year old with SLE who has end-stage renal disease; b. A 54 year old alcoholic with cirrhosis; and c. A 48 year old with class II heart failure
3. a. Start intravenous fluids and broad-spectrum antibiotics with enteric organism coverage, keep the patient NPO, and keep the patient under close observation for progression of her illness.
4. b. Leave the trocar in place, convert to an open laparotomy, and repair the injury.
5. a. A patient presents to the ER 3 days postoperatively reporting nausea, vomiting, and fever.
6. c. Return of bowel function generally occurs at the same rate regardless of early or delayed feeding.
7. c. Lugol’s staining
8. a. Vaginal bleeding
9. c. Entry into the paravesical space
10. a and d. Cervical glandular lesions and suspected microinvasive lesions

CHAPTER 44

1. c. 50%
2. c. Pelvic kidney
3. b. True

CHAPTER 45

1. d. Immunosuppression
2. c. Any location, less than 1 mm invasion
3. c. Preservation of ovarian function
4. a. Intravenous pyelogram
5. b. Pararectal space
6. a. Origin from the hypogastric artery
7. d. Bladder dysfunction
8. c. Staging of the appendix
9. c. Enter into the paravesical space
10. c. 65%–75%

CHAPTER 46

1. a. True
2. d. 80%
3. c. Any location, less than 1 mm invasion
4. c. Close resection with margin less than 1 cm
5. b. Locally advanced disease or lesions encroaching on midline structures for which surgical removal is accompanied by significant morbidity
6. a. True
7. a. Basal cell carcinoma
8. b. Basosquamous carcinoma

CHAPTER 47

1. c. Stage IB
2. b. FIGO stage
3. c. Preservation of ovarian function
4. a. Intravenous pyelogram
5. b. Pararectal space
6. a. It produces a specimen for histologic study.

CHAPTER 48

1. d. Cigarette smoking
2. a. Office endometrial biopsy
3. e. None of the above
4. a. Surgical staging for patients with uterine papillary serous carcinoma includes peritoneal washings and biopsies, pelvic and paraaortic lymph node dissection, and omentectomy.

5. a. History and physical examination

CHAPTER 49

1. c. Unilateral oophorectomy followed by chemotherapy
2. b. Surgery alone
3. c. Capsular rupture
4. a. Unilateral salpingo-oophorectomy with surgical staging
5. d. Transvaginal pelvic ultrasound
6. a. Serum inhibin
7. a. Peripheral vasculature
8. a. Check a CA-125 level, and if normal, repeat the ultrasound in 3 months to determine if any change has occurred.
9. b. 10%–15%
10. d. Nulliparity

CHAPTER 50

1. d. A 56-year-old woman who was treated 15 months ago for stage IB2 squamous cell carcinoma of the cervix now has a biopsy-proven 1.0-cm recurrence in the cervix after previous pelvic radiation and chemotherapy. The mass is freely mobile. Her workup is negative except for a single 1.5-cm node in the low aortic area just above her previous radiation field. CT-guided FNA is positive for squamous cell carcinoma. There is no evidence of other metastatic disease.
2. d. Age older than 70
3. b. Tumor causing a vesicovaginal fistula
4. a. Pouch of Douglas
5. d. It is technically quick and easy to perform.

CHAPTER 51

1. d. Urinary continence
2. b. Superior hemorrhoidal artery
3. d. Sartorius
4. a. Previous Maylard incision
5. c. Increased risk of recurrence
6. b. A flap length 2 cm long and a base of 1 cm
7. b. 80 cm H2O pressure, 500 mL volume
8. c. Retention of 1,000 to 1,500 mL of fluid
9. d. Reinforcing the ileocecal valve by tapering the distal segment is essential for maintaining continence.
10. b. Constipation
Abdominal hernia, defined, 1097
Abdominal examination
Abdominal ectopic pregnancy, diagnosis and laparoscopic techniques, 325–326

endometriosis, hysterectomy and oophorectomy
and, 468
prophylactic oophorectomy and, 731
risks and beneﬁts of, 35–37
Ethics
abortion issue and, 23–24
advanced planning and end-of-life decision
making, 22–23
conﬁdentiality and, 21
human subjects-based research and, 21–22
Jehovah’s Witness patients and, 22
managed care and socialized medicine and,
46–47
medical theory and practice of, 15–16
of pelvic surgery, 15–25
privacy and, 20–21
in surgical training, 18

10:22


Extracardiac obstructive shock
Extra-anal incontinence
External intermittent pneumatic compression,
External iliac artery, anterior abdominal wall, 249,
External anal sphincter, defined, 994
Extended-field irradiation, cervical cancer surgery
Expert witness
Experience in surgical procedures, residents' lack
Excision laser conization, cervix, 305
Examination under anesthesia (EUA), ethical
Evisceration complications
Evidence-based medicine, 62
Evening primrose oil (EPO), mastalgia, 1038
1422 Index
defined, 203
classification and etiopathogenesis, 203–204,
fistulous tract and, 1003
defined, 994
best surgical practices, 535
anomalies, 511–512, 512f–524f, 514–525
anatomy, 82, 83f, 510–511
of endometriosis, 449
vulvar malignancies, 1164–1165, 1165f, 1166t
moderate/severe dysplasia management,
gastrointestinal surgery, 1108–1109, 1109f
defined, 246, 1097
abdominal myomectomy and, 720–721

Extracardiac obstructive shock
Extra-anal incontinence
External intermittent pneumatic compression,
External iliac artery, anterior abdominal wall, 249,
External anal sphincter, defined, 994
Extended-field irradiation, cervical cancer surgery
Expert witness
Experience in surgical procedures, residents' lack
Excision laser conization, cervix, 305

Index

Graft techniques and materials (Contd. )
suburethral sling procedure, stress urinary
incontinence, 951–955, 952f–954f, 955t
urethrovaginal ﬁstula repair, 987–988, 989f
vesicovaginal ﬁstula repair, 982–983, 985f–986f
Gram-negative bacteria
hidradenitis supperativa, 495t
neutropenic fever, 212–213
pelvic inﬂammatory disease, 661
septic shock and, 206–207
adult respiratory distress syndrome, 211
antibiotic therapy, 218–219, 219t
gastrointestinal failure and, 211
Gram-positive bacteria
hidradenitis supperativa, 495t
neutropenic fever, 212–213
septic shock and, 206–207
antibiotic therapy, 218–219, 219t
Granular cell tumors, vulva, 504, 504f
Granuloma inguinale, vulva infection, 492–493
Greater omentum, deﬁned, 1097
Greater vestibular gland, anatomy, 83, 83f, 83t
Gridiron (muscle-splitting) incision
abdominal surgery, 263, 264f
deﬁned, 246
Grief
deﬁned, 26
as response to surgery, 30–31
Groin dissection, vulvar malignancy
invasion levels and, 1160, 1160t
radical vulvectomy/bilateral inguinofemoral
lymphadenectomy, 1172–1181,
1172f–1180f
reconstructive surgery, 1181–1183, 1182f–1183f
Ground pads, electrosurgical generators, 284–285
Ground-referenced electrosurgical generators, 284
Growth factors, endometriosis and, 440
Growth hormone (GH), leiomyomata uteri risk
and, 689
“Guiding catheter,” tubotubal anastomosis,
428–429
Guilt, as response to surgery, 31
Gynaecia, 5
Gynecologic examination, preoperative assessment
including, 122
Gynecologic Oncology (journal), 12
Gynecologic surgery. See also Assisted reproductive
technology; Incision techniques; Laser
gynecology; Postoperative care; Preoperative
care; Wound healing
anal incompetence, 1007–1015
appendectomy incidental to, 1093–1095
cervical cancer, 1236–1238, 1236t, 1237f–1238f,
1238t
fertility-sparing radical abdominal
hysterectomy, 1258–1259, 1262–1263,
1262t, 1263f–1266f
follow-up after, 1283–1284
laparoscopically assisted radical vaginal
hysterectomy, Schauta procedure,
1263–1268, 1266f–1269f
laparoscopically assisted radical vaginal
trachelectomy (Dargent procedure),
1268–1274, 1270f–1272f, 1272t–1273t
laparoscopic radical hysterectomy, pelvic and
aortic lymphadenectomy, 1274–1275, 1274t
laparoscopic surgical staging, 1275–1276,
1275t, 1276f
pelvic anatomy, 1243–1247, 1244f–1247f
postoperative complications, 1276–1280,
1278t
radical abdominal hysterectomy, 1249–1258,
1251f–1255f, 1257f–1261f
radical abdominal hysterectomy/bilateral
pelvic lymphadenectomy, 1247–1249
radical hysterectomy, 1238–1243, 1239t,
1240f, 1243t
specimen pathology, 1276
changes in, 62–71
communication issues in, 28–29, 47–48
cystocele evaluation, 876–881, 876t, 877f–880f
data evaluation in, 70–71, 70t–71t

early principles of, 8–9
ectopic pregnancy
conservative surgery, 809–813, 810f–813f
medical therapy vs., 816
radical surgery, 813–816, 814f–815f
educational changes in, 62–64, 63f, 63t
electronic health record, 64–65
emotional responses to, 30–31
endometriosis, conservative surgery, 453–467
adjunctive procedures, 461–465, 462f, 464f
microsurgery principles, 453
outcomes, 466–467, 466f
recurrent surgery, 467
second-look laparoscopy, 465–466
sites for, 453–461, 454f–459f, 455t
gastrointestinal involvement
adhesiolysis, 1102, 1102f
injury and complications, 1102–1105
preoperative care, 1100–1101, 1101t
historical beginnings of, 3–5
hospitalist practices and, 69–70, 70t
hospital setting for, 44–45
informed consent request forms, 49, 50f–56f
managed care and socialized medicine and,
46–47
nongynecologic conditions and
best surgical practices, 1147–1148
bowel preparation with, 1145
deﬁnitions, 1131
gastrointestinal disease, 1131–1134,
1132f–1139f, 1146
intraoperative management, 1145–1147
nonsurgical acute abdomen, 1145
orthopedic disorders, 1141–1143, 1144f
ovarian metastases, 1146–1147
pelvic metastases, 1143, 1145
preoperative evaluation, 1131
preoperative preparation, 1145
retroperitoneal tumors, 1134, 1137,
1140–1141, 1140f–1143f, 1147
urologic tumors, 1134, 1139f, 1147
vascular considerations, 1143, 1144f
ofﬁce setting and, 43–44
ovarian cancer
advanced-stage cancer, 1321–1328, 1322t
early-stage cancer, 1315, 1317–1321,
1318t–1320t
fertility-sparing surgery, 1319–1320, 1319t
laparoscopy, 1328–1329
secondary cytoreductive surgery, 1331–1332,
1331t
second-look laparotomy, 1330–1331
ovarian tumors, pregnancy and, 846–849,
848f–849f
pay for performance evaluation, 66–67, 69, 69f
pelvic inﬂammatory disease
risk factors with, 662
ruptured pelvic abscess, 672–674
pelvic prolapse management, 870–872, 871t
pelvic tuberculosis, indications for, 683–684,
683t
postgraduate educational trends in, 64
professional liability and risk management in,
42–60
psychodynamics speciﬁc to, 31–33
psychological preparation for, 29–30
psychosexual rehabilitation, 33–34, 34t
quality initiatives in, 65–66, 67t–68t
rectovaginal ﬁstulae, 1016–1024
sexual cycle primer and, 34–35
spontaneous abortion evaluation and
management, 778
surgical instrumentation
clamps, 238f–239f, 240–241
dilators, 241, 241f
overview, 235–236
retractors, 239f–240f, 241
scalpels, 236–237, 236f
scissors, 237, 237f, 240
tissue forceps, 237f, 240
surgical knots, techniques and classiﬁcation,
234–235, 235f–236f

surgical needles, 233–234, 234f
surgical wounding healing, 227–228
suture materials
absorbable sutures, 230–231
facial closure sutures, 232–233, 233f
knot-pull tensile strength requirements,
229–230, 229t, 230f
nonabsorbable sutures, 231–232
training principles for, 73–79
in twentieth century, 9–12, 10f
urethrovaginal ﬁstula repair, 986–988, 987f–989f
vaginal reconstruction
Abbe-Wharton-McIndoe operation, 550–554,
550f–552f
acquired vaginal insufﬁciency, 557
historical development, 549–550
neovaginoplasty procedures, 555–557
Williams vulvovaginoplasty, 554–555, 555f
vaginal tumors, 527–529, 528f, 529t
vesicovaginal ﬁstula, technique overview, 980
wound closure methods and, 228–229
Gynecology
barriers to surgery in, 2–3
deﬁned, 2
ethical dilemmas in, 16
abortion, 23–24
history of, 2
medical-legal aspects of, 19–20
prevalence of malpractice claims in, 42–43
psychological aspects of, 26–40
in twentieth century, 9–12
Gynecology and Abdominal Surgery, 8
Gynecology (Soranus), 2

H
Haemophilus ducreyi, chancroid lesions, vulva
infection, 493
Halban syndrome, functional ovarian cysts, 639
Halsted, William S., 8–9
Halstedian technique, avoidance of pelvic
hemorrhage, 382–383
Hand-eye coordination, training programs for,
75–78
Hand-sewn anastomosis
colon, end-to-end hand-sewn single-layer
technique, 1123–1124, 1124f
small bowel
end-to-end double-layer anastomosis,
1114–1115, 1115f
side-to-side anastomosis, 1116, 1116f
Hands-on surgical training programs, 75–78
Hand washing, postsurgical infection prevention
and, 197–198, 198t
Hank-Bradley dilator
cervical dilation and curettage, 600, 600f
uterine dilation and curettage, 602
Harmonic ACE cutting and coagulating shears
laparoscopic myomectomy, 330–331, 332f
laparoscopic surgery, 324, 324f
Harmonic Scalpel, laparoscopic myomectomy, 709
Hartmann procedure
deﬁned, 1131
rectovaginal ﬁstula repair, 1021, 1024
Haustra, deﬁned, 1097
Health care proxy, ethical and legal principles and,
23
Health Insurance Portability and Accountability
Act (HIPPA), privacy issues and, 20–21
Health maintenance organizations (HMOs),
structure and function, 46–47
Health system improvement, training goals for, 73
Heaney retractor, cystourethrocele repair, 880–881,
880f
Heart, hypovolemic shock and, 210
Heat (thermal energy), deﬁned, 280
Hegar dilator
cervical dilation, 599, 599f–600f
uterine dilation and curettage, 602
Helium neon laser, tissue interaction with, 301
Hemangiomas
hysteroscopic surgery, 365, 365f
vulva, 504–505, 504f

Hemorrhoids
See also Hernias.

Hemorrhoidal complexes

Hemodynamic instability, in shock patients,

Hematosalpinx, imperforate hymen and,

Hematostasis

Hereditary nonpolyposis colon cancer syndrome

Heparin

Hemostatic defects, septic shock and, 207–208

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,
legal abortion complication, 793

Hemostasis

Hereditary nonpolyposis colon cancer syndrome

Hemostasis

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,

Hematoma

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,

Hemorrhoids

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,

Hemorrhoidectomy

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,

Hemorrhoids

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,

Hemorrhoids

Hereditary breast-ovarian cancer syndrome

anal incontinence and, 1002
techniques for, 1161–1162, 1161f–1162f
recurrent vulvar malignancies, 1178–1181,
Incision techniques

Incidental appendectomy, defined, 1084

Incarceration, defined, 1097

Imperforate hymen

Impedance plethysmography, postoperative venous

Immunohistochemistry (immunocytochemistry),

Immobility, postoperative vascular complication

Image-guided ablation techniques, breast cancer

Iliac nodes, pelvic viscera, 104–105

Iliopsoas muscle, vulva anatomy, 85, 85f

Iliopectineal line, anatomy, 99, 99f

Iliohypogastric nerves

Iliococcygeus fascia suspension, vaginal prolapse

Iliococcygeal muscle

abdominal incisions, 254–266
indications and contraindications, 730–731
preoperative, defined, 113
pregnancy, 826
postsurgical infection evaluation, 196
laparoscopy, 320, 320f
anal incontinence analysis, 1004–1005, 1004f
abdominal myomectomy, 710–711, 711f
pelvic lymphadenectomy, radical abdominal
pelvic anatomy, 1243–1245, 1244f–1246f
anatomy, 103, 104f–105f, 105t
ligation of, 103, 104f–105f, 105t
pelvic anatomy, 1243–1245, 1244f–1246f
anterior abdominal wall, 250, 251f
abdominal wall anatomy, 110–111
pelvic floor anatomy, 498–499, 499f
vagina, 499–500
vulvar anatomy, 500–501, 501f
preoperative prophylactic management and, 129,
pelvic masses and, 1141–1142
pelvic inflammatory disease and, 664–665
tubal factor infertility, 403
endometriosis and, 443–445, 443t
laser procedures, 509, 510
leukemia, 1159–1160
ovarian destruction and assisted reproductive
technology for preservation of, 401
pelvic inflammatory disease and, 644
endometriosis, 399, 468–470, 469f
unilateral and bilateral salpingectomy, 550f–552f
ovarian dominance and fertility preservation, 401
pregnancy expectations and, 396–399
tubal infertility, 399–400
unilateral salpingectomy, 400
anatomy, 90–91, 91f
infundibulopelvic ligament

Intramural-ampullary anastomosis, 425, 426f
Intraperitoneal bleeding

Intraabdominal laser surgery, 309–310, 309t

Intestinal obstruction, ovarian cancer, 1332–1333

Interval cytoreduction, advanced-stage ovarian cancer, 1332

Interval bleeding, defined, 585

Interstitial pregnancy

Interstitial needles, vulvar malignancy radiation therapy, 141–142

Interstitial compartments, water and electrolyte balance, 176–177

Interosseous diameter, defined, 854

Interposition graft

Insufflation systems

Insecurity, as response to surgery, 30

Insanity, defined, 26

Inotropic agents, shock management, 216, 217t,

Internal os (cervix), anatomy, 90

Internal oblique muscle, anterior abdominal wall, 469–470

Internal anal sphincter, defined, 994

Intermittent pneumatic compression (IPC), 208–210

Intermittent clean self-catheterization (ICSC), 886

Intermediate shock, etiopathogenesis, 206

Intercostal nerves, abdominal wall anatomy, 671–674

Integrins, endometriosis and, 443

Integration, as response to surgery, 31

Insulin therapy, shock management and, 220

Insulin control, preoperative assessment of patients with diabetes, 1041–1042

Insufflation systems

Insecurity, as response to surgery, 30

Insanity, defined, 26

Inotropic agents, shock management, 216, 217t,

Internal os (cervix), anatomy, 90

Internal oblique muscle, anterior abdominal wall, 469–470

Internal anal sphincter, defined, 994

Intermittent pneumatic compression (IPC), 208–210

Intermittent clean self-catheterization (ICSC), 886

Intermediate shock, etiopathogenesis, 206

Intercostal nerves, abdominal wall anatomy, 671–674

Integrins, endometriosis and, 443

Integration, as response to surgery, 31

Insulin therapy, shock management and, 220

Insulin control, preoperative assessment of patients with diabetes, 1041–1042

Insufflation systems

Insecurity, as response to surgery, 30

Insanity, defined, 26

Inotropic agents, shock management, 216, 217t,

Internal os (cervix), anatomy, 90

Internal oblique muscle, anterior abdominal wall, 469–470

Internal anal sphincter, defined, 994

Intermittent pneumatic compression (IPC), 208–210

Intermittent clean self-catheterization (ICSC), 886

Intermediate shock, etiopathogenesis, 206

Intercostal nerves, abdominal wall anatomy, 671–674

Integrins, endometriosis and, 443

Integration, as response to surgery, 31

Insulin therapy, shock management and, 220

Insulin control, preoperative assessment of patients with diabetes, 1041–1042

Insufflation systems

Insecurity, as response to surgery, 30

Insanity, defined, 26

Inotropic agents, shock management, 216, 217t,

Internal os (cervix), anatomy, 90

Internal oblique muscle, anterior abdominal wall, 469–470

Internal anal sphincter, defined, 994

Intermittent pneumatic compression (IPC), 208–210

Intermittent clean self-catheterization (ICSC), 886

Intermediate shock, etiopathogenesis, 206

Intercostal nerves, abdominal wall anatomy, 671–674

Integrins, endometriosis and, 443

Integration, as response to surgery, 31

Insulin therapy, shock management and, 220

Insulin control, preoperative assessment of patients with diabetes, 1041–1042

Insufflation systems

Insecurity, as response to surgery, 30

Insanity, defined, 26

Inotropic agents, shock management, 216, 217t,

Internal os (cervix), anatomy, 90

Internal oblique muscle, anterior abdominal wall, 469–470

Internal anal sphincter, defined, 994

Intermittent pneumatic compression (IPC), 208–210

Intermittent clean self-catheterization (ICSC), 886

Intermediate shock, etiopathogenesis, 206

Intercostal nerves, abdominal wall anatomy, 671–674

Integrins, endometriosis and, 443

Integration, as response to surgery, 31

Insulin therapy, shock management and, 220

Insulin control, preoperative assessment of patients with diabetes, 1041–1042

Insufflation systems

Insecurity, as response to surgery, 30

Insanity, defined, 26

Inotropic agents, shock management, 216, 217t,
Laparotomy (Cont.)

ovarian cancer, second-look procedures, 1330-1331
pelvic hemmorragh control, 132-133
pelvic inflammatory disease management, 132-133
pelvic abscess, 470-471, 470f
posterior compartment defect repair, 903-905
parietal peritonitis, 427-428, 428f
uterine nerve ablation, 394
Larger intestines. See Colon
Large loop excision of transformation zone (LLETZ), 293
successful pregnancies, 398
Laser (light amplification by the stimulated emission of radiation)
colors and wavelength, 299t

Hartmann procedure, 1021, 1024f
low ﬁstula repair technique, 1016–1020,
1017f–1019f
radiation-induced ﬁstula, 1020–1021,
1020f–1023f
sigmoidovaginal ﬁstula: sigmoid resection with
sigmoidorectostomy, 1021, 1024f
Rectovaginal septum (RVS)
deﬁned, 892
posterior compartment defect
central/lateral defects, 895, 896f
detachment of, 894–895
perineal body detachment, 895–896, 901–902,
902f
uterosacral ligament reattachment, 900–901,
900f
Rectovaginal space, anatomy, 100
Rectum
anatomy, 94, 95f
cancer of, gynecologic surgery in patients with,
1146
cervical cancer surgery and injury to, 1280
pelvic exenteration and functional restoration of,
1371–1372, 1372f
preoperative assessment of, 122–124, 123f
Rectus abdominis muscle
anatomy, 107, 107f
anterior abdominal wall, 247–248, 247f–248f
myocutaneous ﬂap, vulva/groin reconstruction,
1182–1183, 1182f
Rectus abdominis myocutaneous ﬂap
deﬁned, 1353
vaginal reconstruction, 1359–1361, 1360f–1361f
vulvar reconstruction, 1363
Rectus fascia, suburethral sling procedure,
951–955, 951f–954f, 955t
Rectus sheath, abdominal wall anatomy, 108,
108f
Recurrent disease
cervical cancer, radical hysterectomy and, 1242
vaginal tumors, 528f–528–529
vulvar malignancies
modiﬁed vs. radical vulvectomy, 1160–1162,
1161f–1162f, 1162t
squamous cell carcinoma, 1170–1183, 1171t
radical vulvectomy/bilateral inguinofemoral
lymphadenectomy, 1171–1181,
1171f–1180f
Red blood cell (RBC) replacement, hypovolemic
shock etiopathogenesis and, 204–206, 205t
Reﬂux/direct implantation theory, endometriosis,
439–440
Reﬂux menstruation, deﬁned, 438
Refusal for treatment
informed consent and, 48–49
prognosis information and, 49
Regional nodal management, vulvar squamous cell
carcinoma, 1156–1158
Regression, 26
as response to surgery, 30
Relaxation training, chronic pelvic pain and,
656–657
Renal anomalies
ipsilateral renal agenesis, double uterus with
hemivaginal obstruction, 578–580, 579f
Mayer-Rokitansky-Küster-Hauser syndrome, 547
Renal failure, septic shock and, 210–211
renal replacement therapy in, 221

Renal physiology, 162, 163f
intravascular volume assessment and, 169, 169t
pregnancy, 826
sodium balance and sodium loading, 166–167,
167t
hyponatremia, 171–173, 172f
water deprivation, 166
Renin-angiotensin-aldosterone system, shock and
dysfunction in, 210–211
Reoperation, pelvic hemorrhage control, 391–393
Reposable, deﬁned, 319
Reproductive history and function
double uterus with hemivaginal obstruction,
579–580
ectopic pregnancy and, 801
embryology, 629–630
ovarian cancer patients, fertility-sparing surgery,
1319–1320
preoperative assessment and importance of, 118
unicornuate uterus, 574–575, 575f
uterine anomalies, 565–566
Research, on human subjects, ethics of, 21–22
Resectoscope
deﬁned, 336
hysteroscopy instrumentation, 339–340,
342f–343f
bipolar design, 340, 342, 343f–345f
endometrial ablation, 362, 362f
myomata uteri surgery, 359, 360f
submucous myomata resection, 707–708, 708f
Resectoscopic metroplasty, uterine septum
uniﬁcation, 569–570, 569f
Residency Review Committee for Obstetrics and
Gynecology
competency-based training programs, 75
surgical training principles and trends and,
73–74, 78
Resident physicians
changes in duty hours for, 62–64, 63f, 63t, 74
competences for, 73
malpractice risk and role of, 46
surgical education and training techniques,
76–78
training principles and trends for, 73–79
Residual ovary
chronic pelvic pain and, 650
deﬁned, 629
Residual ovary syndrome, 636, 637f
Resolution
as response to surgery, 31
in sexual cycle, 34
Respiratory acidosis
deﬁned, 162
management, 187–188
Respiratory alkalosis, 162
management, 188
Respiratory failure
as postoperative complication, 145–147,
146t
shock and, 211
total parenteral nutrition protocols, 156
Respiratory physiology, postoperative pulmonary
complications and, 143–144, 143t–144t
Respiratory system, pregnancy physiology, 825
Retention sutures, 229
Retractors, surgical
classiﬁcation and properties, 239f–240f, 241
paravaginal defect repair, vaginal retropubic
technique, 888–890, 888f–889f
Retrograde menstruation hypothesis, ovarian
cancer risk and, 1308
Retrograde pyelogram, vesicovaginal ﬁstula
evaluation, 977–978
Retroperitoneal lymph nodes, ovarian cancer and,
1327–1328, 1327f
Retroperitoneal spaces
advanced-stage ovarian cancer, 1323–1324,
1323f, 1324f
anatomy, 100–105
injury, cervical cancer surgery, 1278–1279
lower abdomen, anatomy, 100, 101f
vaginal hysterectomy and dissection of, 749–750

Ventilation/perfusion (V/Q) abnormalities, 133
Veblen, Thorstein, 8
Vasa recta, defined, 1098
Varicocele, vulva, 505, 505f
Varices, vulva, 505, 505f
Venenous system
varicose veins, 248–249, 250t
incontinence, 1095
Vasectomy, as alternative to tubal sterilization,
Vasculature, normal coagulation mechanisms, 372,
Wertheim hysterectomy, vaginal tumors, 527–529
Wet colostomy, defined, 1340
Wharton-Sheares neovaginoplasty, vaginal reconstruction, 555–556
White blood cell count, pelvic inflammatory disease diagnosis and, 662–663
White line of Toldt, defined, 1098
Williams, J. Whitridge, 10
Williams’ Obstetrics, 2
Williams vulvovaginoplasty, vaginal reconstruction, 554–555, 555f
Willobrook case study, human research and, 21
“W” incision of Regnault, technique, abdominal surgery, obese patients, 265–266, 266f
Wire electrodes, loop electrode excision procedures, 295
Wire suture
abdominal incisions and, 251–252, 252t
classification and properties, 252
Wolf, Caspar, 5
Women patients, history of, 5–8
Women surgeons, nineteenth-century history of, 7–8
Word catheter
Bartholin duct cysts, 497, 497f
defined, 490
Wound cellulitis
defined, 190
pathology, 194
Wound classification, abdominal incisions, 251–252
Wound contraction, mechanisms of, 227
Wound dehiscence complications
episiotomy, 836–837, 836f, 837f–838f
inunction and, 271, 271f
wound closure methods and, 228–229
Wound healing
closure methods, 228–229
physiology, 226–227, 251–252
primary intention
defined, 226
surgical wound, 227, 228f
secondary intention
defined, 226
surgical wound, 227–228, 228f
surgical wounding healing, 227–228
third intention, surgical wound, 228, 228f
Wound infection
abdominal surgery
chole patients, 263–264
prevention, 253–254
delayed primary closure techniques and, 268–270
pathology, 193–194, 194f
postoperative, prevention of, 196–199, 199f
Wound seroma
defined, 190
pathology, 194
W-plasty technique, vaginal reconstruction, 557
X
Xenon light generator, hysteroscopy, 337, 339f
Y
Yttrium-aluminum-garnet (YAG) laser, laparoscopy, 310–311
Z
Zepplin clamps, abdominal hysterectomy, 739, 739f
Zoledronic acid, hypercalcemia management, 185
Z-plasty full-thickness pedicle flap, vulvar reconstruction, 1362–1363
Zygote, defined, 398
